Abstract: Motion signals are underlie basic visual tasks, such as figure/ground segregation and navigation. Visual motion analysis is considered to consist of two stages: extraction of local motion cues, followed by integration of these cues across space. Three kinds of local motion signals can be distinguished, based on the kinds of spatiotemporal correlations that generate them: Fourier (F), based on 2-point correlations (Reichardt 1961); non-Fourier (NF), based on 4-point correlations (Chubb & Sperling 1988); and glider (G), based on 3-point correlations (Hu & Victor 2010). G signals have two sub-types, expansion and contraction, associated with objects that are looming and receding, respectively. Detection of isolated G and NF signals cannot be mediated by a purely multiplicative cross-correlator or a purely quadratic motion energy model. G signals have recently attracted substantial attention, following the demonstration that a wide range of species (human, macaque, zebrafish, dragonfly, and fruitfly) respond to them in similar ways - suggesting that there are advantages to using these signals in visual tasks. In natural scenes, F and G signals tend to occur together (Nitzany & Victor, 2014), and this puts a focus on how these motion cues interact. Here, we study this with synthetic movies that contain controlled levels of each kind of signal but are otherwise as random as possible, as formalized by a maximum-entropy criterion. Subjects were asked to report the perceived motion direction in a 2-alternative forced choice task, following viewing of 1-sec clips of these movies (20x30 grids of 0.45 x 0.45 deg checks, 10 frames/sec). Thresholds were determined via standard Weibull-function fits. In separate experiments, two cue combinations (F with G contraction, or F with G

expansion) were studied; within each experiment, various levels of F and G signals were randomly interleaved. For combinations of F with G contraction (N=4), we found that subthreshold cues combine, and the combination is approximately quadratic. In addition, there was a suggestion of light vs. dark asymmetry: F signals interacted more strongly with G contraction signals carried by light regions than with G contraction signals carried by dark regions. Interestingly, for combinations of F with G expansion (N=3, including two studied with G contraction), we observed a different kind of interaction: the sensitivity to F signals was reduced in the context of trials that included G expansion signals. In summary, we report that local motion signals of different types interact at the perceptual level, and that this interaction can include subthreshold summation and context-dependent changes in sensitivity.

Title: Speed encoding in human motion regions for objective and retinal motion

Authors: *D. KORKMAZ HACIALIHAFIZ[1,2], G. DARMANI[1], A. BARTELS[1];
[1]Univ. of Tübingen, Tübingen, Germany; [2]IMPRS for Cognitive and Systems Neurosci., Tübingen, Germany

Abstract: The visual system continuously updates visual perception in order to compensate for eye-, head- or body- movements in order to create a stable perception of the world surrounding us. This mechanism is needed not only for a stable and coherent perception, but also for distinguishing objective (‘real’) motion induced by moving objects from that induced by eye movements. Previously, human visual areas V3A and V6 have been shown to compensate for self-induced retinal motion and to encode objective motion during smooth pursuit eye movements (Fischer et al., 2012). However, it is unclear how responses to objective and retinal motion vary as a function of speed in these and other human motion responsive regions. Prior studies examining fMRI responses as a function of speed always measured joint responses to

objective and retinal motion, as speed of the background motion was varied during fixation (Chawla et al., 1998). In this study we used a pursuit paradigm that allowed us to measure responses to objective and retinal motion separately (Fischer et al. 2012). We did this for 6 different levels of speed (1, 2, 4, 8, 16, and 24 degrees per second) in order to obtain speed tuning profiles for separately localized visual motion regions. Stimuli consisted of moving fourier scrambles derived from natural images. We found that all regions had either a trend or significant response increase with higher speeds for both, retinal and objective motion. V3A stood out in that it was the only region in which speed increases in objective motion lead to a higher signal modulation than speed increases in retinal motion. In other words, the slope related to speed increase was significantly higher for objective than for retinal motion only in V3A. In addition, V3A had significantly higher responses to objective than to retinal motion at all speeds. V6 responses resembled those to V3A, but were less pronounced. V5/MT and MST did not differ in objective and retinal speed slopes, even though both tended to respond more to objective motion at all speeds. These results support the view that human V3A (and V6) play a predominant role in integrating visual signals with efference copies, and that it encodes primarily objective rather than retinal motion signals. Title: Neural activity in occipito-parietal and frontal regions predicts outcome of bistable motion perception

Authors: *Q. CHEN[1], L. SHEN[2], B. HAN[3,4], J. XIA[2], L. CHEN[5];
[1]South China Normal Univ., Guangdong, China; [2]South China Normal Univ., Guangzhou, China; [3]Univ. de Toulouse, Ctr. de Recherche Cerveau et Cognition, Univ. Paul Sabatier, Toulouse, France; [4]Ctr. Natl. de la Recherche Scientifique, Unité Mixte de Recherche 5549, Faculté de Médecine de Purpan, Toulouse Cedex, France; [5]Dept. of Psychology, Peking Univ., Beijing, China

Abstract: Upon viewing dynamic ambiguous visual stimuli, observers often experience spontaneous transitions between two competing percepts although the physical stimulation remains unchanged. This phenomenon is termed as “bistable perception”. It remains unknown the neural causes that generates one specific perception during the bistable phenomenon. By applying fMRI and EEG to record brain activity during the presentation of bistable apparent motion stimuli, we asked participants to report whether the element or group motion they perceived and tested how trial-to-trial variation in pre-stimulus activity predicted element motion or group motion during the bistable perception. Element motion perception arised with enhanced pre-stimulus activity in the parietal and prefrontal cortex and reduced pre-stimulus activity in the default-mode-network, and manifested as increased connectivity between the parietal cortex and the premotor regions upon the appearance of the bistable stimuli. Moreover, reduced alpha/theta power within 400 ms before the stimulus predicts the perception of the element motion. The activation of the parieto-frontal attentional network and reduced alpha power implicated the element motion perception was modulated by attention even before the stimulus appeared. Furthermore, the phase of alpha (7-16Hz) oscillations within 200 ms before the stimulus significantly covaried with the perceptual outcome: if the alpha oscillation reached a certain phase (strong phase-locking value), the group motion percept occurred; if not (weak phase-locking value), the element motion perception occurred. This effect was observed in occipito-parietal regions, as well as in a distant frontocentral region. But the effect appeared earlier in the occipito-parietal regions (~170ms before the stimuli) than in the frontocentral regions (~130ms before the stimuli), indicating the oscillation of the two regions contributed differentially to the bistable motion perception. Therefore, our results suggest the different characters of the neural activity can predict specific motion perception during the bistable apparent motion.

Title: Prediction error signals for visuo-motor mismatch in human visual cortex

Authors: *J. HEINZLE[1], K. STEPHAN[1,2,3], G. B. KELLER[4];
[1]Translational Neuromodeling Unit, IBT, Univ. of Zuerich and ETH Zuerich, Zuerich, Switzerland; [2]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom; [3]Max Planck Inst. for Metabolism Res., Cologne, Germany; [4]Friedrich Miescher Inst. for Biomed. Res., Basel, Switzerland

Abstract: Our own movements change our visual input. In order to detect "true" changes of the environment, the nervous system needs to account for self-generated changes of sensory input. Here, we investigated how a visuo-motor mismatch drives prediction error (PE) signals in the human brain using a paradigm that allowed us to distinguish between purely visual mismatch and mismatch related to how motor actions (moving a joystick with the hand) changed visual sensations. We obtained fMRI data from 31 healthy adult volunteers controlling the movement of an expanding/contracting random dot pattern with a joystick. In 20% of the trials, a visuo-motor mismatch was introduced by inverting the direction of dot movement. In additional runs, participants passively viewed exactly the same visual stimulation, including visual mismatches. After standard preprocessing, we used a general linear model with regressors for run types (active vs. passive), directions of movement (forward vs. back) and the conditions (match vs. mismatch). The main contrast of interest was the interaction between match vs. mismatch and active vs. passive. Statistical significance was assessed using family wise error cluster level correction for multiple comparisons across the whole brain ($p_{cluster} < 0.05$, voxel threshold $p < 0.001$) and permutation testing for regions of interest (ROI) analysis ($p<0.05$). Significant visuo-motor mismatch activity was observed predominantly in bilateral prefrontal and parietal areas. In addition, regions in the right anterior insula, the left inferior temporal gyrus and the right middle occipital gyrus showed whole brain corrected activations. The ROI analysis revealed significant visuo-motor mismatch in human MT, but not in primary visual cortex (V1) or motor cortex (M1). In conclusion, we demonstrate that in addition to strong activation of bilateral parietal and prefrontal areas visuo-motor mismatch leads to activation in early visual area MT. Importantly, these PE signals are driven by mismatch between one's own actions and the resulting visual input - not simply by visual mismatch. The whole brain results are in agreement with other PE studies in humans showing e.g. robust activation of prefrontal areas. In addition, similar to a recent mouse model of visuo-motor mismatch in the context of locomotion (Keller et al., Neuron, 2012), significant activation was observed in an early visual area - but not in V1. Future

studies are required to clarify whether this discrepancy is the result of species differences or related to differences in the paradigm (joystick movements vs. locomotion).

Title: Neural signals of motion integration are modulated by perception

Authors: ***Q. LI**[1,2], N. K. LOGOTHETIS[1,2,3], G. A. KELIRIS[1,2,4];
[1]Max Planck Inst. For Biol. Cybernetics, Tuebingen, Germany; [2]Bernstein Ctr. For Computat. Neurosci., Tübingen, Germany; [3]Div. of Imaging Sci. and Biomed. Engin., Manchester, United Kingdom; [4]Dept. of Biomed. Sci., Bio-Imaging Lab., Antwerp, Belgium

Abstract: A very important feature of primate vision is the ability to integrate motion signals into a coherent percept. To this end, a two-stage motion integration model has been proposed that selectively integrates local signals over time and space to reconstruct the global motion pattern. It has been suggested that the first stage responsible for local motion detection takes place in lower level visual area(s), while a second stage in higher area(s) integrates the local motion signals in order to extract the global motion direction. Support for this hypothesis stems mainly from recordings in anesthetized non-human primates while evidence in awake-behaving ones is very limited. Furthermore, very little is known about how motion integration is influenced by perception. In this study, we designed a novel pseudo-plaid stimulus that can parametrically modulate coherent or transparent motion perception by changing local feature information. The stimulus consists of two types of apertures over a line plaid display. The first group of apertures allows only single contours to pass through while the second only intersections. Human psychophysics demonstrated that the motion perception changes parametrically with the proportion of the two types of apertures from 100% transparent when only single-contour apertures are present to 100% coherent when only intersection apertures are

displayed. Then, we used this stimulus and performed multi-electrode recordings in areas V1 and MT of alert macaques. Analysis of the firing rates during the whole trial (1000 ms) demonstrated that MT neurons were strongly modulated by the proportion of different aperture types reflecting the perception. Specifically, MT neural responses increased when motion perception was more coherent. In contrast V1 neurons did not show any significant changes by using this measure. These data corroborate the hierarchical organization of motion integration and demonstrate the relationship of neural signals with subjective perception.

Title: Spatial integration of visual motion signals for smooth pursuit eye movements in humans and non-human primates

Authors: *C. SIMONCINI, T. MUKHERJEE, L. C. OSBORNE;
Grossman Inst. for Neuroscience, Quantitative Biol. and Human Behavior, Univ. of Chicago, Chicago, IL

Abstract: Humans and monkeys use smooth pursuit eye movements to track moving objects of interest. To determine the appropriate eye movement, the brain must integrate motion signals across the region of interest within the visual field. In order to understand the spatial and temporal extent of motion integration for pursuit, we have analyzed eye movements to motion noise stimuli. We created random dot kinetograms with a constant direction and speed of movement, but we added to each dot a stochastic direction and/or speed at each time step. Dot directions were drawn from a uniform distribution with 1 degree spacing. Dot speeds were uniformly distributed in N-space where v = 2N. We measured the pursuit responses of human subjects with a Dual-Purkinje infrared eye tracker and non-human primates using implanted scleral coils. We found that the spatial-temporal filter that minimized the squared error in predicted eye velocity and direction covered a circularly symmetric Gaussian amplitude profile. We found that the Gaussian filter had a SD of 5 degrees over a range of target manipulations (aperture size, dot density, aperture motion) for both humans and monkeys. The temporal

duration of the filter was 40 ms (FWHM) and was also constant across multiple target forms. The spatial temporal filter accounted for 61% of the variance (corr coeff2). If we differentially weighted sub-regions of the area of interest by local dot density and motion vector similarity, we could account for 80% of pursuit variance over time. The consistency of these findings across dot target forms with different levels of optic flow and species suggests that the integration window for pursuit may be largely constant.

Title: EEG frequency tagging reveals neural integration in the perception of coordinated motion

Authors: *N. ALP[1], N. KOGO[2], B. ROSSION[3], J. WAGEMANS[2];
[1]Lab. of Exptl. Psychology, KU Leuven, Leuven, Belgium; [2]Lab. of Exptl. Psychology, KU Leuven, Leuven, Belgium; [3]Inst. of Res. in Psychology and Inst. of Neuroscience, Univ. Catholique de Louvain, Louvain la Neuve, Belgium

Abstract: The point-light display (PLD) is one of the most frequently used stimuli to investigate the interaction between form and motion in biological motion perception. In a PLD, the motion of the individual dots, their specific configuration, and the spatiotemporal dynamics of their trajectories together give rise to the perception of a human figure carrying out a particular action. Here we combine multiple PLDs in one stimulus to investigate the mechanisms that are involved in processing coordinated movements and to identify the neural activity that is specific for the perception of globally coordinated movements. For this purpose, a frequency-tagging technique was applied in combination with the recording of EEG. In the experimental condition, the motions of the PLDs were coordinated as in a group of dancers. In two control conditions, the

coordinated motions and the perception of biologically plausible motion were diminished, respectively. Frequency tagging was implemented by modulating the luminance intensity of the point lights of the individual dancers with different frequencies for the different dancers (PLD1=f1 and PLD2=f2). Fast Fourier Transform was applied to investigate the effect of coordinated motion. It has recently been shown that neuronal populations that are involved in the integration of two differently-tagged stimulus parts can produce (non-linear) intermodulation (IM:f1±f2) components. Comparing IM effects between our coordinated motion condition and control conditions allows us to analyze the interaction and integration of the biological motions among the dancers, hence enabling us to identify the mechanisms and cortical areas that are involved in the perceptual integration of coordinated biological motion.

Title: A genome-wide association study of human visual motion perception

Authors: ***N. REN**[1,2], B. CHEN[2], Z. ZHU[2], Y. RAO[2], F. FANG[1];
[1]Dept. of Psychology, Peking Univ., Beijing, China; [2]Sch. of life sciences, Peking Univ., Beijing, China

Abstract: Visual motion perception is an essential ability of human visual system. However, there are few genetic studies investigating the heritability of motion perception as a polygenetic cognitive trait. Here we employed a genome-wide association method to examine the genetics underlying visual motion perception. We measured the motion identification and motion discrimination abilities in a cognitively healthy cohort of Han population with normal vision. Visual stimuli were random dot kinematograms (RDKs) consisting of 400 dots moving at a velocity of 10°/s within a 8°-diameter circular area. In the motion identification task, participants were asked to indicate the perceived direction of coherent motion (1 of 8 possible directions: 0°, 45°, 90°, 135°, 180°, 225°, 270°, 315°) in a noisy RDK. We adopted a method of constant stimuli (MCS) to measure the motion coherence threshold for each subject, by changing the fraction of coherently moving dots in the RDK. For the motion discrimination, participants were instructed to discriminate between the motion directions of two successively presented RDKs (at 100% coherence) in a two-alternative forced choice (2AFC) task. We measured the direction

discrimination threshold for each participant, using the MCS. In both tasks, smaller thresholds indicated better performance. Since the behavioral performance showed substantial individual difference, we performed a genome-wide association study in 780 participants to identify motion-perception-related variants. Single nucleotide polymorphisms (SNPs) showing suggestive genomic significance were picked out for further validation study in a second cohort of 1468 Han people. The result showed that the SNP rs600416 linked with CSGALNACT1 (chondroitin sulfate N-acetylgalactosaminyltransferase 1) and rs2673467 related with KCNMA1 (potassium large conductance calcium-activated channel, subfamily M, alpha member 1) were significantly associated with motion identification and motion discrimination, respectively (both $p<0.05$). Evidence from these experiments suggests a possible role for these genes in human visual motion perception.

Title: Receptive field transformations between retinal ganglion cells and superficial inhibitory interneurons in zebrafish larvae

Authors: *F. ABBAS, M. P. MEYER;
MRC Ctr. For Developmental Neurobio., King's Col. London, London, United Kingdom

Abstract: Inhibition plays a crucial role in shaping sensory-evoked activity in the visual system, a better knowledge of inhibitory circuits is necessary for our understanding of how visual circuits operate. Here we use *in vivo* functional imaging to characterise the receptive field properties of superficial inhibitory interneurons (SINs) in the optic tectum of larval zebrafish. SINs are located in the most superficial part of the optic tectum, with arborisations that are laminar and within the superficial layers of the tectal neuropil. Recent studies have implicated these neurons as necessary in prey capture behaviour, as well as showing that these neurons exhibit size selectivity. Using a drifting grating stimulus we demonstrate the presence of three functional

subtypes of direction-selective (DS) SIN with preferred angles matching those of DS retinal ganglion cell inputs to tectum. Further we show that these exhibit bandpass spatial tuning, with preference for smaller gratings, matching the size of stimulus previously reported to elicit prey capture behaviour. Moreover we show that directional tuning bandwidth is significantly narrower than that seen in DS-RGCs- a feature that is insensitive to pharmacological blockade of GABA-A receptors suggesting an intrinsic mechanism that narrows directional tuning bandwidth. Our results show that SINs are highly selective for at least two visual features: size and direction of travel of visual objects. Whilst previous work on SINs has implicated them in a size selective circuit in the tectum, we propose that this may also involve directional selectivity.

Title: Neural motion detection circuits underlying looming-evoked escape behaviors in *Drosophila*

Authors: *Y. KYUNG[1], H. DIERICK[2,1], F. GABBIANI[1,3];
[1]Dept. of Neurosci., [2]Dept. of Mol. and Human Genet., Baylor Col. of Med., Houston, TX;
[3]Computat. and Applied Mathematics, Rice Univ., Houston, TX

Abstract: A recent study proposed that a class of neurons of the lobula/lobula plate, called Foma-1, is critical for the generation of escape jumps elicited by looming stimuli simulating the approach of an object on a collision course (de Vries and Clandinin, Curr Biol 22: 353-362, 2012). The local motion sensitivity of Foma-1 neurons suggests that they may receive directionally selective inputs. Recent electrophysiological evidence shows that T4 and T5 cells play an important role in the detection of directional motion in the context of optomotor behaviors (Mauss, et al., J Neurosci 34.6: 2254-2263, 2014). Several studies proposed that these neurons belong to two pathways originating with L1 and L2 that are specialized in detecting ON/OFF motion stimuli (Rister, et al., Neuron 56:155–170, 2007; Joesch, et al., J Neurosci 33:902–905, 2013; Behnia, et al., Nature 512.7515:427-430, 2014). The neuron L1 is presynaptic to Mi1 and Tm3 which both synapse onto T4, while L2 is presynaptic to Tm1 and Tm2 which

both synapse onto T5 (Stronther, et al., Curr Biol 24:976-983, 2014; Takemura, et al., Curr Biol 21: 2077-2084, 2011). Taken together, these studies suggest that these pathways provide input to Foma-1 neurons. We used a behavioral approach to investigate whether the ON and OFF pathways could provide inputs to Foma-1. To trigger escape jump, we used light (ON) and dark (OFF) looming stimuli presented on a dark and light background, respectively. We used the *GAL4/UAS* system to silence specific cell classes of neurons belonging to the two pathways. The transcription factor GAL4 was expressed specifically in lines targeting the following neurons: L1, L2, Mi1, Tm1, Tm2, Tm3, T4, T5, and Foma-1. GAL4 was used to drive expression of a temperature sensitive dominant negative mutation of *Drosophila* dynamin (*Shibire*) from a UAS promoter (Kitamoto, T, J Neurobiol 47.2:81-92,2001). When we presented ON stimuli at the restrictive temperature of approximately 30 °C, the jump probabilities of T4 blocked flies and L1 blocked flies were suppressed. The decrease in jump probabilities were similar to those observed in Foma-1 blocked flies. In contrast, the jump probabilities of T5 blocked flies and L2 blocked flies were decreased in response to OFF stimuli. Mi1 and Tm1 blocked flies also showed specific behavioral deficits to ON and OFF looming stimuli, respectively. These results show that T4, Mi1 and L1 mediate behavioral responses to ON looming stimuli, while T5, Tm1 and L2 mediate responses to OFF looming stimuli. Thus, our data provide evidence that the parallel pathways provide directional motion input to Foma-1 neurons. We are further investigating this hypothesis using imaging electrophysiology.

Centre, The Univ. of Adelaide, Adelaide, Australia; [9]Royal Women's Hosp., Melbourne, Australia

Abstract: Background: Children born preterm exhibit impaired motion processing. These deficits may be associated with inadequate supply of specific nutrients such as docosahexaenoic acid (DHA, 22:6 n-3) that affect the normal development of the eye and brain. Objective: The current study aimed to investigate the effects of DHA supplementation on motion processing performance and functional brain activation. Design: Follow-up of a subgroup of children from a multi-centre longitudinal randomized controlled trial. Infants were randomly assigned to milk containing a higher concentration of DHA (1% of total fatty acids, higher-DHA group) or a standard amount of DHA (0.2-0.3% total fatty acids as DHA, control group). The randomization schedule was stratified by sex and birth weight <1250 g or ≥1250 g. Functional magnetic resonance imaging scans were obtained during a global motion processing task for 48 (25 in the high-DHA group and 23 in the standard DHA group) children aged 7 years. Participants were also assessed on a high density and low density behavioral measure of global motion processing out of the scanner. Results: There were no behavioral differences in global motion processing between the high DHA and standard DHA groups, however both groups showed high rates of impairment. When attending to low-density dots moving coherently left or right the high DHA group exhibited a trend ($p=0.05$) toward decreased brain activation, primarily in the precuneus and cuneus, relative to the standard DHA group. Conclusions: Supplementing human milk with DHA at a dose of ~1% of total fatty acids given in the first months of life to very preterm infants appears to decrease functional activation relative to controls in the visually-related brain regions, precuneus and cuneus, but has no effect on performance.

Abstract: Everyday life requires dynamic matching of behavior to the tasks at hand. Depending on the task, very different parts of information in the visual field should be used. This is often studied with static attentional paradigms with a single discrete response for each trial. These tasks also typically require significant training. However, this does not match well to natural task-dependent behavior, where both the goal and the distribution of information can change continuously. Thus, very little is known about how the brain accomplishes task-dependent selection and integration of information in more naturalistic continuous behavior. We therefore developed a novel paradigm which allows quantification of the temporal and spatial visual parameters that drive behavior in a continuous ocular tracking task, and which is also suitable for characterizing motion-selective neurons. Here we report behavioral results from this paradigm. The core stimulus consisted of a moving cloud of dots creating a large field optic flow (80 x 50 deg of visual angle). The focus of expansion (FOE) of the flow field moved continuously according to a random walk. To characterize the spatial integration of the visual motion, we divided the field into hexagonal subfields. Each subfield either had a small, random perturbation from the motion associated with the “true” FOE or could be blank. Perturbations of the subfields

were resampled randomly every 33 to 1000 ms. Both macaques and humans intuitively tracked the FOE. To maintain interest and solidify FOE tracking, we dispensed reward periodically whenever gaze was within 7.5 deg of the FOE for a few seconds. Trials ended when gaze left the screen for more than 250 ms or after 300 s of visual stimulation (mean duration, macaque: 23 s, human: 245 s). We used regression to determine the spatiotemporal parameters that best predicted the subject's gaze. When 45% of the subfields contained FOE information, standard deviations of reprojection error were 5.7 deg for macaques and 1.5 deg for humans. Gaze was most influenced by the FOE location from about 250 ms before, with the majority of temporal information being integrated by 800 ms but lasting up to 2 s. Spatial integration was confined to ±4 deg near the gaze location. When another 45% of the subfields were consistent with the motion of a second, independent FOE (with differently colored dots), subjects could still track the FOE of one flow field with a similar profile of temporal integration. The paradigm provides an intuitive and easy to learn framework that can reveal the spatiotemporal profiles of motion integration during continuous behavior, and can be extended to study dynamic selection of information.

Title: Membrane properties of lamprey lateral pallial neurons and their sensory input - dissecting the primordial cortical microcircuit

Authors: *S. MYSORE SURYANARAYANA, B. ROBERTSON, P. WALLEN, S. GRILLNER;
Karolinska Institutet, Stockholm, Sweden

Abstract: The lateral pallium, corresponding to cortex in mammals, is remarkably conserved in terms of its efferent connectivity, and electrical microstimulation of circumscribed regions evokes eye and orienting movements, movements of the mouth, and in some cases, locomotion (Ocaña et al., 2015). Pallium consists of an outer molecular layer and an inner cellular layer which contains neurons that extend their spiny dendrites into the molecular layer and with an axon that projects out of pallium. The larger of these neurons are glutamatergic and there is also a seperate population, which is GABAergic. One of our goals here is to investigate the active and resting membrane properties of these neurons. Whole-cell patch recordings revealed characteristics of action potentials and after-hyperpolarizations, with post-inhibitory rebound spikes in some neurons. Regular spiking neurons, with fast and slow adapting categories, with two subtypes of the slow adapting. One subtype with low input resistance and a slow firing rate and the other with higher input resistance and a faster firing rate. Intracellular labelling revealed two different morphological types – one with two primary spiny dendrites, which proceeded to the outer molecular layer and branched extensively. These two dendrites were spatially separated enabling them to sample input from different regions of the molecular layer. The axons exited either dorsally or ventrally, presumably part of the dorsal palliopallial (intratelencephalic) tract or the extratelencephalic ("pyramidal") tract, respectively. The other morphological type showed a single primary dendrite, which branched extensively in the molecular layer. With respect to interneurons, GABA and calbindin expressing cells are present. An extensive network of fibers was observed to express somatostatin, but no somata were labelled. Sensory input to the lateral pallium, mainly olfactory, bypasses the thalamus as in mammals and is relayed in two ways – direct input and via the relay nucleus, the *dorsomedial telencephalic nucleus* (dmtn), both of which terminate in distinct layers in the outer molecular layer. Visual input from the retina is relayed to pallium via the thalamus and in addition processed visual information also reaches thalamus via tectum. Taken together, our data suggests that the efferent and afferent *bau-plan* of the cortex is ancient; it had already evolved when the lamprey diverged from the main vertebrate line 560 million years ago. These findings represent the first report of cellular properties in the primordial cortical microcircuit.

Title: Functional cerebral networks of prepulse inhibition: A positron emission tomography (PET) study in freely moving rats

Authors: *C. ROHLEDER[1,2], B. NEUMAIER[2], A. DRZEZGA[3], R. GRAF[4], F. LEWEKE[1], H. ENDEPOLS[2,3];

Abstract: So far, functional neural networks have been solely described in sedated or fixated animals. Therefore it cannot be precluded that these data are influenced by sedation or high stress levels. However, this disadvantage can be bypassed by conducting behavioral 2[^{18}F]fluoro-2-deoxyglucose (FDG) PET measurements. We have used this innovative technique to further analyze the functional neuronal networks that are active during prepulse inhibition (PPI) of the acoustic startle response. After intraperitoneal injection of 2 mCi FDG, rats (n = 19) were placed in the startle apparatus (San Diego Instruments) and a classical acoustic PPI-paradigm was applied (test condition) for 45 min. On another day rats were solely exposed to 45 min continuous background noise (control condition, resting state). During the behavioral paradigms FDG accumulated in energy-consuming brain cells. Afterwards rats were anaesthetized and a PET-scan (Focus 220, Siemens) was conducted for 30 min. A seed-based correlative network analysis was done with intensity normalized, intra-individual difference images of both behavioral conditions (control minus test condition). Positive correlations indicate that the respective voxel accumulated FDG analog to the seed region, while negative correlations represent inverse relations. We selected 5 different seeds (6-8 voxels each) according to the following criteria: a) Significantly higher FDG uptake during PPI (versus resting state): Auditory cortex (A1), pedunculopontine tegmental nucleus (PPTg) / cuneiform nucleus (CuN), and ventral tegmental area (VTA). b) Significantly lower FDG uptake during PPI: retrosplenial cortex (RSC), c) Correlated to the number of PPI events: prelimbic cortex (PrL). Correlational analysis revealed 3 separate networks: 1) RSC correlated voxels comprised the default mode network. 2) Both A1 and PrL correlated voxels yielded a lateral network including the auditory pathway, insular cortex, amygdala, and ventral hippocampus. 3) A medial network was observed with both PPTg/CuN and VTA seeds, covering cingulate cortex, nucleus accumbens, superior colliculus as well as dorsal hippocampus. Areas appearing in both networks were PrL and PPTg/CuN. Our results suggest that the previously defined PPI modulation network consists of two separate functional units (medial and lateral network), which are connected through key areas of PPI modulation (PrL) and PPI mediation (PPTg/CuN). Both networks are active during passive PPI sessions, while the default mode network is active during resting state.

Title: Control of midbrain motor output by the basal ganglia

Authors: ***E. A. STUBBLEFIELD**[1,2], J. ESSIG[2], G. J. MURPHY[1], G. FELSEN[2], J. T. DUDMAN[1];
[1]Neurosci., Janelia Res. Campus, Ashburn, VA; [2]Physiol. & Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Orienting to salient stimuli is a fundamental, voluntary behavior. Several lines of evidence have implicated the projection from the substantia nigra pars reticulata (SNr) to the superior colliculus (SC) (i.e., nigrotectal neurons) in mediating this behavior. While most previous research, and models of basal ganglia-midbrain function, have focused on the "uncrossed" input from the ipsilateral SNr to the SC, the anatomy and physiology of "crossed" nigrotectal neurons have recently been described as well. However, whether these classes have distinct functional roles in generating, and perhaps specifying, orienting movements, is unclear. To address this question, we have developed a virtual orienting task in head-fixed mice. Briefly, the mice are trained to move a rotating wheel either to the left or to the right with their forelimbs to bring an eccentric visual stimulus (that initially appears either to the left or right of center) into the center of their visual field via a closed-loop system. Mice move the wheel/bar in the correct direction 85% of the time when the luminance of the bar is high; the percentage of correct movements decreases to near chance levels as the luminance of the visual decreases. *In vivo* recordings are made from identified uncrossed and crossed nigrotectal neurons in mice performing this task. Specifically, we use transgenic mice in which GABAergic neurons of the SNr express ChR2 and optogenetically stimulate one SC hemisphere while performing extracellular recordings of isolated single units from either the ipsi- or contralateral SNr in order to "tag" specific nigrotectal projections with action potential backpropagation. This awake, behaving, cell-type specific recording approach will allow us to elucidate the functional roles of the uncrossed and crossed nigrotectal neurons in mediating orienting movements.

Title: Neural correlates of visually-guided behavior in mouse cingulate cortex

Authors: ***N. A. STEINMETZ**[1], C. P. BURGESS[1], C. ROSSANT[1], S. N. KADIR[1], M. L. D. HUNTER[1], D. F. M. GOODMAN[2], M. CARANDINI[1], K. D. HARRIS[1];

Abstract: Little is known about the cortical microcircuits underlying cognitive behaviors such as making decisions among multiple alternatives. In mice, a cortical area that may perform computations underlying these behaviors is the cingulate cortex (Cg). This midline area exhibits visual responses and reciprocally connects with primary visual cortex (V1) and superior colliculus, among other areas. To understand the role of the Cg in visually-guided behaviors, we trained mice to perform a 3-alternative visual discrimination task and used next-generation microelectrodes to simultaneously record millions of spikes from hundreds of neurons. In the task, mice were shown gratings of varying contrast located to the mouse's left and/or right. The mouse could earn a water reward by selecting the correct response: turn a wheel clockwise if the grating on the left was present and had higher contrast than that on the right; turn counterclockwise if the reverse was true; or refrain from responding for 1.5 seconds if no grating was shown. Mice learned this task well, performing at >66% accuracy (and often much higher) on trials with high contrast stimuli or no stimuli (chance = 33%). While mice performed the task,

we recorded in the Cg or, for comparison, from V1. Recordings were made with 128-channel silicon microelectrodes fabricated by IMEC, allowing for the simultaneous recording of more than 200 isolated neurons in a small region. The unprecedented magnitude of these datasets (>5 million spikes, with individual spikes appearing on up to 12 sites) required new software for the automatic and manual stages of spike sorting, including new versions of KlustaKwik and KlustaViewa. For each neuron, we quantified its responses to the visual stimuli, to the auditory "go cue", to the execution of wheel turns, and to the delivery of positive or negative feedback. A majority of Cg neurons responded significantly to at least one of these task events, and many responded to more than one, indicating a mixed representation. By comparison, in a limited sample of V1 neurons, many responded to visual stimuli, but none responded to the go cue, to the execution of the wheel turns, or to feedback. Finally, we characterized whether the neurons represented the choice of the mouse, independent of the actual stimulus conditions. Only a small fraction of Cg neurons, and no V1 neurons, represented the decision. In summary, the Cg contains neurons representing each aspect of the behavioral task, but only a very sparse subpopulation of its neurons seemed to represent the decision or motor response. Whether and how this population of neurons contributes causally to the performance of the task awaits future experiments.

Title: Fronto-cortical projections to medial and lateral subdivisions of the mouse Superior Colliculus and their potential role in approach and avoidance behaviour

Authors: *M. A. SAVAGE, R. MCQUADE, A. THIELE;
Inst. of Neurosci., Newcastle Upon Tyne, United Kingdom

Abstract: Different types of orienting behaviour require coordination of activity in many different cortical and subcortical areas. It has been shown that the Superior Colliculus (SC)

processes information regarding current goal directed behaviours, and a recent study in rats has suggested that there is a segregation of avoidance and approach behaviours along the medial (m) and lateral (l) divide of the SC. Here we investigate the connectivity of these subregions of the SC with upstream structures associated with orienting behaviours in the mouse. The retrograde tracer Fluorogold (FG) was iontophoresed into the SC(l) or SC(m) of anaesthetised mice. In a separate group, the anterograde tracer biotinylated dextran amine (BDA), was pressure injected either into motor cortex area 2 (M2) or the cingulate area (Cg). 3-4 days post injections the animals underwent cardiac perfusion with paraformaldehyde, and the brains were frozen and 40 µm coronal sections collected. FG retrograde tracer was visualised after incubating with an anti-FG antibody (Millipore AB153I) followed by amplification with biotin and strepavidin Alexa 488. BDA anterograde tracers were visualised by incubation with strepavidin Alexa 488. Tracer signals were mapped onto representative brain atlas images from Franklin & Paxinos. Retrograde tracing: Almost all cortical sensory areas projected to the SC in general, as well as the thalamus and the substantia nigra. The lateral and medial subregions do indeed have differing connectivity profiles, with SC(m) receiving more input from visual areas and areas involved in autonomic responses. Conversely SC(l) receives more somatosensory and whisker based inputs. The prefrontal area of motor cortex 2 (M2) was highly labelled with tracer from SCl (layer 5). The Cingulate cortex (Cg) was labelled more strongly after SCm injection (layer 5). Anterograde tracing: M2 projects to a variety of cortical area, with a preference to somatosensory areas (S1), motor output areas, motor area 1 (M1), and SC(l) compared to SC(m). Cg sends connections to visual area 1 (V1) and the amygdala. Following Cg injections anterograde labelling was much stronger in the SC(m) than in the SC(l). The results presented here are consistent with the known connections which exist onto the SC in other species (e.g. rat). Furthermore the area of highest activation, frontal M2, which appears to be similar to orienting areas characterised in rats, represents an interesting region/area for further study. Cg has also been implicated in orienting behaviours in rats. The different distributions from SCm/l to Cg/M2 are likely to underlie specific types of orienting behaviour relating to avoidance and approach.

Title: Multi-channel recording in the superior colliculus - insights into network computation and communication

Authors: *U. K. JAGADISAN, N. J. GANDHI;
Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The superior colliculus (SC) is one of the most thoroughly studied structures in the brain. Although we know a substantial amount about SC function and its role in mediating sensorimotor transformations through gaze shifts, questions abound about the exact mechanisms by which these transformations are implemented. Furthermore, it is unclear how SC's role in producing gaze shifts meshes with its purported role in processes such as attention, target selection, and post-saccadic feedback, although dynamic information processing within SC and between SC and cortical structures has been hypothesized to play an important role in these functions. These unresolved issues are in part due to the limitations of the traditional approach of recording with single microelectrodes from individual SC neurons. For example, by recording from only a single site in the intermediate layers of the SC, one is left to infer how inter-laminar information flow and feedback in an SC column guide even the simplest of sensorimotor behaviors. To study SC function in finer detail, we combined linear microelectrode array recordings with multi-channel signal analyses. Linear arrays are especially amenable to recording from within a column of neurons to obtain snapshots of the computations evolving in parallel within the column. We recorded from the SC in two rhesus macaques (Macaca mulatta) performing simple oculomotor tasks. The electrode contacts (n=16) spanned the dorso-ventral extent of the SC, allowing for the simultaneous recording of spiking activity and local field potentials (LFPs) from the superficial through the intermediate and deeper layers. Noise correlations between pairs of task-related neurons were low or negative compared to typical values in the cortex, consistent with the idea that the network becomes uncorrelated as you get closer to the end of a sensorimotor decision chain. We have also begun to analyze cross-channel spike-spike coherence (cross-correlations) and spike-LFP coherence and examine the relationship between the neurons' functional properties based on firing rate (e.g., visuomovement index) and their contributions to dynamic information processing in the SC network.

Title: The reliance of FEFsem activity on retinal input

Authors: *L. R. BAKST[1], J. FLEURIET[2], M. J. MUSTARI[3];
[1]Neurobio. and Behavior, Univ. of Washington, Seattle, WA; [2]Ophthalmology, Univ. of Washington, seattle, WA; [3]Ophthalmology, Univ. of Washington, Seattle, WA

Abstract: Primates are highly skilled at foveating moving objects through smooth pursuit (SP) eye movements. These eye movements require the integration of both retinal and extra-retinal signals. Although a growing body of work has shown that the smooth eye movement subregion of the frontal eye fields (FEFsem) is involved in generating voluntary SP, the relative contributions of retinal and extra-retinal signals to FEFsem activity remain an open question. To assess the dependence of the FEFsem on retinal input, we recorded 72 neurons in 3 monkeys during a step-ramp paradigm. We tested two types of visual perturbations: target blink and large-field (LF) background. In the first condition, the target was blinked off for 150 ms at 50, 100, 200, 300, 400, or 500 ms after ramp onset. Neuronal response was measured over a 150-ms interval, 60 ms after blink onset, and compared to the same interval in control trials (no blink). In the second condition, a LF background was moved with the target and neuronal response over the ramp interval was compared to control. Neuronal latency was estimated, and contributions of visual motion and eye motion were assessed using multiple linear regression modeling. Of the 33 neurons tested with target blinks during SP initiation (blink at 50 or 100 ms), 8 had a FR less than 60% of control FR, 18 had a FR greater than 90% of control. Of the 70 neurons tested with target blinks during maintenance (blink at 200, 300, 400, or 500 ms), 2 had a FR less than 60% of control, while 49 had a FR greater than 90% of control. To probe the basis of these differences in response to target blink, we compared the neuronal latency, and eye and visual motion sensitivity as estimated by linear regression. For neurons tested with target blinks during initiation, there was no significant difference between neurons that had FR decreases below 60% of control and those whose FR was above 90% of control. When tested with LF motion, the majority of neurons (16/21) showed an increase in FR when compared with control, and 9 of those showed a FR greater than 125% of control. Only 2 neurons showed a decrease in FR below 75%. Neurons that increase their FR above 125% of control show significantly shorter neuronal latencies than those cells that did not ($p<.002$). These results suggest that neuronal dependence on retinal signals may not be consistent throughout the FEFsem, or even over time for a particular cell. Whether neuronal populations differing on these measures underlie distinct

functions remains unknown. Further work to elucidate the relationship between these characteristics and FEFsem projections is ongoing.

Title: Robustness of direction discrimination performance during LIP inactivation

Authors: *L. N. KATZ, J. L. YATES, A. C. HUK;
Inst. for Neurosci., The Univ. of Texas At Austin, Austin, TX

Abstract: Neural correlates of the accumulation of evidence have been repeatedly observed in the average firing rates of neurons in the lateral intraparietal area (LIP). We tested whether this decision-correlated activity has a causal role by recording and then reversibly inactivating LIP neurons in two macaques performing multiple variants of a motion discrimination task. Neural activity was recorded before and during muscimol infusion with multisite linear electrode arrays. LIP was identified by strong contralateral delay-period activity across the array during an instructed saccade task. During muscimol infusion we recorded electrophysiological silencing of neural activity across the array channels, consistent with a >2mm inactivation (radius) within LIP, centered on choice-selective patches. LIP inactivation produced reliable behavioral effects in a free-choice task where reward was given for saccades to either of two targets, equally. Following inactivation, free choices were biased away from the inactivated field by 13% and saccade accuracy to the inactivated field was decreased (23% increase in endpoint scatter). Given both electrophysiological and behavioral confirmation of LIP inactivation, we then evaluated the effects of inactivation on motion discrimination performance. We found no measurable effect of LIP inactivation on either slope, inflection or lapse-rate of the psychometric function when one target was placed in the inactivated field (6012 trials over 13 sessions). Varying the spatial configuration of the task by placing both targets within the inactivated region produced no effect either (1516 trials, 3 sessions). We further varied the temporal structure of the standard task to test whether limiting motion evidence available to the macaque would increase the behavioral dependence on LIP signals. Motion duration was varied between 150 msec to 1 sec on each trial

but we found no reliable effect on neither psychometric parameter describing choice behavior (5008 trials, 3 sessions). We also explored LIP inactivation of simple visual responses, instead of focusing on decision-correlated activity. We placed the motion stimulus in the inactivated region and positioned targets ipsi-lesionally, which produced a small but non-significant effect on choices (2006 trials, 4 sessions). Taken together, these results limit the range of proposed roles for LIP function in decision making. If decision signals in LIP play a causal role in perceptual decision-making, the means by which choice-related activity is represented and/or read-out may involve far more flexible and spatially-widespread mechanisms than those typically asserted.

Title: Response of neurons in the medial prefrontal cortex during a time interval integration task

Authors: ***S. W. EGGER**[1,2], C.-J. CHANG[2,3], M. JAZAYERI[1,2];
[1]McGovern Inst. for Brain Res., [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [3]Div. of Med. Sci., Harvard Med. Sch., Boston, MA

Abstract: Complex behaviors often require sensitivity to temporal contingencies between stimuli and actions. To play an instrument, for example, the musician must continuously track the note durations while anticipating the upcoming beats. Internal variability, however, limits performance in tasks that require tracking the passage of time. We previously found that humans reduce this variability by both (1) incorporating information from prior experience and (2) integrating multiple measurements when possible (Egger and Jazayeri, 2014). However, the neuronal basis of these computations is not understood. To characterize the underlying neural mechanisms, we trained a monkey to perform a time interval integration and production task. In each trial, the animal was presented with three flashes of light (1, 2 and 3), demarcating two identical intervals (between flashes 1 and 2, and 2 and 3). Across trials, the interval between flashes was randomly sampled from a uniform distribution between 600 and 1000 ms. The

animal was required to measure the interval and reproduce it as accurately as possible with either a saccade or a manual lever press immediately following the 3rd flash. As in humans, the monkey's production intervals were biased toward the mean of the interval distribution, suggesting they used prior information in interval estimation. Moreover, the animal integrated the two measurements with approximately equal weights as indicated by the analysis of behavior in randomly interleaved probe trials in which the two sample intervals were slightly different. Overall, the monkey's behavior was consistent with the predictions of a Bayesian model that optimally integrates the two measurements with the prior distribution of sample intervals. While the monkey performed the interval integration task, we recorded single and multiunit activity in the medial prefrontal cortex, which is thought to play a key role in time perception and production. Some neurons exhibited responses predicted by previous observations such as ordinal selectivity, motor related bursts or response monitoring. Other neurons responded with ramping activity during the measurement and/or production epochs of the task. Interestingly, some of these neurons responded with different ramping activity between the two measurement epochs, indicative of a possible role in measurement integration. Taken together, these results suggest medial prefrontal neurons contribute to a broad basis of high-level functions necessary to perform the task: keeping track of the flash number, integration of measured intervals, preparation for interval reproduction and monitoring the outcome.

Title: Neural correlates of multimodal arm position estimation in the posterior parietal cortex

Authors: *P. VANGILDER, JR, Y. SHI, G. APKER, C. A. BUNEO;
SBHSE, Arizona State Univ., Tempe, AZ

Abstract: In order to improve neural prosthetic design, as well as to fully understand the neural correlates of arm position estimation, it is imperative that we understand how visual and

proprioceptive information interact in arm movement-related regions of the brain. Previous work in monkeys has shown that during the active maintenance of arm positions in 3D space, visuo-proprioceptive integration is associated with suppression of neural firing rates as well as reduced intratrial and across-trial neural variability in the posterior parietal cortex (PPC). To further explore the nature of integration induced changes in variability we compared the spike train and local field potential dynamics in the PPC as animals held their arm at multiple spatial locations while receiving either unimodal (proprioceptive) or bimodal (visuo-proprioceptive) feedback on a pseudorandom basis. Neurons were classified as Poisson, bursty, refractory or oscillatory based on their spike train power spectra and autocorrelograms. Forty percent of the neurons were classified as oscillatory in a 13-30 Hz frequency band in either unimodal and bimodal conditions or both. Significant spike-field coherence was common in this population of cells and under bimodal conditions the incidence of coherence was significantly greater than in cells without oscillatory spiking activity. The results suggest the presence of a temporal code for multimodal information in the PPC during the control of action, which may have important implications for the cortical representation of body schema.

Title: Congruence of spatial selectivity for local field potentials and spiking activity in primate posterior parietal cortex

Authors: ***N. J. HALL**[1,3], R. J. GERTH[2,3], C. L. COLBY[1,3];
[1]Neurosci., [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [3]Ctr. for Neural Basis of Cognition, Pittsburgh, PA

Abstract: A large body of evidence shows that the responses of single neurons in primate posterior parietal cortex are spatially selective. Modulations in the firing rate of individual

neurons reflect an output signal from the neuron. But what about the incoming synaptic activity that drives these neural responses? The synaptic input is thought to be reflected in local field potentials (LFP), which are low frequency fluctuations in the extracellular voltage. We asked whether LFPs are also spatially selectivity. We recorded in area LIP and adjacent parietal cortex in awake behaving monkeys. We used an 8-channel linear array electrode to measure LFPs and single unit activity simultaneously. We found that LFPs are spatially selective. Further, the spatial selectivity is congruent with that of the local single unit activity. These findings are consistent with previous observations on LFPs in parietal cortex (Hagan et al., 2012; Mirpour and Bisley, 2013). Recordings were carried out while the macaque performed a memory guided saccade task. During the task, the animal must perceive a briefly flashed visual stimulus, remember the location of the stimulus, then plan and execute a saccade to the remembered location. This task allows for the temporal separation of neural activity in response to the visual stimulus and saccade execution. Parietal neurons are spatially selective for visual responses and eye movements. Response fields for single neurons are typically at matched locations for each task epoch. We found that LFPs are likewise spatially selective for corresponding locations in each task epoch. We conclude that LFPs and spiking activity have congruent spatial selectivity.

Title: Evoked movement vectors of cortical motor fields in primates

Authors: ***D. J. MILLER**, R. M. FRIEDMAN, I. STEPNIEWSKA, J. H. KAAS; Psychology, Vanderbilt Univ., Nashville, TN

Abstract: The sensorimotor networks underlying coordinated movement useful in neural interfacing systems designed to restore motor behavior extend from primary sensory areas through the parietal lobe and into the frontal cortex. Long train intracortical microstimulation (ICMS) has been used to show the presence of classes of movements within important nodes in

this sensorimotor network, such as primary motor (M1) cortex of the frontal lobe and posterior portions of the parietal lobe (PPC; Stepniewska et al., 2005, 2009). Classes of movements evoked with ICMS are also preferentially connected across brain regions and this circuitry has been shown to mediate specific motor behaviors (Gharbawie et al., 2011). However, the local organization of movements is fractured within the broader movement domains which exhibit a rough somatotopy, making it difficult to determine the contributions these neurons make to coordinated movement. In this project, we investigate the local organization of evoked movement vectors (EMV) within domains in M1 and PPC in prosimian galagos and new world squirrel monkeys. Our data indicate that EMVs from M1 and PPC are highly consistent across individuals and exert excitatory or inhibitory effects upon EMVs from sites in similar or distinct movement domains, respectively. In addition, these results suggest that neurons in these cortical motor fields function in reference to coordinate frames dependent upon proprioceptive input as many EMVs in M1 and PPC show an effect of starting position. These data may help explain motor behavior by providing evidence suggestive of an organizing principle of cortical motor field physiology.

Title: An internal model for reaching using sensorimotor transformations

Authors: *C. USTUN;
Independent Scholar, Pasadena, CA

Abstract: Traditional accounts of visually guided reaching assume that the purpose of sensorimotor computation is to transform representations of reach targets, i.e. the desired final limb position, from visual coordinates into motor coordinates. However, behavioral and neurophysiological studies have increasingly challenged predictions of this movement-planning

framework. As an alternative, I present a model of sensorimotor processing that generates an internal representation of limb kinematics. Simulations show that a network model based on this hypothesis generates population responses consistent with those in reach-related areas of monkey posterior parietal cortex (PPC). In particular, the model provides an explanation for the puzzling phenomenon of intermediate reference frames commonly found in sensorimotor cortex. These results suggest that although sensorimotor representations are typically studied in the moments preceding movement, their proper interpretation requires a consideration of the movement itself.

Title: Visuo-motor processing of objects in pre-supplementary motor area F6 neurons of the macaque

Authors: *L. BONINI[1], A. LIVI[2], M. LANZILOTTO[2], M. MARANESI[1], P. RUTHER[3], F. BARZ[3], L. FOGASSI[2], G. RIZZOLATTI[1];
[1]Italian Inst. of Technol. - BCSMC, Parma, Italy; [2]Univ. of Parma, Parma, Italy; [3]Dept. of Microsystems Engin. (IMTEK), Univ. of Freiburg, Freiburg, Germany

Abstract: Area F6 underlies several high-order motor control functions, such as the learning of new motor sequences, task switching, and the temporal structuring and ordering of forthcoming behaviours based on sensory stimuli, in particular of forelimb actions. Indeed, anatomical studies suggest that F6 constitutes a bridge between prefrontal cortex and the ventral (F5c/p) and dorsal (F2) rostral premotor areas involved in the control of hand and arm motor actions. However, the possible contribution of area F6 neurons to the control of natural limb actions is poorly understood. To fill this gap, here we recorded F6 neurons activity by means of chronically implanted arrays of linear silicon-based multielectrode probes from one monkey while it was performing a visuomotor task including two main (randomized) conditions: one required the

monkey to grasp a target object (action), the other to remain still for the entire duration of the trial (inaction). Each trial started when the monkey engaged fixation in complete darkness. A cue sound instructed it either to grasp (high tone - action) or simply to fix (low tone - inaction) the subsequently presented target. After 800 ms a light switched on, revealing one among three different graspable objects (target presentation). At the end of the sound (go/no-go signal), the monkey had to reach, grasp and pull the object (0.8 s - action), or to remain still (1.2 s - inaction). We recorded 89 task-related neurons. Most of them (78%) showed sensory-evoked activity during the presentation of sensory stimuli, particularly object presentation during go relative to no-go trials, often (32%) followed by motor-related activity. The remaining neurons (22%) discharged only during action preparation/execution, or during the inaction phase. Interestingly, almost half of the visually-responsive neurons showed object-selective activity: when tested with a plastic barrier interposed between the monkey's hand and the object, which typically reduces object presentation responses of area F5 neurons, F6 neurons visual responses remained similar to those evoked by the presentation of the same object during no-go trials. These findings demonstrate that, besides being related to the selection and triggering of intentional actions, area F6 neurons can also show object/grip selectivity. As compared to area F5 neurons, which encode object properties in terms of the potential motor action afforded by it, area F6 neurons seem to encode object properties depending on whether the monkey will actually grasp them.

Title: Mirror neurons respond to the observation of intransitive actions

Authors: *V. PAPADOURAKIS[1,2], V. RAOS[1,2];
[1]Univ. of Crete Med. Sch., Iraklion, Greece; [2]Inst. of Applied and Computat. Mathematics, Fndn. for Res. and Technol. - Hellas, Iraklion, Greece

Abstract: According to the original description by Rizzolatti and colleagues, the prerequisite of triggering the discharge of mirror neurons (MNs) is the interaction of the hand with an object. On the other hand, several studies reported that the MN system in humans can be activated also by non object-directed (intransitive) movements. This difference between human and monkey MN systems has been considered to reflect an evolutionary step. A recent study reported that 73% of MNs recorded were responding to the observation of a pantomimed action, but no other data were provided. Moreover, neuroimaging studies in monkeys revealed that observation of intransitive actions activates the ventral premotor area F5. To resolve this discrepancy MNs were recorded from ventral premotor area F5 while the monkeys observed transitive and intransitive actions. Initially, the monkeys were trained to reach for and grasp 3D objects with the appropriate grips. At the beginning of each trial, a LED above the selected object turned on and the monkey had to fixate it and press a key. Following a fixation period, a dimming of the LED signaled the onset of the reach-to-grasp movement. The monkey had to reach for, grasp, pull and hold the object while fixating it until the extinction of the LED cuing its release. Then, the monkeys were trained to observe the experimenter employing the same object-directed reaching-to-grasp actions, as well as an out-reaching non-goal-directed movement with extended wrist and fingers towards the location where the object was placed during the transitive actions, while maintaining its gaze straight ahead. During observation, no cuing LED was visible to the monkey and the experimenter was getting instructions on a screen out of the monkey's view. The experimenter was standing next to the animal on its right side, and both reaching and grasping components of his movement were visible to the monkey. Out of the 216 MNs recorded, 197 responded to the observation of both transitive and intransitive actions. The discharge to both transitive and intransitive actions initiates with movement onset. The response peak occurs around 70% and 50% of the movement duration for transitive and intransitive actions, respectively. Furthermore, discharge rate for the intransitive actions is 30% and 10% lower than the response to the preferred and not-preferred transitive action, respectively. Finally, responses elicited by intransitive movements, last 60% less than those evoked by transitive ones. These results resolve the long lasting discrepancy on the stimuli triggering the monkey and human MN systems and dictate a reevaluation of the mechanism through which their functions are sub-served.

Title: State-dependent impact of transcranial alternating current stimulation of the motor mirror system

Authors: *M. FEURRA[1], M. NAZAROVA[2], E. BLAGOVESHCHENSKY[2], M. YUREVICH[2], A. LEBEDEVA[2], D. POZDEEVA[2], V. NIKULIN[3];

Abstract: Recent evidence showed that Transcranial Alternating Current Stimulation (tACS) entrains the endogenous cortical oscillatory activity with a frequency and state-dependent specificity. In a previous study we showed state-dependent effects of tACS delivered on the primary motor cortex (M1) during a motor imagery task. The theta and alpha-tACS increase of corticospinal excitability, respectively indicated a reinforcement of working memory processes required to mentally process and "execute" the cognitive task and a synchronization of alpha oscillatory attentional patterns commonly associated with visual imagery. Here we adopted the same experimental setup to test state-dependent effects of tACS during action-observation, a cognitive task which produces the activation of the mirror motor system that simulates what would happen if the observer would execute himself a not goal-directed pinch-to grip action. Motor-evoked potentials (MEPs) were obtained by transcranial magnetic stimulation (TMS) of M1 by using an online-navigated TMS-tACS setup. Preliminary data showed that beta-tACS confirmed to increase M1 corticospinal excitability of subjects at rest. During action observation, the increase of corticospinal excitability was maximal with alpha-tACS, likely reflecting hypothesis that the mu rhythm in alpha range may specifically index downstream modulation of primary sensorimotor areas by mirror neuron activity and appear to reflect the translation of perception into action. Interestingly the absence of theta-tACS enhancement might reflect a lack of working memory engagement which is crucial for visual motor imagery. Our findings help to disentangle similarities and differences between motor imagery and action observation in terms of frequencies specificity and confirmed that tACS could be used to induce state-dependent enhancement effects.

Title: Visual feedback modulates functional connectivity between anterior intraparietal sulcus and ipsilateral motor cortex

Authors: *G. JEGATHEESWARAN[1,2], M. VESIA[1], R. ISAYAMA[1,2], R. CHEN[1,2];
[1]Toronto Western Res. Institute, UHN, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Background: Mirror therapy, an intervention used to treat stroke-related motor dysfunction, uses visual feedback of an active unimpaired limb from a mirror to restore function in an impaired limb. Transcranial magnetic stimulation (TMS) studies suggest that the motor cortex (M1) ipsilateral to the moving hand is activated with mirror visual feedback. The mechanisms underlying this feedback are not well understood. However, with these illusory movements, the mirror neuron system involving neural structures in the parieto-frontal areas are thought to play a role. The anterior intraparietal sulcus (aIPS), in particular, is activated during action observation of a grasping movement. **Purpose:** The purpose of this study is to determine if aIPS causally influences the activity of ipsilateral M1 during movement preparation with mirror visual feedback. **Hypothesis:** We hypothesized that the aIPS-M1 functional connectivity will be modulated by mirror visual feedback. **Methods:** Eight healthy subjects (4 females and 4 males) participated and were tested in 4 randomized conditions: mirror (subjects looked at a mirror where they saw the right hand as an illusory left hand), no-mirror (subjects looked at an opaque board in place of a mirror), action observation (AO; subjects watched a video of a left hand while both their hands were at rest) and rest (subject looked at a mark placed in the centre while both hands were at rest). In the first two conditions, subjects were instructed to grip a force transducer with their right finger and thumb after an auditory "Go" signal. The subjects held the grip with 20% of their maximum voluntary contraction. TMS pulses were delivered before the grip through two coils placed on the right hemisphere separated by 2, 4, 6, 8 or 10 ms; the first pulse over the aIPS (90% resting motor threshold) and the second pulse over the M1 (1 mV). Motor evoked potentials (MEPs), were recorded from the resting left first dorsal interosseous muscle. **Results:** aIPS-M1 MEP ratio was facilitated in the mirror condition compared to rest at 4 ms ($P = 0.03$). Specifically, the MEP ratios (<1 means inhibition, >1 means facilitation) for rest, mirror, no-mirror and AO conditions at 4 ms were: 0.76 ± 0.24 (mean ± SD), 1.02 ± 0.37,

0.95 ± 0.31 and 1.15 ± 0.27, respectively. **Conclusions:** Findings suggest that the aIPS-M1 functional connectivity differed among the conditions at a specific time interval of 4 ms (rest vs. mirror). These findings provide further causal evidence that aIPS-M1 interactions can be modulated by mirror visual feedback.

Title: Enhanced human motor cortical plasticity by combined mirror visual feedback therapy and transcranial direct current stimulation (tDCS)

Authors: *Y. UEKI[1], M. HORIBA[1], Y. SHIMIZU[1], K. SAHASHI[1], K. ITO[1], J. MIZUTANI[1], I. WADA[1], N. MATSUKAWA[1], I. NOJIMA[2];
[1]Nagoya Citiy Univ., Nagoya, Japan; [2]graduate school of medicine, Nagoya university, Nagoya, Japan

Abstract: Non-invasive brain stimulation including transcranial magnetic stimulation and trans direct current stimulation (tDCS) has been shown to modulate brain processing and cortical plasticity non-invasively, which influence human motor behavior. Neuroplasticity based intervention including training and brain stimulation are promising strategy for facilitating motor skills learning. However, it remains unclear whether motor skill learning combined with tDCS induces robust plasticity in human primary motor cortex. To clarify this, we investigated changes motor cortical plasticity associated with the different stage of motor skill learning combined with mirror visual feedback therapy and tDCS. Subjects (Twelve healthy aged volunteers) participated in combined therapy twice on separated days. In Day 1 (early learning condition), they practiced ball rotation task of left hand with mirror visual feedback approach with tDCS or sham. As practice continuing, subjects learned how to rotate the ball and their performance was gradually improve. Seven days after, in Day 2 (late learning condition), they additionally learned the ball rotation with tDCS or sham. To analyze behavioral change, the maximum acceleration and

number of ball rotation of left hand were calculated just before and after the training with tDCS or sham. The motor cortical plasticity was also evaluated using by motor evoked potential. The maximum acceleration and number of ball rotation of left hand were significantly increased both in Day 1 and Day 2 with tDCS compared with sham. In addition, motor evoked potential were significantly increased both in Day 1 and Day 2 with tDCS compared with sham, showing that the combined mirror visual feedback therapy and tDCS induce the cortical plasticity more strongly. In conclusion, combined mirror visual feedback therapy and tDCS is useful tool for inducing motor cortical plasticity during early and late stage of motor learning. This therapy might become new rehabilitation strategy for modulating the brain processing related to the motor skill learning.

Title: A high resolution MEG study of predictive coding in action selection

Authors: ***J. J. BONAIUTO**[1], S. MEYER[2], G. BARNES[2], S. BESTMANN[3];
[2]Functional Imaging Lab., [3]Sobell Dept. for Motor Neurosci. and Movement Disorders, [1]Univ. Col. London, London, United Kingdom

Abstract: Predictive coding accounts suggest that higher cortical regions generate predictive models of the inputs they receive, whereas prediction errors are signalled through ascending connections from lower regions in the hierarchy. One specific hypothesis is that beta oscillations in deep cortical layers are markers of predictions, while prediction errors are reflected in gamma oscillations originating from superficial layers. We used high resolution MEG to test this frequency-specific predictive coding account of action selection. Subjects were first presented with a predictive stimulus (random dot kinematogram with apparent motion to the left or the right at one of three levels of coherence: low, medium, or high). The coherence levels were set for each individual based on their discrimination threshold. After a delay, an imperative stimulus (arrow pointing to the left or the right) required a left or right button press as quickly as possible.

The motion direction of the predictive stimulus was congruent with the imperative stimulus, with three levels of congruency (low, medium, high). The level of congruence thus influenced the strength of the prior expectation in a given context, whereas the level of coherence on a single trial dictated the strength of the prediction about the forthcoming imperative stimulus. Consequently, we reasoned that beta power should scale with motion coherence prior to the imperative stimulus, before the imperative stimulus occurs. By contrast, following the presentation of the imperative stimulus, gamma power should scale with coherence level in incongruent trials, i.e. when a violation of the prediction conveyed by the predictive stimulus occurred. We used subject-specific 3D printed head-casts (Troebinger et al., 2014a) which reduce coregistration and movement error to ~1mm and allow high precision mapping to anatomy (Troebinger et al., 2014b). We found that prior to the imperative stimulus, beta power in primary motor cortex scaled with the motion coherence of the predictive stimulus, consistent with beta oscillations signalling predictions about forthcoming actions. After the imperative stimulus, gamma power increased with decreasing coherence in congruent trials and increasing coherence in incongruent trials, providing support to the proposal that gamma activity encodes the prediction error.

Title: Comparison of TMS elicited and voluntary synergies of the human hand

Authors: *M. YAROSSI[1,3], Y. WEI[3], S. ADAMOVICH[3], E. TUNIK[2];
[1]Grad. Sch. of Biomed. Sci., [2]Sch. of Hlth. Related Professions, Rutgers Biomed. Hlth. Sci., Newark, NJ; [3]Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ

Abstract: Evidence in a non-human primate model suggests a small number of synergies, elicited by electrical microstimulation to M1, can capture the variance of EMG activity patterns elicited by grasping objects. The aim of this study was to establish if a similar relationship

between voluntary and elicited synergies can be determined for the human hand using transcranial magnetic stimulation (TMS) to stimulate motor cortical neurons. Five healthy subjects participated following informed consent. Prior to mapping, the first dorsal interosseous motor hotspot and resting motor threshold (RMT) were determined. High density TMS mapping was conducted at 110% of RMT, using neuronavigated TMS applied to a 7x7 cm area centered over the hotspot. EMG was recorded from 8 hand muscles. An elicited activation tuning (Elicited) was derived for each stimulation by determining the MEP amplitude of each muscle. Following mapping each subject performed hand gestures in the American Sign Language alphabet. Voluntary activation tunings (Voluntary) were determined for each sign by calculating the average rectified amplitude of EMG over a 2 second window. For each subject, we used non-negative matrix factorization (NNMF) to identify a set of synchronous muscle synergies underlying the elicited and voluntary EMG data. For a given dimensionality, the algorithms iteratively updated model parameters, until the total reconstruction error was reduced <5% over 10,000 iterations. These synergies were chosen for further analysis. The ability of the NNMF-decomposed synergies to reconstruct the original data from each task was found using a nonnegative least-squares constraint algorithm, and quantified as the one minus the root-mean-square error (RMSR) between the original and reconstructed data. Five or less NNMF-derived synergies were able to account for 93.0±1.2% (Voluntary) and 98.5±1.1% (Elicited) of the variance in the data set from which they were derived, providing evidence of the usefulness of NNMF for dimensionality reduction. Most interestingly, the elicited synergies accounted for 81.2±9.8% of the variance in the voluntary data set. These data provide evidence in a human model, that magnetic stimulation of a distributed M1 territory evokes a small number of synergies equivalent to those found from voluntary movement. This technique may be useful to assess the development of abnormal synergies in pathology, and track hand recovery associated with reduction of abnormal synergistic movement.

Title: Lysophosphatidylcholine(LPC)-induced pain is medicated by activation of TRPM2 in mice

Authors: P. CHO[1], *J. LIM[1], S. LEE[1], Y. KANG[1], S. OH[2], S. JUNG[1];
[1]Hanyang Univ., SEOUL, Korea, Republic of; [2]Seoul Natl. Univ., SEOUL, Korea, Republic of

Abstract: Lysophosphatidylcholine (LPC) is an endogenous lipid, of which hydrolysis is generally the result of the enzymatic action of phospholipase A2. LPC plays the important roles in the activation of macrophage, demyelinating disease and hyperalgesia and mechanical allodynia in peripheral neuropathy. In neuropathic pain, it was suggested that signaling pathway of LPC was associated with nitric oxide synthase, protein kinase C, or lysophosphatidic acid receptor. However, molecular mechanism of LPC-induced nociception has not been understood. The recent study reported that LPC-induced Ca2+ increase in neutrophil was mediated by transient receptor potential melastatin 2 (TRPM2) ion channel, which is a Ca2+-permeable nonselective cation channel activated by intracellular ADP-ribose (ADPR) and by hydrogen peroxide (H2O2). Thus we investigated whether LPC induce acute nociception, if so, what molecular mechanism is involved in nociception. The intraplantar injection of LPC evoked spontaneous pain behavior (licking and biting) for 30 min and reduced the paw withdrawal latency for 120 min, while LPC-induce nociception in TRPM2 -/- mice was decreased. In whole cell patch clamp, LPC activated the inward current with a biophysical property of TRPM2 and it was abolished by gadolinium and TRPM2 blocker, N-(p-amylcinnamoyl) anthranilic acid (ACA) in mice dorsal root ganglion (DRG) neuron. Taken together, our finding suggest that endogenous lipid, LPC is involved in the acute nociception, which is mediated by the activation of TRPM2 in DRG neuron and LPC/TRPM2 pathway may also be associated with neuropathic pain.

Abstract: TRPV1 channels of nociceptor endings play a critical role in peripheral pain transduction and are considered the final integrators of noxious stimuli. Ostearthritis (OA) is a joint pathology accompanied by intense pain. Nociceptive nerve endings of the joint synovial membrane are normally exposed to high molecular weight sodium hyaluronate (HMW-HA) contained the synovial fluid. HA appears degraded and diluted in painful OA whereas intra-articular injection of HMW-HA (viscosupplementation) reduces pain. We studied whether such pain reduction is mediated through a modulation by HA of the TRPV1 channels present in joint nociceptive terminals. Measurement of intracellular calcium changes (FURA-2AM), and patch-clamp recordings in several configurations were carried out in HEK-293 cells transfected with TRPV1-EYFP, and in cultured DRG neurons responsive to heat, capsaicin and low pH. In both HEK-TRPV1-EYFP and DRG neurons, exposure to HA decreased significantly the amplitude of the [Ca2+]i elevations evoked by these stimuli. Whole-cell membrane currents in HEK-TRPV1-EYFP and firing discharges recorded in cell-attached configuration in DRG neurons evoked by capsaicin, were also significantly reduced by exposure to HA. Single-channel recordings in HEK-TRPV1-EYFP evidenced that the inhibitory effect resulted from a decrease in the opening probability of TRPV1 channels. Intra-articular injection of HA in rats reduced significantly the frequency of nerve impulse discharges evoked by intra-arterial injection of capsaicin. Also, intra-plantar injection of HA in mouse significantly shortened the latency of nocifensive responses to heat (hot plate test). “In silico” docking analysis showed a high probability for an electrostatic-type interaction between HA and a short sequence “H+xRG” located in the extracellular S5-pore helix loop of the TRPV1 channel. Mutation (TRPV1 K615A/R617A) produced a channel whose current density was not significantly reduced by HA. Altogether, these findings suggest that HA inhibits TRPV1 channels in nociceptors, thereby explaining its analgesic effects in osteoarthritis. All experimental procedures were carried out according to Spanish Royal Decree 1201/2005 and the ECC directive 2010/63/EU.

Title: Spontaneous L-glutamate release enhancement and outward current produced by thymol in adult rat spinal substantia gelatinosa neurons

Authors: C. WANG, Z.-H. XU, T. FUJITA, C.-Y. JIANG, L. ZHU, T. YU, R. HIRAO, *E. KUMAMOTO;
Dept Physiol, Saga Med. Sch., Saga, Japan

Abstract: Thymol, which is contained in thyme essential oil, has various actions including antinociception, nerve conduction inhibition and transient receptor potential (TRP) channel activation. It has not yet been examined how thymol affects synaptic transmission. Although TRP channels expressed in the peripheral and central terminals of primary-afferent neuron are involved in nociceptive transmission, the central compared to peripheral terminal TRP channels have not yet been fully examined in property. In order to know whether thymol modulates excitatory transmission with a focus on TRP activation, we investigated its effect on glutamatergic spontaneous excitatory transmission in spinal cord lamina II (substantia gelatinosa; SG) neurons which play a pivotal role in modulating nociceptive transmission from the periphery. The experiment was performed by applying the conventional blind whole-cell patch-clamp technique to the SG neurons of adult rat spinal cord slices. Superfusing thymol (1 mM) for 3 min increased the frequency of spontaneous excitatory postsynaptic current (sEPSC) with a minimal increase in its amplitude in all neurons examined. Seventy-eight % of the neurons also produced an outward current at a holding potential of -70 mV. The sEPSC frequency increase and outward current produced by thymol were concentration-dependent with almost the same half-maximal effective concentration values of 0.18 and 0.15 mM, respectively. These activities of thymol (1 mM) were repeated at a time interval of 30 min, although sEPSC frequency increase in the second application had a tendency to be smaller in extent than that of the first one while the peak amplitudes of the outward currents in the first and second applications were almost the same. Thus, the presynaptic effect but not outward current recovered with a slow time

course after washout of thymol. A voltage-gated Na^+-channel blocker tetrodotoxin did not affect the thymol activities. The sEPSC frequency increase was inhibited by a TRPA1 antagonist HC-030031 but not a TRPV1 antagonist capsazepine, while these antagonists had no effect on the outward current. These results indicate that thymol increases the spontaneous release of L-glutamate onto SG neurons by activating TRPA1 channels while producing an outward current in SG neurons without TRPA1 and TRPV1 activation. These actions of thymol were similar in TRPA1 activation and outward current production to those of its stereoisomer carvacrol which is different in the position of -OH in the benzene ring from thymol. Thymol activities revealed in the present study could contribute to at least a part of its antinociceptive effect.

Title: Carvone presynaptically enhances glutamatergic spontaneous excitatory transmission by activating TRP channels in the adult rat spinal substantia gelatinosa

Authors: Q. KANG, *T. FUJITA, C.-Y. JIANG, L. ZHU, C. WANG, T. YU, R. HIRAO, E. KUMAMOTO;
Saga Med. Sch., Saga, Japan

Abstract: Transient receptor potential (TRP) channels in the spinal dorsal horn lamina II (substantia gelatinosa; SG), which are involved in the modulation of nociceptive transmission, have not yet been thoroughly examined in property. Various plant-derived chemicals including capsaicin, allyl isothiocyanate and menthol activate the TRP channels, resulting in an increase in the spontaneous release of L-glutamate onto SG neurons in spinal cord slices. The property of the TRP channels has been investigated in the cell body of primary-afferent neuron and in heterologous cells expressing the channels. We have recently reported that eugenol and zingerone, which activate TRPV1 channels in the cell body of primary-afferent neuron, activate TRPA1 channels in the SG. 1,8-Cineole, which is well-known to be a TRPM8 agonist, activated TRPA1 channels in the SG, while its stereoisomer 1,4-cineole activated TRPV1 channels. As a

result, we have proposed the idea that TRP channels located in the cell body and central terminal of primary-afferent neuron may differ in property from each other. A monoterpene ketone (-)-carvone, which is contained in spearmint oil, has been reported to activate TRPV1 channels expressed in dorsal root ganglion (DRG) neurons. In order to know a detail of the property of the central terminal TRP channel, we examined the effects of (-)-carvone and its stereoisomer (+)-carvone, which is contained in caraway oil, on glutamatergic spontaneous excitatory transmission by applying the conventional blind whole-cell patch-clamp technique to SG neurons of adult rat spinal cord slices. (-)-Carvone and (+)-carvone increased the frequency of spontaneous excitatory postsynaptic current (sEPSC) in a reversible and concentration-dependent manner with a small increase in its amplitude. This increase in sEPSC frequency was accompanied by a small inward current. Half-maximal effective concentrations of (-)-carvone and (+)-carvone in increasing sEPSC frequency were 0.70 mM and 0.72 mM, respectively. The (-)-carvone but not (+)-carvone activity was inhibited by a TRPV1 antagonist capsazepine. On the other hand, the (+)-carvone but not (-)-carvone activity was inhibited by a TRPA1 antagonist HC-030031. These results indicate that (-)-carvone and (+)-carvone activate TRPV1 and TRPA1 channels, respectively, resulting in an increase in spontaneous L-glutamate release onto SG neurons, with almost the same efficacy. Such a difference in TRP activation between the stereoisomers of carvone as well as cineole may serve to know the property of TRP channels located in the central terminal of DRG neuron in the SG.

Title: Loss of function in trpv3 associated with olmsted syndrome and erythromelalgia

Authors: Z. PANG, Z. LI, *M. J. CATERINA;
Neurosurg., Johns Hopkins Sch. Med., Baltimore, MD

Abstract: Olmsted Syndrome (OS) is a rare human skin disorder characterized by dramatic dermatological and sensory abnormalities. Patients with OS develop multilating palmoplantar

keratoderma and periorificial keratotic plaques, as well as severe pain and itch sensation. Recently, OS has been linked to mutations in the non-selective ion channel Transient Receptor Potential Vanilloid 3 (TRPV3), which is specifically expressed in skin keratinocytes. Several TRPV3 mutations identified in OS patients (Gly573Ser, Gly573Cys, Trp692Gly) as well as their mouse homologues have been shown to be constitutively active and to cause cell death when transfected into HEK293 cells. It remains unclear how the changes of this ion channel in the skin lead to sensory abnormalities, especially the pain phenotype in OS patients. Existing mouse lines carrying these TRPV3 mutations (Gly573Ser, Gly573Cys) have been described as models of Atopic Dermatitis with itch. However, so far there is no mouse model of OS with a pain phenotype resembling that of human patients. In 2014, several new TRPV3 mutations (Leu673Phe, Gly568Cys) were reported in OS patients with erythromelalgia, a condition associated with extreme pain and dramatic vasoreactivity. in the present study, we sought to figure out the functional roles of these mutations, by transfecting them into HEK293 cells and monitoring their effects on cell survival, cytosolic calcium and whole cell current. Mutation TRPV3 Gly568Cys caused dramatic cell death while TRPV3 Leu673Phe had no effect on cell survival. Upon stimulation with the TRPV3 agonist 2-APB, cells expressing the TRPV3 Leu673Phe mutant channel exhibited little calcium influx, while those expressing TRPV3 Gly568Cys showed robust calcium influx. In whole cell patch-clamp recordings, TRPV3 Leu673Phe showed no constitutive activity and could not be activated by 2-APB. However, TRPV3 Gly568Cys demonstrated constitutive activity and a further elevation of current with 2-APB stimulation. Our work provides evidence that both gain-of-function and loss-of-function TRPV3 mutations might contribute to the development of OS with erythromelalgia.

Title: Calcium influx through TRPV1 inhibits mechanosensitive Piezo channels via phosphoinositide depletion

Authors: *T. ROHACS, I. BORBIRO, D. BADHEKA;
Pharmacol. & Physiol., Rutgers, New Jersey Med. Sch., Newark, NJ

Abstract: Piezo2 channels mediate rapidly adapting mechanically activated currents in sensory dorsal root ganglion (DRG) neurons. Expression of these mechanosensitive ion channels in a subset of TRPV1 positive neurons suggests their role in pain related sensory mechanotransduction. We show that capsaicin application inhibited rapidly adapting mechanically activated currents in TRPV1 positive DRG neurons. TRPV1 activation also inhibited heterologously expressed Piezo1 and Piezo2 ion channels in whole-cell patch clamp experiments. Inclusion of the plasma membrane phospholipid phosphatidylinositol 4,5-bisphosphate [PI(4,5)P2] or its precursor PI(4)P in the patch pipette alleviated this inhibitory effect. Activation of PLCβ by stimulating muscarinic receptors only marginally inhibited mechanically activated Piezo1 currents. Experiments using phosphoinositide sensors revealed that activation of PLCδ by a robust calcium influx through TRPV1 severely depleted PI(4,5)P2 and PI(4)P. On the other hand, muscarinic stimulation of PLCβ significantly decreased PI(4,5)P2 levels, but only induced a small decrease of PI(4)P. This differential activation of PLC isoforms may explain the difference between the inhibitory effects of these two PLC pathways. Depletion of PI(4,5)P2 and PI(4)P using a chemically inducible lipid phosphatase replicated the inhibition of Piezo1 currents. Additionally, PI(4,5)P2 and PI(4)P applied to excised inside-out patches inhibited the rundown of Piezo1 activity further emphasizing the significance of these phosphoinositides in Piezo channel regulation. Here we demonstrate that the activity of Piezo channels require the presence of either PI(4,5)P2 or PI(4)P and severe depletion of both phosphoinositides by capsaicin-induced TRPV1 activation limits channel activity. This effect may contribute to the local analgesic effect of capsaicin.

Title: Prostaglandin E2 (through EP1 receptor) decreases the internalization of the transient receptor potential vanilloid type 1 (TRPV1) in dorsal root ganglia (DRG) neurons *in vitro* -a new mechanism in mediating the trafficking of TRPV1

Authors: *S. M. JAFFAL;
McGill Univ., Montreal, QC, Canada

Abstract: Transient receptor potential vanilloid type 1 (TRPV1) is a non-selective cation channel responsible for the pain sensation and is activated by several stimuli (including inflammatory mediators). These mediators act by increasing the availability of TRPV1 at the surface of the dorsal root ganglia (DRG) neurons and/or the activity of the channel. Prostaglandin E2 (PGE2) is a well-known inflammatory mediator that binds to one or more of its 4 receptors (EP1, EP2, EP3 and EP4) and plays a role in modulating TRPV1 and augmenting inflammatory pain. In this study, a new mechanism has been identified for PGE2-EP1 in regulating the trafficking of TRPV1 in the DRG neurons of Sprague Dawley rats. By culturing the rat DRGs, using agonists, internalization assay, collecting-quantification of the images and performing statistical analysis, the following result was found: the level of the labelled internalized TRPV1 receptor decreased, significantly, by 45% upon treating the DRGs with 50 μM of the EP1 agonist (17-Phenyl trinor prostaglandin E2, 17PGE2) compared to control groups. In contrast, no significant difference was found between the neurons that were treated with 50 μM of the EP4 agonist (prostaglandin E1 alcohol, PGE1OH) and the control ones suggesting a possible new mechanism for PGE2 (via EP1 receptor) in mediating the availability of TRPV1 at the surface of DRG neurons (and accordingly increasing inflammatory pain). Moreover, the same dose of the EP1 agonist, 17PGE2, was effective (with a similar potency to the EP4 agonist-PGE1OH) in enhancing the 10 μM capsaicin-induced cobalt influx (an efficient assay used to measure the activity of TRPV1) in the neurons indicating that decreasing the internalization of TRPV1 in the DRGs is a unique mechanism for EP1 receptor. These data are in agreement with my behavioral results, previously presented, in which the intraplantar (ipl) injection of the EP1 agonist (but not the agonists of EP2, EP3 or EP4 receptors) caused prolongation of capsaicin induced mechanical allodynia in the rats. Accordingly, identifying the exact interaction between PGE2/EP1, TRPV1, the internalization machinery & membrane cytoskeletal changes (in more details) and its impact in inflammatory pain can be of therapeutic value.

Title: Acid-sensing ion channels (ASICs) detect moderate acidifications to induce ocular pain

Authors: *X. GASULL[1], G. CALLEJO[1], A. CASTELLANOS[1], M. CASTANY[2], A. GUAL[1], C. LUNA[3], M. ACOSTA[3], J. GALLAR[3], J. P. GIBLIN[1];

Abstract: Sensory nerve fibers innervating the ocular anterior surface detect external stimuli producing innocuous and painful sensations. Protons are among the first mediators released by damaged cells during inflammation, tissue injury or other chronic ophthalmic conditions. Here, we studied whether Acid-Sensing Ion Channels (ASICs) are expressed in corneal sensory neurons from the trigeminal ganglia, their roles in the response to moderate acidifications of the ocular surface and their participation in pathologies producing ocular surface inflammation. Moderate acidic pH (6.6) activated ASIC-like currents in corneal sensory neurons, which were blocked by ASIC1 or ASIC3-specific toxins. Acidic pH depolarized corneal sensory neurons to fire action potentials, an effect blocked by the ASIC3 inhibitor APETx2. GMQ, an ASIC3 agonist, activated a population of corneal polymodal sensory nerve fibers and significantly increased the blinking and tearing rate. ASIC blockers abolished the nocifensive behaviors produced by application of either a moderate acidic stimulus or commercial ophthalmic drugs formulated in acidic solution. In a model of allergic keratoconjunctivitis, ASIC currents were enhanced and nocifensive behavior was greatly reduced by ASIC3 blockade, presumably by reducing nociceptor sensitization during the inflammatory process. In a model of dry eye disease, the role of ASICs was not as prominent. In addition to the well-established role of TRPV1, we show that ASICs play a significant role in the detection of acidic insults at the ocular surface. The identification of ASICs in corneal neurons as well as their alterations during different diseases is critical for the understanding of sensory ocular pathophysiology. They are likely to mediate some of the sensations of discomfort associated with the use of several ophthalmic

formulations and may represent novel targets for the development of new therapeutics for ocular pathologies where discomfort and pain are prominent symptoms.

Title: A-kinase anchoring protein 79/150 coordinates signaling from metabotropic glutamate receptor to transient receptor potential a1 in sensory neurons

Authors: ***K. SZTEYN**[1], R. GOMEZ[1], J. DU[2], S. CARLTON[2], N. A. JESKE[1];
[1]OMS, Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX; [2]Dept. of Neurosci. and Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Glutamate is the dominant neurotransmitter in the nervous system and group I metabotropic receptors (mGluR1/5) are involved in peripheral inflammatory signal transduction. In the present study we identify Transient Receptor Potential A1 (TRPA1) channel as a downstream target of mGluR1/5, as dorsal root ganglia neurons (DRGs) showed significantly increased Mustard Oil (MO) currents after treatment with the specific mGluR1/5 agonist (RS)-3,5-Dihydroxyphenylglycine (DHPG). Research results indicate that this sensitization is dependent on A-Kinase Anchoring Protein 79/150 (AKAP), as neurons isolated from AKAP KO mice demonstrated no change to MO current following DHPG pre-treatment. mGluR1/5 activation has been shown to increase the activity of Protein Kinase A (PKA), a kinase anchored to multiple plasma membrane targets ins sensory neurons. We explored this notion with electrophysiological approaches, revealing WT DRG neurons to demonstrate enhanced TRPA1 activity following 8-Br-cAMP (PKA activator) treatment, whereas DRG neurons isolated from AKAP KO mice were not affected. Further, we were able to confirm electrophysiological data using nociceptive behavioral models. Pre-treatment of WT mice with 8-Br-cAMP resulted in increased nociceptive behavior in response to MO, when compared with control group. This modification of nociceptive behavior was not observed in AKAP KO littermates. In summary,

activation of mGluR1/5 in DRG neurons results in TRPA1 sensitization in an AKAP-dependent manner. Furthermore, it is probable that PKA plays a major role in this signaling paradigm.

Abstract: Spinal cord injury (SCI)-induced pain presents a significant clinical problem for patients with few effective long term treatments. Therefore, it is necessary to identify new therapeutic targets and approaches. Calcitonin gene related peptide (CGRP) is produced by neurons in the dorsal root ganglia and thought to play a key role in nociceptive neurotransmission in the spinal dorsal horn. Hypersensitivity to CGRP and/or sprouting in response to injury may contribute to allodynia and hyperalgesia in persistent neuropathic pain conditions. A truncated CGRP peptide, CGRP8-37, acts as a CGRP antagonist and can reverse symptoms of neuropathic and inflammatory pain in animal models.This study aims to test the analgesic potential of the neuropathic pain gene therapy candidate cDNA encoding CGRP8-37. A truncated CGRP peptide, CGRP8-37, acts as a CGRP antagonist and can reverse symptoms of neuropathic and inflammatory pain in animal models. This study aims to test the analgesic potential of the neuropathic pain gene therapy candidate cDNA encoding CGRP8-37.Human

CGRP cDNA from Open Biosystems was used to amplify analgesic CGRP8-37 sequence. The CGRP8-37fragment was subcloned downstream of the peptidylglycine-amidating monooxygenase (ssPAM/pGEMT) signal sequence to allow CGRP8-37 to be amidated and secreted, and subcloned into lenti-EGFP-WPRE viral vector. Immunocytochemical colocalization of anti-CGRP and Golgi marker anti-Giantin antibody confirmed production of secretable CGRP8-37 peptide. The recombinant lenti-sspam-CGRP8-37-EGFP virus were produced by Miami Project Viral Vector Core. Spinal cord clip compression injury was used to induce pain-related behavior in rats and tactile and cold allodynia were evaluated weekly. At 3-5 weeks post injury when pain-related behavior was clearly established, animals were injected with the lenti-sspam-CGRP8-37-EGFP or control lentivirus intraspinally into lumbar dorsal horn. Attenuation of tactile and cold allodynia was observed by 2-3 weeks post injection with gradual improvement of behavioral outcomes towards pre-injury levels by 8-9 weeks post-SCI. In contrast, allodynia persisted in animals receiving control vector. No effects on motor impairment were observed in any vector treated groups, with comparable BBB scores over the experiment duration. Our findings suggest that engineered compound constructs encoding analgesic agents have the potential to alleviate SCI-induced pain.

Title: RNA-seq based transcriptome profiling of human and mouse dorsal root ganglion yields insight into robustness of mouse models for human pain therapeutic studies

Authors: *A. TORCK, J.-Y. V. KIM, M. Q. ZHANG, G. DUSSOR, T. J. PRICE, P. RAY; The Univ. of Texas At Dallas, Dallas, TX

Abstract: The dorsal root ganglion (DRG) contains sensory neurons that innervate the surface of the body and many visceral organs. Included amongst these neurons are nociceptors, specialized neurons that detect damaging or potentially damaging stimuli, which are required for the detection of acute pain and play a key role in the development and maintenance of chronic pain states. RNA-seq has recently been used to elucidate the transcriptome of this tissue in mouse and rat but the transcriptome of human DRG has not been explored. We obtained fresh, lumbar DRG tissue from female human donors and performed 75bp paired-end polyA+ RNA-sequencing on the Illumina platform. The sequenced fragments were mapped to the Gencode v14 reference transcriptome / hg19 reference genome to yield 80M mapped fragments, and relative transcript abundance in FPKM (Fragments Per Kilobase per Million mapped fragments) was quantified using the TopHat-Cufflinks toolkit. We compared our RNA-seq dataset to publicly available mouse DRG RNA-seq data and performed integrative analysis with RNA-seq data from several tissues associated with drug side effects (e.g. heart, small intestine, whole brain) to perform an unbiased search for conserved gene expression in DRG across both species. We find that there is broad conservation of known DRG and/or nociceptor enriched genes (e.g. P2XR3, SCN10A, SCN11A, NTRK1, MRGPRD) across mouse and human DRGs. However, hierarchical clustering of gene subsets demonstrate clear divergence between mouse and human DRG in some key respects. Information theory approaches were used to identify tissue-specific genes in human and mouse DRG compared to tissues associated with drug side effects. We find strong correlation of expression across tissues between species for a few hundred DRG-specific genes, including known genes enriched in the DRG and previously unidentified ones. However, divergence in expression across tissues amongst a large subset of genes expressed in human and mouse DRG highlight differences in tissue-specific gene regulation that are likely important when considering the relevance of mouse models for development of human pain therapeutics. Ongoing efforts include adding more human DRG samples to the dataset, including samples obtained from chronic pain patients.

Title: Primary afferents temporally encode the noxious stimulus for pain signaling

Authors: *K. CHO[1], J. CHOI[1], D. SIN[2], S.-P. KIM[3], D. JANG[1], S. JUNG[1];
[1]Hanyang Univ., Seoul, Korea, Republic of; [2]Seoul Natl. Univ., Seoul, Korea, Republic of;
[3]UNIST, Ulsan, Korea, Republic of

Abstract: Even though an activation of a primary afferent C-fiber is conceptually assumed to initiate a pain response, there are studies reporting no pain response under the activation of the afferents. One of the strong explanations is the neural network that a fiber's activation is considered as a single input to central nervous system. However, the network process is not enough to interpret all the complex sensations in animal. Moreover, most primary C-fibers contain various chemoreceptors responding to each agonists. For example, TRPV1 and TRPA1 are expressed commonly on a same fiber's membrane. Thus, chemical specific processing might take an account to such a modified pain sensation. In this study, the responses and its characteristics of primary afferents for different chemicals have been investigated on *ex vivo* single fiber recording setup. The time stamps of the evoked action potentials recorded from the skin-nerve preparation from the mice were recorded. A mouse was sacrificed before each experiment, and their hind paw skin including the saphenous nerve was extracted with surgical methods. After the identification of a single fiber on the recording setup, a chemical was applied. As a result, we obtained the response for a single chemicals where the firing pattern of each showed different patterns. In every trial, the chemicals were applied on the different receptive field of the skin to prevent a counter effect from the other.

Title: The role of PLCδ4 in regulation of TRPM8 channels in sensory neurons

Authors: *Y. YUDIN, T. ROHACS;
Pharmacol. and Physiol., Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: The perception of ambient temperature changes is carried out by the peripheral endings of sensory dorsal root ganglion (DRG) neurons. A small population of neurons expressing the Transient Receptor Potential Melastatin 8 (TRPM8) ion channel works as a major sensor for moderately cold temperatures with a threshold of ~28°C. We and others showed that Ca^{2+} influx through recombinant TRPM8 activates a Ca^{2+} sensitive phospholipase C (PLC) isoform, which leads to depletion of phosphatidylinositol-4,5-bisphosphate with a consequent decrease in TRPM8 currents (desensitization). Previously we have found that the most abundant highly Ca^{2+} sensitive PLC isoform in DRG neurons is PLCδ4. Here we performed whole-cell patch clamp experiments on TRPM8 positive DRG neurons from PLCδ4-KO and wild-type (WT) mice. We identified two TRPM8 positive neuronal subpopulations based of their body size. Small neurons had significantly larger menthol-induced inward current densities compared to the medium-large ones. The majority of the small TRPM8 positive cells responded to the TRPV1 agonist capsaicin, while the majority of larger cells did not. In small PLCδ4-KO neurons both menthol and cold induced larger currents compared to cells from WT animals. In medium-large PLCδ4-KO cells however menthol-induced currents were similar to those in WT cells. In current-clamp experiments small neurons had a more depolarized resting membrane potential, and required smaller current injection to generate action potentials (AP) than medium-large cells. In small neurons positive current injection initially caused a train of AP during current pulses; increasing the current magnitude lead to a drastic reduction of the AP frequency in WT but KO neurons were able to generate AP at maximal frequency. In small PLCδ4-KO neurons, menthol application induced a larger depolarization and generation of AP with frequency significantly higher compared to WT neurons. Our electrophysiological experiments indicate possible differences in temperature perception between these two mouse strains. Therefore we performed behavioral experiments on PLCδ4-KO and WT mice and found higher cold sensitivity (acetone evaporation test) in KO animals. Pretreatment with the TRPM8 antagonist PBMC (10 mg/kg) reduced cold-induced responses in both groups. Our presented data support the involvement of PLCδ4 in the mechanism of regulation TRPM8 channel activity and desensitization in-vivo.

Title: Functional characterization of cold-sensitive neurons using constellation pharmacology

Authors: *T. A. MEMON, R. W. TEICHERT, B. M. OLIVERA;
Dept. of Biology, Univ. of Utah, Salt Lake City, UT

Abstract: Cold-sensitive neurons comprise ~8% of the neurons within the lumbar dorsal root ganglia (DRG) of adult C57BL/6 mice. In order to study these neurons, we have employed calcium imaging, which allows us to observe functional responses from >100 cultured neurons simultaneously and to determine the signaling proteins that mediate such responses, using target-specific stimuli and subtype-selective pharmacological agents. In Teichert et al. (2012), we had reported identification of cold-sensitive neurons in DRG culture using cold bath solutions and receptor agonists such as menthol, to activate TRPM8 channels, and allyl-isothiocyanate, to activate TRPA1 channels. These neurons were then classified as cold-thermosensors and -nociceptors based on their response profiles and functional expression of various ion channels, as determined by subtype-selective pharmacological agents. With recent studies using TRPM8-/- and TRPA1-/- mice, and HEK cells overexpressing human TRPA1 channels, we have established the contribution of TRPM8 and TRPA1 channels to cold-sensation in cold-thermosensors and -nociceptors. Furthermore, we have examined the functional expression of the voltage-gated sodium channel subtypes and a broad range of potassium channels using subtype-selective pharmacological agents to comprehend the ion-channel diversity observed in cold-thermosensors and -nociceptors. As a result, we now have a better understanding of the constellations of ion channels that are functionally integrated in these neurons. Similarly, an integrated molecular picture can be determined for cold-related pain disorders such as, cold-allodynia and hyperalgesia. In the future, similar studies may elucidate how the constellations of signaling components within each cell-type change as a function of a disease state, which may ultimately help in developing novel therapies.

Title: Chemokine signaling mediates mechanical and cold hypersensitivity in sickle cell disease

Authors: *K. J. ZAPPIA[1], C. A. HILLERY[2,3], C. L. STUCKY[1];
[1]Cell Biology, Neurobio. and Anat., [2]Dept. of Pediatrics and Children's Res. Inst., Med. Col. of Wisconsin, Milwaukee, WI; [3]Blood Res. Inst., BloodCenter of Wisconsin, Milwaukee, WI

Abstract: Sickle cell disease (SCD) is a genetic disorder characterized by sporadic vaso-occlusive episodes that cause acute painful and debilitating crises. Beyond this acute pain, nearly 50% of adult patients with SCD also develop chronic baseline pain, and experience increased sensitivity to touch and to cold temperatures. Further, there are many reports of increased levels of inflammatory mediators in SCD. Despite the frequency and severity of the pain these patients experience, little is known about the mechanisms underlying the chronic pain and increased thermal sensitivity in SCD, or how inflammatory mediators may contribute to this phenotype. Therefore, the aim of this study is to identify mechanisms leading to mechanical and cold hypersensitivity in the Berkeley transgenic mouse model of SCD. To begin to address a possible role of inflammatory mediators, we observed that the chemokine (c-c motif) ligand 2 (CCL2) is increased in the plasma of SCD mice. CCR2, the primary receptor for CCL2, was expressed in the dorsal root ganglia of sickle and control mice at similar mRNA levels. Behavioral testing for mechanical and cold sensitivity first confirmed that sickle mice displayed both tactile hypersensitivity and enhanced cold aversion. Next, we show pretreatment with a selective CCR2 antagonist effectively alleviated the prominent behavioral mechanical hypersensitivity in sickle mice without impacting baseline sensitivity of control mice. Similarly, blockade of CCR2 significantly reduced the cold aversion in sickle mice. We have previously shown that the cold and mechanical hypersensitivity in SCD appear to be mediated, at least in part, by sensitized peripheral sensory afferents. Therefore we also report the effect of CCR2 blockade in mediating the sensitivity of isolated sensory neurons to both cold temperature and focal mechanical stimulation. The results of these studies begin to provide inside into immune regulation of hypersensitivity in sickle cell disease.

Title: Distinct pathways underlying peripheral thermal and mechanical hypersensitivity induced by C-type natriuretic peptide

Authors: *A. J. SHEPHERD[1], A. TIWARI[2], L. LOO[3], D. P. MOHAPATRA[1];
[1]Dept. of Anesthesiol., Washington University, Sch. of Med., Saint Louis, MO; [2]Sch. of Med., Vanderbilt Univ., Nashville, TN; [3]Sch. of Med., Univ. of North Carolina, Chapel Hill, NC

Abstract: Atrial/brain/C-type natriuretic peptides (A/B/CNP) were originally described for their role in the maintenance of blood pressure. They are also known to be involved in various vascular and inflammatory pathologies, where their release is enhanced by pro-inflammatory mediators. Prior studies have shown that activation of the A- and B-type natriuretic peptide receptors (NPR-A and NPR-B) induce bifurcation of sensory neuron central axons via activation of guanylyl cyclase (GC) and production of intracellular cyclic GMP (cGMP). Furthermore, the NPR-C receptor (originally categorized as the NP clearance receptor, due to its lack of an intracellular GC-coupling domain), is now known to couple to $G\alpha_{i/o}$-containing signaling complexes. Previous studies have shown that the $G\beta\gamma$ subunits of $G\alpha_{i/o}$-coupled NPR-C receptors can upregulate the function of transient receptor potential vanilloid-1 (TRPV1) channel via a non-canonical activation of protein kinase C (PKC) in mouse dorsal root ganglia (DRG) sensory neurons. Such modifications in TRPV1 underlie the ability of CNP to evoke thermal hyperalgesia in mice. Here we show that intraplantar CNP (100 pmol) also elicits robust and sustained peripheral mechanical hypersensitivity, which is blocked by the TRPV1 antagonist AMG9810, and attenuated by the inhibitors of $G\beta\gamma$ signaling (Gallein) and PKC (BIM-I). CNP-induced peripheral mechanical hypersensitivity was also absent in mice lacking functional TRPV1. Given that CNP also induces NPR-B-dependent cGMP production, we verified the role of cGMP-dependent protein kinase (PKG) in this phenomenon. Remarkably, co-injection of CNP with the PKG inhibitor KT5823 completely attenuated mechanical hypersensitivity, without affecting the development of thermal hypersensitivity. CNP administration also led to significant enhancement of nociceptive sensory afferent fiber density in the plantar region of mouse hind paws, and in cultured mouse DRG neurons, as well as the density of TRPV1 protein therein. Interestingly, such CNP-induced morphological changes in sensory neurons were completely attenuated by inhibition of PKG. These observations suggest that CNP released from vascular endothelia in inflamed tissue can elicit both thermal and mechanical hypersensitivity through two distinct signaling cascades: 1) NPR-C/$G\beta\gamma$/PKC-dependent modulation of TRPV1 function elicits thermal hypersensitivity, and 2) NPR-B/cGMP/PKG mediates increased neurite density, in combination with TRPV1 modulation, resulting in the development of mechanical hypersensitivity.

Title: Impaired cholinergic modulation in the prelimbic cortex of a rat model of neuropathic pain

Authors: ***D. RADZICKI**[1], M. MARTINA[2], S. POLLEMA-MAYS[2];
[2]Physiol., [1]Northwestern Univ., Chicago, IL

Abstract: Chronic pain patients suffer from working memory deficits; similarly, chronic pain impairs animal performance on attention and memory tasks. The mechanisms underlying the attention and memory deficits remain unclear. In primates and rodents working memory and attention are encoded in the prefrontal cortex. Recent reports have shown that the prefrontal cortex and other limbic areas undergo functional and morphological reorganization in chronic pain. The medial prefrontal cortex receives extensive cholinergic input from the basal forebrain and cholinergic modulation plays a critical role in cognitive tasks such as attentional processing and working memory. We have studied the cholinergic modulation in the prelimbic (PL) medial prefrontal cortex in the Spared Nerve Injury (SNI) model of neuropathic pain. We performed patch clamp recordings from layer 5 pyramidal neurons in acute rat brain slices of the cortex contralateral to the peripheral injury and found that 1 week after surgery cholinergic modulation was severely impaired in SNI animals. The large ACh-induced leftward shift of the input/output curve observed in sham animals was almost completely abolished in SNI pyramidal neurons and acetylcholine was no longer capable of inducing the persistent firing often observed in recordings from sham animals. These changes were due to the strong reduction (~60%) of an M1-mediated muscarinic current in the pyramidal cells of SNI rats, possibly due to desensitization of the response. We suggest that the impaired cholinergic modulation in the prefrontal cortex may play a critical role in the pain-associated cognitive deficits.

Abstract: Peripheral CB2 receptors have been linked to immune response, inflammation and recently to nociception or allodynia. In central nervous system little is known about its expression and function of CB2 receptors in the integration of nociceptive function. CB2 mRNA has been found in thalamus but their protein expression and participation in the integration of pain signals is not known. To understand the possible effect of CB2 receptor on central nociception in the ventrolateral thalamus, we have evaluated the expression and the effect of their activation on a rat tail flick model of pain. Male Wistar rats were cannulated in the ventrolateral thalamus and microinjected with the CB2 receptor agonist JWH-133 1μM and 10μM. CB2 receptor agonist administration increases the latency to tail-flick evaluated at 15, 30, 45 and 60 minutes after administration. By immunohistochemistry we detected CB2 protein expression in neurons of the ventrolateral thalamus. This data suggested that central CB2 receptor activation can contribute to the observed antinociceptive effect of systemic administration of CB2 selective receptor agonist.

Title: Activation of corticostriatal circuitry relieves acute pain

Authors: *H. Y. LIN, R. YANG, T. MANDERS, M. LEE, J. WANG;
Anesthesiol., NYU Sch. of Med., New York, NY

Abstract: Central circuits that regulate acute pain sensitivity are not well-studied. Our previous study has shown that optogenetic activation of the prefrontal cortex (PFC) produces strong anti-nociceptive effects in rats with chronic neuropathic pain and revealed that projections from the PFC to the nucleus accumbens (NAc) mediate these pain-relieving effects. However, the effect of PFC activation in acute pain states has not been demonstrated. Here, we optogenetically activate the PFC in rats with the paw incision (PI) model of acute pain, and measure the behavioral responses of this activation. Our results indicate that activation of the PFC reduces sensory symptoms of acute pain in rats, and this pain-relieving function is likely mediated by the prefrontal projections to the NAc. Furthermore, the outcome of conditioned place preference shows that PFC activation can also regulate the aversive quality of acute pain. Thus, these results indicate that the PFC can strongly influence both the sensory and affective aspects of acute pain.

Title: Contribution of 5-HT_{2C}R to abnormal synaptic transmission in amygdala pathways in a neuropathic pain model

Authors: *W. ZHANG[1], T. A. GREEN[2], V. NEUGEBAUER[1];
[1]Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [2]Pharmacol. and Toxicology, Univ. of Texas Med. Br., Galveston, TX

Abstract: The amygdala plays critical role in emotional-affective aspects of pain. Abnormally enhanced activity of neurons in the central nucleus (CeA) generates pain-related emotional responses and anxiety-like behaviors. CeA output can be modulated by excitatory and inhibitory synaptic inputs from the basolateral nucleus (BLA). We found impaired synaptic inhibition and increased output of CeA neurons in an arthritis pain model but underlying mechanisms remain to be determined. Serotonin receptor subtype 5-HT_{2C}R in the BLA, but not CeA, has been implicated in anxiety-like behaviors. Here we tested the hypothesis that 5-HT_{2C}R in the BLA contributes to abnormal synaptic transmission in the BLA to CeA pathway in a neuropathic pain model. Whole-cell patch-clamp recordings were made from CeA neurons in brain slices from neuropathic rats (SNL model) and from sham controls. Rats received stereotaxic injections of 5-HT_{2C}R (or control) shRNA viral vector into the BLA to knock-down 5-HT_{2C}R expression. In CeA neurons from neuropathic rats monosynaptic excitatory postsynaptic currents (EPSCs) were increased more strongly than glutamate-driven inhibitory postsynaptic currents (IPSCs), resulting in an increase of the EPSC/IPSC ratio compared to controls. In brain slices from neuropathic rats with 5-HT_{2C}R knock-down in the BLA the balance of the excitatory and inhibitory transmission onto CeA neurons was restored and the EPSC/IPSC ratio was not different from that in sham controls. The data suggest that 5-HT_{2C}R in the BLA contributes to an imbalance of excitatory and inhibitory synaptic transmission in neuropathic pain.

Title: Effect of spinal manipulation on spontaneous and evoked activity of thalamic submedius neurons

Authors: *W. R. REED, J. T. CRANSTON, S. M. ONIFER, R. S. SOZIO;
Palmer Ctr. for Chiropractic Res., Palmer Col. of Chiropractic, Davenport, IA

Abstract: Manual therapies are non-pharmacological interventions shown to be effective for treating low back pain. Their acceptance, use, and optimization have been hindered by a lack of knowledge regarding their mechanisms of action. Widespread and immediate hypoalgesia associated with spinal manipulation and other manual therapies has been attributed to alterations in central pain processing. Neurons in the thalamic nucleus submedius (Sm) respond to convergent noxious input and have large, often bilateral, receptive fields. This makes them good candidates for investigating central mechanisms of spinal manipulation. We determined the effects of simulated spinal manipulation on spontaneous and evoked extracellular activity of Sm nociceptive specific neurons in urethane-anesthetized adult male Wistar rats (n=36). Toothed forceps were attached to the L_5 spinous process and a feedback motor was used to deliver 100ms posterior-anterior manipulative thrusts (85% rat body weight). Changes in spontaneous Sm activity (impulses/s) for time intervals of 10, 30, 60, 120, and 300s before and after a control manipulation (no force) or spinal manipulation protocol were determined (see Table). Neural responses to 10s of noxious mechanical stimulus (tail pinch, 795g arterial clip) were also recorded. Baseline activity (10s immediately prior to noxious stimulus) was subtracted from the 10s evoked response. Changes in evoked Sm activity due to the noxious tail pinch and spinal manipulation are shown in the Table. There appeared to be a small increase of mean spontaneous Sm activity following spinal manipulation at durations of 30, 60 and 120s compared to the control manipulation. Spinal manipulation appeared to result in a decrease in mean evoked response to noxious tail pinch compared to control manipulation. Further statistical analyses are being performed. A significant decrease in evoked noxious response following spinal manipulation could be involved with the immediate hypoalgesia shown clinically to occur.

Spontaneous Activity Intervals	Manipulation Control Mean change impulse/s (SD)	Spinal Manipulation Mean change impulse/s (SD)
10s	0.04 (1.7)	0.02 (1.5)
30s	0.1 (1.6)	0.32 (1.5)
60s	0.18 (1.4)	0.23 (1.2)
120s	0.15 (1.2)	0.22 (1.3)
300s	0.31 (1.5)	0.0 (1.1)
Evoked Activity Tail Pinch	0.13 (6.7)	-0.55 (4.2)

Title: SK channel function in the amygdala in arthritis pain - behavioral evidence

Authors: ***J. THOMPSON**, G. JI, V. NEUGEBAUER;
Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Persistent pain is an important healthcare issue with significant emotional and affective consequences. Here we focus on beneficial effects of activating small-conductance calcium-activated potassium (SK) channels in the amygdala, a brain center of emotions that plays an important role in central pain modulation and processing. SK channels have been reported to regulate neuronal activity in the central amygdala (CeA, output nucleus) but not lateral nucleus of the amygdala. We tested the effects of riluzole, a clinically available drug for the treatment of amyotrophic lateral sclerosis. Actions of riluzole include activation of SK channels. Evidence in the literature suggests that riluzole may have antinociceptive effects through an action in the brain but not the spinal cord. Here we test the hypothesis that riluzole inhibits pain behaviors by acting on SK channels in the CeA in an arthritis pain model. Systemic (i.p.) application of riluzole inhibited audible (nocifensive response) and ultrasonic (averse affective response) vocalizations of arthritic rats (6 h postinduction of a kaolin-carrageenan monoarthritis in the knee) but did not affect spinal withdrawal thresholds, which is consistent with a supraspinal action. Stereotaxic administration of riluzole into the CeA by microdialysis also inhibited vocalizations, confirming the CeA as a site of action of riluzole. Stereotaxic administration of a selective SK channel blocker (apamin) into the CeA had no effect by itself but inhibited the effect of systemic riluzole on vocalizations. In contrast, stereotaxic application of a selective blocker of large-conductance calcium-activated potassium (BK) channels (charybdotoxin) into the CeA did not affect the inhibitory effects of riluzole. Off-site administration of apamin into the basolateral amygdala (BLA) as a placement control also did not block the effects of riluzole. The results suggest that riluzole can inhibit supraspinally

organized pain behaviors in an arthritis model and these beneficial effects are mediated specifically by SK channels in the CeA, but not BLA, and not by BK channels.

Title: Pain increases cortical power and enhances cortico-cortico coupling

Authors: ***B. W. LEBLANC**, P. BOWARY, C. Y. SAAB;
Neurosurg., Rhode Island Hosp., Providence, RI

Abstract: Our lab has previously demonstrated that pain enhances power in the electrocorticographic (ECoG) signal recorded over primary somatosensory (S1) cortex during awake resting states in the rat. The first aim of our current study was to validate an increase in S1 power following pain and, second, to show altered signal coherence between S1 and prefrontal cortex (PFC) using a less-invasive electroencephalographic (EEG) approach. EEG recordings were obtained above S1 and PFC under resting conditions. Power spectral density (PSD) within 3-30 Hz was computed using fast Fourier transform (250 Hz sampling rates, FFT size 256) using Spike 2 (CED). Two pain models were used: Acute pain by intradermal capsaicin injection in the hindpaw; chronic pain by chronic constriction injury (CCI) of the sciatic nerve. In the capsaicin model, PSD increased by 15% in S1 contralateral to capsaicin injection and increased by 18% in PFC (n=6 rats, $p<0.05$). In addition, coherence between PFC and S1 increased by 15% (n=6 rats, $p<0.05$). In the chronic model, 7 days after CCI PSD in S1 was increased by 29%, PSD in PFC was increased by 54%, and coherence between PFC and S1 increased by 15%) (n=6 rats, $p<0.05$) Our results validate our previous EcoG findings using more clinically relevant EEG recordings. Moreover, our data suggest that pain enhances cortico-cortico coupling and that PFC power potentially discriminates between acute and chronic pain.

Title: SK channel function in the amygdala in neuropathic pain - electrophysiological evidence

Authors: *V. A. YAKHNITSA, J. THOMPSON, V. NEUGEBAUER;
Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The amygdala plays a key role in the regulation of the emotional-affective component of pain. Increased activity of amygdala output neurons in the central nucleus (CeA) account for emotional responses and anxiety-like behavior in different pain models. Therefore, control of abnormal amygdala activity would be a useful strategy in pain and associated emotional disorders. Small-conductance calcium-activated potassium (SK) channels are emerging as therapeutic targets for a number of disorders. SK channels have been implicated in the neuroprotective effects of riluzole, a clinically available compound for the treatment of ALS. Here we test the hypothesis that riluzole can mitigate pain-related changes of CeA neurons in a rat model of neuropathic pain. Whole-cell voltage- and current-clamp recordings were made from latero-capsular CeA neurons in brain slices from normal/sham rats (controls) and from neuropathic rats 3-4 weeks after spinal nerve ligation (SNL). Neuropathic rats had developed mechanical hypersensitivity and anxiety-like behavior by the time brain slices were obtained. CeA neurons recorded in brain slices from SNL rats showed increased excitability measured as the number of spikes in response to depolarizing current injections compared to neurons from control rats. Riluzole decreased spiking in brain slices from control and neuropathic rats. Coapplication of a selective NMDA receptor antagonist (AP5) did not reduce the inhibitory effects of riluzole. Riluzole had no effect on the apamin-sensitive medium afterhyperpolarization (mAHP) evoked in CeA neurons from control rats. CeA neurons in brain slices from neuropathic rats lacked an apamin-sensitive mAHP but riluzole was able to restore the AHP. The results suggest that riluzole inhibits abnormal neuronal discharges of amygdala output neurons by activating SK channels and restoring the mAHP in a neuropathic pain model.

Title: Single unit responses to acute pain stimulus in the acc and s1 in awake rats

Authors: *T. R. MANDERS, A. S. TONG, Q. ZHANG, Z. CHEN, J. WANG;
Anesthesiol., New York Univ., New York, NY

Abstract: Pain is a complex, multidimensional experience involving the activation of a number of brain regions. Two of these regions _ the primary somatosensory cortex (S1) and the anterior cingulate cortex (ACC) _ have been well demonstrated to play roles in pain processing. Whereas S1 is thought to be important in the sensory-discriminative aspect of the pain experience, the ACC is thought to be important for the affective-motivational experience of pain. We performed extracellular recordings in both regions in awake, behaving rats using tetrode array microdrives during acute pain episodes. After isolating well-separated units from the spiking activity, we characterized the unique properties of these important regions' responses to acute pain. We found that both the S1 and ACC responded to the acute, noxious stimulus, but the response properties are distinct. Between these regions, we found differences in the percentage of units responding, the duration and the direction of the responses (increase or decrease).

Abstract: Introduction: We previously reported that neurons in the transitional zone (TZ) in rat sensorimotor cortex respond to contralateral nociceptive input. Inactivation of TZ by local cooling or lidocaine injection lowers pain sensibility in the contralateral limb as measured by performance on a water bath foot withdrawal task. Inactivation of TZ by localized injection of lidocaine applied to the cortical surface or by injection into physiologically identified sites in the depths of TZ also reduced pain sensibility in the ipsilateral limb. This finding raised the possibility that TZ may be modulating pain sensibility in the opposite TZ, in part, through an interhemispheric pathway. Following lidocaine injection into TZ, the balance of excitation and inhibition in the opposite TZ most likely becomes transiently disrupted leading to the elevated pain threshold. Methods: Rats were anesthetized with 2.5% isoflurane. The skull was opened to expose sensorimotor cortex, and SI was mapped with microelectrodes to identify a region lying adjacent to the forepaw and hindpaw representations that was minimally responsive to non-noxious stimulation but responded to thermonoxious stimulation. Thermonoxious stimulation, designed to activate C-nociceptor afferents, was applied by lowering the hindlimb in a 47°-48° C heated water bath for a maximum of 15 sec. TZ was inactivated by microinjection of lidocaine into layer V of TZ. Interhemispheric connections between TZ were examined using intercortical microstimulation. Electrolytic lesions were used to mark recording sites. At the end of experiments, rats were perfused, brains were blocked, and hemispheres were flattened and cut tangentially to reveal the barrel field. Results: 1. Thermonoxious stimulation applied to a hindlimb activated neurons in the contralateral TZ. 2. An interhemispheric connection exists between TZ in both hemispheres. 3. Lidocaine injection into TZ lowered pain sensibility in both contralateral and ipsilateral hindlimbs. 4. Pain sensibility was reversed more rapidly in the ipsilateral hindlimb compared to the contralateral hindlimb. 5. Even in cases where pain sensibility was not reversed in the contralateral hindlimb, it was always reversed in the ipsilateral hindlimb. Conclusion: Interhemispheric connections between TZ very likely serve to modulate homotopic sites in the opposite TZ. One role of this modulation is to regulate pain sensibility in the ipsilateral limb.

Title: Role of Cav3.1 T-type Ca^{2+} channel in trigeminal neuropathic pain

Authors: *E. YU, S. CHOI, R. R. LLINÁS;
Dept. of Neurosci & Physiol, New York Univ. Sch. of Med., New York, NY

Abstract: Trigeminal neuropathic pain (TNP) is considered one of the most severe pain syndromes in human experience. Thus, management of TNP has attracted much attention over the years, especially as it is often unresponsive to the existing medical treatments. In this study, we investigate possible mechanism that may underlie pain processing, using an animal model of TNP. Pain was induced by partial ligations of infraorbital nerve (IoN). A clear mechanical allodynia was observed in all animals two weeks following surgery. In all cases allodynia was accompanied by an increment of a low frequency band EEG activity. This modification in brain activity, lead us to consider the possibility that sensory processing change in thalamocortical network could be responsible for this abnormal function, and most particularly, the presence of a thalamocortical dysfunction. Using voltage sensitive dye imaging (VSDI), in thalamocortical slice of TNP induced animal brain, we found, clear loss of lateral inhibition in the somatosensory cortex, following 40 Hz stimulation. This loss of lateral inhibition, we determined, correlates well the augmented peripheral pain in IoN territory after TNP induction. By contrast to deafferentation in normal animals, lateral inhibition found to be retained on the brain slice of TNP induced Cav3.1 T-type Ca2+ channel KO mice, which also showed no evidence of neuropathic pain. The findings thus suggest, that the presence of Cav3.1 T-type Ca2+ channels is one of the crucial elements in chronic pain processing in our model. Thus, modifications in ionic channel properties in thalamocortical network can result in pathophysiological conditions that alter sensory or motor properties leading to functional abnormality. Although the contribution of hyper excitability of peripheral sensory neurons to chronic neuropathic pain is not questioned, the abnormally augmented activity of central nervous system indicate the presence of a central neuropathic mechanism in accordance with the thalamocortical dysrhythmia syndrome hypothesis.

Title: Contribution of 5-HT_{2C}R to CRF1 receptor activation in amygdala neurons in a neuropathic pain model

Authors: ***G. JI**[1], T. A. GREEN[2], V. NEUGEBAUER[1];
[1]Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [2]Pharmacol. and Toxicology, Univ. of Texas Med. Br., Galveston, TX

Abstract: The amygdala plays a key role in emotional-affective aspects of pain and in pain modulation. Evidence suggests that serotonin receptor subtype 5-HT_{2C}R in the amygdala (basolateral nucleus, BLA) contributes to anxiogenic behavior and anxiety disorders. Previous studies from our group and others showed that the central nucleus (CeA) serves major amygdala output functions to generate emotional-affective behaviors and also modulate nocifensive responses. CeA output can be modulated by excitatory and inhibitory inputs from the BLA. Our studies showed that corticotropin releasing factor CRF1 receptor plays a key role in amygdala plasticity in arthritis pain and in the reciprocal relationship between pain and anxiety. The role of CRF1 in neuropathic pain and mechanisms of activation of the amygdala CRF system remain to be determined. Here we addressed the hypothesis that 5-HT_{2C}R in the BLA drives CRF1 activation to increase CeA activity in neuropathic pain. Extracellular single-unit recordings were made from CeA neurons in anesthetized neuropathic rats (SNL model) and in sham controls. Background activity and evoked responses of CeA neurons were increased in neuropathic rats compared to sham controls. Activation of 5-HT_{2C}R in the BLA by stereotaxic application of WAY-161503 increased the responses of CeA neurons in neuropathic rats and this effect was blocked by co-administration of a CRF1 receptor antagonist (NBI27914), implicating CRF1 receptors in the facilitatory effects of 5-HT_{2C}R on amygdala output. Local (BLA) knockdown of 5-HT_{2C}R with stereotaxic injections of 5-HT_{2C}R shRNA viral vector eliminated the inhibitory effect of NBI27914 on the responses of CeA neurons in neuropathic rats. The data suggest that 5-HT_{2C}R in the BLA contributes to neuropathic pain-related amygdala activity through a mechanism that involves activation of CRF1 receptors.

Title: Thalamic interneurons may play a role in altered mechanical thresholds following subthalamic deep brain stimulation in Parkinsonian rats

Authors: *L. GEE[1], A. RAMIREZ-ZAMORA[3], D. SHIN[2], J. G. PILITSIS[4];
[1]Albany Med. Col., Greenwich, NY; [2]Albany Med. Col., Center for Neuroscience and Neuropharmacology, NY; [3]Dept. of Neurol., [4]Dept. of Neurosurg., Albany Med. Ctr., Albany, NY

Abstract: Nigrostriatal degeneration in Parkinson's disease (PD) results in motor and non-motor symptoms. Chronic pain is reported in 65-80% of patients and clinical studies show altered nociceptive responses in PD patients, which may be modulated by subthalamic deep brain stimulation (STN DBS). Others have shown altered nociceptive responses in several rodent models of PD. Here, we explore the mechanism of how STN DBS could alter firing frequency in the ventroposteriolateral (VPL) thalamus in a rodent model of PD. We use the right medial forebrain bundle 6-hydroxydopamine (6OHDA) lesion model of PD. Sham rats received saline injections. Rats were tested behaviorally for mechanical thresholds using vonFrey filaments from 1.0g to 26.0g, during high (HF, 150Hz) and low (LF, 50Hz) frequency STN DBS and off stimulation. We also recorded single unit recordings in the VPL during mechanical stimuli application during and off STN DBS. Cells with receptive fields were found in the left hind paw using gentle brushing. VonFrey filaments of different weights (0.6g, 4.0g and 15.0g) were then applied to the left hind paw during and off HF and LF STN DBS. Behaviorally, mechanical thresholds are increased significantly by STN DBS at both HF and LF in parkinsonian rats ($p=0.004$, $p=0.005$ respectively) but not sham rats ($p>0.05$). Single unit recordings revealed two distinct waveforms in the VPL, which we believe to be relay and interneuron cells. In PD rats, interneurons displayed higher firing rates than in shams in response to the 4.0g ($p=0.034$) and 15.0g ($p=0.007$) fibers. Furthermore, firing frequency increased from 0.6 to 4.0g ($p<0.02$) and 4.0g to 15.0g ($p<0.01$) in parkinsonian rat interneurons, but not in sham interneurons. On HFS, interneuron and relay cell firing frequency may decrease in parkinsonian rats, while interneurons increase in shams. On LFS, interneuron firing frequency may decrease, while relay cell activity increases in parkinsonian rats. We are the first to show that STN DBS increases mechanical thresholds in parkinsonian rats. Furthermore, we hypothesize that STN DBS influences the VPL indirectly to alter sensory processing coming from the periphery by changing firing rates and patterns in both interneurons and relay cells during their response to nociceptive stimuli. Currently, our results are limited by a small sample size, however future experiments will focus on determining whether the VPL plays a significant role in the mechanism by which STN DBS alters mechanical thresholds.

Title: Role of posterior thalamic nuclei in formalin induced nociception of awake behaving mice

Authors: ***Y. HUH**, J. CHO;
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Posterior thalamic nuclei (Po), higher order thalamic structure, receive inputs from the spinal cord, brainstem, and layer5 of the cortex and send output to various parts of the cortex. It has been hypothesized to have roles in somatosensory information processing as part of a paralemniscal pathway and have been implicated to be associated with pathological pain. Neurons in the Po have been shown to increase firing rate in headache and spinal cord injury (SCI) animal models under anesthesia. However, how they respond to repeated inflammatory nociception has not yet been investigated. In this study we investigated whether neurons in the Po progressively increase activity to repeated inflammatory nociception induced by formalin in awake behaving mice. Total of three formalin injections were given with 4 week term between injections to allow time for recovery. Changes in behavioral nociceptive responses to successive formalin injections were first analyzed and then neuronal responses to each injection were analyzed. Results showed that successive exposure to formalin induced greater behavioral nociceptive responses. Neuronal activities in the Po, in contrast, decreased relative to the baseline with successive formalin injections. Discrepant Po neuronal activity changes in our study may be due to different roles in processing pain information; role of Po in processing

greater inflammatory nociception may be different from the role of Po in processing headache or hyperalgesia associated with SCI. It may also be due to differences in arousal state, since our study was done in the awake behaving state while other studies were done under anesthesia. Overall, our study suggest that decreased firing rate of neurons in the Po may actually lead to increased inflammatory nociceptive responses.

Title: SK channel function in the amygdala in neuropathic pain - behavioral evidence

Authors: *V. NEUGEBAUER, G. JI, J. THOMPSON;
Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Neuropathic pain is a serious healthcare problem. Treatment strategies are limited and often have variable efficacy and serious side effects. Neuropathic pain is associated with negative affective states, anxiety and depression. The amygdala plays a key role in the emotional-affective dimension of pain. Here we focused on small-conductance calcium-activated potassium (SK) channels in the amygdala to control pain behaviors. We tested the beneficial effects of riluzole, which is a clinically available drug for the treatment of amyotrophic lateral sclerosis. Riluzole has a number of actions, including activation of SK channels. Some evidence in the literature suggests that riluzole may have antinociceptive effects in neuropathic pain through a supraspinal site of action. We hypothesized that riluzole can inhibit pain behaviors by acting on SK channels in the amygdala output nucleus (CeA) in rat model of neuropathic pain. Supraspinally organized audible (nocifensive response) and ultrasonic (emotional-affective response) vocalizations and spinal reflex thresholds were measured in normal/sham rats (controls) and in neuropathic rats 4 weeks after spinal nerve ligation (SNL). Neuropathic rats showed increased vocalizations and mechanical hypersensitivity. The experimental strategy was to apply riluzole systemically (i.p.) and block SK channels in the amygdala pharmacologically to

determine their involvement in the predicted beneficial effects of riluzole. Systemic application of riluzole inhibited audible and ultrasonic vocalizations, but not spinal reflexes, of neuropathic rats when ACSF was administered stereotaxically into the amygdala (CeA) as vehicle control. In contrast, riluzole had no effect when a selective SK channel blocker (apamin) was administered stereotaxically into the CeA, indicating that SK channels in the CeA mediate the inhibitory effects of riluzole. Off-site administration of apamin into the lateral-basolateral amygdala area as a placement control did not block the inhibitory effects of riluzole. The results suggest that riluzole has beneficial effects on pain behaviors in a model of neuropathic pain that are mediated at least in part by SK channels in the CeA.

Title: Pathophysiological implication of CaV3.1 T-type Ca^{2+} channel in trigeminal neuropathic pain

Authors: *S. CHOI, E. YU, R. R. LLINÁS;
Dept. of Neurosci & Physiol, New York Univ. Sch. of Med., New York, NY

Abstract: The perturbation of normal sensory processing, by internally generated low-frequency brain rhythm, is one of the crucial pathophysiological issues concerning chronic neuropathic pain. To explore the molecular mechanisms responsible for such low-frequency rhythmicity related neuropathic pain, we investigated thalamocortical rhythms in mice lacking CaV3.1 T-type Ca2+ channel (knock-out, KO). Our results determined that such animals show a dramatic attenuation of mechanical allodynia in trigeminal neuropathic pain. Thus, following infraorbital nerve ligations, KO mice demonstrated a significantly reduced of the delta rhythm (1-4 Hz) in primary somatosensory (S1) cortex and its interconnected thalamic nucleus (VPM, ventroposteriomedial), compared to the increased delta rhythm in littermate control mice (wild-type, WT). In addition, the thalamocortical peak frequency rhythm shift, from theta (4-8 Hz) to delta presented in WT, was not observed in CaV3.1 KO mice. The S1-VPM coherence was also higher in theta band of CaV3.1 KO compared to WT. These results indicate the pivotal role of

thalamic CaV3.1 T-type Ca2+ channels in the alteration of thalamocortical rhythm and its functional connectivity in TNP, indicating that central neuropathic pain must be considered as a thalamocortical dysrhythmia. Our results offer clear implications concerning new understanding the pathophysiological mechanisms supporting neuropathic pain and take us one more step closer to develop more effective therapeutic approaches.

Title: Evidence of thalamocortical dysrhythmia in patients with fibromyalgia

Authors: *G. RABELLO, K. WALTON, J. DELFINO, R. LLINÁS;
Ctr. for Neuromagnetism, New York Univ. Sch. of Med., New York, NY

Abstract: Fibromyalgia (FMS) is a chronic pain condition that occurs in 1 in 73 adults in the United States, amounting to around 5 million people. Fibromyalgia Syndrome is characterized by widespread musculoskeletal pain that can be set off by “tender trigger points” in muscle groups throughout the body. Fibromyalgia occurs more often in women (3.4% of women, 0.5% of men), and the prevalence raises sharply in middle age, to a maximum of 7.4% in the 70-79-year age group (Lawrence et. al., 2008). There are no universally accepted best practice guidelines for FMS treatment, mostly because the underlying cause of the pain is not well understood (Clauw, 2009). Methods: MEG recordings of spontaneous activity were made from 22 patients (women, age 27-62) meeting the American College of Rheumatology Criteria for FMS (Wolfe et. al., 2010) using a 275 channel (CTF) instrument. Recordings compared patients suffering from pain with healthy adults (15 women, age 23-64). We performed spectral analysis using the Welch method and independent component analysis (ICA) on the sensor data. Components were localized before and after band pass filtering in the delta-theta, alpha, beta and gamma bands using a recursive weighted minimum norm algorithm. Preliminary Results: MEG recordings from patients suffering from pain showed increased low rhythm activity characterized by peaks in the delta and/or theta ranges. Mean spectral energy (MSE) is positively correlated to the Fibromyalgia Impact Questionaire (FIQ) in the delta, theta, beta and gamma ranges. Source localizations showed increased low frequency activity in the postcentral cortex, orbitofrontal cortex, thalamus and cingulate gyrus in patients. Discussion: Our preliminary findings indicate

that constant low frequency oscillations are present in patients, and their strength is correlated to the severity of FMS. Localizations further corroborate the hypothesis that this abnormal activity is characteristic of thalamocortical dysrhythmia (TCD) (Llinas et. al., 1996). Thus, preliminary results strongly indicate that the mechanism of persistent neuropathic pain entails a resonant interaction between thalamus and cortex. References: 1. Lawrence, Reva C., et al. Title: Nociception related gene expression in the lateral thalamic region during the estrous cycle

Authors: *M. UMORIN, C. JOHNSON, L. L. BELLINGER, P. R. KRAMER;
Biomed. Sci., Texas A&M Univ. Baylor Col. of Dent., Dallas, TX

Abstract: The affect hormonal changes have on central nervous system orofacial mechanisms are largely unknown. Nociception signals can be modulated as they pass through the thalamus and ascend to other brain regions. We hypothesize that sex differences in nociception result, in part, by alterations in central nociception processing, particularly the thalamus. To address this hypothesis all known cDNAs were screened (large gene screen) in the caudalis, pariaqueductal gray, lateral thalamus, cingulate cortex and somatosensory cortex of 250g female Sprague-Dawley rats. Significant changes in gene expression were observed in each brain region, but in the thalamic region a cluster of several gabergic genes showed reduced expression during late proestrus, early estrus as based on vaginal smears. This is a time during the estrous cycle of reduced orofacial nociception. These gene array studies were followed by real-time PCR and ELISA analysis. Estradiol levels were also measured by RIAs. Our results indicate that both RNA and protein expression of vgat, GAD1, GAD2, GABARAPL1 was significantly reduced in the lateral thalamic area when plasma estradiol levels were elevated(i.e. late proestrus, early

estrus). GAD1 and GAD2 are enzymes in GABA production, vgat transports GABA into vesicles and GABRAPL1 functions in GABA receptors signaling. The results are consistent with the idea that during the estrous cycle, when estradiol is elevated, GABAergic signaling in the lateral thalamic region is diminished which can modulate nociception signaling to other regions of the brain such as the somatosensory cortex. Future experiments will test how modulating thalamic gabergic signaling affects orofacial nociception in females.

Title: mGluR5 and endocannabinoids interact at the amygdala-prefrontal cortical synapse to increase pyramidal cell output in a pain model

Authors: *T. KIRITOSHI, V. NEUGEBAUER;
Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Medial prefrontal cortex (mPFC) and amygdala interact and undergo neuroplastic changes in pain states. Our previous studies showed that pain-related decreased pyramidal cell activity is causally linked to increased BLA output and that co-activation of metabotropic glutamate receptor 5 (mGluR5) and cannabinoid receptor CB1 in the mPFC restores pyramidal cell output in a pain model. However, synaptic and cellular mechanisms are not fully understood and the role of BLA input to the mPFC remains to be determined. Here we used optogenetic techniques to test the hypothesis that restoring impaired mGluR5-driven endocannabinoid signaling at the BLA-mPFC synapse removes abnormally enhanced feedforward inhibition and increases pyramidal output in an arthritis pain model. Brain slices containing the mPFC were obtained from rats that received stereotaxic injections of rAAV5/CaMKIIa-hChR2(H134R)-eYFP into the BLA to selectively express channel rhodopsin 2 (ChR2) on axons of BLA pyramidal cells. Whole-cell voltage- and current-clamp recordings were made from visually

identified pyramidal cells in layer V of the infralimbic mPFC in brain slices from normal and arthritic rats (5-6 h after intraarticular injections of kaolin and carrageenan into one knee). Laser light stimulation of ChR2-expressing BLA axons evoked monosynaptic EPSCs (short onset latency, small onset jitter, preserved by TTX+4-AP and blocked by AP5+CNQX) and polysynaptic IPSCs (long onset latency, large onset jitter, abolished by TTX+4-AP and blocked by NBQX or bicuculline). A positive allosteric modulator for mGluR5 (VU0360172) increased light-activated synaptically evoked spiking (E-S coupling) in mPFC pyramidal cells under normal conditions through a mechanism that involved endocannabinoid signaling but failed to do so in the arthritis pain model. Co-application of VU0360172 with a CB1 agonist (ACEA) decreased BLA-driven feedforward inhibition to increase E-S coupling. The results suggest that pyramidal cells in the mPFC receive monosynaptic excitatory inputs and feedforward synaptic inhibition from the BLA and that interaction of mGluR5 and endocannabinoids in this pathway can restore pyramidal cell output in a pain model.

Title: Thalamic trigeminovascular neurons have preferential sensitivity to different colors of light: implications for photophobia during migraine

Authors: *R. NOSEDA, R. SAAVEDRA-WALKER, R.-R. NIR, A. MELO-CARRILLO, R. BURSTEIN;
Anesthesia, Beth Israel Med. Ctr/ Harvard Med. Sch., Boston, MA

Abstract: Exacerbation of migraine headache by light (photophobia) is a disabling neurological symptom experienced by most migraineurs with normal eyesight. To date, there is some information on selective sensitivity to blue light among blind migraineurs with partial light perception, and no data on whether migraine-type photophobia may be color-selective in migraine patients with normal eyesight. While testing color-sensitivity in migraineurs, we also

attempted to determine whether dura/light-sensitive thalamo-cortical neurons (implicated recently in photophobia) respond preferentially to different colors of light and whether their response preference depends on their location in the thalamus. To answer these questions, we used a calibrated LED-based light stimulator and *in vivo* multi-unit electrophysiological recording to sample a large number of dura-sensitive and dura-insensitive thalamic neurons in the rat. We found that stimulation with blue light evoked the strongest activation of dura-sensitive neurons in the lateral posterior (LP) and posterior (Po) thalamic nuclei as compared to white light. Green light induced a mild increase in neuronal firing in LP and Po. Red light, however, did not induce any significant change of baseline activity in neither of the thalamic nuclei recorded. In the ventral posteromedial thalamic nucleus no significant increase was observed with any color of light. Our findings suggest that photoactivation of dura/light-sensitive thalamic neurons is dependent on the relative contribution of retinal photoreceptors, which can explain why some colors of light may be more painful than others during migraine.

Title: Upregulation of Ih expressed in IB4-negative Aδ nociceptive DRG neurons contributes to mechanical hypersensitivity associated with cervical radiculopathic pain

Authors: *D. LIU;
Dept. of Anesthesiol. and Neurobio., Duke Med., Durham, NC

Abstract: Some patients with cervical radiculopathy develop severe pain, which can be extremely difficult to treat and severely limit patients' daily functions. Cervical radiculopathic pain (CRP) often associates with aberrant mechanical hypersensitivity. Primary sensory neuron's ability to sense mechanical force forms mechanotransduction. However, whether this property undergoes activity-dependent plastic changes and underlies mechanical hypersensitivity

associated with CRP are poorly understood. Here we present a new CRP model producing a chronic and stable mechanical compression of C7/C8 dorsal root ganglia (DRG) in rats, which induces dramatic behavioral mechanical hypersensitivity that mimics the pain symptoms observed clinically. Following chronic compression of C7/C8 DRGs, isolectin-B4 (IB4) negative Aδ-type (IB4- Aδ) nociceptive DRG neurons, but not IB4-positive (IB4+) or IB4- C-type nociceptive neurons exhibited frequent spontaneous activity together with hyperexcitability. Focal mechanical stimulation on somata of IB4- Aδ neurons mimicking movements of the neck elicited exaggerated high-frequency firing and long-lasting afterdischarge, indicative of abnormal neuronal mechanical hypersensitivity. Quantitative analysis of hyperpolarization-activated cation current (Ih) revealed that Ih was greatly upregulated in IB4- Aδ neurons, but not in either IB4+ or IB4- C neurons from CRP rats. Mechanistic studies by pharmacological tools indicated that increased Ih on IB4- Aδ neurons underlies the spontaneous activity together with neuronal mechanical hypersensitivity, which further contributes to the behavioral mechanical hypersensitivity associated with CRP. This study sheds new light on the functional plasticity of a specific subset of nociceptive DRG neurons, namely IB4- Aδ neurons to mechanical stimulation and reveals a novel mechanism that could underlie the mechanical hypersensitivity associated with CRP

Abstract: Mechanisms and targets of neuropathic pain remain elusive. The search for them often requires knowledge of anatomical expression of potential pharmacological targets for the treatment of neuropathic pain. Recently, a highly specific angiotensin II type 2 receptor (AT2) antagonist showed efficacy as a treatment for postherpetic neuralgia in clinical trials. A potential mechanism, based largely on preclinical studies, was attributed to the presence of AT2 in nociceptive neurons of the dorsal root ganglion (DRG). However, anatomical expression of AT2 in the DRG had been detected by low-throughput antibody techniques and the specificity of these antibodies has been questioned. We investigated the anatomical expression of AT2 using MATLAB analysis of five Gene Expression Omnibus (GEO) datasets containing microarray expression for normal male and female human tissue and normal mouse tissue from several strains. We also investigated the anatomical expression of AT2 in normal female DRG using RNA Seq. In this high-throughput bioinformatic analysis, we found virtually no AT2 expression in DRG in either normal mouse or human tissue. Additionally, we found virtually no AT2 expression in human TG, human spinal cord, or mouse spinal cord. The conspicuous lack of AT2 expression in DRG and sensory tissues necessitates further examination of the proposed mechanisms by which putative AT2 antagonists may modulate nociceptive transmission.

Title: IB4 expressing, but not TRPV1 expressing nociceptive fibers mediate movement-evoked breakthrough cancer pain

Authors: K. CARLSON[1], I. PELLETIER[1], J. HAVELIN[1], I. IMBERT[1], F. PORRECA[2], *T. E. KING[1];
[1]Biomed. Sci., Univ. of New England, Biddeford, ME; [2]Univ. of Arizona, Tucson, AZ

Abstract: Cancer-induced bone pain is characterized by persistent, ongoing pain, with many patients also reporting breakthrough (BT) pain. BT pain is defined as transient episodes of severe to excruciating pain that “breaks through” medication (i.e., opioids) controlling ongoing pain. In

patients with bone metastases, voluntary (e.g., switching positions in bed) or involuntary (e.g., cough) movements can trigger BT pain that is severe and requires immediate, fast-acting opioid medications. Pain that "breaks through" medication controlled ongoing pain suggests that mechanisms mediating ongoing and BT pain may be distinct. We demonstrate that movement of the tumor bearing hindlimb produces conditioned place aversion (CPA), indicating that this treatment induces increased pain. Such observations are consistent with reports of BT pain in patients with metastases within the bone. Further, movement-induced CPA breaks through morphine administration that is sufficient to block ongoing pain, a key aspect of BT cancer pain within the clinical setting. Using this novel measure we examined the hypothesis that BT pain is mediated by IB4 expressing, non-peptidergic nociceptive fibers, but not TRPV1 expressing, primarily peptidergic nociceptive fibers. Ablation of TRPV1 expressing fibers failed to block movement-induced CPA. In contrast, ablation of IB4 expressing fibers blocks movement-induced CPA. These data indicate that IB4 expressing, non-peptidergic nociceptive sensory fibers mediate BT cancer bone pain whereas TRPV1 expressing, primarily peptidergic nociceptive sensory fibers do not. Title: Tamoxifen-inducible nav1.7 KO mouse: characterization at an RNA, protein and electrophysiological level

Authors: *L. DENG, R. M. REESE, S. D. SHIELDS, K. SCEARCE-LEVIE, D. H. HACKOS; Neurosci. Dept., Genentech Inc., South San Francisco, CA

Abstract: The sodium channel Nav1.7 is an attractive pain target based on human genetic evidence. Gain-of-function mutations in Nav1.7 are associated with inherited severe pain conditions, such as inherited erythromelalgia (IEM) or paroxysmal extreme pain disorder (PEPD), whereas individuals carrying loss-of-function mutations are congenitally insensitive to pain (CIP). Although the role of Nav1.7 in pain perception has been extensively studied, it is still not fully understood how loss of Nav1.7 results in such a severe insensitivity to pain and whether

removal of Nav1.7 in the adult would lead to the same phenotype. In an attempt to answer these questions, we employed a tamoxifen-inducible Nav1.7 cKO mouse (pCAGG-CreERT$^{tg/-}$ x scn9a$^{loxP/loxP}$). Upon intraperitoneal dosing of tamoxifen, Nav1.7 RNA is rapidly removed from the DRG and is undetectable by qPCR within 1-3 days after the final of three tamoxifen doses. In contrast, Nav1.7 protein levels within the DRG decay more slowly with a half-life of approximately 1 week, becoming undetectable by 6-8 weeks. To examine the electrophysiological properties of DRG neurons lacking Nav1.7, we cultured DRG neurons isolated from either Nav1.7 cKO mice or wildtype littermates that had been previously dosed with tamoxifen (8 week timepoint). We employed the Nav1.7-selective scorpion toxin OD1 and the Nav1.7-selective spider toxin ProTx-II to demonstrate the loss of Nav1.7 in DRG neurons from Nav1.7 cKO mice. Further voltage-clamp recordings allowed us to determine the consequences of removal of Nav1.7 on the surface expression of other Nav and Cav channels. Finally, current-clamp recordings allowed us to determine the effects of removal of Nav1.7 on the excitability of different classes of DRG neurons.

Title: Purinergic signaling in trigeminal nociceptive system in meninges and trigeminal ganglia

Authors: *C. GUERRERO-TORO[1,2], G. YEGUTKIN[3], R. GINIATULLINA[1,2], K. KOROLEVA[2], E. KILINC[2], R. GINIATULLIN[1,2];
[1]Neurobio., Univ. of Eastern Finland, Kuopio, Finland; [2]A. I. Virtanen Inst., Kuopio, Finland; [3]Univ. of Turku, Turku, Finland

Abstract: ATP and its degradation products like ADP and adenosine are efficient signaling molecules in the nociceptive system. Previously we suggested a potential role of ATP in migraine pathophysiology (Giniatullin et al., 2008). However, the sources and stability of ATP in meningeal tissues and the role of its degradation products controlled by NTPDases were little studied. In this project, we combined Ca2+ imaging, purine biochemical assays, NTPDase

staining and electrophysiological methods to explore the role of various purines in rat trigeminal ganglion cell cultures and isolated meninges obtained from young and adult Wistar rats. We found a very low nanomolar level of extracellular ATP and ADP in meninges whereas the concentrations of AMP and adenosine were about two orders higher indicating high efficiency of enzymes designed for inactivation of ATP and ADP. Accordingly, both ATP and ADP were able to generated large Ca2+ transients in isolated trigeminal neurons and surrounding satellite cells (satellite glial cells and fibroblasts). Consistent with purinergic hypothesis of migraine, the key migraine mediator neuropeptide CGRP significantly increased the level of extracellular ATP measured with luciferase biochemical assay or explored with the lead nitrate staining. However, CGRP did not change the rate of ATP degradation. The main source of extracellular ATP appeared to be meningeal vessels as indicated by staining of phosphate groups. To test the pro-nociceptive activity of purines in meningeal tissues we used the extracellular recordings of nociceptive firing in hemiskull preparation (Shatillo et al., 2013). We found that ATP is the most effective inducer of nociceptive firing whereas the similar effect of ADP did reach a significant level. In contrast, AMP and adenosine were almost ineffective in meningeal nerves. Our data suggest efficient CGRP-sensitive signaling via extracellular purines in the trigeminal nociceptive system, primarily mediated by ATP. Giniatullin R, Nistri A, Fabbretti E. (2008). Title: Modulation of pain transmission in the dorsal horn circuit: from ionic channels to information transfer of noxious inputs

Authors: P. SACRÉ[1], Y. GUAN[2], W. S. ANDERSON[3], *S. V. SARMA[1];
[1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Anesthesiol. and Critical Care Med., [3]Neurosurg., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Chronic pain affects about 100 million American adults---more than the total affected by heart disease, cancer, and diabetes combined. Despite their great need, neuropharmacology and neurostimulation therapies for chronic pain have been associated with suboptimal efficacy

and limited long-term success as their mechanisms of action are unclear. Understanding the mechanisms of pain transmission to predict its modulation by therapies is therefore essential toward pain management, yet current mechanistic models suffer from several limitations. Among others, they are not amenable to tractable mathematical analysis and fail to provide a comprehensive mechanistic understanding of pain transmission. Using mathematical reduction techniques that exploit time-scale separation, we investigated the cellular dynamics in the dorsal horn circuit of the spinal cord---the first central relay of sensory (innocuous and noxious) inputs to the brain. This study proposes a reduced model of projection neurons in the dorsal horn and discusses the modulation of nociceptive information transfer to the brain. Projection neurons in the dorsal horn can exhibit a rich set of dynamics---from tonically firing to plateau potentials to endogenous bursting. Each firing pattern results in different capabilities of information transfer---from faithful transmission to enhancement to blocking of nociceptive information, respectively. The cellular firing pattern and therefore the functional capability of information transfer are driven by a dynamic balance of intrinsic properties of the neurons. A low-dimensional reduced model is sufficient to capture each firing mode. A first ultraslow variable acts as a positive feedback (ultraslow regenerative ionic channels) and is responsible for the acceleration in the depolarized state and the deceleration in the hyperpolarized state. A second ultraslow variable acts as a negative feedback (ultraslow restorative ionic channels) and is responsible for the interburst period. As a consequence, this balance of negative and positive ultraslow feedbacks plays a critical role in the modulation of pain transmission in projection neurons of the dorsal horn. The dorsal horn circuitry may also affect the capability of information transfer and the dynamics at the circuit level will remain the focus of future work.

Title: Discogenic low back pain (LBP): Is it possible for intervertebral disc (IVD) itself to generate LBP?

Authors: ***E.-H. PARK**, S.-W. MOON, H.-R. SUH, H.-C. HAN;
Physiol., Col. of Medicine, Korea Univ., Seoul-City, Korea, Republic of

Abstract: Intervertebral disc (IVD) can be a major source of low back pain (LBP). A herniated or bulging IVD which is often accompanied by degenerated IVD and spinal stenosis put stressful pressure on adjacent spinal nerves or spinal cord and the leakage of nucleus pulposus (NP) from disc tissues induce inflammatory response, thereby leading to develop chronic LBP. As another possibility, IVD themselves can generate the pain signal because it was found that sinuvertebral nerves or branches of the paravertebral sympathetic trunks (PST) innervate IVDs, and in degenerated IVDs the upregulation of neurotrophins can promote nerve fiber to grow into the deep layer of annulus fibrosus and give rise to painful IVD. However, it is not clear whether afferent fibers innervating IVDs can participate in sensory or nociceptive processing. The purpose of this study was to characterize the responses of IVD afferents in normal and punctured IVD model to intradiscal pressure. Using male SD rats (300-350g; Korea), punctured IVD model was made by puncture of IVD with 22-gauge needle followed by totally aspirating nucleus pulposus of lumbar IVDs with suction pump. *In vivo* extracellular recording of IVD afferents was done on 35 days after surgery. PST was teased into small strands and placed on a unipolar platinum electrode in warm mineral oil pool. The intradiscal pressure was controlled by the injection of saline with 5 ml syringe in a range between 100 and 3000 mmHg. Afferents activities evoked by intradiscal pressure were counted with maximum spikes per second. The firings of afferents in both normal/sham and punctured lumbar IVD were proportionally increased to the intensity of applied pressure. However, afferents in punctured lumbar IVD showed significantly increased response and significantly decreased threshold to the same pressure stimulus compared to those of normal/sham lumbar IVD. The present study implicate that the sensory information from IVDs can be transmitted to spinal cord through paravertebral sympathetic pathways, and punctured IVD model might be useful for discogenic pain study because punctured lumbar IVD apparently showed sensitized response to intradiscal pressure change than normal/sham lumbar IVD.

Title: *In vivo* evaluation of cell activity using manganese-enhanced magnetic resonance imaging (MEMRI) in adult rats after neonatal nociceptive stimulation

Authors: *J. M. MALHEIROS[1], A. TANNÚS[2], R. GUINSBURG[3], L. COVOLAN[1];
[1]Univ. Federal De Sao Paulo, São Paulo, Brazil; [2]CIERMag-Physics Inst. of São Carlos, USP, São Carlos, Brazil; [3]Pediatrics Departament, Univ. Federal de São Paulo, São Paulo, Brazil

Abstract: Neonatal noxious stimulation in rats has been proposed to model neonatal procedural pain performed in neonatal intensive care units. Previous studies have shown that the rate of hippocampal neurogenesis as well as the behavioral repertoire of adult rats may be altered in response to neonatal noxious stimuli. Several studies have used MEMRI (Manganese-enhanced MRI) approach, since the Mn2+ can act as a marker of calcium influx into cells serving as a surrogate indicator of activated areas after stimulation. The purpose of this study is to determine, in adult animals, MEMRI signal alterations in the brain after neonatal noxious stimulation. For this, male and female rats received an intraplantar injection of CFA (complete Freund's adjuvant) on P1 (first postnatal day), P8 or P21. To assess whether nociceptive re-exposure could activate differentially the same brain areas, a subgroup of animals were also noxious-stimulated in the infancy (P1P21 and P8P21). Animals received an injection of MnCl2 (60 mg/kg) 12 hours before the new nociceptive stimulation (CFA) and 14 hours before MRI. MRI was performed on a Bruker electronic (Avance III under Paravision 5.1) adapted to a 2 Tesla superconducting magnet (Oxford Instruments 85310HR). Crossed saddle radiofrequency coil was used as a head probe for the animals, anesthetized by an i.p. injection of ketamine (95mg/kg) and xilazine (12mg/kg). The relative signal intensity was calculated as the ratio of the mean signal intensity in the region of interest (ROI) to the mean intensity of adjacent corpus callosum. Results indicate that the re-stimulated females showed higher signal intensity mainly in areas related to emotional pain control (insular cortex), recognition, learning (secondary somatosensory cortex) and pain memory (dorsal hippocampus). P1 female group showed the same signal intensity as Naïve group in areas related to pain localization (ventrolateral thalamus and primary somatosensory cortex) and showed no signal intensity alterations in the amygdala. In the dorsal hippocampal dentate gyrus, P1 females (1.551 ± 0.053 a.u.) showed higher signal intensity than P1 males (1.203 ± 0.119 a.u., $p<0.05$). This area has been recently related to associative memory. These results show that MEMRI can be used in animal models to map central nervous system areas related to processing long-term nociceptive information.

Title: Does macrophage migration inhibitory factor (MIF) contribute to chronic spontaneous activity in nociceptor somata after spinal cord injury?

Authors: A. BAVENCOFFE[1], Q. YANG[1], O. BLOOM[2], *E. T. WALTERS[1];
[1]Dept Integrative Biol and Pharmacol, Univ. Texas Med. Sch. at Houston, Houston, TX;
[2]Feinstein Institute, Hofstra North Shore LIJ Sch. of Med., Manhasset, NY

Abstract: Chronic pain is often a permanent, severe, and poorly treated problem for people with spinal cord injury (SCI), and its mechanisms remain mysterious. In a rat model of contusive thoracic SCI we discovered that pain-related behavioral changes are associated with persistent hyperexcitability and spontaneous activity (SA) in the somata of primary nociceptors recorded *in vitro* and *in vivo* (Bedi et al. J Neurosci, 30:14870, 2010) and showed that persistent nociceptor hyperactivity plays a critical role in driving SCI pain (Wu et al. Pain, 154:2130, 2013; Yang et al. J Neurosci, 34:10765, 2014). Nociceptors have receptors for many injury- and inflammation-related cytokines and their somata are highly exposed to circulating cytokines because of the lack of an effective vascular permeability barrier in the dorsal root ganglia (DRG). Individuals with SCI show chronic elevation of several circulating pro-inflammatory cytokines, with especially high plasma concentrations of macrophage migration inhibitory factor (MIF) acutely (<2 weeks postinjury) and chronically (>1 year postinjury) after SCI (Bank et al. Arch Phys Med Rehab, 94:1498, 2015, Stein et al. Arch Phys Med Rehab, 94:1498, 2013). Importantly, MIF is reported to be necessary and sufficient for reflex hypersensitivity in nerve injury and peripheral inflammation models (Alexander et al. Exp Neurol 236:351, 2012). As a first step in testing whether circulating pro-inflammatory cytokines contribute to chronic nociceptor SA after SCI, we examined effects of MIF on excitability properties of small DRG neurons 1 day after dissociation from naive, sham-operated, or SCI rats. Extending earlier findings from naive mice (Alexander et al., 2012), we found that MIF at concentrations of 0.5-1 ng/ml (somewhat lower than measured in individuals with SCI) decreased rheobase and significantly increased SA within ~20 sec of application to nociceptors isolated from all three groups of animals. This finding supports the hypothesis that, *in vivo*, SCI-induced elevation of circulating MIF can help to drive chronic nociceptor SA. However, longer treatment with MIF (5-20 min) depolarized resting membrane potential and significantly reduced SA. While this latter result may argue against our hypothesis that MIF helps to drive somally generated SA after SCI, an alternative explanation is that our *in vitro* testing conditions enhance the responsiveness of nociceptors to prolonged exposure to MIF, causing excessive depolarization and the paradoxical decrease in excitability.

We are now exploring this possibility as well as preliminary indications that SCI produces a further increase in the responsiveness of nociceptors to MIF.

Title: Forced exercise alleviates evoked and ongoing pain in a model of advanced, NSAID-resistant osteoarthritis

Authors: *I. IMBERT, M. WALKER, J. ALLEN, G. STEVENSON, T. KING;
Univ. of New England, Biddeford, ME

Abstract: Osteoarthritis (OA) affects an estimated 27 million adults in the US, a number likely to rise due to the aging of the population and other medical issues such as obesity. Advanced OA is often characterized by persistent, ongoing moderate to severe joint pain that is resistant to current therapies including NSAIDs. A commonly recommended non-pharmacological treatment for patients with OA pain is exercise. Clinical studies have demonstrated that aerobic and strengthening exercise can improve function and pain in patients with knee OA. In addition, a small number of studies have examined the effects of exercise on joint pathology, generally finding no benefit or exacerbation of joint pathology as determined by radiographs. The effects of forced treadmill exercise and voluntary wheel running exercise on MIA-induced joint pain were compared across 4 weeks post-injection. Rats received intra-articular monosodium iodoacetate (MIA) (4.8 mg/60 µl) or equivolume saline injection into the knee joint. Starting 10 days following MIA injection, rats in the forced exercise group were placed on a treadmill and forced to run for 30 min across 4 days starting at 12 m/min for 1 week followed by 16 m/min for the remaining weeks. Control (sedentary) rats were placed on the inactive treadmill. Rats in the voluntary exercise group were placed in cages with free access to running wheels overnight for 5 weeks prior to MIA injection to establish stable wheel running behavior. They then received intra-articular MIA or equivolume saline injections into the knee joint and were again given overnight access to the running wheels 10 days post-injection. Weight bearing on each hindlimb was measured pre-injection and weekly post-injection to assess development of weight asymmetry (D7-pre-exercise) and effects of exercise on the MIA-induced weight asymmetry (D14-D35). Treadmill exercise produced a reversal of MIA-induced weight asymmetry and

ongoing pain. Wheel running rats were divided into 2 populations, high and low running rats. MIA produces a drop in speed and distance in the high running, with the average speed at the peak 30 min dropping from approximately 30 m/min to a range of 16-20 m/min post MIA injection. Although this was in the range of the speed of the forced exercise, MIA-induced weight asymmetry remained constant across the 6 weeks post-MIA in the high runner group.

Title: Effects of the natural substance (-)-alpha-Bisabolol on trigeminal central sensitisation and sensorimotor behaviour induced by acute noxious orofacial stimuli

Authors: *L. T. MELO[1,2], V. PANCHALINGAM[2], L. AVIVI-ARBER[2], P. CHERKAS[2], A. R. CAMPOS[1], B. J. SESSLE[2];
[1]Biotech. - RENORBIO, Univ. of Fortaleza, Fortaleza, Brazil; [2]Fac. of Dent., Univ. of Toronto, Toronto, ON, Canada

Abstract: Our previous studies have shown that noxious orofacial stimulation including application of the inflammatory irritant mustard oil (MO) to the rat maxillary molar tooth pulp produces increased activity of medullary dorsal horn (MDH, also known as trigeminal subnucleus caudalis) nociceptive neurons reflecting trigeminal central sensitisation and increased jaw muscle electromyographic (EMG) activity reflecting nociceptive sensorimotor behaviour (eg, Chiang et al, 1998; Sunakawa et al, 1999; Narita et al, 2012). There is evidence that (−)-α-Bisabolol (BISA), a sesquiterpene alcohol presents in the essential oil from Chamomile, acts via 5-HT and TRPV1 receptors to produce anti-nociceptive and anti-inflammatory effects in animal models of acute pain. The aim of this study was to examine whether trigeminal central sensitisation and nociceptive sensorimotor behaviour evoked by orofacial noxious stimuli can be

attenuated by systemic pre-administration of BISA. In anaesthetised adult male Sprague-Dawley rats, EMG activity parameters (threshold, amplitude, duration, area under the curve) were monitored in the masseter and anterior digastric muscles in order to record the jaw-opening reflex (JOR) evoked by electrical stimulation of the tongue. In addition, the activity of functionally identified nociceptive (wide dynamic range) neurones was recorded in the MDH. The effect of BISA (30mg/kg) or vehicle (isotonic saline) on the tongue stimulation-evoked JOR or on MO-induced central sensitisation in MDH neurones was tested by intravenously administering BISA or vehicle at 10 minutes before the tongue stimulation or MO application to the maxillary molar tooth pulp. Pre-medication with BISA but not vehicle significantly reduced the JOR (N=8/group, ANOVA, post-hoc Bonferroni $p<0.05$) and it also reduced central sensitisation as reflected in its attenuation of MO-induced increases in spontaneous neuronal activity and responses to pinch/pressure (N=6/group, ANOVA, post-hoc Bonferroni $p<0.05$). These results suggest that BISA may attenuate nociceptive sensorimotor responses and central sensitisation evoked by noxious orofacial stimuli, and that this natural product may be useful clinically for the treatment of orofacial pain.

Title: Selective CCR2 chemokine receptor antagonists as potential treatment of bone cancer pain

Authors: *E. MIDAVAINE, D. BARRIÈRE, J.-M. LONGPRÉ, P. SARRET;
Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Many types of cancers have a propensity to metastasize to the bone microenvironment. In 75-90% of patients coping with metastatic cancer, tumor-induced bone remodeling results in moderate to severe pain, which significantly compromises the patient's

quality of life. Unfortunately, current pain relieving treatments, primarily relying on opioid analgesics, become ineffective over time and the most severe type of pain, called breakthrough pain, often remains uncontrolled. Treatments for painful osseous metastases thus require designing new therapies for improving pain control. In recent years, the CCL2/CCR2 chemokine system has gained a prominent place in the field of spinal nociceptive processing, notably in the genesis and maintenance of metastatic breast cancer-induced bone pain. Likewise, the CCL2/CCR2 axis was shown to play a central role in the bone-tumor ecosystem, establishing a fine dialogue between invasive breast carcinoma cells, infiltrating inflammatory cells, and osteoclast/osteoblast bone resident cells. The project was thus aimed at investigating the efficacy of targeting the CCL2/CCR2 axis in both acute and bone cancer pain models. First, we tested the efficacy of the CCR2 antagonist, RS 504393 (25 μg/rat, intrathecally) to alleviate mechanical allodynia in a CCL2-induced acute pain model. We observed that RS 504393 produces a significant long-duration reversal of the mechanical allodynia induced by CCL2. The breast cancer bone metastasis pain model, consisting in injecting MRMT-1 carcinoma cells (endogenously expressing CCL2/CCR2) into the female rat femoral medullary cavity, was then used to evaluate the role of CCL2 in bone pain facilitation. Cancer-induced bone destruction was observed using histological, PET and MR medical imaging. Bone matrix pathological destruction was explained by an osteoclast/osteoblast imbalance in cancer-bearing animals. In the spinal cord dorsal horn, bone cancer progression induced major glial cells activation, as observed by an increased in GFAP and Iba1 immunostainings. Moreover, pERK and pp38 stainings were observed over neuronal and glial cell population in cancer-bearing rats, respectively. CCL2 immunolabeling further revealed that CCL2 is anterogradely transported along the sciatic nerve, probably contributing to the mechanical sensitivity. Punctual spinal injection of RS 504393 significantly reduced tactile allodynia in tumor-bearing rats achieving up to 48% of pain relief. In conclusion, blocking CCL2/CCR2 axis represents a promising avenue to control bone cancer pain and improve the quality of life of patients dealing with bone metastases.

Title: The contribution of nucleus accumbens brain derived neurotrophic factor to persistent hyperalgesia development

Authors: *C. H. TAMBELI, L. CAMARGO-CALILI, E. DIAS-VIEIRA, G. G. SANTOS, C. SARTORI, C. A. PARADA;
UNIVERSITY OF CAMPINAS, CAMPINAS, Brazil

Abstract: Introduction - Enhanced dopaminergic activity in the nucleus accumbens (NAcc), an important component of mesolimbic system, facilitates persistent hyperalgesia development (Dias et al., 2015). Brain Derived Neurotrophic Factor (BDNF) is a neurotrophin that influences the release of dopamine in the mesolimbic dopamine system (Goggi et al., 2003). Therefore, the aim of this study was to investigate the role of NAcc BDNF in persistent hyperalgesia development. Methods - We used male Wistar rats (200-250g) and an animal model of persistent hyperalgesia in which daily subcutaneous PGE2 injection (100ng/50µl) into the rat's hind paw for 14 days induces a state of nociceptor sensitization that lasts for at least 30 days following the cessation of the PGE2 treatment. The mechanical nociceptive threshold was quantified using the paw-withdrawal test (Randall & Selitto, 1957) on days 1, 5, 7 and 14 of the persistent hyperalgesia induction and on days 1, 7, 14 and 21 after the discontinuation of the PGE2 treatment. The selective TrkB receptor agonist 7.8 Dihydroxyflavone (DHF), the selective TrkB receptor antagonist K252a or their vehicles were bilaterally administered in the NAcc during the initial 7 days of daily PGE2 treatment by two cannulae connected to osmotic mini-pumps subcutaneously implanted. The stereotaxic coordinates used were: 1.3mm anterior to Bregma; L1.7mm; V7.2mm below the skull surface. Two-way ANOVA followed by Bonferroni test was used for statistical analysis ($P<0.05$). Rats per group = 6 to 9. Results - Blockade of nucleus accumbens TrkB receptors prevented the development of persistent hyperalgesia. The mechanical nociceptive threshold of rats receiving K252a (0.016µg/µL) in the NAcc and PGE2 in the hindpaw (Mean±EPM: 112.92±3.8g) was significantly greater than that of rats receiving vehicle in the NAcc and PGE2 in the hindpaw (88.33±4g) from the 7th day of persistent hyperalgesia induction. In contrast, the activation of nucleus accumbens TrkB receptors facilitated the development of persistent hyperalgesia. In animals receiving DHF (0.83µMolar/µL) in the NAcc and PGE2 in the hindpaw the persistent hyperalgesia developed 2 days earlier and the mechanical nociceptive threshold was significantly lower (86.11±1.8g) than that of animals receiving vehicle in the NAcc and PGE2 in the hindpaw (116.11±2.5g) from the 5th day of persistent hyperalgesia induction. Conclusion - NAcc BDNF plays an essential role in the development of persistent hyperalgesia, suggesting that the action of this neurotrophin in nucleus accumbens is important for the development of chronic pain.

Title: Sensitization of C-fiber nociceptors in a murine model of Sickle Cell Disease (SCD) is decreased by the inhibition of anandamide hydrolysis through local administration of URB597

Authors: *M. L. UHELSKI, K. GUPTA, D. SIMONE;
Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Sickle cell disease (SCD) describes a group of disorders resulting from a point mutation in the beta chain of hemoglobin. This mutation leads to the creation of sickle hemoglobin (HbS) and causes distortion of erythrocytes through polymerization under low oxygen resulting in characteristic sickle red blood cells (sRBC). Vaso-occlusion caused by accumulation of sRBCs results in ischemia-reperfusion injury, reduced oxygen supply to organs, organ damage and severe pain. Further, many patients suffer from chronic pain, including increased sensitivity to light touch and spontaneous pain. Pain may result from both inflammatory factors as well as neuropathy, which creates a complex pain syndrome that may not respond well to currently available therapies. Mouse models of SCD have been developed which expresses human hemoglobin (normal HbA or sickle HbS). Homozygous HbSS-BERK sickle mice, expressing exclusively human beta-sickle hemoglobin or HbAA-BERK control express normal human hemoglobin A were used in this study. Sickle mice develop hyperalgesia around 5 months of age, and demonstrate enhanced pain responses following hypoxia-reoxygenation. Control mice do not exhibit hyperalgesia. Since there is growing evidence that increasing local levels of endocannabinoids can decrease hyperalgesia, we examined the effect of URB597, a fatty acid amine hydrolase (FAAH) inhibitor that blocks the breakdown of the endogenous cannabinoid anandamide (AEA), on the sensitization of peripheral nociceptors in hyperalgesic sickle mice. We characterized the sensitization of C- and Aδ-fiber nociceptors in hyperalgesic sickle mice in comparison to their normal HbAA controls. In the current study administration of URB597 (10 μg in 10 μl) into the receptive field of sensitized C-fiber nociceptors significantly decreased spontaneous activity (from 0.82 ± 0.67 Hz at pre-injection to 0.19 ± 0.08 Hz at 90 min post-injection), increased mechanical response thresholds (from 5.77 ±

2.37 mN to 41.80 ± 9.16 mN at 90 min post-injection), and decreased responses evoked by 147 mN von Frey stimulation (from 105.9 ± 11.9 impulses to 13.7 ± 1.8 impulses at 90 min post-injection). These results paralleled behavioral studies in which intraplantar administration of administration of URB597 decreased mechanical hyperalgesia in HbSS mice. It is suggested that enhanced endocannabinoid activity in the periphery could alleviate chronic pain associated with SCD without undesirable side effects associated with activation of cannabinoid receptors in the CNS.

Title: Mouse physiology changes over time during isoflurane anesthesia but remains within normal limits

Authors: *L. BAUER, L. LOW, C. BUSHNELL;
NCCIH, NIH, Bethesda, MD

Abstract: Anesthetized mice can be used in neuroimaging studies to explore neural pathways. Anesthesia can affect cerebral blood flow and oxygenation, which are important variables for functional brain imaging. Hence, it is necessary to know about the baseline physiology of mice under anesthesia. Aim: To monitor how physiological parameters change over time in mice under isoflurane and alpha chloralose anesthesia. Methods: Male C57bl/6 mice were anesthetized with either isoflurane (n=19) or alpha chloralose (n=7). Isoflurane mice were induced at 4% and maintained at 1.5-2% in a 60:40 O2:medical air mixture. Alpha chloralose-anesthetized mice were induced with 4% isoflurane, and then given an 114mg/kg i.p. injection of alpha chloralose. Breathing rate was measured using a pressure-transducer pillow; heart rate was measured with s.c. ECG leads. Core body temperature was measured with a rectal probe and maintained via an automatic temperature feedback system. Arterial blood samples were taken from a tail artery at early, mid and late time points, and pH, oxygen and carbon dioxide saturations quantified. Mice were monitored under anesthesia for up to 150 minutes. Results: Over a period of 150 minutes under isoflurane, breathing and heart rate significantly decrease ($p<0.0001$ and $p=0.036$, respectively). Core body temperature can be maintained (36.5±0.5°C). Blood pH decreases significantly over time, but does not reach the point of acidosis (pH<7.2). Also under isoflurane,

blood CO2 decreases as average respiration rate increases (p=0.133, r2=0.21). With alpha chloralose, breathing rates are lower than those of mice under isoflurane (p=.003), heart rate is below the accepted range of 450-500bpm (310-420bpm), and blood becomes acidotic (pH<7.2) over periods up to 105 minutes. Conclusions: Using isoflurane, heart rate stays within published acceptable limits of 450-500 bpm, as does blood pH (7.2-7.4), even during extended periods, but alpha chloralose causes considerable blood acidosis. There is limited information about acceptable respiration rates for an anesthetized mouse, but lower breathing rates are associated with higher blood CO2 levels, creating a potential for blood acidosis. It can be deduced that alpha chloralose does not maintain stable physiology over long periods of time, which may interfere with brain imaging results. These results suggest that mouse physiology can be effectively maintained using isoflurane in order to have a consistent baseline for blood flow to the brain, making it possible to obtain reliable results from functional brain scans which depend on blood flow and oxygenation measures.

Title: Effects of bacterial virulence factor applied to the rat dental pulp on nociceptive sensorimotor behaviour and medullary dorsal horn (MDH) nociceptive neurons

Authors: *V. PANCHALINGAM[1,2], V. FENG[1], L. MELO[1], L. AVIVI-ARBER[1], P. GAZERANI[2], P. CHERKAS[1], B. SESSLE[1];
[1]Fac. of Dent., Toronto, ON, Canada; [2]Hlth. Sci. and Technol., Aalborg Univ., Aalborg, Denmark

Abstract: Symptomatic irreversible pulpitis is a bacteria-induced painful inflammatory disease of the dental pulp. In an inflammatory dental pain model, we have shown that pulpal application of the inflammatory irritant mustard oil (MO) induces increased activity of medullary dorsal horn (MDH) nociceptive neurons reflecting trigeminal central sensitization and increased jaw muscle electromyographic (EMG) activity reflecting nociceptive sensorimotor behaviour (e.g. Chiang et al, 1998; Sunakawa et al, 1999; Narita et al, 2012). Given this and recent findings that

bacterial virulence factors can activate nociceptors (Chiu et al. 2013), the aim of this study was (a) to investigate whether application to the rat maxillary molar dental pulp of the gram-negative virulence factor lipopolysaccharide (LPS) or the gram-positive virulence factor lipoteichoic acid (LTA) can induce nociceptive sensorimotor behaviour and trigeminal central sensitization of MDH nociceptive neurons, and (b) compare the effects with those of MO. Electrophysiological recordings were made of bilateral masseter muscle EMG activity or the activity and responses to graded pinch of MDH wide dynamic range nociceptive neurons before (i.e., baseline) and after LPS (1mg/mL), LTA (5mg/mL), MO or vehicle (α-MEM) application to the pulp of adult male Sprague-Dawley rats (n=5-7/group) under general anaesthesia. As compared with baseline, both MO and LPS (but not LTA or vehicle) produced a significant (RM ANOVA, Tukey test, $p<0.05$) increase in EMG activity (e.g. peak amplitude, area under the curve) that began within 1 minute and lasted for 3-5 minutes. Only MO and LPS produced evidence of trigeminal central sensitization as indicated by a significantly (RM ANOVA, Tukey test, $p<0.05$) increased spontaneous activity or pinch-evoked responses of the MDH nociceptive neurons. These findings suggest that, like MO, the presence of the bacterial virulence factor LPS in the dental pulp can evoke trigeminal central sensitization and nociceptive sensorimotor behaviour and may play a role in the pain associated with symptomatic irreversible pulpitis in humans.

Title: An *in vivo* electrophysiological assay to assess blood-nerve barrier penetration in the sciatic nerve

Authors: *K.-C. CHOONG, T. M. WALL, J. L. KRAJEWSKI, X. CHI, T. E. FITCH, B. FORSTER, B. S. WILENKIN, M. J. KRAMBIS, K. M. GARDINIER, T. J. RAUB, K. RASMUSSEN, J. S. MCDERMOTT, K. K. PALMER, B. T. PRIEST, L. R. KEHN, E. S. NISENBAUM;
Neurosci. Discovery, Lilly Res. Labs., Indianapolis, IN

Abstract: A perennial challenge in the pursuit to discover novel peripherally-restricted analgesics is determining the extent to which drugs can cross the blood-nerve barrier (BNB) to engage the intended target and modulate nociceptive signaling. While electrophysiological responses of specific primary afferent fibers have been well-characterized in teased fiber preparations, these techniques disrupt the integrity of the epineurium, precluding assessment of BNB penetration of novel compounds *in vivo*. In the current study, we develop a simple and rapid method to assess BNB penetration using multi-unit extracellular recording of the intact sciatic nerve *in vivo* in mice. Sensory afferent action potentials were recorded in the intact sciatic nerve bundle using a hook tungsten electrode following stimulation of the plantar surface of the hindpaw with a pair of fine needle electrodes. Electrically-evoked A- and c-fiber responses were identified based on their conduction velocities. The identity of c-fibers responses was further confirmed by demonstrating that longer latency discharges were initially increased for 5-10 min following intradermal injection of capsaicin (10 µl, 1%) into the hindpaw and subsequently eliminated due to desensitization of nociceptors. We subsequently validated this functional BNB penetration assay by measuring A- and c-fiber responses following systemic administration of lidocaine, a non-selective sodium channel blocker which can readily penetrate the BNB and Compound A, a Nav1.7-preferring blocker that does not appreciably cross the BNB. Results showed that both A- and c-fiber action potentials were blocked by lidocaine at unbound plasma concentrations that were also effective in a complementary *in vitro* sciatic nerve assay in which the BNB was disrupted. In contrast, systemic administration of Compound A did not affect A- or c-fiber responses despite achieving unbound plasma concentrations that were shown to preferentially suppress c-fiber responses *in vitro*, consistent with the expression of Nav1.7 on this fiber type. Moreover, local administration of compound A to the sciatic nerve based on the effective concentration observed *in vitro*, potently inhibited c-fiber responses after removal of the epineurium covering the sciatic nerve.. Collectively, these results indicate that this method can be used as a simple functional assay to measure BNB penetration of novel compounds *in vivo*.

Abstract: The incidence of chronic pain is 20-25% worldwide, setting the research focus on revealing the basic mechanisms of pain and the development of more effective pain treatments. As human nociceptors are only rarely available, the cellular mechanisms of nociception are mostly studied in sensory neurons of rodents. Since chronic pain cannot be adequately mimicked in animal models, we took advantage of using human pluripotent stem cells (hPSC) to generate nociceptor-like neurons. Using a chemical based approach, we differentiated hPSC into human nociceptive sensory neurons that expressed BRN3A, Peripherin, TrpV1 and P2RX3, all markers of nociceptors. These stem cell derived sensory neurons showed electrophysiological properties indicative for the presence of tetrodotoxin sensitive (TTXs) and resistant (TTXr) voltage-gated sodium channels (Navs). In contrast to their counterparts from rodent dorsal root ganglia neurons, TTXr currents of hPSC-derived nociceptors unexpectedly display a significant shift of the voltage dependence of activation and fast inactivation towards more hyperpolarized potentials. The reason for this apparent discrepancy is most likely a substantial expression of the developmentally important Nav1.5 channel. In view of the limitations of animal models to recapitulate neuropathic pain, our data advances hPSC-derived nociceptors as an additionally necessary model to study developmental and pathogenetic processes underlying pain in humans and may help to develop new pain treatments.

Title: Right side specific potentiation of parabrachial-central amygdala transmission by trigeminal nerve-mediated inflammatory pain

Authors: Y. MIYAZAWA[1], M. SUGIMOTO[1], Y. TAKAHASHI[1], A. M. WATABE[1], *F. KATO[2];
[1]Dept Neurosci, Jikei Univ. Sch. Med., Tokyo, Japan; [2]Dept Neurosci, Jikei Univ., Tokyo, Japan

Abstract: Nociceptive signals arising from the superficial layer of the spinal dorsal horn (sDH) and the caudal part of the spinal nucleus of the trigeminal nerve (Sp5c) converge in the lateral parabrachial nucleus (LPB) and then are sent to the capsular part of the central amygdala (CeC). This spino-(trigemino-)parabrachio-amygdaloid pathway (Gauriau & Bernard, 2002) forms the direct route for the nociception-emotion link and shows robust potentiation in various types of pain models in rodents (Veinante et al., 2013). Lines of evidence indicate that the synaptic potentiation of the LPB-CeC transmission and increased expression of phosphorylated ERK occur exclusively in the right amygdala regardless of the side of nociception in the animal models with arthritis and formalin-induced inflammatory pain models (Guangchen & Neugebauer, 2009; Carrasquillo & Gereau, 2007). To determine whether such laterality depends on the difference in the specific mechanism in the CeC, we employed a trigeminal inflammatory pain model because, 1) unlike sDH neurons, Sp5c neurons project to bilateral LPBs, and 2) this model unexpectedly shows bilateral mechanical sensitization in the hindlimb (Sugimoto et al., 2015), which are interesting properties to compare with the spinal inflammation models. Injection of 5% formalin solution into the upper-lip of adult Wistar rats resulted in manifest face-rubbing behaviors lasting for < 1 h and bilateral mechanical sensitization in the hindlimb, where there was no injury, after 3 h. Six hours after injection, we made acute brain slices and measured LPB-CeC synaptic transmission. A marked LPB-CeC potentiation was observed in the right CeC of the orofacial formalin model regardless of the injection side. This potentiation was accompanied by decreased paired-pulse ratio and increased quantal size, suggesting changes in pre- and post-synapses characterize the functional alteration of this pathway. However, we did not find any apparent changes in NMDA/AMPA ratio in either side. These results indicate that the right amygdala plays specific primary role in regulating the strength of nociception-emotion link regardless of the location of painful sensation and inflammation at least in persistent pain lasting for several hours.

Title: Nociceptive sensitization of a defensive strike occurs centrally in Manduca sexta

Authors: *D. TABUENA, C. MOFFATT, M. FUSE;
San Francisco State Univ., San Francisco, CA

Abstract: Current preclinical models of nociception in animals such as mice or rats require multiple levels of protocol and logistical regulation. This presents an economic burden to research in the field. Here we characterize a model for hypersensitization of nociception of the defensive strike response in the insect Manduca sexta. This terrestrial caterpillar can bridge the gap between aquatic invertebrate and traditional, mammalian preclinical models. This work was based on a previous behavioral assay where a hypersensitive state was induced with a noxious stimulus. In this study, we demonstrate the ability to use M. sexta as an electrophysiological model for nociception, through development of both an *in situ* and an *in vitro* preparation. We were able to correlate nerve activity in the ventral nerve cord (VNC) with the defensive behavior and identified the afferent nerve pathway from the body wall to the VNC using mechanical stimulation with calibrated von Frey filaments and simultaneous extracellular nerve recordings, by systematically eliminated nerve projections. We then assayed both hypersensitive and non-treated animals in this manner, using a pinch as the noxious stimulus. We found that force required to induce a half maximal response in the ventral nerve cord was significantly reduced after the pinch. However, the response in afferent nerves was unchanged. The lack of significant change in afferent nerve pressure response or basal firing rate suggests that the hypersensitivity to nociception is driven by signaling factors at or after synapses in the ventral nerve cord ganglion. Furthermore, we measured changes in habituation to mechanical stimuli in a similar manner and found that habituation is attenuated peripherally but not centrally. This system provides a novel *in situ* model for studying modulation of nociception and “pain” signaling in a cheaper and less strictly regulated animal.

Title: Sex differences in BDNF expression after exposure to early life stress leads to susceptibility to neuropathic pain-induced emotional dysfunction

Authors: *T. NISHINAKA, K. NAKAMOTO, S. TOKUYAMA;
Kobe Gakuin Univ., Kobe, Japan

Abstract: Early life stress leads to the pathogenesis of psychiatric disorders and chronic pain in adult patients. We have recently demonstrated that exposure to early life stress exacerbates nerve injury-induced thermal and mechanical hypersensitivity in adult male and female mice. Accumulating evidence suggests that chronic pain causes emotional dysfunction, such as anxiety and depression. The emotional dysfunction induced by persistent pain is related to functional alterations in the brain, such as frontal cortex, hippocampus and striatum. It is well known that neuronal dysfunction in these regions of the brain is also induced by early life stress. In the present study, we investigated the effect of early life stress on depression-like behavior after nerve injury in mice. In addition, we examined the expression of brain-derived neurotrophic factor (BDNF), which is known to be involved in the pathogenesis of depression. Early life stress was induced by maternal separation between 2 and 3 weeks of age combined with social isolation after weaning (MSSI). At 9 weeks of age, the sciatic nerve was partially ligated to elicit neuropathic pain. Depression-like behavior was evaluated using the forced swim test at 12 weeks of age. Tissue samples from different regions of the brain were collected at the end of maternal separation (3 weeks of age) or after the forced swim test (12 weeks of age). At 12 weeks of age, immobility time in the forced swim test was increased only in MSSI-stressed female mice with nerve injury. BDNF expression was increased in male, but not female, MSSI-stressed mice at 3 weeks of age. However, MSSI stress did not influence BDNF expression in male or female mice at 12 weeks of age. Our findings suggest that exposure to early life stress exacerbates emotional dysfunction induced by neuropathic pain in a sex-dependent manner. Changes in BDNF expression after early life stress may be associated with neuropathic pain-induced depression-like behavior in adulthood. Furthermore, sex differences in BDNF expression after exposure to early life stress may contribute to sex-specific susceptibility to neuropathic pain-induced emotional dysfunction.

Title: Multi-molecular and structural profiles of the skin and cutaneous innervation that validate a pig proximal nerve injury models for translational research on human peripheral neuropathic pain

Authors: *S. B. MEILIN[1], M. DOCKUM[2], D. CASTEL[3], I. SABBAG[4], F. L. RICE[2];
[1]MD Biosci., Ness Ziona, Israel; [2]Integrated Tissue Dynamics LLC, New York, NY; [3]The Neufeld Cardiac Res. Institute, Sheba Med. Centre, Sackler Sch. of Med., Tel Aviv, Israel; [4]Lahav Res. Institute, Kibutz Lahav, Negev, Lahav, Israel

Abstract: Current therapeutics for human peripheral neuropathic pain afflictions (PNPA) typically provide at best 50% relief in less than one third of patients most of whom have debilitating side effects. A major challenge to translational research for safer, more effective therapeutics is the development and validation of cost-effective non-human models of CNPA. The pig is particularly useful especially because of comparable-to-human body size, metabolism, skin structure and innervation, as well as nerve, DRG, and spinal cord dimensions. Moreover, pigs are plentiful, relatively cheap, breed easily, have multiple offspring, and are more ethically preferable than non-human primates. We have developed a sciatic nerve trauma model performed by pre CFA-soaked loose sutures that produces hindlimb pain responses consistent with human regional CNPA such as radicular pain, sciatica, and complex regional pain syndrome. In addition to assessments of response to threshold like those tested in rodent models and humans, pigs also have complex social interactions that are negatively impacted like many in humans. In order to further validate whether this model is indeed comparable to human CNPA, we used combinations of immunomarkers for a wide variety of functionally-implicated neurochemical markers in order to compile immunocytochemical and morphological profiles of the hindleg skin and innervation as we have done previously for a variety of human CNPA, including CRPS type 1. Assessments were made on alternating sections of skin biopsies fixed by immersion in 4% paraformaldehyde as routinely done with human skin punch biopsies. Consistent with many human CNPA, the innervation of the epidermis, upper dermis and deep dermal innervation was substantially reduced with preferential preservation of sensory fibers that express calcitonin-gene-related peptide and 200kD neurofilament protein indicative of likely Aδ fibers which have been implicated in mechanical allodynia. Of particular importance, the keratinocytes of the thick multi-layered epidermis (identical to that in humans) exhibited induced alterations among a variety of normally stratified algesic and analgesic neurochemical properties like those that we have previously documented in several human CPNA including CRPS type 1.

Title: Test-retest reliability of 10 Hz conditioning electrical stimulation inducing long-term potentiation-like pain facilitation in humans

Authors: ***W. XIA**, C. D. MØRCH, O. K. ANDERSEN;
Hlth. Sci. and Technolody, Aalborg Univ., Aalborg, Denmark

Abstract: Background: 10 Hz conditioning electrical stimulation (CES) has been shown to induce long-term potentiation (LTP)-like pain facilitation similar to traditional 100 Hz CES in healthy humans. The aim of the study was to assess the test-retest reliability and to estimate sample sizes required for future crossover and parallel pharmacological testing studies. Methods: Sensory changes and neurogenic inflammatory vascular reactions after 10 Hz CES to the volar forearm were assessed in 20 subjects during two identical experimental sessions separated by at least one week. Perceptual intensity ratings to single electrical stimulation at the conditioned skin site and to mechanical stimuli (pinprick and light stroking) in immediate vicinity to the conditioned skin site were recorded. Superficial blood flow and skin temperature were assessed as indicators of neurogenic inflammation. All outcome measures were assessed with 10 min intervals three times before and six times after CES. The coefficient of variation within session (CVwi) and between sessions (CVbt), and intra-class correlation within session (ICCwi) and between sessions (ICCbt) were calculated. Systematic bias was analyzed by repeated measures analysis of variance. Subsequently, the sample sizes were calculated for potential future crossover (Ncr) and parallel (Np) drug testing studies expected to detect a 30 % decrease for the individual outcome measures following 10 Hz CES. Results: For assessment of neurogenic inflammation, the superficial blood flow was found to significantly increase after CES then declined until reaching a plateau 20 minutes post CES. The blood flow showed the highest reliability (ICCwi=0.79, CVwi=3%, Ncr=3; ICCbt=0.62, CVbt=3%, Np=13) within and between 10 Hz CES sessions. Perceptual intensity ratings to light stroking (allodynia) (ICCwi=0.96, CVwi=8%, Ncr=2; ICCbt=0.89, CVbt=13%, Np=33) and pin-prick stimulation (50.1g,

secondary mechanical hyperalgesia) (ICCwi=0.9, CVwi=14%, Ncr= 6; ICCbt=0.88, CVbt =14%, Np=54) were found to significantly increase after CES and showed better reliability in crossover than parallel designs. The single electrical stimulation showed high reliability (ICCwi=0.94, CVwi=10%, Ncr=634; ICCbt=0.85, CVbt=14%, Np=11310) but with large estimated sample sizes due to a small effect by CES. Conclusion: The reliability of 10 Hz CES was acceptable in inducing LTP-like effects in the assessments of superficial blood flow, secondary mechanical hyperalgesia and allodynia in terms of sample sizes for potential crossover experimental designs.

Title: Parental modeling of stoicism and its effect on pain outcomes: Preliminary findings

Authors: *C. A. STURYCZ, B. L. KUHN, E. W. LANNON, S. T. PALIT, Y. M. GÜERECA, M. F. PAYNE, K. A. THOMPSON, J. O. SHADLOW, J. L. RHUDY;
Univ. of Tulsa, Tulsa, OK

Abstract: Past research has shown an influence of self-reported levels of stoicism on pain outcomes. Specifically, those who report higher levels of stoicism are similar to those who report low levels of stoicism in spinal nociceptive input (e.g. nociceptive flexion reflex; NFR) but differ in the report of pain sensation (e.g., pain threshold, pain tolerance). However, it is unclear if a relationship exists between parental transmission of stoicism and self-reported stoicism or pain outcomes. The current study utilized a semi-structured interview to assess attitudes about pain and history of painful experiences. One item that specifically inquired about what parents taught participants about pain was coded for the presence or absence of a stoic attitude. The relationship between this variable and self-reported stoicism (measured from fortitude, concealment, and superiority subscales of the Pain Attitudes Questionnaire, PAQ) and pain outcomes (heat, cold, ischemia, and electrocutaneous pain thresholds/tolerances). 47 healthy, pain-free participants. All statistical assumptions were tested and passed and extreme outliers were replaced using the nearest neighbor, plus one unit substitution technique. Groups did not differ on the subscales of

the PAQ (ps>.05) or NFR (ps>.05). However, those individuals taught to be stoic by their parents (n=14) had significantly higher heat pain thresholds (p<.02) and higher ischemia (p<.05), cold (p<.05), and electrocutaneous (p<.05) pain tolerances than those participants who were not taught to be stoic (n=33). Further, when PAQ subscales were entered into regression models to predict pain outcomes, the subscales were positively correlated with electric (R2=.22, p<.01), heat (R2=.18, p=.02), and cold pain tolerance (R2=.24, p<.01). These preliminary findings suggest that a family history of stoicism and trait stoicism are related to increased pain outcomes across a number of pain outcomes, primarily measures of tolerance.

Title: The influence of placebo analgesia on pain and the nociceptive flexion reflex (NFR): Is descending inhibition engaged?

Authors: *Y. M. GUERECA, B. KUHN, S. PALIT, J. L. RHUDY;
Psychology, The Univ. of Tulsa, Tulsa, OK

Abstract: Placebo analgesia is pain reduction evoked by an inert treatment and is mediated by at least two psychological factors: expectations for pain relief and classical conditioning (e.g., pairing an inert treatment with pain reduction). Although placebo analgesia is well established, it is not clear if it influences descending inhibition of spinal nociception. Past fMRI studies suggested that supraspinal regions involved with descending modulation of pain are activated during placebo analgesia. Yet, evidence for inhibition of spinal nociception is mixed. A study

found that an expectation + conditioning (E+C) manipulation decreased dorsal horn activity. However, another study failed to show that the nociceptive flexion reflex (NFR, physiological measure of spinal nociception) was inhibited by placebo. That study used a placebo manipulation with only an expectation manipulation, and the strongest placebo effects are observed when both expectations and conditioning are manipulated. Indeed, that study also failed to show placebo effects on pain ratings. Interestingly, a recent EEG study used an E+C manipulation and found that placebo analgesia was related to cortical modulation but not spinal inhibition. Thus, the present study was designed to examine whether pain and NFR are inhibited by placebo involving E+C. 140 healthy, pain-free individuals were randomly assigned to a Natural History control group (NH, n=35), or one of three placebo manipulations: Expectation for pain relief only (E, n=35), Conditioning only (C, n=35), or Expectation + Conditioning (E+C, n=35). Suprathreshold electric stimulations were delivered to the ankle to evoke pain and the NFR before and after two sham cream applications. To induce expectation for pain reduction, the E+C and E groups were told the cream was a strong and effective painkiller (Lidocaine) whereas the NH and C groups were told it was sensor gel. However, after the first application, electric stimulus intensity was surreptitiously reduced in the E+C and C groups to include conditioning (i.e., cream paired with pain relief). Since intensity was not reduced after the second cream application, placebo analgesia was defined as the change in pain and NFR associated with the second cream application. Results show that pain was inhibited in the E+C ($p<.001$) group. However, NFR was not inhibited in any group. In fact, NFR increased for the E+C ($p=.02$) and E ($p<.001$) groups. Findings suggest that placebo-induced pain inhibition is not mediated by descending inhibition of spinal nociception and instead may be influenced by other cortical processes.

Title: Wearing video goggles inhibits spinal nociception

Authors: *E. W. LANNON, J. RHUDY;
The Univ. of Tulsa, Tulsa, OK

Abstract: Viewing a stimulated body part has been shown to result in inhibition of pain and supraspinal nociception. However, it is unknown whether this involves descending inhibition of spinal nociception. The present study attempts to examine this issue by measuring the nociceptive flexion reflex (NFR), a spinally mediated reflex in the leg that is evoked by painful stimulation. Because the NFR is highly correlated with painful stimulus intensity and subjective pain report it is often used as an indirect measure of spinal nociception that can be influenced by descending modulatory pathways. The current study used a within-subjects design to manipulate the participant's visual input while pain report (intensity/unpleasantness) and the NFR were measured in response to painful electric stimulations to the sural nerve. 13 healthy pain-free individuals (8 women) underwent three conditions in which their visual input was manipulated with the use of a video camera connected to video goggles (VG). In two conditions, participants received live video feedback of the stimulated body part (their leg) or the projector screen in front of them (control). In another condition, participants were asked to look at the screen in front of them without VG (as a control for wearing VG). Results indicated that viewing a stimulated body part did not change pain report (intensity/unpleasantness) or the NFR (ps>.05). However, wearing video goggles significantly reduced the NFR and pain intensity (ps<.05). These results suggest that wearing VG activates descending inhibition of spinal nociception which results in pain reduction.

Title: Predictors of placebo analgesia of pain and spinal nociception

Authors: *S. PALIT, Y. M. GUERECA, B. L. KUHN, J. L. RHUDY;
Univ. of Tulsa, Tulsa, OK

Abstract: Placebo analgesia refers to a sham treatment that results in pain reduction and is mediated by expectations for reduced pain and conditioning (e.g., inert treatment + pain relief). Nevertheless, individual differences in placebo response exist, and identifying its predictors may improve pain treatments. Several predictors have been previously identified, including optimism

(positive beliefs about future outcomes), expectation for pain relief, and reward motivation (e.g., drive towards a goal). However, these predictors have not been used together to determine which best predicts placebo response. Further, predictors of placebo analgesia of spinal nociception have yet to be examined. The current data were taken from a study of placebo analgesia that randomized 134 participants to 1 of 4 conditions: natural history (NH) control, conditioning (C), expectation (E), or expectation and conditioning (E+C). Suprathreshold stimulations were delivered to the ankle to evoke pain and the nociceptive flexion reflex (NFR; physiological measure of spinal nociception) before and after application of an inert cream. The E+C and E groups were told the cream was a "powerful painkiller" while the NH and C groups were told it was "sensor gel." Placebo response was defined as post- minus pre-cream changes in pain and NFR. Participants rated their expectation for pain relief following cream application. Individuals also completed the Life Orientation Test-Revised (LOT-R) and the Behavioral Inhibition System/Behavioral Approach System (BIS/BAS) scales to assess optimism and motivation, respectively. For the purposes of the present study, the NH group was excluded and all placebo groups (N = 104) were examined together to identify predictors of placebo response. Multiple regression indicated drive was a significant predictor of change in pain, such that higher drive was associated with greater post-pain ($p = .05$). The effect of optimism approached significance ($p = .06$), indicating a trend for higher optimism being related to less pain. Expectation of pain relief ($p = .01$) and drive ($p = .05$) were significant predictors of NFR change, such that higher expectation and higher drive were associated with increased NFR (nocebo response). These findings suggest that expectations and drive can have different associations with spinal and supraspinal outcomes. Drive is a significant predictor of nocebo response at both the supraspinal and spinal levels. In contrast, expectation for pain relief was only a significant predictor of spinal level nocebo.

Title: Heart rate variability is not associated with placebo analgesia

Authors: *B. KUHN[1], Y. GUERECA[2], S. PALIT[2], J. RHUDY[2];
[1]Psychology, [2]The Univ. of Tulsa, Tulsa, OK

Abstract: Placebo analgesia is pain reduction induced by a sham treatment. Heart rate variability (HRV) is a measure of autonomic nervous system control over the heart. Commonly used variables to analyze HRV are high frequency HRV (HF-HRV) and a ratio of low to high frequency HRV (LF/HF). HF-HRV is typically assessed from the frequency band corresponding to human respiration (.15-.40 Hz) and is believed to measure parasympathetic influence over the heart (from respiratory sinus arrhythmia), with larger values representing greater parasympathetic control. LF/HF is thought to reflect the balance of sympathetic and parasympathetic influences over cardiac functioning, with larger values representing greater sympathetic influence. Prior research has found HF-HRV is associated with decreased pain. The present study examined whether HRV metrics are associated with placebo analgesia. Specifically, we examined whether HRV is related to a change in pain ratings and the nociceptive flexion reflex (NFR; a physiological correlate of spinal nociceptive processing) following placebo manipulations. Participants were 139 healthy, pain-free individuals (69 females) involved in a placebo analgesia study. Individuals were randomly assigned to either a natural history control group (NH=35), an expectation only group (E=36), a conditioning only group (C=33), or an expectation plus conditioning group (EC=35). An inert cream was applied on two different occasions in the same day and pain and NFR were tested before and after each application. HRV metrics were assessed between the two cream applications. For our analysis, we computed a change score for both pain and NFR (post- minus pre-test). An ANOVA indicated that there were no group differences in HRV metrics (HF-HRV: $p = .13$; LF/HF: $p = .07$), although there was a trend for LF/HF to be lower in the E, C, and EC groups relative to NH (pairwise $ps < .05$). Additionally HRV was not significantly correlated with change in pain ratings (HF-HRV: $r = -.06$, $p = .46$; LF/HF: $r = .05$, $p = .60$) or change in NFR (HF-HRV: $r = .02$, $p = .87$; LF/HF: $r = -.04$, $p = .75$). These data suggest that placebo manipulations did not lead to group differences in HRV and that HRV is not a good predictor of placebo response.

Title: Role of potassium channel TREK1 in formalin-induced acute and chronic nociception

Authors: *V. A. MARTÍNEZ-ROJAS, G. GARCÍA, A. HERNÁNDEZ MENDOZA, A. COVARRUBIAS CAMARILLO, J. MURBARTIÁN;
Cinvestav Sede Sur, Mexico City, Mexico

Abstract: TWIK-related 1 potassium channels (TREK1) are members of the two-pore domain potassium channel family that contribute to background conductances. TREK1 are expressed in nociceptors and their activity contributes to modulate nociception in acute inflammatory pain. However, the effects of this channel in chronic nociception are unknown. The aim of the present investigation was to assess the role of TREK1 in formalin-induced acute and chronic nociceptive responses in the rat. For this, rats were injected with formalin (1%, 50 μL, s.c.) in to dorsal hind paw. Acute nociception was determined by the number of flinches elicited by the injected paw every 5 min during 1 h. Chronic nociception was assessed 6 days after formalin injection by the application of von Frey filaments to the formalin-treated (ipsilateral) and untreated (contralateral) paw. Formalin injection produced acute nociceptive behaviors (1 h) followed by long-lasting evoked secondary allodynia and hyperalgesia in both paws (6 days). Local peripheral pre-treatment (-10 min) with the selective TREK1 activator BL-1249 (0.01-1 mM/paw) prevented formalin-induced flinching behavior in phase II but not phase I of the formalin test. Furthermore, local peripheral pre-treatment with BL-1249 (0.01-1 mM/paw) prevented in a dose-dependent manner the long-lasting evoked secondary mechanical allodynia and hyperalgesia in both paws. Local peripheral post-treatment (6th day after formalin injection) with BL-1249 (1 mM/paw) reversed formalin-induced secondary mechanical allodynia and hyperalgesia in both paws. TREK1 channels were detected in dorsal root ganglia and dorsal spinal cord of naïve rats without any significant change in TREK1 expression at 6 days after formalin injection. Our results implicate that TREK1 is present in sites related with nociceptive processing and modulates acute and chronic nociception induced by formalin in rats. VAM-R, GG and CC-A are Conacyt fellows.

Title: Gender specific effects of fluoxetie, duloxetine and amitriptyline in pain behavior and spinal BDNF expression in mice

Authors: M. ZAMMATARO[1], M. BARRESI[1], S. MERLO[2], L. CUCCI[4], M. SORTINO[2], *S. CHIECHIO[3];
[1]Drug Sci., [2]Biomed. and Biotechnological Sci., [3]Univ. of Catania, Catania, Italy; [4]Chem. and Mol. Biol., Univ. of Gothenburg, Sweden., Gothenburg, Sweden

Abstract: Antidepressant drugs are commonly used in various chronic pain syndromes. While there is a general consensus that the tricyclic antidepressant (TCA), amitriptyline, is the gold standard of analgesic antidepressants, analgesia obtained with selective serotonin reuptake inhibitors (SSRI) is less consistent. On the contrary, the dual serotonin/norepinephrine inhibitor (SNRI), duloxetine, has been shown to be efficacious both in persistent and inflammatory pain states. Although the serotonergic and noradrenergic systems have been implicated in the descending inhibitory control of pain and therefore in the analgesic effects of antidepressant drugs, in this study we evaluate whether brain-derived neurotrophic factor (BDNF) might also be involved. Long-term treatment with antidepressant drugs is known to increase hippocampal BDNF, a mechanism that supports the effectiveness of these drugs in depression. However, BDNF is also considered a central modulator in the development of pain sensitization. Furthermore, a number of studies point to a gender distinct effect of BDNF on depression-like behavior in rats, suggesting that there may be a sexual dimorphism in BDNF function. Based on this evidence, in this work we sought to evaluate the effect of long-term treatment of different classes of antidepressants on pain behavior and on BDNF expression in the spinal cord of male and female mice. We selected fluoxetine, amitriptyline and duloxetine as representative for SSRI, TCA, and SNRI classes of antidepressant drugs, respectively. Pain behavior and BDNF expression in the dorsal horn of the spinal cord were evaluated after a 21-day treatment (10 mg/kg, ip) with the three antidepressants both in male and female CD1 mice. Our results show a gender differentiated behavior in the formalin test of male and female littermate mice after a long-term administration. Specifically, a 21-day treatment with fluoxetine was unable to elicit analgesic response in both phases of the formalin test in male mice, but was able to significantly reduce the second phase of the formalin test in females. On the contrary, duloxetine and amitriptyline did not affect nocifensive behavior in the formalin test, in female mice, but they induced analgesia in males. Moreover, western blotting and immunohistochemistry analyses show that antidepressant drugs can differently modulate BDNF expression in the dorsal horn of male and female CD1 mice, suggesting that BDNF participates to pain modulation by antidepressant drugs in a gender specific manner.

Title: The biophysical basis of rapidly adapting mechanoreceptor currents in *C. elegans* touch receptor neurons

Authors: A. L. EASTWOOD[1], A. SANZENI[3], B. C. PETZOLD[2], S.-J. PARK[2], B. L. PRUITT[2], M. VERGASSOLA[3], *M. B. GOODMAN[1];
[1]Mol. and Cell. Physiol., [2]Mechanical Engin., Stanford Univ., Stanford, CA; [3]Dept. of Physics, Univ. of California at San Diego, San Diego, CA

Abstract: Our perceptions and reactions to the physical world are deeply rooted in our sense of touch and depend on somatosensory neurons that invade and innervate the skin. It is supposed that these neurons filter and convert the mechanical energy delivered in each touch into excitatory membrane currents carried by mechanoelectrical transduction (MeT) channels. Somatosensory neurons are classified according to their mechanical sensitivity and adaptation rate. The gentle touch receptor neurons (TRNs) of the nematode Caenorhabditis elegans have low thresholds for activation and adapt rapidly to both the application and removal of mechanical loads. These response dynamics are shared by other somatosensory neurons in *C. elegans* and by Pacinian and Meissner corpuscles in mammals. Yet, the mechanisms responsible for rapid adaptation and symmetrical on and off responses have remained enigmatic. To learn more, we developed the FALCON system and used it to record membrane current, applied force, and the resulting indentation in parallel. The system combines *in vivo* whole-cell patch clamp recording with a custom microcantilever and feedback control. Here, we use FALCON to show that MeT current amplitude increases with both indentation and stimulus rate. Rapid adaptation is robust to dramatic changes in body mechanics and persists under both force clamp and displacement clamp. Armed with these experimental findings, we also develop a physical model in which activation of the MeT channels that decorate TRN neurites is linked to body indentation via a viscoelastic element embedded in the animal's skin or cuticle. The model reproduces the observed indentation and rate sensitivity as well as the symmetrical on and off responses.

Because the model is independent of the molecular identity of the MeT channel and of any particular accessory structures, it provides a general mechanism for rapid adaptation that may be applicable to diverse mechanosensory cells across phyla and sensory modalities.

Title: The role of arachidonic acid containing-membranes in modulating mechanoreceptor currents *in vivo* in *C. elegans*

Authors: ***S. KATTA**[1], V. VÁSQUEZ[1,2], A. L. EASTWOOD[1], M. B. GOODMAN[1]; [1]Stanford Univ., Stanford, CA; [2]Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Although we have known for two decades that bacterial mechanosensitive channels open in response to membrane tension, we have yet to determine what gates eukaryotic mechanotransducers. Given the variety and complexity of mechano-electrical transduction (MeT) apparatuses, we need a system in which we not only understand the identity of the MeT channel and its interacting partners, but can also explore the mechanics of the microenvironment and surrounding tissue. One such system is the MEC channel complex in *C. elegans* touch receptor neurons (TRNs). Previously, we determined that certain polyunsaturated fatty acids (PUFAs), contained in membrane phospholipids, affect behavioral responses to touch. In particular, we showed that *fat-1fat-4* worms, which lack arachidonic acid (AA), were partially defective in their responses to touch, and that supplementation of AA but not its metabolites rescued this phenotype (Vásquez et al., Cell Reports, 6:70-80, 2014). Optogenetic activation of the TRNs showed that the defect in *fat-1fat-4* worms was upstream of synaptic transmission and atomic force microscopy revealed that PUFAs modulate the mechanical properties of TRN plasma membranes. These results pointed to a change in either the initial mechanoreceptor

currents (MRCs) or the subsequent opening of voltage-gated calcium channels that amplify the MRC signal, but we had not yet characterized the currents in these animals. Here, we use *in vivo* whole-cell patch clamp electrophysiology to determine how the absence of AA in TRN membranes affects voltage-activated currents and MRCs. We combine a piezoelectric stack for driving the mechanical probe with a segmented photodiode system for measuring actual indentation (Peng et al., Neuron, 80:960-72, 2013), which allows us to apply larger indentations at a faster rate than was previously possible. We look at MRC kinetics and inactivation rates, the indentation-current curve, and the effect of indentation rate as we investigate the role of the membrane environment in MeT channel gating.

Title: Segregated population of layer 5 sensorimotor cortex neurons projects to superficial and deeper laminae of the same spinal cord segment

Authors: *R. OLIVARES-MORENO[1], Y. MORENO-LOPEZ[1], L. CONCHA[1], M. CORDERO-ERAUSQUIN[2], G. ROJAS-PILONI[1];
[1]UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, QUERETARO, Mexico; [2]Inst. des Neurosciences Cellulaires et Intégratives, Strasbourg, France

Abstract: Through projections to the spinal cord (CSP), the cortex modulates the sensory information flow as well as contributes to motor execution and control. However, it is not clear if corticospinal projections involved in these two different functions (sensory vs. motor) are strictly segregated or part of partially overlapping functional systems. In this work, we studied the

distribution of corticoespinal neurons (CSN) by injecting two different retrograde tracers in the spinal cord at the DH and intermediate zone-ventral horn the same segment in the rat. Our results show a partial segregation for both neonate and adults sensorimotor cortex, the main difference is that while in neonates this segregation extends to S1(probably due the immature development of corticospinal tract) in adults is more restricted to M1. On the other hand, in the adult about 93 % of the CSN reach DH while only 5 % arrive to deeper spinal cord laminae. This data suggests that M1 CSN drives in parallel distinct segmental neural circuits part of the sensory and pre-motor pathways, representing a new and additional level of sensorimotor integration.

Title: Corticospinal segregated projections activates distinct segmental interneurons in rat spinal cord

Authors: Y. MORENO-LOPEZ[1], R. OLIVARES-MORENO[1], M. CORDERO-ERAUSQUIN[2], *G. ROJAS-PILONI[1];
[1]Univ. Natl. Autonoma Mexico, Queretaro, Mexico; [2]Dept. Nociception et Douleur, Inst. des Neurosciences Cellulaires et Intégratives, Strasbourg, France

Abstract: Corticospinal (CS) descending projection plays a major role in motor control by means of modulation of pre-motoneuron interneurons. Additionally this system is also involved in a selective and complex modulation of sensory information which is also important for the proper execution of movements. However, the segmental interneurons and the downstream networks driven by CS projection are poorly characterized. The objective of this study was the *in*

vivo electrophysiological characterization of neurons in the spinal cord that are modulated by CS tract in order to analyze if there are a different subpoblations of spinal interneurons related to sensory and motor control. We found two type of spinal interneurons responding to sensorimotor cortex according with their activation latency located in dorsal (laminae II-IV) and intermediate (lamina VII) grey matter. Both type of neurons receiving inputs from cortex also are activated by fast myelinated primary afferents. Our results suggest that the CS projection in parallel drives distinct segmental neural circuits all of them necessary for proper execution of volitive movements.

Title: Peptidomic investigation of rat dorsal root ganglia

Authors: *E. G. TILLMAAND, N. YANG, E. V. ROMANOVA, S. S. RUBAKHIN, J. V. SWEEDLER;
Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Peripheral neuropathies affect 2.4% of the population (Hughes, R. *BMJ*. 2002). Peripheral sensory disorders such as diabetic and HIV-induced neuropathies and post-herpetic neuralgia manifest in debilitating symptoms that include burning pain, numbness and tingling, reduced proprioception, and allodynia. To better understand what drives these disease states, the neurochemical mechanisms of sensory response in healthy neurons must first be understood. Primary sensory neurons, located in the dorsal root ganglia (DRG), are prime models for such studies. In-depth characterization of the peptide content within and released by these cells would improve our understanding of specific mechanisms of peripheral sensory information transmission as well as the functional role of sensory neurons and their peptides in both normal and pathological states. We performed peptidomic analyses of both whole DRGs and cultured DRG cells from *Rattus norvegicus* using liquid chromatography electrospray ionization Fourier transform mass spectrometry (LC-ESI-FT MS). In a peptidomic analysis of six sets of DRG

samples, *de novo* sequencing resulted in the identification of over 2500 peptides from 297 proteins. Neuropeptides derived from six prohormones: calcitonin gene-related peptide, calcitonin, osteocalcin, protachykinin-1, proSAAS, and secretogranin II were observed. To better understand the peptide content of cellular release, DRG cells were cultured in 2 mm diameter restricted spaces and stimulated using a high potassium extracellular media. Samples of releasates before, during, and after stimulation were collected from over 140 cell cultures developed from six rats. Matrix-assisted laser desorption/ionization time of flight MS analysis of the samples revealed 41 signals of interest. Molecular mass-matching of the signals to the LC-ESI-FT-MS analysis data sets revealed 24 known peptides from 20 protein precursors, including neurologically relevant proteins such as neurofilament heavy, medium, and light polypeptides, vimentin, high mobility group protein B1, gamma synuclein, and peptidyl-prolyl cis-trans isomerase FKBP1A, as well as periaxin and myelin protein P0, which are involved in glial cell function. Interestingly, one potential hemorphin peptide was observed. Hemorphins are known to activate opioid receptors and play a role in the anti-pain response (Honda, M. et al. *Jpn J Pharmacol.* 2001). This study provides information on the peptide contents of whole DRGs and cultured DRG cells and is a first step toward a more complete peptidomic characterization.

Title: Reflexive voice pitch responses to laryngeal mechanosensory stimulation

Authors: *M. J. HAMMER, S. A. PALM, A. BHATTACHARYA;
Univ. of Wisconsin, Madison, WI

Abstract: I. INTRODUCTION: Evidence suggests that laryngeal mechanoreceptors provide perceptual and proprioceptive afference for a variety of essential human functions including airway protection, breathing, and voice. These stretch, touch, and pressure sensitive mechanoreceptors within the laryngeal mucosa appear to be exquisitely arranged for the rapid transmission of a constellation of movement and voice related afferent information. It has been

reasonably argued that mechanosensory and auditory mechanisms are each important for optimal voice control. However, our understanding of mechanosensory mechanisms remains incomplete. Therefore, our objectives were to test whether mechanosensory input to the laryngeal mucosa during vocalization evokes a reflexive voice pitch response and to determine whether the response size may be associated with stimulus magnitude. II. METHODS: The institutional ethics committee for the safety of human subjects approved this protocol; written informed consent was obtained from each participant. An endoscopic approach was used to deliver a 135ms pressure-calibrated air stimulus to the mucosa surrounding the arytenoid/corniculate cartilage within the larynx as each participant sustained the vowel "eeee". Each participant completed 10 trials at each of 5 stimulus pressures (2, 4, 6, 8, and 10 mmHg). The voice signal was recorded using a head-set microphone. Fundamental frequency (in Hz) was extracted from each raw voice acoustic signal and normalized by converting into cents (100 cents = 1 semitone) to enable us to average data across participants. III. RESULTS/DISCUSSION: We found that the mechanosensory stimulus consistently evoked a reflexive voice pitch response. We also observed an increase in response magnitude as stimulus pressure increased. The direction of these responses and the fact that response size was modulated by stimulus magnitude suggests that the vocal sensorimotor system may utilize input from laryngeal mechanoreceptors to correct for errors in vocal pitch. Therefore, our findings support the important role of mechanosensory input for fine voice control.

Title: A multiphysics model of the pacinian corpuscle

Authors: ***J. QUINDLEN**[1], H. K. STOLARSKI[2], M. FLANDERS[3], V. H. BAROCAS[1]; [1]Biomed. Engin., [2]Civil Engin., [3]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The Pacinian corpuscle (PC) is a cutaneous mechanoreceptor located in the dermis. It responds to high frequency (20-1000 Hz), low amplitude vibrations. At the tip of a myelinated sensory axon, an unmyelinated neurite is surrounded by concentrically-aligned lamellae

separated by pressurized fluid. When a stimulus is applied to the PC, the deformation is passed through the lamellae, distorts the neurite, opens stretch-gated ion channels, and initiates a neural response. Loewenstein and Skalak (1966) proposed that the interaction between fluid and lamellae causes the PC to act as a high-pass filter, as compression of the PC causes viscous forces to develop due to fluid flow between lamellae. Fluid-lamellar interactions determine the subsequent deformation on the neurite. The first step in the modeling embedded PCs of different orientations at different depths in the skin. To create a model of the mechano-to-neural transduction process that accounts for fluid interactions, a finite-element mechanical model used a spherical PC as an approximation of its ellipsoidal shape. Shell and lubrication theories were used to reduce the problem dimension. The solid and fluid layers were coupled through fluid velocity and pressure. The PC was modeled as a series of 30 shells with a lubricating fluid between each shell and a central incompressible core. Lamellar thickness ranged from 0.1-0.4 μm, increasing with distance from the core. Pressure was applied to the outer shell at 1 Hz-10^8 Hz frequencies. The simulations calculated the ratio of displacements of the inner and outer shells, thus determining neurite stretch at various indentation amplitudes and frequencies. The model showed stretch amplification in layers close to the core, making it possible for the neurite to initiate a response to low amplitude stimuli. The mechanical model will be modified to incorporate the inner core of the PC in addition to the previously modeled outer core. The inner core contains approximately 60 closely packed lamellae that are bilaterally arranged on either side of the neurite, with longitudinally-oriented clefts. Since the current model approximates the PC as 30 concentric layers, the inner core will be included to capture the mechanics of the entire PC structure. The next step is to create a neural model that can input the neurite stretches calculated from the mechanical model and predict known response properties. The geometry of the neural model will be refined to incorporate the detailed morphology of the neurite, including its filopodia. The overall aim is to generate a skin vibration to action potential model including the global morphological characterization of the PC system of human hand.

Title: Cold temperature stimulates IP3R-mediated calcium release in skin cells

Authors: *S. E. PIERCE, N. W. BELLONO, E. OANCEA;
Brown Univ., Providence, RI

Abstract: While the temperature of internal organs is tightly regulated, human epidermal melanocytes (HEMs) are constantly exposed to the fluctuating temperatures of the external environment. Mechanisms for detecting and responding to such changes are important for preventing hypo and hyperthermia at the organismal level. Previous research suggests that responses to temperature are mediated by thermoreceptor neurons innervating the skin. In particular, transient receptor potential (TRP) channels have been implicated in the cold temperature response in sensory neurons, including TRPA1 (<17 degrees C) and TRPM8 (<22 degrees C). However, the mechanisms that allow skin cells to directly detect such changes remain unknown. Here, we investigated cold-temperature responses, defined as a temperature ramp from 22 degrees C to 12 degrees C, in human skin cells. Using fluorescence calcium imaging, we found cold-temperature evoked calcium responses in HEMs and a model melanoma cell line MeWo that were independent of extracellular calcium. These responses in melanocytes are up to 4.7-fold higher than in cell types that are not normally exposed to the external environment, such as human embryonic kidney (HEK) cells. Exposing these skin cell lines to cell-permeant TRPA1 and TRPM8 inhibitors had no effect on the temperature response. Therefore, in contrast to sensory neurons, TRP channels are likely not involved. Further fluorescence microscopy with SERCA inhibitors prevented any calcium response to cold temperature, implying that these responses are caused by calcium release from endoplasmic reticulum (ER) stores. Whole-cell patch clamp experiments with IP3R antagonists similarly blocked the response. Our results suggest that human melanocytes have a cold-activated signaling mechanism that is independent from neuronal ones, triggering an IP3R-mediated calcium release from the ER. This pathway could have important implications in temperature regulation and cold temperature related pathologies, such as cold urticaria.

Title: Development of a screening platform for natriuretic peptide receptor 1 antagonists

Authors: H. SOLINSKI, S. MISHRA, J. HUANG, M. KRIEGBAUM, *M. HOON;
NIDCR, Bethesda, MD

Abstract: In mammals, a variety of different chemicals cause the sensation of itch. These chemical agents activate itch-specific primary sensory neurons in the skin. This information, in turn, is transmitted to second order neurons in the spinal cord. Interestingly, primary pruriceptors primarily use the neuropeptide natriuretic peptide B (NppB) to activate secondary pruriceptors via the NppB receptor Npr1. Thus, blockage of Npr1 is an attractive strategy to interfere with acute itch and may be useful in ameliorating some forms of chronic itch. However, there are no available potent and selective Npr1 antagonists. Therefore, we embarked on the development of a high-throughput screening platform for small molecule Npr1 antagonists. Specifically, we are expressing human Npr1 in HEK293 cells and detect its activation by measuring elevated cellular cGMP levels, generated by the enzymatic portion of Npr1. The assay currently undergoes primary high-throughput screening in a 1536-well format. Our future plans include *in vitro* validation of candidate molecules to ensure their specificity and direct action. Lastly, we hope to eventually test verified candidate molecules in mouse models for acute and chronic itch.

Title: TLR signaling in mast cells contributes to chronic pruritus in a rat model of atopic dermatitis

Authors: *T. HAN[1], H. LEE[1], J. LEE[1], S.-K. BACK[2], H. NA[1];
[1]Korea Univ. Col. Med., Seoul, Korea, Republic of; [2]Dept. of Pharmaceutics & Biotechnology, Col. of Med. Engineering, Konyang Univ., Chungnam, Korea, Republic of

Abstract: Chronic pruritusof atopic dermatitis (AD) causes the patients to scratch the affected skin and thereby deteriorates the disease. Thus, relieving pruritus has been accepted as an

optimal management of AD. In a series of our studies elucidating the pathophysiological mechanisms underlying AD using a rat model, we have found that enhanced responses of DRG neurons to serotonin released from mast cellscontribute topersistent pruritus of AD. Mast cells express a variety of Toll-like receptors (TLR) allowing the immune cells to recognizepathogen-associated molecules. Some of TLR ligands are endogenous molecules which are released from damagedor inflamed tissues. In the present study, we examined whether TLR signaling in mast cells plays a role in chronic pruritus of AD.Bone marrow mast cells (BMMC) were obtained from adult male rats and used for RT-PCR, quantitative real-time RT-PCR and serotonin ELISA. Of total 12 TLRs (TLR1 to TLR12) checked in the present study, 10 TLRs (TLR1 to TLR10) were expressed by BMMCof which mRNA expression of pro-inflammatory cytokines (IL-1β, TNF-α, IL-4, IL-5, IL-6 and IL-13) were significantly increased when stimulated by TLR ligands, such as LTA, LPS, polyI:C (pIC), and extract of necrotic neuronal cells. In addition, TLR-mediated activation of BMMC led to increase of serotonin content in the culture mediumwhich induced scratching behaviors when applied to the skin of naïve animals. Our results indicate that Toll-like receptor mediated activation of mast cell drives chronic pruritus by secreting serotonin and pro-inflammatory cytokines

Title: Transmembrane guanlylyl cyclases and CaMKI mediate thermosensory signaling and thermal acclimation

Authors: *Y. YU, A. TAKEISHI, V. HAPIAK, H. BELL, P. SENGUPTA;
Biol., Brandeis Univ., Waltham, MA

Abstract: Animals actively seek optimal temperatures for survival and reproduction. Unlike many organisms that exhibit a constant temperature preference, the preferred temperature of *C. elegans* is plastic, and set by their experience of their cultivation temperature. The AFD neurons are the primary thermosensory neurons in *C. elegans*, and drive thermosensory navigation behaviors on thermal gradients. Although the AFD neurons are known to respond to temperature

variations of as little as 0.01ºC, how worms sense temperature and set their temperature preference are still largely unknown. Thermosensation in AFD requires cGMP signaling, and molecules implicated in this pathway have been identified. These include receptor guanylyl cyclases (rGCs) expressed specifically in AFD, as well as phosphodiesterases, and cGMP-gated cation channels. To determine whether the AFD-specific rGCs GCY-8, GCY-18 and GCY-23 act as thermosensors, we misexpressed these rGCs singly or in combination in non-thermosensory neuron types, as well as in non-neuronal cells. We found that misexpression was sufficient to confer thermosensory responses onto both neuronal and non-neuronal cells. Each rGC appears to elicit temperature responses with different response thresholds. However, although the thermosensory response threshold in AFD adapts upon long-term exposure to a different temperature, the response threshold of rGC-misexpressing cells do not adapt similarly. Our work suggests that AFD-specific mechanisms including the function of the CMK-1 CaMKI enzyme may be important in regulating rGC gene expression and thermosensory adaptation in AFD. We are currently determining whether rGCs are sufficient to confer temperature responses upon heterologous expression, and identifying domains that may be sufficient to confer thermosensation onto other cell types.

Title: Mechanisms underlying the scratching behavior induced by the activation of proteinase activated receptor-4 (PAR-4) in mice

Authors: *R. COSTA[1,2], E. S. PATRICIO[2], C. P. FIGUEIREDO[1], M. A. BICCA[2], G. C. SEGAT[2], E. S. FERNANDES[3], T. M. CUNHA[4], S. BEVAN[5], J. B. CALIXTO[2];
[1]Univ. Federal do Rio de Janeiro, Rio De Janeiro, Brazil; [2]Univ. Federal de Santa Catarina, Florianópolis, Brazil; [3]UNICEUMA, São Luiz, Brazil; [4]USP, Ribeirão Preto, Brazil; [5]King's Col. London, London, United Kingdom

Abstract: A role for proteinase-activated receptor-4 (PAR-4) was recently suggested in itch sensation. Here, we investigated the mechanisms underlying the pruriceptive actions of the selective PAR-4 agonist AYPGKF-NH_2 (AYP) in mice. Dorsal intradermal (i.d.) administration

of AYP elicited intense scratching behavior in mice, which was prevented by the selective PAR-4 antagonist (pepducin P4pal-10). PAR-4 was found to be co-expressed in 32% of tryptase-positive skin mast cells and AYP caused a 2-fold increase in mast cell degranulation. However, neither the treatment with cromolyn nor the deficiency of mast cells (WBB6F1-Kit$^{W/Wv}$ mice) were able to affect AYP-induced itch. PAR-4 was also found on gastrin releasing peptide (GRP)-positive neurons (pruriceptive fibers), and AYP-induced itch was reduced by the selective GRP receptor antagonist RC-3095. In addition, AYP evoked calcium influx in ~1.5% of cultured DRG neurons also sensitive to TRPV1 (capsaicin) and/or TRPA1 (AITC) agonists. Importantly, AYP-induced itch was reduced by treatment with either the selective TRPV1 (SB366791), TRPA1 (HC-030031) or NK1 (FK888) receptor antagonists. However, genetic loss of TRPV1, but not of TRPA1, diminished AYP-induced calcium influx in DRG neurons and the scratching behavior in mice. These findings provide evidence that PAR-4 activation by AYP causes pruriceptive itch in mice via a TRPV1/TRPA1-dependent mechanism. **Keywords:** PAR-4, scratching behavior, TRPV1 and TRPA1.

Title: Identification of interneurons that mediate nociception in *Drosophila* and are modulated by touch sensing neurons

Authors: ***A. BURGOS**[1], K. HONJO[2], C. QIAN[1], L. VENKATASUBRAMANIAN[1], L. MACPHERSON[1], D. GOHL[3], D. W. TRACEY[4], M. SILIES[5], W. GRUEBER[1]; [1]Columbia Univ., New York, NY; [2]Univ. of Tsukuba, Tsukuba, Japan; [3]Stanford Univ., Stanford, CA; [4]Indiana Univ., Bloomington, IN; [5]European Neurosci. Inst., Göttingen, Germany

Abstract: Nociceptive circuits are crucial for the detection and avoidance of harmful stimuli. Vertebrate studies have long proposed that mechanosensory input can modulate nociceptive circuits. One prominent example is the gate control theory where interneurons receiving input from nociceptive neurons can be inhibited by the activity of low-threshold mechanosensory neurons. Studying a relatively simple nervous system that has anatomically defined neural substrates, which can be reproducibly and simultaneously manipulated, can facilitate our understanding of somatosensory transduction and integration. In *Drosophila*, class IV (cIV) dendritic arborization neurons (da) function as the primary nociceptors. Upon exposure to noxious stimuli, larvae exhibit rapid withdrawal, or nocifensive, behaviors, which include 360° rolling, followed by an increase in crawling speed, or escape crawling. Although cIV sensory neurons have been shown to be necessary and sufficient for nociceptive behavior, the downstream neural circuitry underlying these behaviors is only beginning to be understood. We have identified a population of projection neurons, termed sPN1s, and provide anatomical and functional evidence that these neurons are functional targets of cIVs, and required for rapid nocifensive rolling behavior. We also show that sPN1s receive input from class III (cIII) gentle touch neurons, and that the activity of these neurons modulates sPN1-mediated nocifensive behavior. These results provide a starting point for functional dissection of diverse central circuits underlying nociception, and how these circuits are modulated by input from gentle touch receptors. We aim to identify additional neurons that participate in the sPN1 circuit to further probe integration of these modalities.

Title: Proprioceptive trigeminal neuron activity modulated by locus coeruleus by hyperpolarization-activated current inhibition

Authors: *J. WON[1,2], M. SAITO[2], Y. KANG[2,1], S. OH[1];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Osaka Univ., Osaka, Japan

Abstract: Locus coeruleus (LC) is a small population of noradrenergic neurons located in the rostral pons with projections widely distributed in the central nervous system, thereby involved in multiple brain functions such as arousal, attention and stress. The proprioceptive sensory neurons innervating jaw-closing muscles are exceptionally located in the mesencephalic trigeminal nucleus (MTN), which medially adjoins or intermingles with the LC nucleus. MTN neurons can display two distinct firing patterns by either relaying spike trains arising from muscle spindles or generating bursts in response to synaptic inputs. MTN neurons express hyperpolarization-activated current (I_h), which can attenuate EPSPs mediated by glutamate receptors, thereby suppressing bursts. We aimed to investigate whether I_h in MTN neurons would be affected by the activity of LC neurons. Coronal slice preparations were made from the brainstem of Wistar rats(p14-20). Dual or single whole-cell patch-clamp recordings were obtained from MTN and LC neurons or MTN neurons alone. LC neurons were activated by injection of current pulses(200-300pA, 1s) or microstimulation (3-5V, 0.2 ms, 100 Hz train for 1s) while I_h was induced in MTN neurons. Recorded neurons were labeled by injection of Lucifer yellow, and tyrosine hydroxylase immuno-staining was carried out to identify LC neurons. I_h was either reduced (n = 7/10) or showed no change (n = 3/10) during LC stimulation. In the presence of α2 adrenoceptor antagonist, I_h reduction was significantly suppressed (n = 4). Immuno-staining results showed that I_h reduction was seen in MTN neurons when tyrosine hydroxylase positive LC neurons were activated (dual recording, n = 4/4). I_h reduction in MTN neurons may enhance excitatory synaptic responses, which can lead to altered proprioception of the jaw-closing muscles. In view of our findings, enhanced activity of LC by prolonged stress may disturb the proprioceptive control for appropriate masticatory functions, thus leading to masticatory muscle disorders.

Title: Social touch and fast-spiking interneurons of rodent somatosensory cortex

Authors: *C. LENSCHOW, A. CLEMENS, M. BRECHT;
Bernstein Ctr. For Computat. Neurosci., Berlin, Germany

Abstract: Facial touch is an important behavior for social interaction in rodents. Neuronal responses to artificial stimulation of the whiskers have been extensively studied, however responses to facial touch appear to be quite different when stimulation occurs with natural, socially evoked stimuli. Interaction evoked action potential firing and membrane potential dynamics in the somatosensory cortex differ in males and females; additionally, socially evoked neuronal firing appears to depend on the estrus cycle in females. In order to more closely examine the mechanistic underpinnings of these sex-related differences, we performed chronic juxtacellular recordings in head-fixed male and female rats while monitoring the estrus phase of the females. We found that the neuronal response to social touch was dependent on cell-type, where fast-spiking (FS) interneurons in males and females responded better to social touch when compared with regular-spiking principal neurons. Upon closer examination of the physiological properties of FS neurons in freely cycling females, we found that the baseline firing and response to social touch in FS interneurons is cyclical in nature. In estrus, the baseline firing is highest and the response to social touch is the lowest. To determine a possible molecular mechanism for the observed cyclical pattern of neuronal behavior, we are currently searching for hormonally modulated targets that co-localize with fast-spiking neuronal markers. The outcome of these experiments will advance our understanding of how cortical processing is modulated by neuroencrinological signals and mediates socio-sexual behavior.

Abstract: The properties of dorsal root ganglion (DRG) neurons are defined by their responses to peripheral stimuli. Cellular characteristics of DRG neurons contribute to their physiological functions. Recently, the transcriptome of DRG neuron has been uncovered by single cell RNA-sequencing. However, there is still an obvious gap between cellular character and physiological function of DRG neuron. We intend to link physiological function directly with cell character of DRG neuron. We performed *in vivo* whole-cell patch clamp to record the response of lumbar 5 DRG neurons to cutaneous thermal (heat and cold) and mechanical (brush, pressure and pinch) stimuli in adult mouse. After recording, the internal solution was subjected to reverse transcription and amplification. Then we performed quantitative single cell real-time PCR to evaluate the gene expression level of neuronal markers. Recorded neuron was sorted into corresponding cluster according to their biomarkers. We found that the Nppb-positive neurons were sensitive to noxious heat and mechanical stimuli (pinch), but insensitive to innocuous mechanical stimuli. The Th-positive neurons were specifically response to innocuous mechanical stimuli (brush), sensitive to pressure and pinch, but not to heat and cold. The Mrgprd-positive neurons showed response to all stimuli with a preference to heat stimuli. These results provide a new understanding of physiological functions of somatosensory neurons.

Title: A neuronal brake on itch through metabotropic glutamate receptor activation

Authors: *F. B. FREITAG, K. ROGOZ, B. ARESH, H. PETTERSON, L. INGWALL, E. MAGNÚSDÓTTIR, H. ANDERSEN, C. NAGARAJA, K. KULLANDER, M. LAGERSTRÖM; Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: Aim: The aim of this study was to identify the possible involvement of inhibitory G-protein coupled metabotropic glutamate receptors in itch regulation. Methods: Itch behavior was assessed in mice injected with a mGluR agonist prior to i.d. injection of several histaminergic and non-histaminergic itch inducing agents. To confirm the inhibitory effect of activation of the mGluR on histamine activated peripheral neurons, calcium imaging was performed in DRG culture cells. Results: mGluR agonist treatment reduced itch behavior provoked by histamine, 48/80 and α-methyl serotonin. Histamine and α-methyl serotonin are both associated with the activation of the intracellular enzyme PLCß3 which we could confirm was co-expressed with the mGluR as well as Hrh1, indicating that the mGluR regulates histaminergic and PLCß3-associated itch. This inhibitory effect was functionally confirmed on a neuronal level, where mGluR agonist strongly modulated histamine calcium evoked responses. Conclusion: Here we show that peripheral histamine sensing neurons, which express the mGluR regulates itch through an inhibitory effect. This finding raises a potential alternative to treat itch in its chronic states, where a down-regulation of itch-related neuronal activity would be achieved through mGluR activation.

Title: A human deafness gene (TMC1) homolog regulates locomotion via multiple dendritic sensory neurons in *Drosophila* larvae

Authors: *W. ZHANG[1], S. MELTZER[1], D. ZANINI[2], J. LI[1], T. CHENG[1], M. C. GÖPFERT[2], L. Y. JAN[1], Y. JAN[1];

Abstract: *Drosophila* larvae exhibit rhythmic locomotion behavior, which is modulated by peripheral sensory neurons. The relative contributions of different sensory neurons in coordinating locomotion behavior have not yet been elucidated. Here we study the roles of two types of multiple dendritic neurons, class I da neurons and bd neurons, in regulating larval locomotion. *Drosophila* larvae exhibit spontaneous turning during locomotion to explore the environment. Acute activation of Class I and bd neurons led to an increase of this turning frequency. Conversely, silencing those neurons reduces the turning frequency (Correct?). These neurons are likely proprioceptor for body posture during locomotion as we found that they could be directly activated by body curvature. We further found dmTmc, a *Drosophila* homolog of the human deafness gene (Tmc1), is expressed in class I da neurons and bd neurons. Knocking down dmTmc expression in these neurons pheno-copied the behavioral defects caused by dmTmc mutations, which reduced turning during locomotion. The dmTmc mutants' behavioral defects could be rescued by expressing dmTMC in class I and bd neurons. Importantly, we could induce spontaneously active currents by heterologously expressing dmTmc in cell lines. Our results suggest that dmTmc, a putative channel gene, is required for normal functions of class I da neurons and bd neurons in regulating larval locomotion behaviors.

Abstract: C-fiber low threshold mechanoreceptors (C-LTMR) mediate the discriminative and affective touch in the skin. Previous attempt to characterise the C-LTMR has been constrained by the inability to selectively activate those afferents without affecting other myelinated nerve fiber or C-mechanonociceptors *in vivo*. Taking advantage of tools in mouse genetic using Cre-LoxP system, Cre reporter transgenic and a novel chemical luminopsin (LMO3) design, we reported here an example to activate these C-LTMR specific either with blue light or a chemical compound. The LMO3 is designed by fusion of an extracellular ligand (coelenterazine: CTZ)-inducible light-generating protein (Gaussia luciferase) to a light-activated channelrhodopsin and an intracellular EYFP. Downstream the human synapxin promoter, we placed a floxed-STOP cassette before the LMO3 and the whole construct is target to the mouse Hipp11(H11) locus with Transcription activator-like effector nucleases technique (TALEN). After germline transmission, we crossed the LMO3 mouse with Mas1-related G protein-coupled receptor B4 (MrgprB4)-Cre and generated the MrgprB4-Cre::LMO3 double transgenic mice. In this mouse, LMO3 is selectively expressed in the MrgprB4-positive C-LTMRs. We examined the expression of LMO3 with anti-GFP immunofluorescence and colocalization with Cre reporter. Result indicated that LMO3 is faithfully target to the MrgprB4-positive neurons and voltage clamp confirm the respond of LMO3 by either the presence of CTZ or 473nm blue light. In subsequent behavioural study, we discovered a significance preference to blue light chamber in the MrgprB4-Cre:LMO3 mice. Our findings suggest that we can specially evoke the pleasant touch without touching them. Long-term goal is to reveal the pleasant somatosensory pathway in the central nervous system.

Title: Somatosensory function of the dermal papillae in humpback whale skin

Authors: *S. A. ELDRIDGE[1,2], F. MORTAZAVI[2], F. L. RICE[3], D. R. KETTEN[4,5], D. L. ROSENE[2];

Abstract: The glabrous skin of Cetacea (whales, dolphins and porpoise) confronts different sensory challenges than terrestrial mammalian skin. Understanding species-specific adaptations may elucidate life history or habitat use, such as compression receptors that respond to hydrostatic pressure and dive depth. However, little is known about innervation in cetacean skin. The glabrous skin of terrestrial mammals has molecularly unique afferents associated with: the encapsulated, rapidly-adapting low threshold mechanoreceptor (LTMR) Meissner's corpuscles in the dermal papillae (light touch and low frequency vibrations), and Pacinian corpuscles in the reticular dermis (high frequency vibrations); the slowly-adapting LTMR Merkel cell neurite complex (MCNC) in the stratum basale (light touch); and free nerve endings (temperature, nociception and high threshold mechanosensation). Sensory end-organs are presumed essential for low threshold mechanoreception, but only the Pacinian corpuscle has been found in Cetacea, where they are limited to lips, eyelids and skin around the blow hole. We investigated innervation in flank skin biopsies collected from the baleen whale *Megaptera novaeangliae* (humpback whale) (NMFS Permit #15240). Immunohistochemistry was used to search for functionally implicated sensory afferents. Serial immuno-stained sections were imaged and

reconstructed to visualize fiber organization, morphology and location of ramified endings. Axons extended to the apical end of the papillae, and a putative MCNC was found. The diverse population of axons in the papillae was characterized as presumptive low- and high-threshold mechanoreceptors by molecular homology, morphology, axon diameter, Schwann cell association, and ending specializations. Histological stains also showed the cellular organization of tissues. In the 8 mm epidermis, the closely packed papillae were ~100μm in diameter and ~5 mm long. As in terrestrial skin, the connective tissue had elastic fibers and capillaries that ran the entire length of the papillae. In all species, dermal papillae are subject to mechanical forces transmitted by stretch, retraction and shear that occur within and between tissue layers. However, in cetacean skin, the dense interdigitation of the pencillate papillae and epidermal pegs suggest a dynamic system. In addition to their roles in homeostasis, we propose the dermal papillae function as inherent sensory accessory structures that house LTMR fibers and novel receptors, allow innervation to reach within 2-3 mm of the body surface, and amplify and filter signals through their semi-enclosed tubular form.

Title: Stiffened membrane by STOML3 for the sense of touch

Authors: ***Y. QI**[1,2], L. ANDOLFI[3], F. FRATTINI[1], M. LAZZARINO[3], J. HU[1];
[1]Ctr. For Integrative Neurosci., Tübingen, Germany; [2]Grad. Sch. of Cell. & Mol. Neurosci., Tuebingen, Germany; [3]Inst. Officina dei Materiali-CNR, Trieste, Italy

Abstract: Sensing force is crucial in maintaining the viability of all living cells. Despite its fundamental importance, how force is sensed at molecular level stays largely unknown. Stomatin-like protein-3 (STOML3) has been shown to be essential for touch sensation in mouse. However, the molecular mechanisms by which STOML3 contributes to mechanotransduction remain mysterious. Here we hypothesize that STOML3 tunes sensitivity of mechanically gated ion channel by controlling the membrane mechanical properties of sensory neuron through

recruiting cholesterol. First, we show STOML3 is detected in the cholesterol-rich membrane fractions. Electrophysiological studies using whole patch clamp recording show depletion of membrane cholesterol with Methyl-β-cyclodextrin, a cholesterol chelating agent, abolishes slowly adapting (SA) mechanosensitive currents and reduces the amplitude of rapidly adapting (RA) mechanosensitive currents in sensory neurons from C57BL/6N but not STOML3-/- mice. Second, a STOML3 mutant deficient in cholesterol binding fails to restore the mechanosensitivity of STOML3-/- sensory neurons. Third, through atomic force spectroscopy (AFS), we discover that sensory neurons from STOML3-/- mouse exhibit softer membrane and smaller membrane tension when compared to wild-type. Importantly, we demonstrate that an intact STOML3 is essential to maintain membrane mechanics to sensitize mechanically gated channel Piezo1 in heterologous system. Finally, using behavioral test, tactile allodynia could be attenuated by injecting Methyl-β-cyclodextrin in C57BL/6N but not STOML3-/- mice, suggesting that stiffened membrane by STOML3 is essential for the tactile sensitivity. Altogether, we suggest that STOML3, as a member of stomatin like protein family, via binding cholesterol, controls membrane mechanics, thus facilitates the force transfer and tunes the sensitivity of mechano-gated channels, including Piezo channels. Targeting the cholesterol associating site of STOML3 might offer a novel peripheral means of chronic pain control.

Title: Fear conditioning induces expression of cannabinoid 1 receptors (CB1) in barrel cortex of adult mice

Authors: ***E. SIUCINSKA**, W. BRUTKOWSKI, T. BERNAS;
Nencki Inst., Warsaw, Poland

Abstract: Three days of whisker-shock fear conditioning expands the representation of "trained" vibrissae, which can be demonstrated by labeling with 2-deoxyglucose in layer IV of the barrel cortex in primary somatosensory cortex (S1) of adult mice. Results also show that functional

reorganization of the barrel cortex induced inhibitory synaptogenesis, increased expression of GABA transporter 1, affected cholecystokinin interneurons (CCK) expression in the hollows of trained barrels. There is the well known fact that CCK are containing of CB1 receptors. The CB1-expressing GABAergic axon terminals formed symmetric synapses. Endocannabinoids are powerful mediators of the short and long-term forms of plasticity at synapses via retrograde activation of presynaptic the CB1 receptors. Therefore, it is important to determine the expression of CB1+ puncta in the barrel cortex of mice 24h after whisker-shock associative learning paradigm. We hypothesize that CB1 receptors action would be to modulate GABAergic transmission in this region. In the whisker-shock conditioning group and all controls (pseudoconditioning, whisker stimulation-alone, shock-alone, and naïve animals) precise location of layer IV cells were identified using Hoechst 33258 staining of tangential sections. A method using confocal microscopic stereology has been applied to quantify the numerical density of CB1+ puncta in trained and control barrel hollow cortex in all groups of animals. Trained barrel hollow cortex activation by whisker-shock conditioning lead to a significant increase in the expression of CB1+ puncta, whereas similar changes in expression of CB1+ puncta were not found in the control groups. Our findings suggest that increasing activity of endocannabinoid system following locally amplified density of CB1+ puncta may modulate GABAergic neurotransmission at the synapses 24h after fear conditioning-dependent plasticity in the S1. Title: Operant conditioning of cutaneous reflexes in freely moving rats: Initial development

Authors: *Y. CHEN[1,2], L. CHEN[1,2], J. R. WOLPAW[1,2,3], X. Y. CHEN[1,2];
[1]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Dept of Neurology, Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning is a powerful method for inducing motor learning. Studies in both animals and humans have shown that H-reflex conditioning can change the neurons and synapses of the pathway physiologically and anatomically, and can thereby affect complex behaviors such as locomotion that use the pathway (Encyclopedia of Neuroscience, 7:225-233, 2009). Recent studies in rats and humans show that appropriate H-reflex conditioning improves locomotor function after spinal cord injury (SCI) or peripheral nerve injury (for review Front Integ Neurosci (2014) doi: 10.3389/fnint.2014.00025). To further broaden the scientific and clinical applications of operant conditioning, we are developing new operant conditioning protocols that can target beneficial plasticity to other CNS pathways. Cutaneous reflex (CR) pathways play important roles in normal locomotion (J Neurophysiol 63:1109-1117, 1990; J Neurosci 17:3804-3814, 1997; Physiol. Rev 86:89-154, 2006) and contribute to spasms and abnormal postures after SCI or in other disorders (Exp Brain Res 196: 341-351, 2009; J Physiol 104:230-238, 2010). We are seeking to learn whether an operant conditioning protocol might modify CR pathways to improve functional recovery. Rats are implanted with EMG electrodes in right biceps femoris (BF, knee flexor), soleus (SOL, ankle extensor), and tibialis anterior (TA, ankle flexor) muscles and a nerve cuff on the right posterior tibial nerve (PT). The wires from all electrodes pass subcutaneously to a head-mounted tether. When BF and AT EMG activity stays in a defined range for several sec, a PT nerve cuff stimulus elicits a CR in the BF and/or TA. PT stimulus amplitude is automatically adjusted by the computer to produce a stable M response in SOL throughout data collection. Each rat is first studied under the control mode for 20 days. It is then exposed to a conditioning mode for 50 days. Under the control mode, no reward is given. Under the CRup (i.e., to increase the CR) or CRdown (i.e., to decrease the CR) conditioning mode, a food-pellet reward is given 200 ms after PT nerve stimulation if the BF (or TA) CR (typically 10-18 ms after PT stimulation in BF) is more (CRup mode) or less (CRdown mode) than a criterion value. The effect of conditioning is determined by comparing average CR size for the final 10 days of up- or down-conditioning to average CR size for the final 10 days of control-mode exposure. Successful conditioning is defined as a change of ≥20% in the correct direction (Exp Brain Res 97:31-39, 1993; J Neurophysiol 73:411-415, 1995).

Title: Inferior olive ablation markably changes spinal cord GABAergic circuitry and KCC2 expression on motoneuron

Authors: *Y. WANG[1,2], Y. CHEN[1,2], L. CHEN[1,2], J. R. WOLPAW[1,2,3], X. Y. CHEN[1,2]; [1]Wadsworth Ctr. NYS Dept Hlth. & SUNY, Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Dept of Neurology, Stratton VA Med. Ctr., Albany, NY

Abstract: The inferior olive (IO) and the cerebellum are essential for acquisition and long-term maintenance of a down-conditioned (i.e., smaller) H-reflex (HR) (Learn Mem 12: 248-254, 2005, 13: 208-215, 2006; SFN Abs 475.17, 2012). In normal rats, conditioned HR decrease is associated with more motoneuron GABAergic terminals and GABAergic interneurons in the ventral horn (Eur J Neurosci 23: 141-150, 2006; Neurosci Lett 452: 124-129, 2009). To further explore IO participation in HR decrease, we assessed in rats the impact on GAD65 and GAD67 GABAergic terminals and potassium-chloride co-transporter (KCC2) expression of IO ablation before or after HR down-conditioning. Rats were implanted with chronic EMG electrodes in right soleus (SOL) muscle and a nerve stimulating cuff on right posterior tibial nerve. Each rat underwent chemical IO ablation before (acquisition (AC) rats) or after (maintenance (MA) rats) a 50-day exposure to the HR down-conditioning protocol. After IO ablation, MA rats continued under the down-conditioning protocol for 100 more days. At the end of data collection, each rat was injected in right SOL with CTB-Fluor 488 and perfused 3 days later. Lumber spinal cord was sectioned (16 μm) and processed for GAD65, GAD67, and KCC2 immunoreactivity. GAD65 and GAD67-positive terminals on identified SOL motoneurons, KCC2 expression on the

motoneurons, and GAD67-positive interneurons in ventral horn were assessed in a blinded fashion with the NIH image J program. IO ablation prevented acquisition. HR size in AC rats at the end of down conditioning was 96(±6SEM)% of its initial (i.e., control-mode) value (P=0.48, paired t-test). In these AC rats, the number of GAD67 terminals, the size and immunoreactivity of GAD67 and GAD65 terminals, and the size and IR intensity of GAD67 interneurons in ventral horn were significantly decreased ($p<0.0001$ vs. Naïve Control (NC) rats). In MA rats, HR size immediately before IO ablation averaged 59(±5)% of initial value ($P<0.001$), rose to 75-80% in the next 12-14 days, remained there for ~40 days, and then rose over 10 days to above its initial value and remained high (158(±19)% for days 91-100 post-ablation (P=0.025 vs. initial)). In these MA rats, the numbers of GAD67 terminals and GAD67 interneurons were decreased ($p<0.05$ and $p<0.001$ vs NC, respectively). KCC2-IR on SOL motoneurons was significantly decreased in both AC and MA rats ($p<0.001$ vs NC for both). These results provide new insight into the complex hierarchy of brain and spinal cord plasticity that underlies the induction and maintenance of HR down-conditioning.

Title: H-reflex conditioning after transection of dorsal ascending (DA) tract disturbs key locomotor features in rats

Authors: *L. CHEN[1,2], Y. CHEN[1,2], X. X. YANG[1,2], Y. WANG[1,2], J. R. WOLPAW[1,2,3], X. Y. CHEN[1,2];
[1]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Dept of Neurology, Stratton VA Med. Ctr., Albany, NY

Abstract: In normal rats, right soleus H-reflex (HR) conditioning affects locomotor EMG activity and kinematics but does not disturb key locomotor features (e.g., right/left symmetry in timing and hip height (J Neurosci 25:6898-6906, 2005)). According to the negotiated equilibrium hypothesis (Neuroscientist 16:532-549, 2010; nearby poster), locomotor features are preserved through an iterative process, a negotiation, in which the old behavior (i.e., locomotion) repeatedly induces compensatory plasticity that preserves its key features despite the plasticity concurrently induced by the new behavior (i.e., a larger or smaller HR). Ascending sensory input is thought to guide the brain in inducing this compensatory plasticity. If this is correct, HR conditioning should produce asymmetrical locomotion in rats in which ascending sensory input has been greatly reduced; and the severity of the asymmetry should be correlated with the magnitude of HR change. We tested this prediction. Under general anesthesia, 32 Sprague-Dawley rats were implanted with EMG electrodes in both solei and a nerve stimulating cuff on the right posterior tibial nerve. Thirty days later, they were exposed to an HR conditioning protocol (i.e., 20 days of control mode followed by 50 days of right soleus HR up- or down-conditioning mode). In each rat, the DA was transected bilaterally at T8-9 under anesthesia either 50 days before HR conditioning (Study 1), or at the end of 50 days of HR up- or down-conditioning, after which up- or down-conditioning continued for 50 more days (Study 2). Locomotor EMG activity, kinematics, and HRs were assessed before and after conditioning (Study 1), or before conditioning, after conditioning just before DA transection, and 50 days later (Study 2). DA transection itself did not affect the HR or disturb right/left step symmetry; and HR conditioning prior to DA transection did not affect step symmetry ($r=0.08$, $p=0.83$). In contrast, in DA-transected rats, HR up- or down-conditioning markedly affected step symmetry, and the magnitude of HR change induced by the conditioning strongly correlated with the magnitude of step asymmetry ($r=0.84$, $p=0.002$). These results indicate that HR conditioning in the absence of adequate ascending sensory information disturbs locomotion. Thus, they support the prediction of the negotiated equilibrium hypothesis: ascending sensory input is essential for inducing the compensatory plasticity in spinal cord and brain that ensures preservation of an old behavior (i.e., locomotion) when a new behavior (i.e., a larger or smaller HR) changes the spinal cord.

Title: Magnitude of reciprocal inhibition on plantarflexor H-reflex increases non-linearly with level of dorsiflexor muscle activity in non-neurologically impaired humans

Authors: J. LIANG, *R. L. SEGAL;
Dept of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC

Abstract: Reciprocal inhibition from ankle dorsiflexors (tibialis anterior, TA) onto plantarflexor (soleus, SOL) H-reflexes has been observed in non-impaired individuals. However, these findings were under resting conditions or at a single level of TA activity, and may not be generalizable across a range of TA activity. The objective of this study was to explore the association between the magnitude of TA muscle activity and the concurrent SOL H-reflex amplitude in order to more completely examine the reciprocal inhibitory relationship between TA activity and SOL H-reflexes. Participants were seated with knee flexed and feet strapped on a customized instrumented footplate with ankles in neutral position. At rest, we elicited a SOL H-reflex recruitment curve by increasing the stimulus intensity in small increments until a maximal H-reflex was obtained followed by attainment of a maximum M wave. From the recruitment curve, we identified the intensity needed to elicit a SOL H-reflex slightly smaller than the maximal H on the ascending limb of the recruitment curve. We then elicited 20 H-reflexes at this stimulus intensity at rest. Then, with visual feedback, participants generated various magnitudes of TA contractions within specified windows of TA muscle activity that varied randomly in blocks of small to large magnitudes. For each level of TA muscle activity, 20 SOL H-reflexes were elicited. For each trial, when participants maintained the TA activity in the target window for 1 second, an electrical pulse was delivered, eliciting a SOL H-reflex. To ensure consistency of stimulations, we monitored the corresponding M waves and adjusted the stimulus intensity to keep the M wave in the desired range across all trials. TA EMG activity prior to electrical stimulus and peak-to-peak amplitudes of the baseline and SOL H-reflexes were analyzed offline. The coefficient of determination (R^2) was used to examine the percentage of the total variance in SOL H-reflex amplitude that could be explained by the TA muscle activity. We observed a decrease in SOL H-reflex amplitude with increase in TA activity that levels out as TA activity continues to increase. Although both linear (R^2 0.57 to 0.78) and logarithmic (R^2 0.72 to 0.93)

fits result in high R^2 values, the relationship is best described with a logarithmic fit, indicating high probability of predicting SOL H-reflex amplitude based on magnitude of TA activity using the fitted logarithmic function. This modulatory relationship on the SOL H-reflex by the TA muscle potentially provides a more informative method to assess reciprocal Ia inhibition in neurologically-impaired nervous systems where contradictory findings have been reported.

Title: Operant conditioning of motor evoked potential (MEP) in free moving rats: Initial study

Authors: *X. Y. CHEN[1,2], Y. CHEN[1,2], L. CHEN[1,2], Y. WANG[1,2], J. R. WOLPAW[1,2,3]; [1]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Dept of Neurology, Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning is a powerful method for inducing motor learning. In animals and humans H-reflex operant conditioning can change the neurons and synapses of the spinal reflex pathway physiologically and anatomically, and can thereby affect behaviors such as locomotion that use the pathway (Encyclo of Neurosci, 7:225-233, 2009). In both rats and humans appropriate H-reflex conditioning improves locomotor function after spinal cord injury

(SCI) or peripheral nerve injury (for review Front Integ Neurosci (2014) doi: 10.3389/fnint.2014.00025). To further broaden the scientific and clinical applications of operant conditioning, we are developing new operant conditioning protocols that can target beneficial plasticity to other CNS pathways. Corticospinal pathways play a key role in motor control and their impairment contributes greatly to the disabilities produced by SCI or other disorders (Eur J Neurosci 34:1839-1846, 2011; Neurorehabil Neural Repair 26:7-19, 2012). The motor evoked potential (MEP) recorded in a skeletal muscle after motor cortex stimulation reflects corticospinal pathway strength. We are seeking to learn whether an operant conditioning protocol can strengthen this connection in rats. Rats are implanted with EMG electrodes in right soleus (SOL) muscle, epidural recording electrodes over the dorsal surface at T8-9 of the spinal cord, and epidural stimulating electrodes over the dura of the left sensorimotor cortex (SMC) hind-limb area. The wires from all electrodes pass subcutaneously to a head-mounted tether. When soleus EMG stays in a defined range for several sec, SMC stimulation elicits a small SOL MEP. SMC stimulus amplitude is automatically adjusted by computer to maintain a constant small (i.e., threshold) cord volley throughout data collection (so that any MEP change noted can be confidently ascribed to change at the spinal level. Each rat is first studied under the control mode for 20 days. It is then exposed to the conditioning mode for 50 days. Under the control mode, no reward occurs. Under the MEPup (i.e., to increase the MEP) or MEPdown (i.e., to decrease the MEP) conditioning mode, a reward (a food pellet) is given 200 ms after SMC stimulation if the SOL MEP (typically 7.5-18 ms after stimulation) is more (MEPup mode) or less (MEPdown mode) than a criterion value. The effect of conditioning is determined by comparing average MEP size for the final 10 days of up- or down-conditioning to average MEP size for the final 10 days of control-mode exposure. Successful conditioning is defined as a change of ≥20% in the correct direction (Exp Brain Res 97:31-39, 1993; J Neurophysiol 73:411-415, 1995).

Title: The negotiated equilibrium hypothesis of spinal cord function

Authors: *J. R. WOLPAW[1,2,3];
[1]Wadsworth Center, NYS Dept of Hlth., Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Dept of Neurology, Stratton VA Med. Ctr., Albany, NY

Abstract: This hypothesis is a response to the question of how the spinal cord remains a reliable common pathway throughout life. Its impetus is a long series of studies of the CNS plasticity associated with acquisition of a simple motor behavior – a larger or smaller H-reflex – and the impact of that acquisition on an important older behavior – locomotion. Their results, together with other laboratory and clinical data, have led to the following hypothesis: Ø **Substrate and Maintenance of a Motor Behavior.** Throughout life, the CNS acquires and maintains a repertoire of motor behaviors. New motor learning induces plasticity in the brain that leads to plasticity in the spinal cord. Brain and spinal cord plasticity combine to produce and preserve satisfactory performance, which is defined by a set of key features (e.g., key locomotor features include right-left symmetry in step timing and hip height). Each time the behavior occurs, deviations from these features induce plasticity that reduces the deviations. Ø **Negotiation Among the Behaviors.** All the motor behaviors in the repertoire undergo this process concurrently. Each is an independent agent that repeatedly induces spinal cord (and brain) plasticity that preserves its key features despite the plasticity induced by other behaviors. The aggregate process is a negotiation among the behaviors. *They negotiate the properties of the spinal neurons and synapses that they all use.* This ongoing negotiation keeps spinal neuronal and synaptic properties in an equilibrium – a *negotiated equilibrium* – that serves all the behaviors. When new learning changes the spinal cord, it begins a new negotiation among the new behavior and the old behaviors. The outcome is a new equilibrium that serves all the behaviors in the expanded repertoire. While the new negotiation preserves key features of old behaviors, it may change their muscular and kinematic details. A new negotiation may also occur when CNS trauma or disease impairs old behaviors. In this case, the negotiation often fails to fully restore the key features of old behaviors. Ø **Therapeutic Value of a New Behavior.** When a behavior is impaired, new learning that targets appropriate plasticity to a spinal site important in the behavior can improve it. Furthermore, by changing the ongoing negotiation among behaviors, this targeted plasticity can lead to plasticity elsewhere that further improves the old behavior: the targeted plasticity can enable the old behavior to escape a suboptimal local

minimum and can thereby more nearly restore its key features. Thus, new learning that induces targeted plasticity could supplement other therapies and enhance functional recovery.

Title: Recording of reticulospinal neurons to understand their participation in upper limb bilateral exertion

Authors: *A. M. BURNS[1,2], H. ADELI[3], J. BUFORD[4];
[1]Biomed. Engin., [3]Neurosci., [4]Physiol. and Cell Biol., [2]The Ohio State Univ., Columbus, OH

Abstract: Movements produced by patients recovering from stroke tend to reflect outputs typical of the reticulospinal system. This supports the concept of reticulospinal neuron participation in the recruitment of muscles otherwise impaired by stroke. Focusing on upper limb movement, a better understanding of the reticular formation's role in limb control can be ascertained through recording reticular neurons during a bimanual isometric force task. The hypothesis that neural activity in the reticulospinal system encodes the force of both upper limbs was tested by recording from electrodes in the pontomedullary reticular formation (PMRF) in two non-human primates, M. fascicularis, during a bimanual isometric force task similar to BATRAC (bilateral arm training with rhythmic auditory cueing) rehabilitation used for humans. The task used in this study involves the use of force-sensitive joysticks for the measurements of exertion and completion of the following four trial types: (1) bilateral pushing (2) bilateral pulling (3) right limb flexion with left limb extension (4) left limb flexion with right limb extension. A predetermined amount of force was required of the subject to complete each trial and receive a reward. Twenty-four EMG electrodes were placed in twelve upper limb and trunk muscles bilaterally to monitor flexion and extension. Principal component analysis was conducted on recorded PMRF spikes to isolate neurons to then determine facilitative and suppressive firing patterns for muscle flexion and extension. With respect to the location of recorded reticular neurons, we expect that ipsilateral flexion and contralateral extension patterns demonstrated in trials three and four will output the highest level of activity, while the opposite pattern (ipsilateral

extension and contralateral flexion) will output the lowest levels of activity, as suggested from our previous studies. The results from this study will contribute knowledge important for the understanding of reticulospinal participation in the control of movements in stroke rehabilitation therapies.

Title: Combined corticospinal and reticulospinal effects on upper limb muscles: Cooperation and competition of motor systems uncovered using stimulus trains

Authors: *A. ORTIZ-ROSARIO[1,2], H. ADELI[2,3], J. A. BUFORD[4,2,3,1];
[1]Sch. of Hlth. & Rehabil. Sci., [2]Biomed. Engin., [3]Neurosci., [4]Div. of Physical Therapy, The Ohio State Univ., Columbus, OH

Abstract: The participation of muscle recruitment in the upper limb from the corticospinal and reticulospinal tracts has been studied separately. Their cooperation and competition for motor control, however, has not been explored experimentally. The purpose of this study is to present the effects of combined stimulus train pulses in both tracts to observe their effect on upper limb muscles of an awake, behaving primate (Macaca Fascicularis). Three cortical areas: primary motor cortex (M1), premotor area (PMA), and supplementary motor area (SMA), and two sides (left and right) of the ponto-medullary reticular formation (PMRF), the origin of the reticulospinal tract, were studied. Single and combined stimulus trains were applied on both areas eliciting muscle facilitation, suppression, or a combination of the two (Figure 1). One of the goals of this study is to observe the preferred pathways of these two regions and if events such as summation and gating are evident. Preliminary results show that on average 14% of events display summation of responses, and 5% of events displayed possible gating, mainly driven by the corticospinal tract. Understanding these pathways have far reaching consequences in rehabilitation approaches for stroke patients and improve the understanding of the intrinsic wiring of these two motor systems. **Figure 1: Example of the stimulation paradigm. RF**

denotes duration of stimulation on the PMRF, and CX denotes duration of stimulation on the motor cortex.

Title: Interactions between corticospinal and reticulospinal outputs determine muscle response in the upper limbs and trunk as revealed with stimulus-triggered averaging

Authors: *S. HULBERT[1,2], H. ADELI[1,3], J. BUFORD[4,2];
[1]Biophysics, [3]Neurosci., [4]Physiolgy and Cell Biol., [2]The Ohio State Univ., Columbus, OH

Abstract: It is known that both corticospinal and reticulospinal tracts individually contribute to the stability and movement of the upper limbs and trunk. Using stimulus-triggered averaging (StimTA) of motor cortex and pontomedullary reticular formation (PMFR) outputs, we tested the hypothesis that these regions also interact to produce effects (suppression or facilitation) in the upper limbs and trunk. In our paired pulse paradigm, three areas of the cortex-primary motor cortex (M1), supplementary motor area (SMA), and dorsal premotor area (PMA)-were electrically stimulated at varying time shifts with respect to the electrical stimulation of either the right or left PMRF during a bilateral reaching task. Specifically, three paradigms were used: 1) Cortical area stimulated before PMRF, 2) Both areas stimulated simultaneously, 3) The PMRF stimulated before the cortical area. These experiments were conducted in three non-human primates, M. fascicularis. We studied 12 bilateral pairs of muscles in the upper limbs and trunk.

By comparing EMG results from the individual stimulation of the cortex or the PMRF to EMG results from the paired pulse paradigms, we were able to identify patterns that were indicative of dominant contribution from the PMRF or the cortex. We were also able to identify several patterns associated with summation or gating of the signals from the two brain regions. Preliminary results show that, of all patterns identified, about 22.84% are attributed to either PMRF or cortical activation alone, while the remaining patterns are associated with summation, gating, or other interactions between the regions. Results will be presented with respect to differences between cortical motor areas as they interact with the PMRF in the ipsilateral and contralateral limb. Taken together, these results show that corticospinal and reticulospinal systems can interact to produce muscle recruitment. Therefore, a systems approach is needed to fully understand the outputs of these motor systems.

Abstract: In the presence of epidural stimulation, individuals with complete motor paralysis after spinal cord injury (SCI) have shown the ability to voluntarily execute movement in the lower limbs, suggesting descending connections may have existed since the time of injury that were not detected clinically. Currently these pathways cannot be determined due to a lack of sensitive and quantitative measures. The purpose of this study is to develop a tool capable of assessing the viability of descending supraspinal pathways in humans with SCI. Multi-segmental monosynaptic reflexes (MMR) were evoked via transcutaneous electrical stimulation over the lumbosacral enlargement while lying in a supine position (n=13, 4 AIS A, 2 AIS B, 4 AIS C, 3 AIS D). Electromyographic activity was recorded in bilateral rectus femoris, vastus lateralis, medial hamstrings, tibialis anterior, medial gastrocnemius, soleus, and adductor hallucis brevis. MMRs were conditioned by an auditory stimulus (30 ms tone of 90dB @ 700Hz) delivered using binaural headphones to elicit the acoustic startle reflex (ASR) for evaluation of the reticulospinal pathway. MMRs were conditioned with galvanic vestibular stimulation (GVS) (rectangular pulses, 300ms) directly over the mastoid processes for evaluation of the vestibulospinal pathway. Condition-test intervals (CTI) ranging from 60-300 ms were used. Conditioning of lower limb muscles varied depending on severity of injury. Preliminary results indicate conditioning is present in at least 1 muscle in 13/13 participants in both GVS and ASR conditions. With GVS conditioning, 1/13 participants had all muscles conditioned, whereas with ASR conditioning, 2/13 participants had all muscles conditioned. Facilitation was most robust at CTI's of 140 ms and 190 ms with GVS conditioning and CTI's of 90 ms and 110 ms in ASR conditioning. This method of evaluating descending translesion pathways in SCI population may have potential in more effectively diagnosing individuals after neurological injury. New Orleans, New Orleans, LA; [7]Pavlov Inst. of Physiol., St. Petersburg, Russian Federation

Abstract: Quantification of the function of the descending vestibulospinal, reticulospinal, and corticospinal pathways is critical to understanding the connectivity and neuroplasticity in the central nervous system. Previous works have examined the effects of galvanic vestibular stimulation (GVS), auditory startle response (ASR), and transcranial magnetic stimulation (TMS) at the spinal level using the soleus H-reflex to assess motor neuron excitability. The H-reflex is limited in that it only provides information from unilateral spinal segments projecting to a single muscle. The present study was designed to systematically investigate the bilateral effects of the multi-segmental convergence of the vestibulospinal, reticulospinal, and corticospinal pathways on lumbosacral motor pools, using transcutaneous electrical spinal cord stimulation (TESS). We hypothesized that modulation of spinal motor output due to the convergence of descending and afferent volleys will depend on the specific pathway tested, as well as on the delay between the conditioning and test stimuli. Spinally evoked motor potentials were recorded in non-injured individuals using TESS, delivered over the intra-spinous space between the spinous processes of the T10 and T12 vertebrae, with subjects lying in a supine position.

Reponses were recorded via surface electrodes in vastus lateralis, medial hamstrings, tibialis anterior, and soleus muscles bilaterally. Vestibulospinal, reticulospinal, and corticospinal pathways were evaluated using conditioning binaural GVS (200 ms, up to 4 mA), ASR (30 ms, 90 dB, 700 Hz), and TMS (sub- and supra-motor threshold intensity), respectively, at different conditioning-test intervals (CTI). The conditioning stimulation resulted in the most robust facilitation at CTI between 90 and 160 ms following GVS and ASR, and at CTI between 10 and 25 ms and 90 and 140 ms following TMS. These results demonstrate that the lumbosacral motor pools can interact with the supraspinal descending volleys to facilitate the motor response. This method of investigating the descending supraspinal pathways allows objective quantification of the multi-segmental convergence of the vestibulospinal, reticulospinal, and corticospinal descending pathways with lumbosacral motor pools. Ultimately, this approach may provide a way to monitor and predict neuronal network plasticity associated with motor learning and functional recovery.

Ctr., New Orleans, LA; [7]Pavlov Inst. of Physiol., St. Petersburg, Russian Federation

Abstract: Ongoing studies of the effects of spinal cord epidural stimulation in human spinal cord injury (SCI) suggest the presence of descending neural influence which cannot be detected using current methods of SCI evaluation1. Electrophysiological assessments of descending pathways, such as the long propriospinal pathways, provide an alternative technique for assessing residual descending influence on motor neuron excitability below the level of lesion. The present study was designed to determine whether descending influence on lumbosacral motor neuron excitability could be detected via the effects of ulnar nerve stimulation on multi-segmental muscle responses (MMRs) of leg muscles. MMRs were evoked in 14 spinal cord injured participants (3 AIS As, 4 Bs, 4 Cs, and 3Ds) by transcutaneous electrical stimulation over the lumbosacral enlargement while lying in supine. MMRs were recorded via surface electrodes in bilateral rectus femoris, vastus lateralis, medial hamstrings, tibialis anterior, gastrocnemius, soleus, and adductor hallucis brevis muscles. MMRs were conditioned by non-noxious electrical stimulation of the ulnar nerve at a range of condition-test intervals (40-300ms). A functional neurophysiological assessment (FNPA)3 of volitional muscle activation and the International Society for Neurological Classification of Spinal Cord Injury (ISNCSCI) exam2 were also performed to assess volitional supraspinal drive to muscles below the level of injury. Conditioning stimulation delivered to the ulnar nerve resulted in facilitation of MMR amplitudes in at least one muscle group in 10/14 participants, with all muscles being facilitated in 3 participants. The condition-test intervals which most frequently and distinctly caused facilitation ranged from 90-140 ms. MMR modulation revealed descending influence on motor neuron pools below the level of SCI, which was not detectable during voluntary muscle activation attempts (assessed by FNPA and ISNCSCI exam) in 5 participants; MMR modulation was always seen in individuals (n=6) who demonstrated volitional activation of leg muscle(s). This method of assessing descending propriospinal influence on lumbosacral motor neuron excitability allows quantification of pathway-specific contributions to spinal excitability in multiple bilateral leg muscles, which are not detected by other methods. Results of this study, in conjunction with ongoing experiments involving reticulospinal, vestibulospinal, and corticospinal pathway modulation of MMRs, may aid in understanding the neurophysiology mediating voluntary movement observed in the presence of epidural stimulation after human SCI.

Title: Modulation of motoneuron excitability by α5GABAA receptors

Authors: *M. CANTO-BUSTOS[1], E. LOEZA-ALCOCER[2], R. FELIX[3], R. DELGADO-LEZAMA[2];
[2]Physiology, Biophysics and Neurosci., [3]Cell Biol., [1]CINVESTAV-IPN, Mexico City, Mexico

Abstract: The γ-aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the central nervous system. By activating synaptic and extrasynaptic specific receptors GABA can regulate neuronal activity. GABAA receptors are pentameric complexes of a diversity of subunits (α1-6, β1-3, γ1-3, δ, ρ1-3, ε, θ, and π), each with unique developmental and regional patterns of expression and distinctive biophysical and pharmacological properties. It is generally accepted that extrasynaptic GABAA receptors expressed in the cell body, dendrites and axons of neurons are tonically activated by GABA present in the extracellular space. Activation of these receptors produces a persistent conductance with several functional consequences. In this work we show that α5GABAA receptors are tonically active in motoneurons and modulate synaptic transmission between these cells and the funiculus dorsolateral terminals (FDL), in an *in vitro* preparation of the turtle spinal cord. Our results indicate that application of L-655,708 (inverse agonist with high affinity for the α5 subunit) inhibit α5GABAA receptor activity and in consequence produces the increase of monosynaptic excitatory postsynaptic potentials (EPSPs) and changes in the electrophysiological properties of motoneurons. These changes include an increase in input resistance and in the time constant, though the membrane potential remained constant. Furthermore, there was an increase in motoneuron excitability, because the rheobase was lower in the presence of L-655,708 than in the control condition. Finally, the presence of the α5GABAA receptor subunit in turtle motoneurons was confirmed by immunohistochemistry. We conclude that the tonic activity of postsynaptic α5GABAA receptors regulates the synaptic intensity in the synapses between the dorsolateral funiculus and the motoneurons and also regulates the firing of action potentials of turtle motoneurons.

Title: Increasing Motoneuron persistent inward current as treatment for Sepsis-Induced Weakness

Authors: *M. M. RICH[1], P. NARDELLI[2], R. POWERS[3], T. COPE[2];
[1]Dept Neurosci, Cell Biol & Physiol, Wright State Univ., Dayton, OH; [2]Sch. of Applied Physiol. and Dept. of Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA; [3]Univ. of Washington, Seattle, WA

Abstract: Despite years of study, the mechanisms underlying intensive care unit acquired weakness (ICUAW) remain unclear. Earlier studies had suggested myopathy and neuropathy were the primary causes of weakness. However, we recently identified a novel contributor to weakness in patients: difficulty with recruitment of motor units. Using the rat cecal ligation and puncture model of sepsis we found that a defect in motoneuron (MN) excitability is an important contributor to weakness induced by sepsis (Nardelli et al., 2013). The defect in MN excitability was not appreciable from firing threshold of single action potentials. Instead the defect was apparent only when MNs were driven to fire repetitively. During a 5s injection of current, septic MNs fired erratically with pauses of up to several seconds such that force generation by individual motor units was reduced by 80%. These data suggest that inability to sustain MN firing may be the primary mechanism underlying sepsis-induced weakness. The ability of MNs to repetitively fire is dependent on subthreshold persistent inward current (PIC). We examined the membrane depolarization leading up to spike initiation and found dramatic differences between control and septic MNs. In control MNs the approach to threshold was smooth and continuous. In septic MNs, there were oscillations during the approach to threshold such that the timing between spikes was variable and firing was inconsistent. Computer simulation of the defect in repetitive firing of septic MNs was possible with either a decrease in PIC or an increase in subthreshold voltage-gated K conductance. We wished to determine whether reducing the ratio of PIC to subthreshold K conductance could selectively impair repetitive firing of MNs *in vivo*. Using dynamic clamp of MNs we either subtracted PIC or increased subthreshold K in control MNs. Either manipulation was sufficient to induce septic-like deficits in repetitive firing. We next used dynamic clamp to either increase PIC or decrease subthreshold K conductance in

septic MNs and found that either manipulation was sufficient to correct repetitive firing such that that failure of muscle force generation was fully reversed. Our data suggest that increasing the ratio of PIC to subthreshold K may provide effective therapy to treat ICU acquired weakness in patients. Title: Estimates of persistent inward current in human soleus motor units decline during fatigue

Authors: K. MENDES, *J. M. KALMAR;
Dept. of Kinesiology, Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: Persistent inward currents (PIC) prolong and amplify the response of spinal motor neurons to synaptic input and are important for motor output. These currents, which are increased by monoaminergeric drive and reduced with inhibitory inputs, are thought to be both state and task dependent. We hypothesized that PIC would decline during fatigue either through a decrease in monoaminergic drive or an increase in inhibitory input to spinal motor neurons. If reductions in estimated PIC are due to fatigue-induced changes in reciprocal inhibition (RI), then brief stimulation of the nerve innervating the antagonist muscle should decrease estimates of PIC prior to fatigue and reduce the subsequent decline during fatigue. Motor unit firing was recorded from low threshold soleus motor units. PIC was estimated during isometric, plantarflexion, triangular-ramp contractions using the paired motor unit technique, which uses the difference between the firing rate (ΔF) of a low threshold "control" motor unit at the recruitment and derecruitment of a higher threshold "test" unit. ΔF estimates of PIC were made before, between, and after sets of fatiguing contractions, and at the same time points on a no-fatigue control day in this repeated-measures study. ΔF was significantly reduced throughout the last half of the fatigue protocol ($p<0.01$), and returned to baseline after a recovery period. No changes in ΔF occurred over the course of the control protocol. On each day, RI was elicited via common peroneal nerve stimulation just before peak force during alternate ramps over the course of the protocol. ΔF

estimates of PIC were lower for these ramps compared to ramps without stimulation ($p<0.05$), and did not decline over the course of the fatigue protocol. These findings suggest PIC declines with fatiguing muscle activity, possibly due to afferent inhibition.

Title: Is motor neuron excitability modulated by sex hormones across the menstrual cycle ?

Authors: E. K. CASEY[1], M. E. REESE[2], E. OKAFOR[2], D. CHUN[2], C. GAGNON[2], F. F. NIGL[2], *Y. Y. DHAHER[3];
[1]Family Med., Drexel Univ. Col. of Med., philadelphia, PA; [2]The rehabilitation Inst. of Chicago, Chicago, IL; [3]Northwestern Univ., Mount Prospect, IL

Abstract: The significant sex-disparity in sports-related knee injuries may be due to underlying differences in motor control. While the development of sex-specific movement patterns is likely multi-factorial, there is significant interest in the potential modulatory role of sex hormones. We have demonstrated that the muscle stretch reflex (MSR) changes throughout the menstrual cycle; however, further exploration is necessary to determine the origin of this change. This study examined the Hoffman Reflex (HR), electrical analogue of the MSR, across the menstrual cycle. Our aim was to measure motoneuron excitability across the menstrual and oral contraceptive pill cycle. Our hypothesis was that we would see an increase in motoneuron excitability during the peri-ovulatory phase in regularly menstruating women, due to the excitatory effects of the unopposed peak in estrogen concentration prior to ovulation. In addition, we hypothesized that the magnitude of change would be greater in eumenorrheic women with greater changes in hormonal concentrations than in women on oral contraceptives who have a fairly stable sex hormonal milieu. A Case-control trial with Thirty women ages 18-35 volunteered for this study: 15 “non-users” (emenorrheic) and 15 “users” (taking oral contraceptives). The “Non-users” were tested in the follicular (lowest estrogen; days 1-3), peri-ovulatory (highest estrogen; days 12-14) and luteal phases (highest progesterone; days 20-24). “Users” were tested on corresponding days. Testing included serum hormonal analysis and HR testing (maximum H Reflex to maximum M-

wave ratio [Hmax/Mmax]) at three time points during the menstrual and contraceptive pill cycle. A series of 2 (Group: Users vs. NonUsers) x 3 (Time: menstrual and contraception cycle phase-Follicular, Ovulatory, and Luteal) mixed-model analyses of variance were conducted as the primary analyses. There were no significant differences between the groups with respect to age or body mass index. The H/M Ratio was lower in the "users" compared to the "non-users" in all phases, but the ANOVA examining H/M Ratio yielded no significant interaction, $F(2, 56) = 0.671$, $P = 0.515$, partial $\eta 2 = 0.023$ or main effects for group $F(1, 28) = 2.748$, $P = 0.109$, partial $\eta 2 = 0.089$ or phase in the cycle $F(1, 28) = 0.742$, $P = 0.481$, partial $\eta 2 = 0.026$. Our conclusion is that the basic neuromuscular control, as measured by the MSR, changes throughout the menstrual cycle. In this study, motor neuron excitability did not demonstrate a concordant change. Therefore, it is possible that the origin of hormonally-mediated changes in the MSR occurs in the connective tissue rather than the neural circuitry.

Title: Persistent Inward Currents of adult mouse spinal motoneurons, recorded *in vivo* using single electrode discontinuous voltage clamp (SEDVC)

Authors: *S. HUH[1], C. J. HECKMAN[2], M. MANUEL[3];
[2]Physiol., [1]Northwestern Univ., Chicago, IL; [3]Univ. Rene Descartes Paris, Paris, France

Abstract: Motoneurons possess a unique set of channels that generate a large persistent inward current (PIC). Because this current is activated near cell resting potential and inactivates very slowly, it plays a vital role in setting the intrinsic excitability of a MN as well as in amplifying synaptic inputs. To record PICs one needs to be able to control the voltage of the neuron, using SEDVC. Voltage clamp of adult spinal MNs have been performed in cats and larger rodents but has never been carried out in smaller rodents, such as mice, partially because of the difficulty of

the *in vivo* preparation necessary to keep adult spinal MNs viable. Thus, the goal of this study is to verify the role of PICs and their effect on MN firing patterns in adult mice. Not only do the sizes of MNs differ between cats and mice (mouse MNs are approximately half the size of cat MNs), some differences have already been observed in mouse motor unit firing patterns compared to cats. Unlike cat or rat motor units, mouse motor units require a wide firing range to accommodate the faster rate of muscle fiber contraction. Thus, mouse MNs have a faster membrane time constant, faster after hyperpolarization (AHP) and high frequency subthreshold oscillations at around 100-150 Hz that create a subprimary range (SPR) of firing where firing rate increases non-linearly with increasing current injection. Our preliminary data suggest there is a strong correlation between size of motoneurons (measured by input conductance) and current threshold to fire action potentials as well as voltage at which PICs activate and deactivate. Our data also show motoneurons that are able to fire repetitively have significantly larger PICs compared to ones that are not able to repetitively fire. In addition, motoneurons become larger with age, while PIC amplitude tends to decrease , resulting in a larger percentage of motoneurons from older animals that cannot repetitively fire. In Amyotrophic Lateral Sclerosis, exitotoxicity has been implicated in motoneuron degeneration, and this process could be exacerbated by increased PICs, we will therefore compare PIC amplitude in SOD1 and WT mice.

Title: Developmental modulation of persistent inward currents in XII MNs

Authors: *A. L. REVILL[1,2,3], N. Y. CHU[1], M. J. LEBLANCQ[3], C. T. DICKSON[3,4], G. D. FUNK[1,3,2];
[1]Dept. of Physiol., [2]Women and Children's Hlth. Res. Inst., [3]Neurosci. and Mental Hlth. Inst., [4]Dept. of Psychology, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Hypoglossal (XII) motoneuron (MN) activity helps to maintain airway patency during wakefulness by preserving tone in the genioglossus muscle (GG), a tongue protruder. During REM sleep, however, atonia in the GG is implicated in obstructive sleep apnea. Thus, understanding the mechanisms that underlie the REM-sleep atonia of airway muscles is crucial. Active inhibition contributes in XII MNs, but the major mechanism appears to be disfacilitation; i.e., state-dependent loss of excitatory modulation, primarily α_1 noradrenergic and muscarinic, although serotonergic mechanisms also contribute. Over the first two postnatal weeks, 5-HT_{2A} receptor expression increases as does α_1-receptor mediated potentiation of XII inspiratory output. In spinal MNs, monoamines potentiate persistent inward currents (PICs), which are long-lasting, voltage-dependent Ca^{2+} and Na^{+} currents that increase excitability by amplifying synaptic inputs. Whether loss of modulatory tone and resultant reduction in PIC amplitude contributes to REM-sleep atonia is not known for any MN pool. The objectives of this study were to assess in XII MNs from neonatal (postnatal day, P1-4) and juvenile SD rats (P14-23), postnatal changes in PIC amplitude and sensitivity to α_1 noradrenergic, muscarinic and serotonergic modulation. Using whole-cell patch clamp techniques, we evoked PICs with slow voltage ramps (-80 to 0 to -80 mV, 5 to 14 mV/s) before and after bath application of 1 or 10 μM phenylephrine (PE, α_1-receptor agonist), 10 μM serotonin (5HT) or α-methyl-5HT, or 25 μM muscarine. PICs were evident in all MNs (neonates, n=28; juveniles, n=22) and there was a developmentally significant increase in baseline PIC amplitude from -195 ± 12 pA in neonatal to -342 ± 33 pA ($p < 0.05$) in juvenile MNs. As membrane capacitance does not change significantly over this time frame, postnatal increases in PIC amplitude represent an increase in PIC current density. PE and muscarine potentiated (>10%) PICs in a greater percentage of juvenile (PE: 86%, 6/7; muscarine: 50%, 6/12) than neonatal MNs (PE: 50%, 6/12; muscarine: 0%, 0/8). Serotonin potentiated PICs in 1/8 neonatal and 1/3 juvenile MNs. In sensitive neurons, the magnitude of PE potentiation did not change developmentally (16 ± 3% vs 19 ± 5%), but the efficacy of muscarine increased from -12% in neonates to 48% in juveniles. These data demonstrate that PIC current density, the number of MNs expressing a modulator-sensitive PIC and PIC sensitivity to muscarine increase postnatally. Measurements of MN properties during natural sleep will be required to fully address the functional significance of these observations. Supported by CIHR, NSERC, AIHS, CFI and WCHRI.

Title: Motoneuron excitability regulation changes during C-bouton development in mice

Authors: *I. PANEK[1], A. THANA[2], R. M. BROWNSTONE[2,3];
[2]Med. Neurosci., [3]Surgery (Neurosurgery), [1]Dalhousie Univ., Halifax, NS, Canada

Abstract: Modulation of motoneuron (MN) input-output gain is a key mechanism implicated in generating appropriate motor output. Cholinergic C-bouton synapses play an essential role in regulating MN excitability. Previous anatomical studies suggest that C-boutons undergo postnatal maturation, which involves clustering of delayed rectifier Kv2.1 channels, small-conductance Ca2+-gated K+-channels (SK2 & SK3) and type 2 muscarinic receptors (M2R) at the postsynaptic site. Whether this anatomical clustering relates to physiological properties is not known. Using patch-clamp recordings in spinal cord slice, we describe the electrophysiological properties of immature (P3) and adult (P20+) mouse MNs. We show that the SK channel blocker apamin (100nM) produces a smaller increase in excitability in neonatal than adult MNs (f-I slope increase of 238 ± 101% vs. 544 ± 464% in adult MNs). Correspondingly, activation of M2Rs by muscarine (50μM) application has minimal effect on the input-output gain of neonatal MNs, but increases the frequency-current slope by 80% in adult MNs. That is, we have demonstrated that physiological maturity occurs at the time of clustering of channels at the post-synaptic membrane. We hypothesize that channel clustering is needed for functional cooperation between these C-bouton elements. For example, M2Rs and SK channels may need to reside close together in order to exert a full range of modulatory effects.

Title: Transient receptor potential vanilloid 1 (TRPV1) and transient receptor potential ankyrin-1 (TRPA1) activators reduce muscle cramping

Authors: *G. SHORT, B. W. HEGARTY, C. H. WESTPHAL, J. M. CERMAK;
Flex Pharma Inc, Boston, MA

Abstract: Muscle cramps can be painful and debilitating, for healthy athletes as well as patients suffering from nocturnal leg cramps, multiple sclerosis, amyotrophic lateral sclerosis, and other neurological diseases. Flex Pharma is developing treatments for neuromuscular disorders including muscle cramps and spasms. Recent studies have demonstrated that hyperexcitability of α-motor neurons in the spinal cord is likely the underlying cause of cramps and spasticity. Based on a general property of neuronal circuits, whereby strong excitatory input increases inhibitory tone and reduces responsiveness to excitation, we hypothesized that transient receptor potential channel (TRP) activation could yield sufficient excitatory input to dampen motor neuron hyperexcitability. To test this hypothesis, we conducted human studies to assess the effectiveness of TRP activation in inhibiting electrically-induced cramps of the foot. An oral solution containing a mixture of TRP activators derived from natural extracts was shown to prevent cramps within minutes of ingestion, lasting up to 6-8 hours. The aggregated results from three independent, randomized, blinded clinical studies showed a significant reduction in cramp intensity by 3-fold ($p<0.0001$). Review of EMG output showed that cramps were reproducibly elicited with little intra-subject variation for threshold settings and cramp profile. However, EMG patterns varied considerably between subjects. Cramp profiles (area under the curve for cramp intensity and duration) fell under several sub-types: 1) low intensity but sustained for several minutes on EMG, 2) high intensity with a rapid return to baseline, 3) delayed onset, 4) high intensity and sustained, and 5) multi-phasic sustained. Most subjects fell into subtype 1. Interestingly, pain related to cramp induction often subsided well before resolution of cramp by EMG. There was no difference between the threshold settings to induce cramp and cramp profile. The Flex proprietary formulation was effective at reducing cramp intensity across all cramp subtypes. The results demonstrate that TRP activators may be an effective new treatment in individuals suffering from cramps and spasms. Flex Pharma has initiated a study in nocturnal leg cramps and may initiate studies in multiple sclerosis, and other neurologic disorders, in addition to studies in healthy athletes.

Abstract: Sensory feedback from skeletal muscles is essential for fine, coordinated motor control. The gatekeepers of this feedback are the proprioceptive sensory neurons (PSNs) whose cell bodies are in the dorsal root ganglia (DRG), and are classified into three subtypes (Ia, Ib, and II) depending on their anatomy and physiology. Currently only electrophysiology allows precise discrimination between the different subtypes of PSNs, critically hindering investigations into these important cells and the networks of which they are a part. Here we address this problem, uncovering the genetic identity of the PSN subtypes in mice, with an initial focus on Ia PSNs, using a powerful combination of mouse genetics, rabies virus mediated retrograde tracing and single cell transcriptomics. Our first approach consists of classifying PSNs subtypes by single cell RNA-seq analysis of hundreds of genetically labelled parvalbumin (PV) positive PSNs in mice of different ages. In our second approach, we employ monosynaptic tracing from motor

neurons in the spinal cord by injection of modified rabies virus in the ventral horn of the spinal cord of mice, specifically retrogradely labelling Ia PSNs in the DRGs. These specifically labelled Ia PSNs are then analysed by single cell RNA-seq, revealing for the first time the genetic identity of the Ia PSNs. We are currently validating our single cell data and are comparing them to the transcriptome profile of non-PSN DRG and spinal cord cells in order to define specific genetic markers of Ia PSNs. Our final aim is to produce knock-in mouse lines to allow fast and accurate *in vivo* and *in vitro* labelling and manipulation of Ia PSNs.

Title: The effect of joint flexibility and knee pain upon corticospinal and reflex control of quadriceps

Authors: *C. M. ALEXANDER[1], J. KASSAM[2], M. LONG[3];
[2]Therapies, [1]Imperial Col. Healthcare NHS Trust, London, United Kingdom; [3]Therapies, Imperial Healthcare NHS Trust, London, United Kingdom

Abstract: Joint Hypermobility Syndrome (JHS) is characterised by overly flexible joints alongside symptoms[1]. Symptoms range from longstanding multi-joint pain, joint instability, soft-tissue injury and skin abnormalities[1] as well as muscle weakness[2]. It is unclear why some flexible people have symptoms and some do not however, it may be due to impaired mechanisms of control[4]. Surprisingly, mechanisms of control comparing overly flexible people with and without pain and the normally flexible have not been thoroughly investigated; this is the aim of the study. With ethical approval and informed consent, 55 age-matched people were recruited. As pain is most severely but not exclusively felt in the knees of people with JHS[3], the following cohorts were recruited; people with JHS and knee pain (Beighton=7/9±2, n=15), people with JHS without knee pain (Beighton=6/9±2, n=20) and people with normal flexibility (Beighton=1/9±1, n=20). JHS and pain were classified using Brighton Criteria[1], pain mapping and visual analogue scales respectively. Transcranial magnetic stimulation was delivered over

the hotspot for the quadriceps motor cortex using a figure of eight coil and the stimulus intensity was incrementally increased. Electromyographic activity was recorded from the quadriceps of the dominant leg[5] in asymptomatic knees or the most painful side. Separately, the femoral nerve was stimulated incrementally over the skin within the femoral triangle to evoke the Motor (M) response and Hoffman (H) reflex. Outcomes measured were MEP threshold, latency, slope of the MEP recruitment curve where MEPs were normalised to Mmax and the MEPmax/Mmax. In addition, the slope of the ascending limb of the normalised H-reflex recruitment curve and Hmax/Mmax were recorded. MEP Threshold, latency, MEPmax/Mmax, H-reflex slope and Hmax/Mmax were no different across the three cohorts however; MEP slope was steeper in people with JHS and knee pain compared to people with JHS without pain and people with normal flexibility (0.02±0.01, 0.01±0.01, 0.01±0.01 respectively; p=0.03). One interpretation is that people with JHS and knee pain are compensating for their lack of strength by modulating corticospinal recruitment. It seems that pain is a critical factor rather than the degree of flexibility as people with JHS without knee pain are no different to the normally flexible. 1 Grahame R et al. Title: An optogenetic approach to understanding fine control of fast locomotion

Authors: ***O. CAPPELLARI**[1], K. E. WELLS[1], S. D. WILSHIN[2], J. CHARLES[1], J. R. HUTCHINSON[2], A. J. SPENCE[3], D. J. WELLS[1];

[1]Comparative Biomed. Sci., [2]Structure and Motion Lab., Royal Vet. Col., London, United Kingdom; [3]Dept. of Bioengineering, Temple Univ., Philadelphia, PA

Abstract: Optogenetics refers to the use of light to activate or inactivate excitable tissues that have been genetically modified with light-sensitive proteins (opsins). Despite widespread use in basic neuroscience and in application to neurological disorders, optogenetics has not been extensively used to study locomotion, and especially fast locomotion, for which it's high temporal resolution is ideally suited. Moreover there are not many studies with optogenetics applied in the periphery. This project aims to use optogenetics to dissect the coupled interaction of the nervous system, musculoskeletal system, and physics of the moving body. Using these tools it is becoming possible to precisely perturb specific neuronal pathways during locomotion in freely running animals. Here we present work seeking to specifically activate muscles on one hand, meanwhile on the other hand silence sensory feedback, in freely moving mice. The scientific goal accompanying the former technological aim is to understand how gait control is regulated in the presence of perturbations, without causing spurious sensory feedback (as would result from electrical nerve stimulation) through optical stimulation of motor neurons in the sciatic. The mouse model being used for this aim is a ChAT-Chr2-EYFP transgenic (Zhao et al., Nat Methods. 2011, 8(9):745-52.) which has the optical activator channelrhodopsin driven by the mouse choline acetyltransferase promoter, which in the periphery is exclusively expressed in motor neurons. An optical implantable microLED cuff has been built in order to stimulate the opsin solely at the level of the sciatic nerve. This mouse has also helped us to identify some limitations of optogenetics when used in the peripheral nervous system, as compared to the central nervous system. The selected line demonstrated severe developmental issues including delayed growth and impaired locomotion. We partially correct these issues by outbreeding the mouse line on a different genetic background. Moreover an interesting muscle fiber typing shift has been observed. We also noted that mouse to mouse anatomical variation in motor neuron distribution modulates the response to optogenetic stimulation. To achieve the second aim of sensory silencing, a second mouse model is currently under construction in which the neuronal silencer halorhodopsin is expressed under the control of a muscle spindle specific promoter, which represents a major component of the proprioceptive feedback in locomotion. Finally by crossing these two mice we will be able to both stimulate muscle activity and dampen feedback in the same mouse, in order to dissect the neuromechanical basis of locomotion.

Title: Presynaptic histaminergic inhibition of synaptic transmission from mesencephalic trigeminal afferents to masseter motoneurons in juvenile rats

Authors: *K. NAKAYAMA[1], C. GEMBA[2], S. NAKAMURA[1], A. MOCHIZUKI[1], M. INOUE[2], T. INOUE[1];
[1]Dept. of Physiol., [2]Dept. of Pediatric Dent., Showa Univ. Sch. of Dent., Tokyo, Japan

Abstract: Histamine receptors are densely expressed in brain regions that control oral-motor activity such as mesencephalic trigeminal sensory nucleus (MesV) and trigeminal motor nucleus. Previously, we have reported that histamine reduces the peak amplitude of the postsynaptic currents (PSCs) in the masseter motoneurons (MMNs) evoked by electrical stimulation of the trigeminal nerve tract (5N), which includes MesV afferents from the jaw-closing muscles and the periodontal ligaments. In the present study, we examined the mechanisms of histaminergic modulation of the 5N stimulation evoked-PSCs in MMNs using whole cell patch-clamp recording technique in brainstem slice preparations from Wister rats aged between postnatal days 7 and 13. To block antidromic activation of MMNs by 5N stimulation, 5 mM lidocaine *N*-ethyl bromide (QX-314) was added to the pipette solution. The inhibition of the 5N stimulation-evoked PSCs by histamine was mimicked by 100 μM 2-pyridylethylamine dihydrochloride, an H1 receptor agonist. Bath-application of 2-pyridylethylamine reduced the peak amplitude of the evoked PSCs by 47 ± 6.3% (n = 7). The inhibition of the evoked PSCs by 2-pyridylethylamine and histamine was blocked by 10 μM triprolidine hydrochloride, an H1 receptor antagonist. In contrast, 100 μM dimaprit dihydrochloride, an H2 receptor agonist, and 100 μM immethridine dihydrobromide, an H3 receptor agonist, produced little effect on the peak amplitude of the evoked PSCs. These results suggest that histaminergic inputs via H1 receptors likely inhibit the PSCs evoked by stimulation of the MesV afferents. Next, we investigated the effects of 2-pyridylethylamine on monosynaptic PSCs in MMNs evoked by 5N minimal stimulation at an intensity just above the threshold. Bath application of 100 μM of 2-pyridylethylamine significantly increased the failure rate of the monosynaptic PSCs by 101 ± 20% (n = 7, P = 0.010), although the differences in mean peak amplitudes were not significant (P = 0.086). Such increase in the failure rate was antagonized by triprolidine. Subsequently, we studied the effects of 2-pyridylethylamine on the paired-pulse ratios (PPRs) of the evoked PSCs in MMNs. Bath application of 2-pyridylethylamine increased the PPRs significantly (n = 9, P = 0.001) and the increase in the PPRs by 2-pyridylethylamine was antagonized by triprolidine. These results

suggest that a presynaptic mechanism via H1 receptors is involved in the histaminergic inhibition of synaptic responses to MMNs from MesV afferents.

Title: Shared synaptic input to motoneuron pools from different limbs in essential tremor

Authors: *J. GALLEGO[1], J. L. DIDERIKSEN[2], A. HOLOBAR[3], J. L. PONS[4], E. ROCON[5], D. FARINA[6];
[1]Dept. of Physiol., Northwestern Univ., Chicago, IL; [2]Aalborg Univ., Aalborg, Denmark; [3]Univ. of Maribor, Maribor, Slovenia; [4]Spanish Natl. Res. Council, Madrid, Spain; [5]Spanish Natl. Res. Council, Arganda del Rey, Spain; [6]Georg-August Univ., Göttingen, Germany

Abstract: Essential tremor (ET) manifests as a bilateral tremor of the hands. Imaging and electrophysiological studies suggest that ET originates from pathological oscillatory activity in the cerebello-thalamo-cortical pathways. The projection of this oscillatory activity to motoneurons innervating the affected muscles ultimately generates the tremulous movement. Previous studies examining “inter-limb coupling” in ET patients indicated that the tremor in different arms originates from different brain sites, based on the lack of significant coherence between their rectified EMGs. This was interpreted as implying the existence of multiple somatotopically organized pathological oscillatory circuits in the brain. We investigated, using direct measures of common input to motoneurons, whether muscles in different limbs receive a common tremor synaptic input. We recorded multichannel EMGs from the wrist extensors and flexors of 14 ET patients bilaterally, while they performed a postural task. We decomposed those signals into motor unit spike trains using the convolution kernel compensation algorithm, and characterized the neural drive to each of this four muscles as the composite spike trains (sum) of all the identified motor units. The average number of accurately detected motor units per muscle

was 7.5 ± 4.6. In four patients, the motoneuron pools from different arms received the same common tremor synaptic input, as revealed by the analysis of coherence between their composite spike trains. For the other ten, we did not find significant inter-limb coupling. In the patients with tremor inputs shared across limbs, one pair of neural drives was synchronized, according to the analysis of phase difference using the Hilbert transform. This indicates that motoneuron pools from different arms received the same supraspinal tremor drive. The tremor frequency was not identical across limbs, which suggests an effect of spinal and/or mechanical factors. In addition to the shared tremor drive, we found a bilaterally shared common voluntary input in 28 of the 45 examined pairs of motoneuron pools (six of them along with the shared tremor drive), suggestive of shared supraspinal control. We argue that a single central oscillator may be causative of the bilateral tremor in some ET patients, and that the pathophysiology of ET is widely dissimilar across individuals.

Title: Topographical distribution of corticospinal axons in the mouse spinal cord

Authors: *H. KAMEDA[1], N. MURABE[1], H. MIZUKAMI[2], K. OZAWA[2], M. SAKURAI[1]; [1]Teikyo Univ. Sch. of Med., Tokyo, Japan; [2]Jichi Med. Univ., Tochigi, Japan

Abstract: The corticospinal (CS) tract is essential for voluntary movement. Despite numerous studies, what we know about CS tract organization remains limited. Our previous study using retrograde tracers showed that CS neurons projecting to the 7th cervical cord (C7) distributed not only in the primary motor cortex (M1), but also in the primary (S1), secondary somatosensory (S2) and secondary motor cortices (M2), which is also referred to as rostral forelimb area (RFA) in the recent literature. There are several studies about projection of M1 and S1 CS neurons in rodents: M1 CS neurons send their axons mainly to the ventral part of the spinal cord, where motoneurons are located, and S1 to the dorsal part, which receives sensory inputs. These results imply that M1 CS neurons are related more directly to movements, and S1 to modulation of sensory processing. However, the comprehensive study of the CS neurons located in the other motor-related cortices is lacking and the role of these neurons is still unknown. In the present

study, to investigate the axonal distribution of CS neurons located in the other areas, we first injected adeno-associated virus (AAV) serotype 1 vectors expressing fluorescent proteins of different colors, which were fused with channelrhodopsin-2 (ChR2-XFPs) into the cortical areas separately at P56. ChR2-XFPs labeled axons clearly without gaps down to their terminals because ChR2 is the transmembrane protein, and the tagged XFPs are located just beneath the plasma membranes of axons. The mice were fixed two or three weeks after viral injections. We analyzed the axonal distribution in the C7 and found that CS neurons were divided into three groups according to the innervating area in the spinal cord: (1) CS axons from RFA and M1 were mainly distributed in the intermediate and ventral parts, (2) rostral part of S1 projected mainly to the mediodorsal part, (3) caudal part of S1 and S2 to dorsolateral part. There was almost no overlap in innervating areas, raising the possibility that these projection systems play separate roles. Double immunostaining of XFP-positive CS axons and NeuN revealed that the axons from RFA and M1 distributed mainly at inner lamina V to lamina VII, and those from S1 and S2 at lamina III to outer lamina V. We also investigated the axonal distribution of the three groups at other spinal segments and found that the similar topography was observed in the C5 and first thoracic cord. We further injected AAV into the several parts of cortical hindlimb area and found that the rostromedial part projected mainly to the intermediate and ventral parts, and caudolateral part to the dorsal part in the L4.

Title: Epimuscular myofascial loads affect tendon organ firing behavior

Authors: *H. A. SMILDE[1,2], J. A. VINCENT[2], G. C. BAAN[1], P. NARDELLI[2], T. C. COPE[2], H. MAAS[1];
[1]VU Univ., Amsterdam, Netherlands; [2]Wright State Univ., Dayton, OH

Abstract: Skeletal muscles are not exclusively connected to bone via their tendons, but also via connective tissues to neighboring muscles. Via such epimuscular myofascial connections length changes of a muscle can cause local force differences within an adjacent muscle. Our aim was to investigate myofascial effects on feedback from tendon organs. We hypothesized that output from tendon organs can be affected by length changes of adjacent muscles and that these effect are dependent on tendon organ location. In fully anesthetized female Wistar rats (n=7), the distal tendon of soleus (SO) and those of gastrocnemius and plantaris (GAS+PL) were attached to servo motors, which controlled muscle-tendon unit length and measured tendon force. Reference length (Lref) corresponded to ankle and knee angle at 90°. Connective tissues at the muscle belly level were left intact. Action potentials from single afferents were measured intra-axonally in response to ramp stretches of the agonistic muscle for different lengths of its synergist. Firing responses of an afferent located within one muscle were measured also during ramp stretches of its synergist. The muscle surface was probed to localize the afferent. The following parameters were assessed: length and force at the occurrence of the first action potential (thresholds), instantaneous firing rate (IFR) at peak of the ramp and halfway through the hold phase, the difference between these parameters (dynamic index, DI), and the rate of change in IFR during the ramp (ramp slope). SO (n=10): Lengthening GAS+PL from Lref-2 to Lref+4 mm decreased force threshold ($p=0.020$) from 0.37 N to 0.21 N, despite an equal ramp stretch to SO. Also DI decreased from 45 to 34 pps ($p=0.011$). Length threshold, IFR peak ramp, IFR half hold and ramp slope were also affected in most afferents, but in various directions. All SO tendon organs responded to a ramp stretch of GAS+PL. LG (n=14): Lengthening SO decreased IFR peak ramp ($p<0.001$, from 111 to 88 pps), IFR half hold ($p=0.016$, from 50 to 42 pps) and DI ($p=0.014$, from 60 to 46 pps) of LG tendon organs. The length threshold increased ($p=0.003$) with 0.46 mm; length threshold at Lref=1.04 mm. The changes in force threshold and ramp slope varied between afferents. Twelve LG afferents fired in response to a SO ramp stretch. These results indicate that feedback from tendon organs of an agonist can be affected by length changes of synergistic muscles. Although the individual differences could not directly be linked to the location of afferents within the muscle belly, such differences are in agreement with our hypothesis that tendon organs in different locations are affected differently by myofascial loads.

Title: Reflex activity of pubococcygeus muscle motoneurons by clitoris stimulation in the rat

Authors: *O. LARA GARCIA[1], D. PÉREZ GARCÍA[2], M. MARTINEZ GOMEZ[3,4], M. LARA GARCIA[4], P. PACHECO[3,2];
[1]Ctr. de Investigaciones Cerebrales, UV, Xalapa, Mexico; [2]Inst. de Neuroetologia, UV, Xalapa, Mexico; [3]Inst. de Investigaciones Biomedicas, UNAM, Mexico, DF, Mexico; [4]Ctr. Tlaxcala Biologia de la Conducta, UAT, Tlaxcala, Mexico

Abstract: We have described that pubococcygeus muscle (Pcm) of the female rat, which participates in reproductive processes (copulation, delivery) as well as in micturition, responds to clitoris stimulation depending to gonadal hormonal levels. It has been proposed that spinal cord interneurons participate in the response of its motoneurons. In order to further analyze this response we used electrical stimulation to the dorsal nerve of the clitoris (DNC). Bilateral EMG recordings were obtained using bipolar stainless steel electrodes (0.1mm) by clitoris and vagina-cervix-uterus junction (VCUJ) pressure, and electrical pulses to the DNC. Phasic and tonic on-off activity was recorded during clitoris pressure. The VCUJ stimulation blocks both tonic and phasic responses. A single pulse to the DNC produce ipsilateral electromyographic Pcm potentials with 10 msec of latency; trains of 10 per second produce ipsilateral tonic on responses and bilateral tonic off responses, but phasic responses. Our results suggest that the tonic on motoneuronal discharge is ipsilateral while tonic off is bilaterally activated. According to the EMG latency (15msec) of the evoked potential response obtained during the electrical stimulation of the DNC, A β afferent and efferent transmission (0.7msec each), neuromuscular junction delay (1.2msec) and 6 interneuronal synapses delay (approx. 1.2 msec each) are involved in the clitoris-Pcm reflex. Genital tactile stimulation including the clitoris in women is regarded as a precursor to sexual arousal, effect that is claimed beginning at the receptors level and following a course through the central nervous system (CNS). However, there is not information regarding the physiological connections of the clitoris with pelvic floor musculature, notwithstanding that Kegel´s exercises could be involved in this connection. Moreover, it is known that gonadal hormones variations affect synaptic strength at neuromuscular junction in striated muscles related to reproduction; therefore, Pcm activity besides of its relation with reproductive processes is highly involved in sexual responses, such as orgasm.

Title: Enhanced muscle connectivity changes neural control of synergistic muscles during locomotion

Authors: ***M. BERNABEI**, J. H. VAN DIEËN, H. MAAS;
Human Movement Sci., MOVE Res. Inst. Amsterdam, Amsterdam, Netherlands

Abstract: Altered intermuscular connectivity, associated with neuromuscular diseases, muscle injury and reconstructive surgery, has been found to affect force transmission between individual muscles within a synergistic group. To date, it is unknown whether the neural control of synergistic muscles adapts to such changes in muscle connectivity. Therefore, the aim of this study was to investigate effects of enhanced connectivity between ankle plantar-flexors on muscle activity patterns during locomotion. Wistar rats (n=3), trained for trotting on a treadmill, were instrumented with electromyographic (EMG) electrodes in soleus (SO) and lateral gastrocnemius (LG). After recording baseline EMG activity and hindlimb kinematics, the stiffness of intermuscular connective tissues was increased by implanting a tissue-integrating mesh between SO and LG (n=2). Three weeks post surgery, the root-mean-square (RMS) of SO EMG was decreased by 38.5% and 61.6% ($p<.001$), while RMS of LG was increased by 125.8% and 187.2% ($p<.001$) in the rats with increased connectivity. While at baseline EMG activity of SO was higher than that of LG, increased intermuscular connectivity caused a reversal of this pattern to preferential recruitment of LG. Ranges of motion for hip, knee and ankle joints were within two standard deviations from baseline values, while stride length and duration appeared to deviate from baseline, but with opposite trends between rats. No significant changes in hindlimb kinematics, RMS values or recruitment patterns were found in the control animal over the same measurement period. Enhanced mechanical coupling between SO and LG yielded substantial changes in the magnitude and coordination of plantar-flexor activity. Possibly the reduction of mechanical degrees of freedom is sensed by the central nervous system (CNS), as the mechanical effects of SO and LG activation around ankle and knee joints may become more similar.

Consequently a loss of muscle recruitment selectivity could evolve as an adaptation to the peripheral changes. Alternatively, given the difference between SO and LG in cross-sectional area and fiber type composition, maintenance of the functional output with a loss of torque capacity may require the CNS to change the contribution of the two synergists. These results may have implications for surgery involving connective tissue disruption and for pathological conditions, such as stroke and cerebral palsy, often associated with abnormal connective tissues.

Title: The severity of the central neuroimmune response following peripheral nerve injury correlates with the amount of proprioceptive IA afferent loss from injured motoneurons

Authors: *T. M. ROTTERMAN, F. J. ALVAREZ;
Physiol., Emory Univ., Atlanta, GA

Abstract: Following peripheral nerve injury there is a central immune response in which native microglia cells and infiltrating peripheral macrophages surround injured motoneurons (MNs). In parallel, proprioceptive IA afferent synapses are permanently deleted from MNs, which ultimately results in persistent motor deficits. We hypothesized that 1) a sciatic (proximal) nerve transection will result in an enhanced immune response compared to a tibial (distal) nerve injury and 2) an enhanced immune response will correlate with a larger depletion in IA afferent synaptic inputs. To test these hypotheses we used dual heterozygous "knock-in" CX_3CR1 (EGFP/+) and CCR2 (RFP/+) transgenic C57Blk/6 mice to respectively label microglia (EGFP) and infiltrating peripheral macrophages (RFP). In these mice we retrogradely labeled lateral gastrocnemius MNs with Fast Blue, and this was followed by a second surgery in which either a sham, tibial, or sciatic nerve transection was performed. Fourteen days (before muscle reinnervation) or 2 months (after muscle reinnervation) following the injury we immuno-labeled for vesicular glutamate 1 transporter (VGLUT1), a marker of IA afferents. Labeled MN somas were imaged using confocal microscopy and reconstructed in 3D using the Neurolucida software to map their VGLUT1+ synapses. In addition, microglia and macrophages were quantified in a

volume of $2.2x10^6$ μm^3 (50 μm tissue section thickness) around labeled MNs using Imaris software. Fourteen days after injury the number of EGFP+ cells increased by 177% in the tibial nerve injury model and 347% after sciatic nerve injury compared to sham operated animals. Two months after injury the microglia reaction decreased and the number of microglia cells were now increased to only around 23% and 65% of controls. In contrast, there were no significant numbers of RFP+ cells in the ventral horn of sham operated animals, these cells were recruited after injury, and we detected 5 times more RFP+ cells 14 days after injury in sciatic transections compared to tibial nerve injuries. Similar to microglia the numbers of RFP+ cells diminished 2 months after injury. The density of VGLUT1 synapses on the cell bodies of injured MNs partially decrease after tibial nerve injury by 37% 14 days after injury and remained similarly depleted (26% decrease) after 2 months and muscle reinnervation. This depletion was much larger after sciatic nerve injury: 60% depletion 14 days after injury and 77% depletion at 2 months after. Taken together, our data indicates that a sciatic nerve transection induces a larger immune response that correlates with a larger depletion in somatic VGLUT1 synapses compared to a tibial nerve injury.

Title: The property of Ia excitation and recurrent inhibition of abdominal motoneurons in the cat

Authors: *M. NIWA[1], N. MUTO[2], S.-I. SASAKI[3];
[1]Kyorin University, Fac. of Hlth. Sci., Tokyo, Japan; [2]Grad. Sch. of Hlth. Sci., Kyorin Univ., Tokyo, Japan; [3]Ctr. for Med. Sci., Ibaraki Prefectural Univ. of Hlth. Sci., Ibaraki, Japan

Abstract: The abdominal (Abd) muscles have divergent functions such as respiration, postural control, vomiting and defecation. However, it is not well known about reflex actions exerted on Abd motoneurons. The present experiments were undertaken to investigate how reflex actions exerted on the motoneurons work and whether recurrent inhibitory pathways are present in Abd motoneurons. Experiments were performed on adult cats anesthetized with sodium pentobarbital. The bipolar cuff electrodes were put in Abd nerves for electrical stimulation. The spinal cord was

exposed by a laminectomy. To eliminate descending supraspinal input, the spinal cord was transected at the junction of T12/T13. Animals were immobilized and maintained on artificial ventilation. Intracellular recording was made from Abd motoneurons (external oblique, internal oblique, transversus abdominis and rectus abdominis) to record antidromic spikes and excitatory post synaptic potentials (EPSPs) following stimulation relevant peripheral Abd nerves. All the experimental procedures were approved by the Animal Ethics Committee of Ibaraki Prefectural University of Health Sciences. The preparation of dorsal roots were as follows: 1)Dorsal roots were intact and muscle nerves electrically stimulated to activate Ia afferents. Ia-EPSPs elicited were found in almost all motoneurones following the stimulation of the homogeneous nerve in the same spinal segment. They are responsible for the monosynaptic EPSP of motoneurones of their muscles, although these values are longer than those values of the hind limb and the intercostals muscles. It suggests that the extent of Ia-EPSP of Abd motoneurones seem to be limited in the same spinal segment and the homogeneous motoneurone. 2) Dorsal roots were sectioned and muscle nerves were electrically stimulated to activate motor axons. Recurrent inhibitory post synaptic potentials (RIPSPs) elicited were found in approximately one quarter of abdominal motoneurons with an intensity subthreshold activation for axon of the impaled motoneuron. It is likely that abdominal motoneurons has few recurrent inhibitions, although it may be underestimated due to the stimulus condition of peripheral nerves. The present results provide evidence of Ia excitation and recurrent inhibition of abdominal motor nucleus. These neuronal circuits might be related to the control of abdominal muscles during various motor activities.

Title: Spinal direct current stimulation enhances vertical jump power in healthy adults

Authors: *H. R. BERRY[1], B. A. CONWAY[2];
[2]Biomed. Engin., [1]Strathclyde Univ., Glasgow, United Kingdom

Abstract: Transcutaneous spinal direct current stimulation (tsDCS) is a safe, non-invasive neuromodulation tool that can affect sensory, motor and pain spinal cord circuits and pathways. The polarity dependent neuroplastic effects are reported to persist after stimulation in a dose dependent manner. It is not known whether tsDCS neuromodulation can translate to any measurable change in functional motor power production post stimulation. In this study we investigate the effect of 15 min of anodal lumbosacral cord level tsDCS on vertical countermovement jump (VCJ) power production up to 3 hours after stimulation in healthy volunteers: the VCJ is a test of maximal lower limb power and involves a powerful eccentric countermovement. In tandem with this, we mapped concomitant changes in lower limb posterior root-muscle (PRM) reflexes over the same time course. We employed a double-blind, randomized, crossover sham-controlled design approved by our local ethics committee. 13 healthy individuals completed 5 maximal effort VCJs on a force platform before and 0, 20, 60 and 180 min after sham and active tsDCS (25 VCJs per session, at least 7 days apart). 6 of the subjects completed 2 further sham/active tsDCS session where lower limb PRM reflexes were induced before and up to 180 min after tsDCS using single pulse biphasic stimulation of the spine via the same electrode montage as in place for tsDCS. tsDCS induced a mean (95% CI) 15.4 (7.4_23.5)% difference in max (sham - 6.4%, active + 9%, $p < 0.001$) and a 11.4 (5_17.8)% difference in ave (sham - 5%, active + 6.4%, $p < 0.001$) countermovement power, leading to an overall difference of 4.2 (2.1_6.4)% in max (sham -3.6%, active +0.6%, $p < 0.001$) and 3.7 (1.9_5.6)% difference in ave peak to peak VCJ power (sham -2.7%, active +1%, $p < 0.001$). These changes did not significantly differ between time point post tsDCS. We found that over both tsDCS conditions, changes in hamstring PRM reflexes were positively correlated with changes in ave VCJ force ($r = 0.60$, $p < 0.001$). Anodal tsDCS preserved and enhanced countermovement power production over three hours, whereas there was a significant fatigue effect after sham tsDCS. These changes appear to be due to changes in force potentiation mechanisms, demonstrated by excitability changes in reflex circuitry. We have shown for the first time that anodal tsDCS quickly, easily and painlessly counters the fatigue normally associated with repeated maximal power performance. tsDCS-induced fatigue resistance and an enhancement of motor power in the absence of physical training have important implications for rehabilitation after central nervous system injury.

Title: Reorganization of locomotor bursts by proprioceptive feedback

Authors: *J. BACQUE-CAZENAVE[1], B. CHUNG[1], D. CATTAERT[2], W. HEITLER[3], D. H. EDWARDS[1];
[1]Neurosci. Inst., Atlanta, GA; [2]INCIA, Bordeaux, France; [3]Univ. of St Andrews, St Andrews, United Kingdom

Abstract: During walking in crayfish, leg Depressor (Dep) and Levator (Lev) muscles are active and the coxobasal chordotonal organ (CBCO) provides proprioceptive feedback to the thoracic nervous system. We found that CBCO feedback in closed loop accelerates the walking rhythm and organizes motor bursts. The CBCO is a stretch receptor that codes up and down movement around one crayfish leg joint. Activity of the CBCO nerve and Dep and Lev motor nerves of one leg were recorded from an *in vitro* preparation of the thoracic nerve cord. Dep and Lev motor activity excited corresponding Dep and Lev muscles of a computational crayfish leg model (AnimatLab.com) to lower and raise the model leg, respectively. The resulting model leg movements controlled mechanical stimulation of the real CBCO stretch receptor of the *in vitro* preparation and excited CBCO afferent responses that completed the proprioceptive feedback loop in real time. The feedback loop was opened by uncoupling motor nerve responses to the corresponding model muscles. Exposure of the preparation to a muscarinic agonist (oxotremorine) induced an active state in which resistance reflexes to leg perturbation reversed to become assistance reflexes and irregular low-frequency (~1/30s) Lev/Dep motor burst pairs occurred when the feedback loop was open. Closing the feedback loop accelerated the motor rhythm three-fold, restructured motor bursts and increased the reproducibility of each burst. In closed loop, bursts began more abruptly, reached a high spiking frequency and ended earlier than bursts in open loop. Spike train analysis of motor nerve activity revealed that the firing patterns of most MNs differed significantly between closed and open loop conditions. When the loop was closed, three principal classes of MN activity are apparent: i) MNs active before the high frequency burst discharge , called pre-burst MNs, ii) MNs discharging only at the onset of bursts, called burst onset MNs and ii) MNs active during bursts, called in-burst MNs. In open loop, these patterns changed or disappeared during bursts. In each experiment (n=8), burst onset MNs are involved in assistance reflex and their initial firing rates in closed loop occurred earlier, increased more quickly to a higher level and ended also earlier than under open loop condition. The in-burst MNs often followed the burst onset MNs with a phasic discharge that occurred earlier and with a higher frequency than in open loop. These burst changes produced a more abrupt, faster, shorter and regular leg movement during each locomotion cycle when the feedback was closed.

Title: Electrophysiological responses to joint rotation in acute stroke

Authors: ***N. L. SURESH**[1], J. EWOLDT[2], E. LAZZARO[1], G. JARAMILLO[1], W. Z. RYMER[1]; [1]Sensory Motor Perf Prgm, Rehabil. of Chicago, Chicago, IL; [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: The most common clinical test used to assess spasticity is the modified Ashworth test(MAS). Although weaknesses in the MAS test are largely acknowledged, it is still the standard measure used to characterize the level of resistance to stretch in spasticity. In stroke survivors, the MAS is used to identify the 'catch' angle as well a generalized resistance to joint rotation, the resultant score reflects both and therefore does not provide information that would allow a differentiation of one versus the other. The goal of our study was to conduct the MAS test and to assess differences between acute and chronic stroke survivors while tracking the results over a period of several months. Our objective was to quantify the differences in the nature of the stretch response, i.e., a sudden catch versus overall resistance, as well as to track any changes, particularly in our acute subjects, over time. Our methods involved conducting the MAS test with added sensors to quantify changes in joint angle position, joint angle velocity and EMG activity in the biceps muscle in response to rotation of the elbow joint. We tested two chronic and two acute stroke survivors over a period of 3 months. The subjects were comfortably seated in a chair with the arm initially at rest. Surface EMG electrodes were placed on the subjects' biceps and triceps to characterize muscle responses, if any. An electronic goniometer was placed across the elbow joint, and an accelerometer was placed on the lower arm. Data was digitized and recorded on a laptop computer. Our research physical therapist then positioned the joint in the maximum flexed position and slowly rotated the joint to the maximum extension over a period of 1 second for five trials, separated by 15 seconds each. These tests were also done with the arm rotated as fast as possible for five trials. The EMG onset time, as well as duration and magnitude of the EMG response were quantified. The catch angle and change in angular

velocity were derived from the goniometer and accelerometer data. Our results show that in the chronic stroke survivors there was a significant EMG response that lasted longer than the stretch duration, as well as a consistent 'catch'. The resistance to stretch occurred subsequent to the 'catch'. In our acute subjects, the predominant response involved a resistance to stretch, with few subjects exhibiting a catch angle, the EMG response was transient and increased in duration and amplitude over the three month testing period. These differences between acute and chronic stroke survivors could be attributed to changes in passive muscle properties that develop over time as well as change in motoneuron excitability that occur over time post-stroke.

Title: Prefrontal cortex modulation of cerebellar motor learning

Authors: *M. T. DE JEU, P. J. HOLLAND, C. M. PARISIUS;
Erasmus MC, Rotterdam, Netherlands

Abstract: While the cerebellum undoubtedly plays a role in motor control and motor learning, there is increasing anatomic and electrophysiological evidence (Kelly and strick, 2003; Watson et al., 2009, 2014) for a functional connection between the Prefrontal Cortex (PFC) and the cerebellum that could affect these processes. However, the behavioral implications of this connection are still unknown. We posit that inputs from the Prefrontal Cortex (PFC) could modulate motor learning. In order to investigate this hypothesis, lesions were induced in the medial and ventral PFC of adult c57bl/6 mice and their consequences on motor behavior were studied. Motor performance and motor learning was assessed using the rotarod task and by using a cerebellar specific eye movement task. The lesioned animals were grouped according to their motor learning behavior in comparison to the average learning rate of control and sham operated animals. For each learning task, a histogram of the control data was made and the upper 20th and the lower 20th percentile was used to calculate the cutoff points that defined the high learning (HL), medium learning (ML) and low learning (LL) groups. The day 1 latency to fall was analyzed for possible effects of the lesions on the baseline motor performance in the rotarod task. No significant differences in the distribution of baseline motor performance between the groups

were found. The baseline eye movements (vestibulo-ocular reflex, optokinetic reflex and visual-enhanced vestibulo-ocular reflex) indicated also no performance impairment between these groups. Comparing the 3D reconstructed lesion sites of the different motor learning groups (i.e. HL, ML and LL) revealed that lesions in the lateral and ventral orbital regions of the prefrontal cortex reduces motor learning and the consolidation of the learned task, whereas lesions in the prelimbic and medial orbital regions of the prefrontal cortex has only very limited effects on these motor learning processes. These results demonstrate that lesions in specific PFC regions have a clear effect on motor skill acquisition, including cerebellar specific motor skill acquisition. These results imply that the PFC can modulate the cerebellum and thereby influence motor learning.

Title: Depression of the cerebellar vermis alters the direction of postural sway to a vestibular perturbation

Authors: ***C. LAM**[1], C. TOKUNO[2], L. R. BENT[1];
[1]Human Hlth. and Nutritional Sci., Univ. of Guelph, Guelph, ON, Canada; [2]Kinesiology, Brock Univ., St. Catherines, ON, Canada

Abstract: Background: Balance is best maintained with the integration of available sensory input. The vestibular system reports on accelerations of the head and this information can be manipulated by a technique called stochastic vestibular stimulation (SVS). SVS involves passing an electrical current behind the ears, which alters the firing of vestibular afferents and generates a reflexive postural sway response. The sway occurs in the intra-aural direction so when facing forward the response is in the mediolateral (ML) direction and when the head is turned over the shoulder the response occurs anterioposteriorly (AP) [1]. This response also incorporates proprioceptive input from the neck and it is postulated that the cerebellum plays an important role in the generation of this appropriate postural response. **Aim**: To determine if cerebellar depression modulates the postural sway direction to a vestibular stimulus. **Methods**: Twenty

subjects (age 19-27) were tested in one of two groups, a test group, where subjects received continuous theta burst stimulation (cTBS – to cause cerebellar depression), and sham, where subjects received paired pulse TMS. SVS (±2 mA, 0-20 Hz) was delivered for six trials of 90 seconds with the head facing either forward or over the left shoulder. Subjects then received TMS over the cerebellar vermis using a MagStim rapid^2 stimulator (test: cTBS, 600 stim over 40 s at 100% AMT; or sham: 2 stim, 10 ms apart at 50% AMT) [2]. Following TMS, six more trials of SVS were repeated. Shear data were collected using an AMTI force plate and kinematic head position was collected using an Optotrak 3D Investigator. Cumulant density plots of the shear data to SVS were generated and shear axes were rotated 180^o to determine the direction of sway based on the angle of highest correlation. **Results**: There were no significant changes in head position for any condition. Head-referenced sway direction did not significantly differ with head forward for either test or sham conditions. With the head turned over the left shoulder there was no change in the sham condition but there was a significant change in sway to a more ML direction after cTBS (88.2^o to 95.2^o, p=0.017). **Discussion**: By depressing the function of the cerebellum we were able to evoke a change in the postural response to a vestibular perturbation from AP to a more ML sway. This could be due to the inability of the cerebellum to integrate neck and vestibular input to generate directionally appropriate postural responses. This work provides further insight into how our body processes various sensory input to help control our posture and balance. Title: Purkinje cell activity modulated by the transcranial direct current stimulation (tDCS) in rats

Authors: N. VUKMER[1], P. DOMENIG[1], K. SHIN[1], *H. LU[2];
[1]GA Campus, Philadelphia Col. of Osteo. Med., Suwanee, GA; [2]PCOM - Georgia Campus, Suwanee, GA

Abstract: Cerebellar ataxia encompasses a wide range of neurological disorders characterized by a lack of coordinated movements. Recently, transcranial direct current stimulation (tDCS) has

been shown to be a possible therapy of cerebellar ataxia in humans. Animal studies have demonstrated that the cerebellar tDCS is capable of modifying the output of the motor cortex through the cerebello-thalamo-cortical pathway. However, the cellular mechanism of the Purkinje cells due to the cerebellar tDCS treatment is unclear. In this study, extracellular potentials were recorded from Purkinje cells in Sprague Dawley rats to determine if the cerebellar tDCS altered the activity of these cells. The tDCS was delivered using a metal electrode positioned immediately posterior to the recording site in crus I or II (anode, intensity: 100 - 200 μA) for 20 min. The recordings from four Purkinje cells showed an average increase in firing rate of 26.8% during the application of the cerebellar tDCS. Only one cell with a fluctuating base firing rate showed a decrease in the average firing rate during the stimulation. From the same recordings, local field potentials were analyzed using power spectrum in which no significant change was observed to the main peak at 2 Hz. In one case (tDCS with 200 μA), the amplitude of the second peak between 7 and 8 Hz increased. The results support the previous studies that electrophysiological changes occur in the motor cortex as a consequence of altered Purkinje cell firing. In order to investigate the mechanism of these changes, future experiments will be performed with simultaneous recordings from Purkinje cells and motor cortical neurons with the application of tDCS.

Title: Cerebellar tDCS alters resting-state connectivity in cerebro-cerebellar cognitive networks

Authors: ***A. M. D'MELLO**[1], D. SHOOK[1], W. HAYWARD[2], P. E. TURKELTAUB[2,3], C. J. STOODLEY[1];

Abstract: The posterolateral cerebellum is functionally connected to cortical networks implicated in cognition, including the default mode (DMN) and fronto-parietal cognitive control and attention networks. In addition, during language tasks the right posterolateral cerebellum is functionally activated in conjunction with supratentorial language regions, such as the inferior frontal gyrus. Disrupted functional connectivity between the right posterolateral cerebellum and supratentorial language regions has been noted in neurodevelopmental disorders such as autism, and might underlie language deficits in these populations. However, the role of the cerebellum in modulating long-distance cortical regions has not been directly explored. Our aim was to examine the effects of cerebellar transcranial direct current stimulation (tDCS) on functional connectivity between the cerebellum and cerebral cortical regions. We hypothesized that right cerebellar tDCS would alter functional connectivity between the right posterolateral cerebellum and cerebral regions involved in language and cognition. We applied 20min of 1.5 mA anodal tDCS over the right posterolateral cerebellum (1 cm down and 4 cm lateral from the inion) in healthy young adults (n=8; μ=26.5 years). Eight minutes of resting-state data were acquired pre- and post-tDCS. Functional connectivity between cerebellar right Crus I and the pars opercularis of the left inferior frontal gyrus decreased post-tDCS ($p < 0.05$, FDR corrected). These results are consistent with the functional and anatomical connections between the right posterolateral cerebellum and contralateral supratentorial language regions. The current results suggest that cerebellar tDCS is able to modulate cerebro-cerebellar circuits involved in language and cognition.

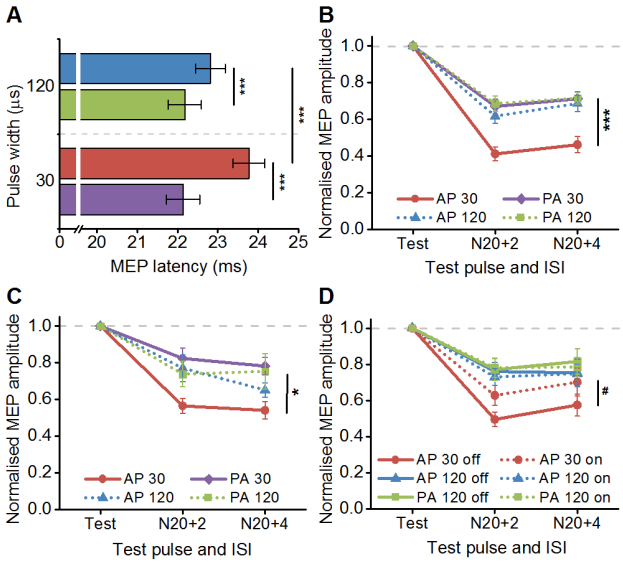
Title: Differential modulation of interneuron circuits in human motor cortex by afferent input and cerebellar direct current stimulation

Authors: ***R. HANNAH**, D. AUSTIN, J. C. ROTHWELL;
UCL Inst. of Neurol., London, United Kingdom

Abstract: We tested the hypothesis that distinct excitatory circuits in primary motor cortex (M1) are differentially affected by sensory input from the hand (Ni et al. 2011, J Neurophysiol) and by transcranial direct current stimulation over the cerebellum (cDCS). A controllable pulse parameter TMS (cTMS; Rogue Resolutions Ltd.) device was used to activate distinct independent interneuron circuits in the hand area of M1 by changing the coil orientation (posterior-anterior, PA; anterior-posterior, AP) and TMS pulse width (30 and 120 μs). An electrical stimulus to median nerve or digital nerves provided sensory input. We measured its effect on the amplitude of MEPs elicited by the different directions/widths of pulses ~25ms later (inter-stimulus intervals: N20 latency +2 and +4 ms; short latency afferent inhibition, SAI). Anodal or sham cDCS (2 mA) was applied concurrently in different sessions to examine any cerebellar influence on SAI. Experiments were performed whilst participants maintained voluntary muscle contraction (5-10% MVC). Single motor unit potentials (Exp. 1, n=6) and surface EMG (Exp. 2, n=20; Fig A) recorded from the first dorsal interosseous confirmed that short AP pulses (AP30) recruited longer latency inputs than long AP and short/long PA pulses. SAI tested with median nerve stimulation was greater for AP30 responses compared with the other three conditions (Exp. 2, n=20; Fig B). Similar effects were found with digit stimulation (Exp. 3, n=10; Fig C), implying that the differential response to AP30 was not due to a preference for cutaneous versus muscle afferent input. Online anodal cDCS reduced SAI for the AP30 condition only (Exp. 4, n=11; Fig D). Short AP-oriented pulses appear to activate interneuron populations distinct from those activated by long AP- and short/long PA-oriented pulses. The AP30-sensitive populations are associated with the longest latency MEPs, and appear more sensitive to SAI. cDCS reduced the inhibition associated with AP30-sensitive interneurons implying that these populations receive indirect sensory inputs from the cerebellum.



Influence of pulse width and coil orientation on MEP latencies (**A**) and SAI tested with median nerve (**B**) and digit stimulation (**C**). Interaction of anodal cDCS with SAI (nerve) tested with different pulse widths and coil orientations (**D**). Off refers to measurements prior to cDCS and On refers to measurements during. ***P < 0.001 for comparisons between conditions (**A**), ***P < 0.001 between AP30 and other conditions (**B**), *P < 0.05 between AP30 vs. AP120 and PA30 (**C**), $^{\#}P$ < 0.05 for comparisons between AP30 Off vs. On cDCS (**D**).

Abstract: Transcranial direct current stimulation (tDCS) of the cerebellum can offer new insights on the cerebellar function and disorders by modulating non invasively the activity of cerebellar networks. Taking into account the functional interplay between the cerebellum and the cerebral cortex, we addressed the effects of the unilateral cerebellar tDCS on the electroencephalographic (EEG) oscillatory activity and the cortical network organization at resting state. Eight healthy volunteers participated in the study (age: 30.1±5.4 years). Three randomized stimulation sessions, anodal, cathodal tDCS (20 min duration; 2 mA; active electrode positioned over the right cerebellar hemisphere) and sham were performed. Scalp EEG potentials (48 position electrode cap) were recorded (commercial EEG system) during 2 minutes of eyes-closed resting state, before (pre) and after (post- 15, 35 and 60 min) each session. After data preprocessing, the power spectral densities (PSD) were computed and averaged within 4 frequency bands (from theta to gamma band). Single subject PSD values obtained after anodal and cathodal tDCS were contrasted against sham PSD (t-test; $p<0.5$, post-hoc correction). Effective connectivity was estimated by means of Partial Directed Coherence (PDC) and synthetic indices describing the network topology were extracted based a graph theoretical approach (global efficiency, local efficiency). Analysis of variance (ANOVA; within factor "latency"; 4 levels: pre, post-15, post-35, post-60) was carried out for each index, stimulation type and frequency band. At post-15 min from anodal stimulation, a significant increase (synchronization) in the alpha and beta PSDs was observed mainly over the left centro-parietal and posterior temporal scalp regions. At post-15 min, cathodal tDCS resulted in a significant theta band synchronization occurring over the central and parietal midline and the bilateral centro-parietal regions. Such synchronization lasted no longer than 15 min. Only a significant increment of local efficiency was observed after 15 min from the anodal tDCS. Present data demonstrate different modulatory effects of unilateral cerebellar anodal/cathodal tDCS on brain oscillatory rhythms. Lateralized sensorimotor rhythm synchronization would be in line with current interpretation of a reduced cortical motor excitability after anodal cerebellar tDCS. Under this condition, the topology of brain networks seems to shift towards a higher segregation of information flow. Cerebellar modulation on diffuse midline thalamo-cortical circuits might account for the observed effects of cathodal tDCS.

Title: Cerebellar activity during a visually cued finger tapping task in adolescents with Fetal Alcohol Spectrum Disorder (FASD): a Magnetoencephalographic (MEG) study

Authors: *C. M. GARCIA[1], P. W. KODITUWAKKU[2], C. D. TESCHE[2];
[1]Psychology, [2]Univ. of New Mexico, Albuquerque, NM

Abstract: Exposure to substantial amounts of alcohol *in utero* is known to produce structural and functional brain anomalies in offspring. While ethanol-induced abnormalities are found throughout the brain, some regions (e.g. cerebellum, caudate) appear to be more affected than other regions. Converging evidence from animal models and human imaging studies has shown that prenatal alcohol exposure is associated a range of alterations in the cerebellum, including a reduction in volume, changes in the surface area and a thinner vermis. Therefore, it is reasonable to hypothesize that the functions that are held to be mediated by the cerebellum -balance, bimanual coordination, attention (Norman et al., 2009; Luo, 2012)-are impaired in children with prenatal alcohol exposure. It can also be expected that alcohol-exposed children are impaired at internal timing of both motor and non-motor tasks, since the cerebellum plays a key role in timing (Tesche and Karhu, 2000; Spencer et al., 2003). In the current research, we probed differences in brain dynamics in children with fetal alcohol spectrum disorders (FASD) and aged-matched controls during performance of a visual-motor task, which is known to involve the cerebellum. The FASD group comprised 20 children who had been diagnosed having a prenatal alcohol diagnosis (FAS, partial FAS, and ARND); the control group included 22, age-matched (12-19 years of age) children who did not have prenatal exposure to alcohol. Data were recorded with a 306-channel MEG array. The finger tapping task employed 6 - 8 visually presented cues. Subjects were told to make a motor response with the right index finger to presented visual stimuli. The visual stimuli were presented for 350 ms, and had an interstimulus interval of 750 ms. BrainStorm (Tadel et al. 2011) was used to extract spatio-temporal patterns of activation in the Rt Crus I and Vermis time-locked to the initial four motor responses. The FASD group had less activation compared to the controls. In the Rt Crus I, amplitude differences were found prior to the motor response to the 1st cue and 4th cue, but not the 2nd and 3rd cues. In the Vermis,

amplitude differences were present prior to the motor response to the first cue. Little or no differences were present prior to motor responses to the 2nd and 3rd cues. For the 4th cue, amplitude differences are only present after the motor response. Behavioral reaction times were also significantly different with the FASD group having both longer reaction times and greater temporal variability. The differences in behavioral reaction times and cerebellar activation by the FASD group suggests a disruption of the cerebellum in producing and maintaining timed movements.

Title: Updating inverse models for head movement control does not require cerebellar integrity

Authors: N. LEHNEN[1], *S. GLASAUER[2], M. SAğLAM[3];
[1]Munich Univ. Hosp., Munich, Germany; [2]Ludwig-Maximilian-University, Munich, Germany; [3]Gediz Univ., Izmir, Turkey

Abstract: The cerebellum is considered essential for implementing internal models, of which inverse models generate motor commands for a desired movement and forward models predict sensory consequences of applied motor commands. Cerebellar damage impairs internal model adaptation, leading to deficient motor performance against perturbations or changes in plant properties. However, in recent reaching studies, cerebellar patients could adapt to gradually applied perturbations. This was linked to their remaining ability to learn inverse model dynamics. Recently, we showed that cerebellar ataxia patients could also re-optimize head movement kinematics during large gaze shifts when head dynamics were perturbed by an experimental increase in head inertia. Here, we investigate whether this optimization depends on updating the intended movement, inverse or forward models, or all of them. Using a control systems model, we assessed the contributions of inverse and forward model plasticity on updating head movement kinematics to an increase in head inertia in nine cerebellar ataxia patients and ten healthy controls. We found that the experimentally observed changes in head movements of cerebellar patients are best explained by assuming that the inverse model, but not

the forward model, is adapted to match the new plant characteristics. We show that by adapting the inverse model it is still possible to optimize head movement kinematics, i.e., to decrease suboptimal oscillations, maintain optimal movement durations, and increase peak velocity towards the new optimum. This suggests that the residual extra-cerebellar motor control network can implement inverse models, update intended movements and re-optimize without correctly predicting sensory consequences of action.

Title: Differential roles of the cerebellar hemisphere and dentate nucleus in temporal processing across sub- and supra-second durations

Authors: *E. PETTER, N. A. LUSK, W. H. MECK;
Duke, Durham, NC

Abstract: Elijah A. Petter, Nicholas A. Lusk, and Warren H. Meck, Department of Psychology and Neuroscience, Duke University, Durham, North Carolina, USA The ability to accurately and precisely time intervals from ten's of milliseconds to hours relies on coordinated activity across multiple brain regions. Two of the most investigated regions are the cerebellum and striatum. Based on evidence from both lesion and neurodegenerative studies, the canonical belief is that the cerebellum mediates timing in the sub-second range (i.e., durations than 1s). A major confound in many of these earlier studies was the performance of a timing task exclusively in either the sub- or supra-second range. Compounded by the fact that many studies differ in task demands (e.g., comparison, production, reproduction, and discrimination), it is unclear how to interpret these results. The neural architecture of the cerebellum makes it an ideal structure for temporal processing, with Purkinje cells (PCs) within the cerebellar hemispheres integrating temporal aspects of salient stimuli. Previous work has shown that tonic firing rates of PCs can be modulated to reflect a criterion duration. Furthermore, neural activity in downstream cerebellar deep nuclei are modulated by the temporal regularity of stimulus presentations. In the current study, we attempted to identify the role of the cerebellum in both sub- and supra-second timing using the duration bisection task with anchor durations of 200 vs. 800 ms and 2 vs. 8 s alternating within subjects and between sessions. In order to investigate the different components

of the cerebellar-striatal network, our study included groups with bilateral excitotoxic lesions to either the dentate nucleus (the primary cerebellar output to the striatum) or the lateral cerebellar hemisphere (containing PC projections to the dentate nucleus) of sprauge dawley rats. Preliminary findings suggest differences in temporal accuracy and precision, evidenced by shifts in the point of subective equality and increased variability among experimental and sham-lesioned groups. Specifically there was a severe disruption in sub-second timing for hemisphere lesioned rats, and a rightward shift in point of subjective equality in supra-second durations for dentate lesioned rats.This study is the first to examine the different roles of the cerebellar hemisphere and dentate nucleus in time perception across sub- and supra-second durations. Taken together, the evidence suggests a dissociation in the roles of the cerebellar hemisphere and dentate nucleus in terms of temporal *Initiation, Continuation, and Adjustment.*

Title: Early postnatal methylazoxymethanol administration leads to cerebellar hypoplasia and supra-second timing deficits in adult rats

Authors: *N. A. LUSK, E. A. PETTER, W. H. MECK;
Psychology & Neurosci., Duke Univ., Durham, NC

Abstract: Methylazoxymethanol (MAM), a powerful antimitotic, has been extensively used to affect rodent CNS development. When MAM is administered at critical developmental periods neuroanatomical effects in adulthood have been particularly apparent in the cerebellum with reductions in size as well as disruption of the cytoarchitecture. Specifically, purkinje cells retain immature characteristics as well as contain multiple climbing fiber innervations. Functional changes have also been observed as evidenced by impairments in reversal learning, set shifting, reaction time, and interval timing depending upon the age of treatment. Here we show that MAM injected during postnatal days 1-4 produced an 18% reduction in cerebellar weight at 150 days of age, with relatively little change in the weight of other regions such as the forebrain or striatum (3% and 6% reductions, respectively). As the cerebellum has been shown to be involved in temporal processing in the msec-sec range, we investigated the effects of MAM induced cerebellar hypoplasia on timing using a temporal bisection procedure with 2-sec vs. 8-sec anchor

durations. To evaluate differences in temporal processing we used the point of subjective equality (PSE), the duration between the two anchor durations that is classified as subjectively 'long' 50% of the time, and the Weber fraction (WF), which provides a measure of temporal sensitivity accounting for the just noticeable difference between durations normalized to the PSE. Our findings reveal that reductions in cerebellar weight correlate with a decrease in temporal sensitivity as measured by the Weber fraction (WF), $R2 = 0.51$, $p < 0.002$. Moreover, there was a significant between-group effect on the WF, $F(1,13) = 9.9$, $p < 0.0001$, and the PSE, $F(1,13) = 6.36$, $p < 0.05$, indicating a decrease in temporal sensitivity and an underestimation of signal duration for the MAM group. Taken together, the current study identifies the potential importance of the cerebellum for timing in the supra-seconds range. Although the effects of MAM were predominantly observed in terms of cerebellar volume, more subtle changes to cytoarchitecture in other brain areas as well as inter-region connectivity cannot be ruled out. As timing and time perception are believed to rely on multiple brain areas as well as distinct regions within the cerebellum, further work needs to be done in order to determine how selective lesions of the cerebellar hemisphere and dentate nucleus affect timing for both sub- and supra-second durations (see Petter, Lusk, & Meck, 2015 - SfN Abstract).

Abstract: There have been attributed to the cerebellum multiple and varied roles of such importance as the coordination of intentional and spontaneous movements, regulation of posture and vestibular function, participation in the specificity of reflex responses, as well as its participation in memory and emotional experience, sex and orgasm, language, planning and forecasting; and the ability of perception. Studies have shown that stimulation distance in male rats by sexual cues (stimulation without contact), and the acquisition of experience in sexual behavior significantly increases the expression of Fos in the granular layer in each lobe of the cerebellum. Although this activity could corresponds to sensory stimulation (visual, auditory or olfactory) or the motor execution. There is almost no information on the cerebellum in sensory integration, particularly about smelling. The objective of this study is to analyze and compare the expression of Fos protein in the cerebellar vermis in Purkinje layer of male rats who have performed sexual behavior after being olfactory stimulated. Wistar male rats (250-300 g) experienced copulatory sessions when they were placed for 24 hours inside a transparent acrylic cubic box (30 X 30 X 60 cm) with a double bottom. They remained within 70 min, 10 min initial habituation, pre olfactory stimulation; which consisted on placing between the double bottom of the chamber, a vessel containing the controls, almond and a receptive female stimulus. The test lasted 60 minutes, passing a rat and a stimulus at a time. At the end of the test, rats were anesthetized with an overdose of pentobarbital sodium (60 mg / kg), and a transcardiac perfusion was performed. The cerebellar vermis was processed and underwent immunohistochemical reaction to detect the Fos protein. The expression of Fos in Purkinje neurons in the cerebellar vermis of male rats is diminished. That pattern in all three groups decreased with the acquisition of experience in sexual behavior. According to the obtained results from the analysis of Fos in the layer of Purkinje we observed that these were completely contrary to those obtained from the analysis in the granular layer of the cerebellar vermis (increased expression of the protein). To find the relationship of this finding we discussed complies with the principle described as long-term depression, essential for memory consolidation and learning process.

Title: Assessing control mechanisms and leader-follower roles in human-human and bimanual interactions during object manipulation

Authors: *K. MOJTAHEDI, M. SANTELLO;
Sch. of Biol. and Hlth. Systems Engineering,, Arizona State Univ., Tempe, AZ

Abstract: Physical interactions can be intrapersonal, e.g., manipulating an object using two hands, or interpersonal, e.g., transporting an object with another person. In both cases, each agent is required to ensure spatial and temporal relations among the effectors to attain a specific performance goal, i.e., preventing the object from slipping or tilting. However, little is known about how humans coordinate their physical interactions for object manipulation, and in particular how the role of each participant emerges during collaborative tasks. We investigated joint action using an object-balancing task performed by two agents or bimanually by the same agent. The task goal was to grasp and move a U-shape grip device while keeping it horizontal by observing a bubble level located on the object. We asked participants to move the grip device at two predefined heights. The task consisted of static (holding) and dynamic (moving) phases. Auditory cues were given to specify the initiation of the dynamic phases. We measured forces and moments exerted on each handle and grip device kinematics. Three groups of subjects, bimanual (Bi, 9 subjects), human-human (H-H, 9 dyads), and Leader-Follower (L-F, 9 dyads), participated in the experiment. L-F group is similar to H-H group, with the exception that only the leader was given the auditory cues. We quantified (1) the role of potential asymmetries for interlimb coordination during bimanual interaction (Bi group), (2) how the role of each agent emerges during physical interactions (H-H group), and (3) behavioral features to identify the leader versus follower roles (L-F group). Continuous wavelet transform (Mojtahedi et al., 2015) revealed that dyads relied more on feedback control than individual subjects performing the task bimanually. Furthermore, the results of cross wavelet spectrum analysis showed that the extent to which the rate of moments was synchronized was higher in dyads than individual subjects. Therefore, both of these performance metrics indicate that dyads were significantly more accurate than individual subjects. Furthermore, all subject groups were characterized by a ‘leader-follower’ relation. Specifically, in the Bi group, the dominant arm was identified as leading the physical interactions in all movement phases. Interestingly, dyads in H-H group exhibited the same role specialization as the L-F group, even though leader-follower roles were not explicitly specified for the H-H group. These preliminary results point to an asymmetrical role assignment during physical interactions involving two limbs of the same or different agents. The underlying sensorimotor mechanisms remain to be investigated.

Title: Somatosensory electrical stimulation added to motor practice modifies neuronal excitability but does not have additive effects on interlimb transfer in humans

Authors: *M. P. VELDMAN[1], I. ZIJDEWIND[2], N. A. MAFFIULETTI[3], T. HORTOBÁGYI[1]; [1]Ctr. for Human Movement Sci., [2]Dept. of Neurosci., Univ. Med. Ctr. Groningen, Groningen, Netherlands; [3]Neuromuscular Res. Loboratory, Schulthess Clin., Zurich, Switzerland

Abstract: Introduction: Sensory input modifies motor function. Previous data showed that sensory input in the form of somatosensory electrical stimulation (SES) can increase stroke patients' manual motor function. An understanding of how such modifications occur is important in the rehabilitation of patients with sensory deficits. In addition, SES bilaterally activates sensory cortices that are directly connected to the primary motor cortex. These findings led to the hypothesis that SES combined with motor practice (MP) could increase interlimb transfer of a motor skill. We examined if SES added to motor practice (MP) could augment interlimb transfer of a visuomotor skill and if changes in neuronal excitability mediated this transfer effect. Methods: Young adults (18-30y, n = 25) received either MP, SES, or MP+SES. Interlimb transfer was quantified by the reduction in deviation in degree from the preprogrammed template measured in the left-transfer hand after a right-hand intervention. MP consisted of 300 5-s-long visuomotor trials with the right hand. SES consisted of 1-s-trains of weak electrical stimulation of the radial and median nerves above the elbow at 10 Hz. Single- and double pulse transcranial magnetic stimulation (TMS) was used before and after the visuomotor intervention to determine changes in neuronal excitability. Results: The magnitude of transfer of the visuomotor skill was significant after the three interventions combined ($p < 0.001$) and separately (MP: 4.4°; 12%, SES: 3.0°; 6%, MP+SES: 3.2°; 8%). However, the magnitude of interlimb transfer was not different between groups (Group by Time interaction, $p = 0.35$). Corticospinal excitability in the non-practice and non-stimulated left hand increased more after SES (54%) compared to MP (1%) and MP+SES (-14%) ($p = 0.023$), possibly mediated by a 8% decrease in interhemispheric inhibition after SES ($p < 0.05$). However, there were no correlations between interlimb transfer and changes in TMS metrics (all $p > 0.05$). Conclusion: MP and SES each can produce interlimb transfer but when combined, the individual effects are not additive and are likely mediated by different mechanisms. The observed crossed effects illustrated by the transfer of skill after SES can possibly accelerate the rehabilitation of patients with sensory deficits through mechanisms of motor cortical plasticity.

Title: Facilitation of triceps brachii motoneurons by contralateral elbow flexion

Authors: *I. ZIJDEWIND[1], M. A. PEREZ[2,3];
[1]UMC Groningen, Groningen, Netherlands; [2]Dept. of Physical Med. and Rehabil. Systems, Neurosci. Inst. Ctr. for the Neural Basis of Cognition, University of Pittsburgh, PA; [3]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Miami, FL

Abstract: During strong unilateral contractions activity is not confined to the target muscles but contralateral homologous muscles also become active. During bilateral contractions however, transcranial magnetic stimulation (TMS) showed facilitatory connections between contralateral antagonistic muscles. Here, we examined the effects of unilateral contractions on contralateral activity, corticospinal (MEPs) and spinal excitability (CMEPs) in contralateral homologous and heterologous muscles. Eleven volunteers (5 females) were included in the study. Subjects performed maximal voluntary contractions (MVC) with either elbow flexors or extensors of the dominant side. During the contractions EMG, force and TMS evoked responses were recorded in the non-dominant muscles. In six subjects (3 females) additional experiments were performed to assess spinal excitability with transmastoid stimulation during maximal elbow flexion with the dominant arm and low force elbow flexion and extension with the non-dominant arm. MEP and CMEP were expressed as % of maximal M-wave (Mmax). During maximal elbow flexion significantly different amounts of contralateral associated EMG were observed in the biceps brachii (3.4% MVC, 2.3 SD) vs triceps brachii (10.6% MVC, 6.7 SD; p=0.007); whereas during maximal elbow extension, similar amounts of associated EMG were observed (biceps: 2.8% MVC, 2.6 SD; triceps: 3.2% MVC, 2.9 SD; p=0.67). Thus, activity in the triceps was greater during contralateral elbow flexion than extension (p=0.001). The MEPs data revealed similar results: a difference was observed in the triceps MEPs during contralateral flexion (34.4%

Mmax) vs extension (10.6% Mmax; P=0.03); whereas in the biceps no difference was found (flexion: 17.1% Mmax; extension 20.0% Mmax). The MEP data reflected mainly differences in associated activity because if we only selected MEPs with matched background EMG no difference in triceps MEPs were found (flexion: 8.6% Mmax; extension: 8.5% Mmax). In the triceps, CMEPs during contralateral elbow flexion were greater (15.4% Mmax, 8.1 SD) than CMEPs evoked during voluntary activation (at similar background EMG, 9.6% Mmax, 5.7 SD). During contralateral elbow flexion the excitability of the triceps increased significantly more than during extension. The data indicate that excitability changes were mainly situated on a spinal level. The results suggest that combining voluntary triceps activity with contralateral flexion could help to activate triceps motoneurons in subjects suffering from impaired voluntary drive.

Title: Motor control efficiency in bimanual and collaborative tasks

Authors: E. J. AVILA MIRELES, *V. SQUERI, D. DE SANTIS, P. MORASSO, J. ZENZERI;
Inst. Italiano Tecnologia, Genova, Italy

Abstract: Many human-performed tasks are inherently unstable. These tasks are difficult to carry out because they are sensitive to different initial conditions and factors as neuromotor noise and external perturbations that can cause an unpredictable and unsuccessful performance. These peculiarities make them particularly suitable for investigating kinematic strategies used by humans to solve problems of stabilization. In previous studies, it was shown that trained subjects could stabilize a compliant tool in an unstable environment using two different control strategies: stiffness and positional. The first strategy is faster from the dynamics point of view, but more energy consuming. The second one is more efficient in terms of effort. When the participants were asked to perform the same task in a dyad, the results highlighted a beneficial effect of

collaboration in terms of effort. However, previous results focused only on the kinematic aspects of the task, without considering the muscular activity. The mechanisms that simultaneously accommodate kinematics and muscular aspects to achieve stability remain still unclear. To look into this interrelation, we asked 3 subjects, trained in the bimanual task, to grasp the handle of a bimanual robotic manipulandum, and to stabilize a virtual mass immersed in a saddle-like force field that provides instability, first bimanually and then forming dyads. During the task we acquired the kinematic data together with the corresponding EMG signals from 13 muscles of each arm. We computed the root mean square (RMS) of the EMG signals and an Effort Index evaluated from the kinematic data. To understand how a subject solves the stabilization problem, we first considered the bimanual condition. Both the evaluated indexes were greater for the stiffness strategy than for the positional one, underlining that the stiffness strategy is more costly in terms of effort. When subjects were solving the task as dyads, we found that the Effort Index was smaller for the positional strategy, as in the case of the bimanual condition. Conversely, the muscular activity provided no clear evidence that the muscular effort was systematically lower in the positional strategy. Indeed, the RMS values of the dyads in the positional strategy showed a non-uniform behavior and were very similar to or in some cases, even higher than in the stiffness condition. These results suggest that even if kinematic strategies can be easily generalized to different environmental conditions, such as dyadic collaboration, they may not be reflected by the strategies at a muscular level. These latter may be more sensitive to other factors, like predictability of the interaction.

Title: Modulation of corticospinal excitability of wrist muscles depending on the phase of cyclic illusory movement of the contralateral limb

Authors: *K. NAKAGAWA[1,2,3], Y. UMESAWA[4], Q. WEIHUANG[3], K. NAKAZAWA[1], M. G. FUJIE[5], H. FUJIMOTO[4], K. KANOSUE[3];

Abstract: Symmetrical bimanual movements are more easily performed than asymmetrical movements (Swinnen, Nat Rev Neurosci, 2002). As a one of neural basis of the symmetrical tendency, corticospinal excitability of the resting wrist muscles modulates depending on the phase of cyclic voluntary movement of contralateral hand (Carson et al. J Physiol. 2004). The detailed neural mechanisms of the phase-dependent neural modulation in remote limb are still hardly known. In order to investigate the effect of kinesthetic sensation on the neural modulation, we tested whether just kinesthetic illusion (Goodwin et al. Science, 1972) as well as voluntary movement modulates corticospinal excitability depending on the phase of illusory movement. The experimental tasks were 1) voluntary movement, 2) kinesthetic illusion induced by tendon vibration (80Hz), 3) passive movement. Each task was periodical movement of left hand (0.75Hz). Transcranial magnetic stimulations of the left motor cortex were delivered during the phase of extension or flexion of left wrist, and then motor evoked potentials (MEPs) were recorded from of resting right forearm muscle (extensor and flexor). In each task, MEPs were divided into two movement phases (extension and flexion), and the significant differences in MEP amplitude between them were ascribed to the occurrence of the phase-dependent modulation. The results showed that kinesthetic illusion of the left wrist modulated the MEPs amplitude in the resting right wrist muscles depending on illusory movement phase just as observed during voluntary or passive movement. These results indicate that irradiation of motor commands during motor execution should not be a necessary condition for production of functional connection between bimanual hands. In conclusion, kinesthetic illusion of single limb may produce the phase-dependent modulation of corticospinal excitability of contralateral limb, which suggests the importance of kinesthetic sensation for the functional connection between bimanual hands.

Title: Variances of joint configuration and muscle activity patterns during arm cycling against external resistances

Authors: M. MRAVCSIK[1], L. BOTZHEIM[2], N. ZENTAI[1], *J. LACZKO[1,2,3];
[1]Univ. of Pecs, Pecs, Hungary; [2]Fac. of Information Technol. and Bionics, Pazmany Peter Catholic Univ., Budapest, Hungary; [3]Wigner Res. Ctr. for Physics, Budapest, Hungary

Abstract: Variances of limb movement patterns depend on environmental forces. Here a motor task for human forelimbs is investigated in which the variance of the endpoint trajectory (hand path) assumed to be very small. 17 right-handed, able-bodied participants (Age: 23.76, ±2.33 y.) performed arm cycling movements under 3 resistance conditions (RC): low, moderate, high crank resistance on a MEYRA (Kalletal, Germany) ergometer. Surface EMGs were recorded from biceps, triceps, delta anterior, delta posterior. Positions of markers placed on the participant's arm were recorded by a ZEBRIS (Isny Germany) movement analyzer. Intersegmental angles in the shoulder, elbow and wrist were computed from marker positions. Time courses of joint angles and muscle activities (EMG amplitude) were segmented based on the number of cycles the subjects completed. The frames in which the elbow reached the most flexed positions were used to define the starts of separate cycles. Joint angle and EMG data obtained in separate cycles were time normalized and their variances across cycles in each condition for each participant were computed. The variances obtained in low, medium and high resistances were compared applying repeated measures ANOVA. When cycling with 2 arms, it was found that for the left arm there is a significant difference in the muscle activity variances obtained in low and high RCs. For the right arm, significant differences were found between low and high and also between low and medium RCs. Higher resistance induced higher variances of muscle activity profiles. When cycling only with the left arm, there were significant difference between low and medium and also between low and high RCs and the difference was marginally significant between data obtained in medium and high RCs. In contrast, when cycling only with the right arm, resistance condition did not affect muscle activity variances. Joint angle variances didn't differ significantly for the 3 resistance conditions, neither in bimanual nor in unimanual cycling. Conclusion: the movement is stabilized at kinematic level. To keep this stability when cycling against higher resistance, muscles employ more variable activity patterns. The movement is controlled through stabilizing arm configurations and less by stabilizing muscle activity patterns. The exception is when cycling only by the right arm, the reason of this may be that the central neural control of the dominant arm is so robust that even muscle activity patterns are stabilized and their variance isn't affected by external resistances. Although the left arm's less stable muscle activity patterns affect muscle activity variances of the right arm when cycling bimanually.

Title: Effects of varying visual feedback on learning a bimanual birhythmic (2:1) isometric force coordination pattern

Authors: M. LEWIS, M. DUNN, E. SHIREMAN, K. MULLER, D. DEAN, Jr, A. CHAUDHARI, N. PATEL, R. T. EAKIN, W. W. SPIRDUSO, *L. D. ABRAHAM; Kinesiology and Hlth. Educ., Univ. Texas Austin, Austin, TX

Abstract: This study replicated a recent unpublished study (Wilson, 2012) which found the bimanual coupling effect was not overcome in a birhythmic isometric force tracking task, unlike the results of Kovacs et al. (2010, 2011) for polyrhythmic bimanual kinematic tasks. Thirty-three right-handed volunteer participants, 13 men and 20 women with a mean age 20.7 (SD = 1.5) years, free from any neurological disorder or physical ailment, were randomly assigned to one of three groups that differed in percent of visual feedback provided during practice trials (100%, fading 50% or 0%). The participants then performed a bimanual birhythmic isometric force tracking task (requiring a 2:1 rhythm between the two index finger forces to move a computer screen cursor with a moving target along a path shaped like a backward C through two complete trips up and back for each trial). The forces required to complete the task were scaled for each participant so that the peak force required for each digit was 30% of that individual's mean maximum voluntary contraction (MVC) digit flexion force, measured at the fingertips. After initial orientation to the apparatus, all participants performed five blocks of five practice trials with the feedback schedule assigned to their group, rested for 30 minutes, then performed an additional five trials as a retention test. During the retention test all groups were provided visual feedback only during the first 12.5% of the task. During practice blocks, the three groups differed in average Root Mean Square Error (RMSE), measured as distance of the cursor from the moving target. The 100% feedback group had consistently low RMSE; the 0% feedback group had consistently high RMSE, and the fading 50% feedback group had steadily increasing RMSE as the visual feedback was reduced across practice blocks. Interestingly, smoothness of the cursor movement, assessed by coefficient of variation of error (CVE) was consistently lower for the 0% feedback group than for the other two groups. Despite these differences between the

groups during the practice trials, no differences occurred between the groups in RMSE or in CVE during the retention block. These results across different schedules of visual feedback during learning support the guidance hypothesis that while performance is enhanced, learning is not optimal when feedback is provided on every trial. These findings also support the position that the bimanual coupling effect in birhythmic isometric force coordination tasks is very strong and cannot be as easily overcome as it is in kinematic bimanual tasks. This may be due in part to the different sensory feedback systems used in isometric force production versus limb movement tasks.

Title: Manual asymmetry during a bilateral reach and hold task

Authors: ***E. J. WOYTOWICZ**[1], J. WHITALL[1,2], K. P. WESTLAKE[1], R. L. SAINBURG[3,4]; [1]Physical Therapy and Rehabil. Sci., Univ. of Maryland, Baltimore, MD; [2]Univ. of Southampton, Southampton, United Kingdom; [3]The Pennsylvania State Univ., University Park, PA; [4]Penn State Milton S. Hershey Med. Ctr. and Col. of Med., Hershey, PA

Abstract: We have previously characterized interlimb and interhemispheric assymetries for unilateral coordination tasks. This work has led to a model of motor lateralization in which one hemisphere is specialized for impedance control that is robust to unstable environmental conditions, while the other hemisphere is specialized for predictive mechanisms that can specify efficient and smooth trajectories under stable environmental conditions. We hypothesize that these two specializations are distributed across the arms during everyday bilateral tasks that involve holding and manipulating, such as when holding a baguette with one hand to slice it with the other hand. We predict that each hand should demonstrate different specializations for each

of these task elements during bilateral behaviors. In order to test this hypothesis, we designed an experimental equivalent of the hold and slice task. In this task, performed in a virtual environment with the unseen arms supported by frictionless air-sleds, the arms are connected by a spring, while one hand maintains its position at the origin of the task, and the other moves to a series of targets distributed across a range of directions. Thereby, the reaching hand is required to take account of the spring load to make smooth and accurate trajectories, while the stabilizer hand must impede the spring load to keep a constant position. Right-handed subjects performed each of two sessions of this task, with the order of the sessions counterbalanced between groups. In one session, the right hand reached while the left hand stabilized, and the second session the left hand reached while the right hand stabilized. Our very preliminary results indicate a hand by task component interaction, such that the right hand showed better reaching performance , with faster and smoother (Jerk) reaching. In contrast, the left hand stabilized better, showing less displacement than the right hand. These findings suggest that the specializations of each cerebral hemisphere for impedance and predictive mechanisms are expressed during bilateral interactive tasks, such as the reach and hold task. To date, this is the first demonstration of the dynamic dominance hypothesis within the context of an asymmetric bilateral task.

Title: Entrainment of movement kinematics as the default mode of human joint actions: A cooperative grasping study

Authors: *L. GUO[1], M. NIEMEIER[2,3];
[2]Psychology, [1]Univ. of Toronto at Scarborough, Toronto, ON, Canada; [3]Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Humans can be highly effective in coordinating their actions with others. To perform such “joint actions,” the co-actors need to align temporal and spatial aspects of their motor control with great precision. But to study interpersonal coordination most research has

investigated rhythmic limb movements during socially coordinated behaviour with many degrees of freedom in the way the tasks could be performed, and largely the tasks could be performed by one person alone. To probe joint actions affording a maximum amount of cooperation, here we used a task that was irreducible to a single person's actions with low degrees of freedom. We asked two participants at a time to cooperatively grab an object with a precision grasp such that each person used their index and middle fingers of one hand to push from opposite sides of the object and to lift it. As a control condition, we asked the participants to compete in speed as they reached for the opposite sides of the object. We hypothesized that cooperative grasping should yield higher degrees of coordination than competitive reaching, in particular over the course of the experiment. Using infrared motion capture, we recorded the hand movements of 11 pairs of participants. As expected we found that movement coordination for cooperation versus competition became different over time, i.e., towards the end of the experiment, hand velocities were more correlated during cooperative grasping. However, the change came from the competitive condition where correlations started high and declined over time, whereas the cooperative condition showed high correlations throughout. Our data suggest that joint action entrains people's movement kinematics into temporal synchrony, arguably based on forward models that anticipate the movements of the co-actor. Moreover, during competition actors might need to learn to de-synchronize to overcome the default mode of cooperation.

Title: Effect of handedness on the generation and execution of upper limb planar movements

Authors: *M. COSCIA[1], E. PIRONDINI[1], N. DUTHILLEUL[2], S. EL KHOURY[3], R. L. DE SOUZA[3], A. BILLARD[3], S. MICERA[1,4];
[1]Bertarelli Fndn. Chair in Translational Neuroengineering, [2]École Polytechnique Fédérale De Lausanne, Lausanne, Switzerland; [3]Learning algorithms and systems Lab., École polytechnique fédérale de Lausanne, Lausanne, Switzerland; [4]The Biorobotics Inst., Scuola Superiore Sant'anna, Pisa, Italy

Abstract: Handedness is the tendency to prefer the use of a limb in performing motor tasks. Handedness seems result from differences in the neural control of the limbs due to functional and

anatomical asymmetries in the motor cortex, in the corticospinal tract, in the peripheral nervous pathways, in muscle fiber composition, in the motor unit firing rate, and in muscle activity. In this work, we deepen the mechanisms which underlie difference in motor performance on the left and right side by investigating the movement execution, the muscular activity and the force generation in both sides from a group of five right and five left handed subjects while executing motor tasks requiring precision in inter-joint coordination and trajectory formation. The hand dominancy was determined by the Edinburgh inventory test. The subjects executed wide and tight circular movements 8 times clockwise and anticlockwise with no interruptions between repetitions, at comfortable speed, following circles drawn on the center of a table, using at first the dominant and afterwards the non-dominant arm. While performing the motion, subjects held in a tight grip a cylindrical tool whose tip was in contact with the table. The tool included a sensor to measure forces and torques generated at the end-point. Additionally, we recorded upper limb kinematics by placing 29 markers for motion tracking, and the electromyographical (EMG) activity of 15 muscles. The trajectory of the marker in correspondence to the ulnar styloid process, the forces and torques provided by the sensor, and the muscular organization highlighted by muscle synergies obtained factorizing the EMG activity with the non-negative matrix factorization algorithm were compared between sides, and between right and left handed subjects. Our preliminary results showed that right and left handed subjects performed the circular trajectories with different strategies and muscle organization. Muscle synergies were similar between sides during the execution of wide movements; whereas, during the execution of tight movements, the muscle activity of the dominant side required the activation of an additional module compared to the non-dominant side. The results of this work have an important impact from a clinical point of view, as handedness-related differences in movement execution and muscle synergies need to be considered in rehabilitative applications for subjects characterized by motor and muscular asymmetry, such as stroke patients. However, deeper analyses on a larger cohort of subjects are necessary to confirm our preliminary results and to better understand the origin for the handedness-related difference in muscle synergies.

Title: The effects of bilateral reach tasks on postural control in older adults

Authors: M. CAMINITA[1], H. HIBINO[1], *K. KERN[1], M. HUANG[2], S. BROWN[1];
[1]Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Michigan Flint, Flint, MI

Abstract: Many goal-directed behaviors require the coordinated action of both hands which, in older adults, may comprise over 50% of activities of daily living (Killbreath & Heard, 2005). To what extent aging impacts the performance of bilateral tasks is unclear. For example, Stelmach et al. (1988) reported slowing of bilateral reaching movements while Coats & Wann (2012) found that movement time during a bilateral reach, grasp and place task did not vary between older and young adults. Most studies examining bilateral arm function have been performed from a seated position despite recent findings indicating age-related declines in postural control during task-related reaching (Huang and Brown, 2013, 2015). The purpose of this study was to determine the effects of aging and postural configuration on bilateral reaching performance. Fourteen young (mean age 20.6 y) and 16 older adults (mean age 74.4 y) performed unilateral (dominant, non-dominant) and bilateral reaching movements from either a seated or standing postural configuration. Participants reached to illuminated targets located at shoulder and waist heights as fast and as accurately as possible. During the standing condition, participants stood barefoot on a force plate with a shoulder width foot separation. Target-embedded touch sensors recorded movement time. Center of pressure path length was used to assess postural control during the reaching tasks. Postural configuration testing order was counterbalanced in each age group. Postural control demands (i.e. seating vs standing) had no effect on movement duration regardless of reach task (unilateral vs bilateral) in either age group. When reaching from standing, COP excursion increased in both groups during coupled bilateral tasks compared to unilateral reaching. In young adults, COP excursion increased by approximately 30% compared to dominant arm reaching. A much greater effect was seen in older adults where COP excursion increased by over 60% during bilateral tasks. This observation was driven, in part, by greater COP excursions when reaching unilaterally with the non-dominant compared to the dominant arm. In contrast, no arm differences were seen in the young adults. These findings demonstrate that dynamic postural control during bilateral reaching movements is compromised to a larger extent in older adults compared to their young counterparts, possibly due to age-related declines in on-line sensory control of goal-directed movements. Training programs aimed at improving balance control and fall prevention in the elderly should consider the inclusion of goal-directed bilateral reaching tasks, particularly from standing positions.

Title: The influence of biomechanical constraints on bimanual coordination

Authors: *D. CORDOVA BULENS, F. CREVECOEUR, J.-L. THONNARD, P. LEFÈVRE; Univ. catholique de Louvain, Louvain La Neuve, Belgium

Abstract: Most daily tasks involve bimanual coordination, which in many cases offers redundancy in the way the two limbs can achieve task success. To date, handedness has been considered as the main factor driving bimanual coordination, despite the presence of biomechanical constraints that also induce asymmetries across limbs. For instance, producing a leftward force with one arm will recruit different muscle groups depending on the arm being used. Here we address this issue by showing the impact of these biomechanical constraints on distributed force control. The task consisted in producing a 20 N force using both arms towards visual targets representing the resultant force in the horizontal plane. Visual feedback was provided by mapping the sum of forces applied on the fixed robotic interface onto cursor motion in a virtual reality display (KINARM, BKIN Tech., Kingston, Canada). The force distribution across the two arms was unconstrained and sixteen different directions of force production were tested. We varied the joint configuration to highlight the influence of biomechanics on bimanual control. We modeled this task using human-inspired two-segments upper-limbs acting on the horizontal plane. The two arms are actuated by six groups of muscles, representing mono- and bi-articular flexors and extensors at each joint. The strength of each muscle group was adjusted based on physiological cross-sectional areas of human subjects. The only parameter that varied across simulations, as in the experiment, was the joint configuration, which is expected to impact force production through changes in the Jacobian matrix linking the joint torques to the end-point force. We used a standard optimal feedback control model coupled with positivity constraints on the control variable representing muscles activation. The model predicted that varying the joint configuration should impact the force distribution across the two limbs. Participants' behavior directly supported the model predictions. More specifically, a change in joint configuration modifies the direction of the end-point force produced by each muscle group, therefore modifying the orientation of preferred force direction of each limb. A repeated measures ANOVA confirmed the significant influence of upper-limb configuration on the preferred force

direction of each limb following changes in joint configuration ($F(X,Y) = 36.23$, $p<0.001$). These results emphasize that the nervous system distributes control across the two limbs while taking upper-limb geometry into account. We conclude that biomechanical constraints are an important factor for understanding how the nervous system performs bimanual control.

Title: Different levels of intracortical inhibition are involved in bimanual common vs. dual-goal tasks and related to interlimb interaction

Authors: *W.-W. LIAO[1], J. WHITALL[1,2], J. BARTON[1,3], S. MCCOMBE WALLER[1]; [1]Physical Therapy and Rehabil. Sci., Univ. of Maryland Baltimore, Baltimore, MD; [2]Fac. of Hlth. Sci., Southampton, United Kingdom; [3]Dept. of Neurol., Univ. of Maryland, Baltimore, MD

Abstract: Individuals following stroke have exhibited various degrees of deficits in both paretic and non-paretic arms. Nevertheless, the majority of activities of daily living require collaboration between the arms. Some tasks involve a common-goal in which two arms sharing a single focus, such as pulling out a drawer with both arms. Others involve similar but separate goals for each arm, such as picking up different items with each arm separately. The ability to restore function of both arms in bimanual tasks is crucial for stroke survivors to achieve independent living. We hypothesize that different cortical control parameters are involved in bimanual common versus dual-goal tasks, and that this difference will be demonstrated in interlimb performance interaction as well. In this pilot we determine intracortical inhibition and its relationship to interlimb interaction in bimanual common-goal vs. dual-goal isometric force tasks in young non-disabled adults. Subjects: Eight right-handed subjects. Methods: Isometric force tasks with visual feedback were undertaken in three conditions: unimanual, bimanual dual goals for each arm and bimanual common-goal for both arms. Force production of each arm during 10% submaximal tasks and intracortical inhibition (SICI) of both hemispheres for biceps were evaluated during the three conditions. Results: A significant reduction of SICI was found in both bimanual tasks compared to the unimanual tasks ($p<.05$) in dominant hemispheres, with a trend toward greater reduction in dual-than common-goal tasks ($p=.06$). Both bimanual tasks showed less intracortical

inhibition compared to unimanual tasks in non-dominant hemispheres, but only dual-goal tasks reach a statistically significant difference ($p<.05$). A significant relationship was found between the difference of force variability of each arm and total motor output (the sum of force during bimanual contractions) in common but not dual-goal tasks based on a linear regression model ($p<.05$, $R2= .805$). Conclusion: Bimanual common and dual-goal tasks could release both hemispheres from mutual inhibition. The levels of SICI within and between hemispheres as well as force organization pattern were different in common- vs. dual-goal tasks, and this may suggest that these two tasks were modulated by potentially different inhibitory cortical parameters. Our findings indicate that task specific training might be needed for different types of bimanual tasks in healthy as well as patients with neurological disorder.

Title: Effects of task constraints bimanual coordination in patients post-stroke

Authors: R. L. MCGRATH, *S. S. KANTAK;
Moss Rehabil. Res. Inst., Elkins Park, PA

Abstract: Coordination during goal-directed movements emerges from an interaction of task and individual constraints. In this study, we investigated the effects of two task constraints on bimanual coordination in patients with stroke and age-matched controls. Two specific task constraints were manipulated: symmetry and angular displacement. The goal of the bimanual task was to cooperatively use two hands to move a virtual block in to a goal window. Symmetry was manipulated along two dimensions: symmetric and asymmetric. During symmetric task, two hands reached forward to cause upward displacement of the virtual block. During the asymmetric task, the upward movement of the block resulted from one hand reaching forward and the other pulling backward. During standard angle condition, the angle of the block changed dependent on the displacement of the two hands relative to the starting position. In the fixed angle condition, the virtual block was locked in a horizontal position and did not depend on the displacement of the two hands relative to the starting position. Bimanual coordination was determined using two separate analyses: individual contribution of the two hands and cross-correlation. Cross-correlation analyses yielded a cross-correlation coefficient and time-lag. During the symmetric

task, control participants moved the two hands equally during both standard and fixed angular positions. In contrast, patients demonstrated reduced movements of the paretic arm during the fixed angular condition, but not the standard angle condition. During the asymmetric task, there was a differential effect of the angular displacement. In the fixed angle asymmetric condition, control participants demonstrated different displacements of the two arms: the pulling hand had significantly greater excursions compared to the reach hand, irrespective of the dominance. This suggests that biomechanical factors play an important role in control and coordination of bimanual movements. In patients with stroke, however, the paretic arm showed reduced excursion irrespective of the action (reaching or pulling) required. During the standard angle asymmetric condition, the relative contributions of the two arms were restored to being almost equal, thus providing evidence that task constraints can be manipulated to improve bimanual coordination in patients with stroke.

Title: Multi-frequency bimanual force production: symmetric and asymmetric interference

Authors: *D. M. KENNEDY[1], J. RHEE[2], C. H. SHEA[2];
[1]Dept. of Hlth. & Kinesiology, [2]Hlth. and Kinesiology, Texas A&M Univ., College Station, TX

Abstract: Results from a recent experiment (Kennedy et al., 2015) indicated consistent and identifiable distortion of the left limb forces that could be attributable to the production of right limb forces during a multi-frequency bimanual force task. However, distortions in the forces produced by the right limb that could be attributable to the production of force in the left limb were not observed. The present experiment was designed to determine whether an increase in the force requirements for one limb would result in an increase in the interference observed in the contralateral limb and to determine if the strength of the interference was influenced by the limb performing the higher force and/or frequency. Participants (N=40) were required to rhythmically coordinate a pattern of isometric forces in a 1:2 or 2:1 coordination pattern. The 1:2 task required the right limb to perform the faster frequency while the 2:1 task required the left limb to perform the faster frequency. In each task (1:2, 2:1) participants were also randomly assigned to a force condition in which the left or right limb was required to produce a force pattern of 5 N while the

contralateral limb was required to produce a 5N, 15N, and 25N force pattern. Each participant performed 13 practice trials and 1 test trial per force level. Lissajous displays were provided to guide performance. The results indicated that the right limb influenced the left limb regardless of force level, loading condition, or frequency assignment in both the 1:2 and 2:1 tasks. However, the left limb only appeared to influence the right limb when assigned the faster frequency. This result is consistent with the notion that neural crosstalk is asymmetric with the dominant hemisphere exerting a stronger influence on the non-dominant limb than the non-dominant hemisphere does on the dominant limb.

Title: Mirror training augments the cross-education of strength and reduces the contralateral silent period duration in the untrained but not the trained wrist

Authors: *T. ZULT[1], S. GOODALL[2], K. THOMAS[2], S. SOLNIK[3,4], T. HORTOBÁGYI[1,2], G. HOWATSON[2,5];
[1]Ctr. for Human Movement Sci., Univ. of Groningen, Groningen, Netherlands; [2]Dept. of Sport, Exercise and Rehabil., Northumbria Univ., Newcastle-upon-Tyne, United Kingdom; [3]Dept. of Kinesiology, Pennsylvania State Univ., Pennsylvania, PA; [4]Univ. Sch. of Physical Educ., Wroclaw, Poland; [5]Sch. of Biol. Sci., North West Univ., Potchefstroom, South Africa

Abstract: Introduction: Unilateral resistance training strengthens the actively contracting muscles and also the homologous muscles on the untrained side – a phenomenon called cross-education. The increased neural drive from the untrained primary motor cortex (M1) to the transfer muscles is thought to contribute to cross-education, but also intracortical paths seem to play a role. The magnitude of cross-education is modest, however, it has been hypothesized that mirror-viewing of the exercising hand can augment cross-education by modulating intracortical and corticospinal paths. Consequently, we examined the idea that mirror training augments the cross-education of strength by modifying corticospinal excitability (CSE) and short-interval intracortical inhibition (SICI) of the untrained M1 and contralateral silent period (cSP) duration recorded from the right-trained and left-untrained flexor carpi radialis (FCR). **Methods:** Healthy, young right-handed adults, were allocated to a mirror (N = 11) and no-mirror training group (N =

12) and performed 640 right wrist flexions (contraction speed: 20°/s) at 80% maximal voluntary contraction (MVC) during 15 sessions over three weeks. Pre- and post-test neurophysiological measurements were performed. CSE and SICI of the right-untrained M1 were measured during right wrist flexion in a mirror and no-mirror condition. The cSP was only measured in the no-mirror condition during isometric wrist flexion. All contractions were performed at 60% pre-test MVC and 60% absolute MVC. **Results:** MVC of the trained wrist increased equally in the mirror (71%) and no-mirror groups (73%; $P = 0.961$). MVC of the untrained wrist improved more in the mirror (61%) than no-mirror group (34%; $P = 0.047$). A 16% reduction in the untrained FCR's cSP duration was observed for the mirror group, while the no-mirror group showed a 12% increase ($P = 0.008$) when measured at 60% pre-test MVC (15% decrease vs. 8% increase when measured at 60% absolute MVC; $P = 0.030$). No changes in the trained FCR's cSP duration were found ($P > 0.05$). CSE increased and SICI decreased across groups for the no-mirror and mirror condition at 60% absolute MVC, while no changes were observed at 60% pre-test MVC. **Discussion:** Augmented sensory feedback by mirror-viewing the exercising hand increases cross-education by reducing the $GABA_B$ mediated cSP duration. CSE and $GABA_A$ mediated SICI of the untrained M1 were modified by the strength training itself, but were not additionally affected by mirror training. Although there is the suggestion that $GABA_B$ receptor function affected cross-education, it is conceivable that other neural circuits are implicated that we did not measure.

Title: Crossed reflexes in distal muscles in the upper limb

Authors: *D. S. SOTEROPOULOS;
Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: In response to a mechanical perturbation, stretched muscles produce a burst of muscle activity, typically composed of multiple components (mediated by multiple pathways). During

bimanual movements, a response can be seen in the opposite, and unperturbed limb. Such crossed reflexes have been rarely studied for more distal movements involving finger muscles. We examined crossed reflexes for an intrinsic hand muscle, the first dorsal interosseous (1DI), to assess if finger muscles show crossed responses to unilateral stretch, and if yes, how these responses depend on the perturbation parameters of the opposite hand. Subjects performed a bimanual finger abduction task with the left finger performing an isometric contraction and the right finger an isotonic contraction. Force and position signals were collected from the left and right manipulanda respectively, and these were used to control the position of a cursor on a visual display. The task required subjects to move the cursor from a starting position to a target position following an audio-visual cue, and hold in target for ~1.5s. Feedback was given at the end of the trial on their performance. The cursor could only be moved in the horizontal direction, and its position was determined by an average of the left and right finger signals. On some trials a perturbation was given to the right finger in a clockwise or anticlockwise direction (randomly chosen). Muscle activity was recorded from 1DI bilaterally during the task. Analysis was carried out on the rectified muscle activity (EMG) aligned to perturbation onset. Subjects were able to carry out the task successfully, scoring >95% on trials with no perturbations. Most subjects (9/11) showed a response in the left (unperturbed) 1DI with an onset latency <100ms. The crossed response had two components - an early inhibitory one (mean onset latency 56ms) and a later excitatory component (mean onset latency 83ms). The peak amplitude of these responses relative to the baseline EMG levels varied from subject to subject and ranged from -40% to -15% (mean -25%) for the early suppression, and 5% to 43% (mean 25%) for the later facilitation. The crossed response depended on the direction of the perturbation- a clockwise perturbation of the R1DI produced much less suppression in the L1DI compared to the anticlockwise perturbation (-25% vs -13%, anticlockwise vs clockwise). The inverse was seen for the later crossed component (12% vs 25%, anticlockwise vs clockwise). Our results show that intrinsic finger muscles can show long latency responses to a stretch in the opposite finger, and that these responses depend on the parameters of the perturbation given to the opposite finger.

Title: Bilateral movement time delays when reaching and grasping one or two objects

Authors: *Y. LEI[1], F. CALABRO[2], M. PEREZ[1,2];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL;
[2]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Most of our daily tasks involve reaching and grasping movements with the arms. However, the extent to which motion of one arm affects movement of the contralateral arm remains poorly understood. Using kinematics analysis we measured arm acceleration (time between movement onset and peak arm velocity), hand opening (time between hand opening onset and maximum aperture size between the index finger and thumb) and closing (time between the maximum aperture size and grasp) during unilateral and bilateral self-paced and ballistic reach-to-grasp movements of one or two small and large cylinders in healthy controls. We found that when reaching for a single object, the time to close the hand was largely increased during bilateral compared to unilateral trials, regardless of the object and movement speed tested. Whereas, arm acceleration and hand opening times remained similar across trials. Notably, bilateral movement time delays were present at different phases of the reach-to-grasp movement when reaching for two objects. Here, arm acceleration time remained similar but the time to open and close the hand progressively increased during bilateral compared with unilateral movements, regardless of the object and movement speed tested. Our findings indicate that extrinsic (object size) and intrinsic (movement speed) variables influence the grasping but not the arm acceleration phase of the reach-to-grasp task, consistent with the view that demands for precise control during grasping gradually increases when approaching the object. We argue that the distribution of the bilateral movement time delays during reach-to-grasp are object-directed.

Title: Neuronal substrate supporting hand function in chronic stroke patients with incomplete motor recovery

Authors: *J. J. FREEMAN[1], K. P. REVILL[1], M. W. HAUT[2], G. M. KOWALSKI[1], M. WISCHNEWSKI[1], S. R. BELAGAJE[1], F. NAHAB[1], D. J. COBIA[3], X. HU[1], G. HOBBS[2], C. M. BUETEFISCH[1];
[1]Emory Univ., Atlanta, GA; [2]West Virginia Univ., Morgantown, WV; [3]Northwestern Univ., Chicago, IL

Abstract: Ischemic stroke often impacts the integrity of the primary motor cortex (M1) and its corticospinal projections (CST) resulting in incomplete recovery of hand function. The neural substrate supporting compromised hand function in the chronic phase of stroke is not well understood. Here we determine in chronic stroke patients the relationship between hand function and reorganization of ipsilesional M1 and CST. Sixteen patients (64.37±9.21 yr.) with incomplete recovery from stroke (>6 months) involving M1 or/and CST participated in the study. Their affected hand was functionally impaired as demonstrated by the higher scores on Jebsen- Taylor Test ($t(15)=7.668$, $p< .0001$) and of limited use in activities of daily living (Motor Activity Log score 1.05±1.03, scale 0-5, lower score = less use). In all patients M1 and CST structure and function were determined using magnetic resonance imaging (MRI) and transcranial magnetic stimulation (TMS). An input-output curve of the ipsilesional M1 hand area was acquired with TMS. A Boltzmann sigmoidal function was fitted to extract maximum motor evoked potential amplitude (MEPmax), inflection point (S50), and slope-parameter. M1 intracortical inhibition was measured using paired pulse TMS. TMS measures of stroke patients were compared to 11 age-matched, healthy subjects. For measures of M1 structure, the distance between representations of the gray-white boundary and pial surface was calculated. These measures were then applied to a standard atlas to extract M1 cortical thickness (FreeSurfer). For CST fractional anisotropy (FA) measures, TRACULA within FreeSurfer was used. We found that in patients, MEPmax and S50 were lower when compared to healthy subjects (MEPmax:$t(25)=23.28$ $p< .0001$; S50:$t(25)=3.88$, $p = .0007$) indicating that maximum CST output was reduced and excitability of surviving M1 neurons increased. Further, in patients, there was a trend towards reduced M1 intracortical inhibition which did not reach statistical significance. TMS measures correlated with mean ipsilesional M1 volume (maxMEP ($r= -.502$, $p = .04$); S50 ($r= .489$ $p = .045$); and SICI ($r = -.054$ $p = .0453$)). There was no significant correlation between hand function (Jebsen Taylor Test score) and any of the TMS or MRI measures of ipsilesional CST or M1. In contrast, impaired hand function correlated with greater

FA values of contralesional CST (r = .666, p = .025). In conclusions, the lack of strong correlations between hand function and measures of ipsilesional M1 and CST reorganization indicates that compromised hand function in the chronic stroke patients likely depends on additional brain areas, possibly involving the contralesional hemisphere.

Title: The relationship between muscle synergies and limb dynamics is altered after a stroke

Authors: ***E. V. OLESH**[1], V. GRITSENKO[2];
[2]Human Performance, [1]West Virginia Univ., Morgantown, WV

Abstract: Stroke is the leading cause of adult disability in the United States and second globally. Persistent post-stroke movement disorders affect nearly one third of all individuals who suffer from a stroke. It is known that motor deficits in stroke survivors are linked to altered muscle activation patterns. Current theories of motor control postulate that the nervous system produces the normal repertoire of movements by combining several muscle synergies that represent basic units of control. Here we sought to investigate how changes in muscle synergies post-stroke relate to changes in limb dynamics that accompany arm motor impairment. Stroke patients were recruited to perform a set of twenty-eight reaching tasks with both their paretic and non-paretic arm. Center-out reaching tasks were presented in horizontal and vertical planes using a virtual reality headset (Oculus Rift). Movements were performed in three dimensions without external constraints other than the instruction not to move the wrist. Muscle activity from twelve muscles of the arm that span shoulder, elbow, and wrist joints were recorded during the movements synchronously with motion capture. Joint angles, angular velocity, and torques for shoulder, elbow, and wrist joints were calculated from the motion capture data. To examine the

relationship between muscle activity and limb dynamics, non-negative matrix factorization (NNMF) was used to extract synergies from both kinematic-dynamic data and EMG data. The kinematic-dynamic data set included joint angles, velocity and torques subdivided into gravitational and inertial components for all twenty-eight movements. Joint torques were further subdivided into flexion and extension components to create non-negative profiles of limb dynamics suitable for NNMF analysis. Resulting synergies from the kinematic-dynamic decomposition were then compared to each of the synergies extracted from the EMG data using cross-correlation analysis. Results indicate that the relationship between certain EMG synergies and kinematic-dynamic synergies is reduced post-stroke compared to that of healthy individuals. This suggests that stroke disrupts the assembly of specific motor synergies, which causes unique patterns of motor impairment.

Title: Altered spatial muscle activation patterns reveal possible mechanisms of motor impairment in stroke

Authors: *G. RASOOL[1], B. AFSHARIPOUR[1], N. L. SURESH[1], X. HU[1], W. Z. RYMER[1,2]; [1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Dept. of Physical Med. and Rehabil., Northwestern Univ., Chicago, IL

Abstract: We investigated the spatial electromyogram (EMG) patterns using the high density grid electrodes to explore possible mechanisms of motor impairment in stroke survivors. The study was focused on spatial analysis of the high density EMG data where we transformed the conventional time-domain EMG data into spatial root man square (RMS) maps. We recorded EMG data from the muscle biceps bachii during sustained, non-fatiguing, voluntary contraction at various force levels using 128-channel grid electrodes arrange in two 16x4 grids covering both the long and the short heads. The EMG data was processed and RMS values were calculated over the total length of signal (5 sec) for each channel. Thus we calculated spatial maps of muscle activity (EMG signal) from both affected and contralateral sides at various force levels.

We calculated EMG spatial maps and their normalized (to the maximum RMS within the map) maps for five different force levels (20%, 30%, ⋯, 60% of the maximum voluntary contraction). We found significant differences between the spatial distributions of normalized RMS maps of both sides (affected vs contralateral arm) at all force levels. However, no such differences were observed in healthy control group. We postulate that multiple mechanisms can cause the altered spatial patterns in stroke survivors. The altered neural control as a result of lesion (and later on due to neuroplasticity) is probably the leading cause of the observed differences. We assume that a snapshot of the average electrical activity over the whole muscle provides important information about the neural control of the muscle. A changed spatial pattern of the activity can directly result from an altered neural control where some parts of the muscle are no more used for force generation (at any force level). Such a phenomenon may results into muscle atrophy or at the worst motor unit death. A correct identification of such mechanisms of motor impairment is crucial for developing intervention therapies.

Title: Reconstructing the three-dimensional ultrasound elastography of human biceps muscle

Authors: ***X. HU**[1], A. LAI[2], M. DUFF[2], N. L. SURESH[2], W. Z. RYMER[2];
[1]Sensory Motor Performance Program, [2]SMPP, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Quantifying the mechanical properties (e.g., elasticity) of skeletal muscle *in vivo* can be helpful in understanding the tissue characteristics of the muscle in both intact and pathological conditions. Shear wave elastography is a promising technique that can quantify tissue elasticity noninvasively. The objective of this study was to reconstruct the three-dimensional spatial features of the elasticity in human biceps muscle. Using dense scans of two-dimensional ultrasound shear wave imaging of the biceps muscle combined with spatial tracking of the upper limb and the ultrasound probe, we reconstructed the three-dimensional elasticity estimates of the biceps muscle. Such information potentially provides us with a non-invasive and low-cost tool to assess the spatial features, such as the homogeneity, of the muscle elasticity, which can be used for clinical diagnosis and treatment assessment.

Title: Effects of wrist tendon vibration on cortical activity during arm stabilization

Authors: *D. B. SNYDER, S. A. BEARDSLEY, B. D. SCHMIT;
Marquette Univ., Milwaukee, WI

Abstract: Artificial activation of sensory afferents by way of wrist tendon vibrations (TV) has been shown to improve end point stabilization in neurologically intact and post stroke populations. This improvement in the ability to stabilize may be due to enhanced sensorimotor integration within cortical networks. In the work presented here, we use electroencephalography (EEG) and electromyography (EMG) together with goal directed stabilization tasks to examine if cortical changes contribute to enhanced end point stabilization during TV. Ten healthy controls performed a series of 2D reach and hold tasks using a passive arm support system (recording limb position) to control a cursor projected onto a horizontal display. Each task condition consisted of a point to point movement to a target followed by a 4 second stabilization period with either no perturbations, perturbations, or perturbations and TV. TV (70 Hz) was applied to the forearm wrist musculature. EEG data were recorded using a 64 channel electrode system, bandpass filtered from 0.1 to 100 Hz, notch filtered at 70 Hz, amplified and processed using independent component analysis to remove artifacts. EMG data were recorded from the flexor carpi radialis, extensor carpi ulnaris, biceps, lateral head of the triceps, and the anterior and posterior deltoid, bandpass filtered from 10 to 350 Hz, notch filtered at 70 Hz, amplified by 1000, root-mean squared (100 ms window) and normalized to their respective maximum voluntary contraction. MATLAB was used for all data analysis. Time courses and source localizations of Beta band (13 - 26 Hz) and Gamma band (27 - 50 Hz) power were computed from EEG data to examine the spatiotemporal aspect of cortical activity. Time course and source localization results of conditions with TV and following TV showed an increase in Beta band event related desynchronization (ERD) compared to conditions pre-TV. Analysis of the TV condition revealed higher Gamma band power in the sensorimotor cortex contralateral to the arm

being moved. These results suggest TV enhances sensorimotor integration resulting in enhanced end point stability.

Abstract: Stroke leads to deficits such as weakness, spasticity and incoordination affecting upper-limb reaching. Reaching is also affected by stroke-related postural control problems characterised by an increase in lateral deviations of the centre of pressure (evaluated with Limits of Stability (LoS) index). Deficits in the coordination of a redundant number of degrees-of-freedom (DFs) of the body (excess DFs), may also affect reaching. We characterised reaching ability of both arms, with and without the involvement of additional trunk DFs in patients with chronic stroke (18-75yrs; Fugl-Meyer Assessment (FMA): 54.0±12.5/66; Reaching Performance Scale for Stroke (RPSS): near=15.6±2.9/18; far=15.7±3.0/18 target) and Chedoke Arm and Hand Activity Inventory (CAHAI): 47.4±12.8/63) compared to healthy age-matched controls. Kinematics of two arm tasks involving a target located at 66% arm length were recorded in seated subjects without vision: stationary-task (maintaining finger above target) and reaching-task, while leaning the trunk forward (total of 40 trials). For each task, in 40% of trials, trunk movement was unexpectedly blocked such that movements were made with and without trunk involvement. LoS in sitting was measured in 8 directions separated by 45° intervals using a force-plate. The primary outcome measures were gain (G) for stationary-task defined as the degree to

which the potential contribution of trunk displacement to hand motion was compensated by appropriate changes in arm DFs (G=1: complete compensation, G=0: no compensation); and endpoint position difference in reaching-task. Comparisons were made with Mann-Whitney U tests. Clinical measures and LoS area were correlated with primary outcomes. G of more-affected arms was lower (G=0.49±0.19) compared to less-affected arms (G=0.69±0.14; U=20.5, p=0.02) and controls (G=0.74±0.16; U=7.00, p=0.04). There was no correlation between the more-affected arm G and FMA, CAHAI, LoS area. Endpoint position differences were similar between groups but those of the more-affected arms correlated with FMA (r=-0.76), RPSS (near: r=-0.85, far: r=-0.87) and LoS area (r=0.71). Stroke affects the ability to compensate for additional trunk movement when the hand is held stationary. During reaching, excessive trunk movement compensates for deficits in upper limb motor function. Patients with stroke have deficits in condition-specific adjustment of intersegmental coordination. Understanding motor control deficits in managing redundant DFs will help clinicians develop targeted interventions to improve upper limb reaching ability in individuals with stroke.

Title: Temporal and spatial upper-limb interjoint coordination in chronic stroke subjects versus healthy individuals when reaching

Authors: M. R. M. RODRIGUES[1,2], M. SLIMOVITCH[1,2], A. K. BLANCHETTE[3,2], *M. F. LEVIN[1,2];

[1]McGill Univ., Montreal, QC, Canada; [2]Ctr. for Interdisciplinary Res. in Rehabil. of the Greater Montreal, Montreal, QC, Canada; [3]Dept. of Rehabil., Laval Univ., Quebec City, QC, Canada

Abstract: Movement coordination which plays a major role in upper-limb(UL) function is commonly affected after stroke. We assessed UL interjoint coordination (IJC) deficits in people with stroke compared to age- and gender-matched healthy subjects and the influence of these deficits on the performance of a simple reaching task. UL kinematics were recorded using 28 markers on the arm, trunk, nose and target (Optotrak, 30s, 100Hz). Two trials of 10 movements each in which subjects (n=20) alternatively touched their nose and a target (ReachIn; ReachOut) located at 90% arm-length, as fast as possible were recorded for each arm. Healthy subjects (n=20) made the same reaching movementsat self-paced and slow speeds to match speeds of stroke subjects. Data for movements in each direction were analyzed to determine relationships between time to perform the task and arm and trunk kinematics. The relationships between temporal and spatial IJC kinematic measures and clinical scores were determined.Compared to healthy subjects, stroke subjects made more curved endpoint trajectories (Index of curvature: stroke=1.23, control=1.04, $p < 0.05$, ReachIn) and used less shoulder horizontal abduction (stroke=11.8º, control=17.6º, $p < 0.001$, ReachIn).Stroke subjects moved their affected arm slower than their less-affected arm (ReachIn: 18%, ReachOut: 43%; for both directions $F=14.136$, $p<0.001$) and had more curved trajectories (ReachIn: 18%, ReachOut: 27%; for both directions $F=6.003$, $p<0.05$).Interjoint coordination was similar between the two arms. Stroke severity was moderately correlated with endpoint speed ($r=-0.55$, $p=0.006$) and straightness ($r=-0.47$, $p=0.018$) but not precision. Time to perform the task correlated with endpoint straightness ($r=0.77$, $p=0.001$), temporal ($r=0.63$) and spatial ($r=-0.61$) interjoint coordination. Shoulder horizontal abduction range ($\beta=0.127$), temporal ($\beta=0.855$) and spatial ($\beta=-0.191$) interjoint coordination explained 82% of the variance in the time to perform the task. Shoulder movement and temporal and spatial interjoint coordination were predictive of the time to perform the task, indicating the influence of UL joint configuration limitation for the performance of reaching movements after stroke.

Title: Corticospinal resetting of the threshold (referent) position for activation of muscles during motion at the elbow joint

Authors: *S. K. SUBRAMANIAN[1,2], L. RODRIGUES[2,3], L. RYCKEMBUSCH[2,3], T. BROHMAN[2,4], D. BARTHELEMY[2,5], M. F. LEVIN[2,6], A. G. FELDMAN[1,2];

De Montréal, Montreal, QC, Canada; [6]Sch. of Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada

Abstract: Muscles become active when the actual position of body segments deviates from their threshold positions. Threshold positions represent the origin of the spatial frame of reference (FR) for muscle action. The level of muscle activity depends on the difference between the actual and threshold body segment positions. Voluntary motor actions result from central shifts in the threshold position, thus shifting the FR. It has been shown that the corticospinal (CS) system is involved in threshold position resetting underlying motion at the wrist joint. We investigated whether or not the CS system accomplishes threshold position resetting at the elbow joint. We also investigated how injury affecting the CS tract influences threshold position resetting. Subjects with upper limb hemiparesis after stroke (Fugl-Meyer scores: 20-65/66) and two groups of healthy controls (young: aged 20-35) and older (age-matched to the stroke group) participated in the study. All subjects voluntarily moved their elbow joint from an initial flexed to a final extended position and vice-versa for a total of 30 trials. CS influences at both positions were measured using MEPs elicited by transcranial magnetic stimulation to the biceps site in the contralateral motor cortex. Passive elbow muscle forces were compensated with an elastic band such that elbow muscle activity was approximately equalized at the two positions. Muscle activity was recorded from two elbow flexors (biceps brachii and brachioradialis) and extensors (lateral and medial heads of triceps brachii). Although the EMG activity of elbow muscles was similar, CS influences were different at the two positions. In the healthy groups, flexor MEPs were greater in the elbow flexion than the extension position and vice versa for extensors (reciprocal pattern). Similar patterns were observed only in a subgroup of patients. In the remaining patients, the pattern was either absent or reversed. Results support the notion that CS system participates in threshold position resetting underlying active motion and that this capacity may be affected by stroke. Results also reinforce previous findings suggesting that the motor cortex controls motor actions by shifting spatial FRs. Deficits in shifting spatial FRs may underlie motor deficits in stroke.

Title: Residual deficits in arm coordination in an obstacle avoidance reaching task in individuals with good arm recovery after stroke

Authors: ***M. C. BANINA**[1,2], M. F. LEVIN[1,2];
[1]Physical & Occup. Therapy, McGill Univ., Montreal, QC, Canada; [2]Ctr. for Res. in Rehabil. of Greater Montreal (CRIR), Montreal, QC, Canada

Abstract: After stroke, 40-78% of individuals recover a good amount of arm function. Clinical evaluation of these individuals demonstrates that arm function falls within normal physiological limits. Based on their high level of recovery, these individuals should not have any major activity limitations, yet many studies have shown that well recovered people after stroke do not use their arm to the expected amount in everyday life activities. Decreased use may be associated with undetected motor deficits only identifiable when individuals attempt higher order tasks requiring complex coordination and quick changes in movement. One higher order motor task, obstacle avoidance (ObAv) while reaching, commonly occurs in everyday environments but is not routinely assessed by clinical scales. We hypothesized that well recovered people after stroke would have altered arm coordination and poor performance in an ObAv reaching task compared to healthy controls. A virtual environment (VE) was developed simulating a refrigerator with 2 sliding glass doors stocked with bottles on 2 shelves. Subjects reached as fast as possible with their affected/dominant arm into the refrigerator and retrieved a bottle (unobstructed reach, U). In random trials (RAND, 30% of 60 trials), the door ipsilateral to the reaching arm closed soon after reach initiation and partially obstructed the bottle (Ob trials). Subjects were instructed to retrieve the bottle without the hand/arm hitting the door. Arm and trunk movements were recorded with 24 active markers by an Optotrak system. Overall success rates, task performance and movement quality variables for U, successful avoidance (ObS) and failed avoidance (ObF) trials were recorded. Mean endpoint phase plots of ObS and ObF were overlaid on U and divergence points between the plots were determined (DP=% of reach distance). In RAND, at a

success level of 65%, the proportion of subjects who achieved success was significantly lower for the stroke group (12%) compared to controls (42%; $z=1.85$, $p<0.05$). For both groups, U reaching was similar and ObS was characterized by DP occurring closer to the starting position (Ctrl: DPS=11±6%, DPF=33±38%, $p<0.05$; Stroke: DPS=23±17%, DPF=65±33%, $p<0.05$). However, the margin of error in the stroke group was about half that of the controls. In addition, stroke subjects used altered shoulder/elbow coordination patterns compared to controls to successfully avoid the door. Stroke subjects had residual movement deficits that were revealed through a challenging motor task. The potential of using challenging UL tasks to identify higher order motor control deficits should be considered when assessing post-stroke motor recovery.

Title: Motor unit coherence among muscles of the flexion synergy in individuals with chronic hemiparetic stroke

Authors: *L. C. MILLER[1,2], F. NEGRO[3], C. HECKMAN[1], D. FARINA[3], J. P. A. DEWALD[1]; [1]Northwestern Univ., Chicago, IL; [2]Florida Intl. Univ., Miami, FL; [3]Univ. Med. Ctr. Gottingen, Gottingen, Germany

Abstract: For individuals with chronic hemiparetic stroke with moderate-to-severe motor impairment, movement of the paretic upper limb is typically constrained to an abnormal muscle co-activation pattern of shoulder abductors and elbow, wrist, and finger flexors. This pattern is described clinically as the flexion synergy (FS), and it is postulated to be due to an increased influence of the anatomically diffuse reticulospinal tract following stroke-induced corticospinal

tract damage. Coherence among motor unit (MU) discharge is used to determine the frequencies at which motor units are co-modulated, particularly when it is calculated on cumulative spike trains composed of multiple concurrently active MUs rather than MU pairs. Previous studies in humans examining EMG coherence in bilateral arm muscles during startle (Grosse & Brown, 2003) and in neck muscles (Blouin et al, 2007) have suggested that the low-beta frequency band (~10-20 Hz) may reflect reticulospinal drive. The goal of the study was to examine coherence among cumulative MU spike trains from deltoid (DELT), biceps (BIC), and finger flexors (FF) of post-stroke individuals during shoulder abduction (SABD) to explore the frequencies at which coherence appears in muscles of the FS. 6 post-stroke participants with moderate-to-severe impairment and 2 control participants completed the study. The forearm of seated participants was casted to a device capable of measuring isometric shoulder, elbow, wrist, and finger torques simultaneously. 64-channel surface EMG grids were placed on DELT, BIC, and FF. Signals were decomposed into MUs using the Convolution Kernel Compensation technique. Participants performed 2-6 isometric SABD trials at 10%, 25%, and 40% of maximum voluntary torque. For this preliminary analysis, coherence spectra were pooled across all torque levels for each participant group. Pooled spectra were z-transformed and baseline corrected to enable comparison between groups. During SABD, the paretic arm of the post-stroke participants generated substantial elbow and finger flexion torques consistent with FS expression. Participants in the control group did not generate appreciable elbow or finger torques, but MU could be extracted from BIC and FF due to activity related to postural stabilization. In the control group, there was little-to-no significant coherence in the beta band of DELT, BIC, or FF, but significant peaks emerged in the stroke group in all muscles. These preliminary results support the hypothesis of an increased influence of reticulospinal motor pathways in the upper limb following stroke.

Title: A computational approach to understand a valley of motor recovery

Authors: *J. IZAWA[1], Y. MURATA[2], T. HIGO[3], N. SCHWEIGHOFER[4];
[1]Univ. of Tsukuba, Tsukuba/Ibaraki, Japan; [2]The Natl. Inst. of Advanced Industrial Sci. and Technol., Tsukuba, Japan; [3]Natl. Inst. of Advanced Industrial Sci. and Technol., Tsukuba, Japan; [4]Univ. of Southern Calfornia, Los Angeles, CA

Abstract: Improvements in functional performance following a brain lesion can result either from compensation or from true recovery of normative movements. Because compensation can ultimately impede recovery, it is desirable to promote true recovery of normative movements. However, patients are often "trapped" in producing the less effective compensatory movements. What are the computational principles underlying this difficulty in transitioning from compensatory to normative movements? Here, we considered a computational model of neuro-rehabilitation based on Han et al. (2008), in which supervised learning updates the preferred directions (PDs) of motor cortical neurons, and reinforcement learning (RL) updates the values of different actions (see Izawa and Shadmerh 2011 for a similar scheme in motor adaptation). In this scenario, the excessive initial value assigned to the compensatory movements following lesion could prevent a smooth transition to normative movements. To validate this hypothesis, we examined whether the model could replicate the "valley of motor recovery", a drop of the performance in the course of transition between the compensatory and normative movements. In rehabilitation of grip task, monkeys with lesions on the motor cortex exhibit a decline of reward probability when shifting from the compensatory grip to the precision grip (Murata et al. 2008). Assuming vector coding of finger movements, the lesion was modeled by the loss of 50% of cells related to thumb flexion and inaccuracy of the compensatory movement was modeled with a larger motor variability. At the initial stage of the training, the success rate gradually increased as RL assigned higher value on the compensatory movements because the precision grip generated a large biased error due the lesion. Then, as in Murata et al. (2008), we progressively increased the task demand by gradually decreasing the goal size. Then, because the compensatory movements with higher variability led to difficulty in satisfying the required accuracy, the RL decreased the value of the compensatory movements. Since PDs of thumb movement have not yet recovered, the success rate decreased. However, after a selecting two movements with roughly equal probability, the PDs recovered, leading to increased reward probability, and in turn to higher value to the precision grip, overcoming the valley. Our simulation results thus suggest that manipulating rewards to guide the patients to use the damaged skill might be effective to overcome the valley of the recovery.

Title: Hemisphere-specific motor adaptation deficits in the ipsilesional arm of stroke patients

Authors: *V. YADAV[1], D. C. GOOD[2], R. L. SAINBURG[3];
[1]Kinesiology, The Pennsylvania State Univ., University Park, PA; [2]Neurol., Penn State Hershey, Hershey, PA; [3]Kinesiology and Neurol., The Pennsylvania State Univ. and Penn State Hershey, University Park, PA

Abstract: Our previous research has elaborated hemispheric specialization for different aspects of motor control. The hemisphere contralateral to the dominant arm is specialized for mechanisms that can specify smooth and efficient trajectories under consistent environmental conditions, while non-dominant system is specialized for impedance control mechanisms that can stabilize performance under unpredictable conditions. This hypothesis predicts that adaptation to novel dynamics should be learned more readily by the dominant arm, and that this learning should lead to substantial after-effects, reflecting the learned dynamics. In contrast, the non-dominant arm should be able to adapt through impedance mechanisms, but aftereffects should be reduced or inconsistent, since this system did not "learn" dynamics, but rather impeded the applied loads. This prediction was previously tested in healthy adults by our laboratory (Yadav and Sainburg, 2014) and by Schabowski et al. (2007). We now test whether these interlimb differences in learning can be extended to the hemispheres. We have previous detailed hemisphere specific motor deficits in ipsilesional, non-paretic, arm of stroke patients that reflect loss of the contribution of the ipsilateral hemisphere to motor processes. We now test the hypothesis that learning of novel dynamics is disrupted by left (LHD), but not right hemisphere damage (RHD). Stroke survivors performed reaching movements while holding the handle of a robotic device. The robotic device applied a velocity-squared curl field. Our results indicate a limb X hemisphere interaction, such that patients with LHD showed greater deficits in adapting to the field than those with RHD. In addition, movement errors scaled with the extent of damage (Fugl-Meyer score) for the LHD, but not for RHD patients. These results support the hypothesis that the left hemisphere is specialized for predictive control of limb dynamics.

Title: Comparing disruption of bihemispheric motor sites on a reaching task in mild and severe arm impairment after stroke

Authors: *R. HARRINGTON[1], E. CHAN[2], S. MOHAPATRA[3], C. J. WUTZKE[3], A. K. ROUNDS[4], D. ABRAHAM[3], M. L. HARRIS-LOVE[3];
[1]Georgetown Univ., Washington, DC; [2]Medstar Hlth. Res. Inst., Washington, DC; [3]Medstar Natl. Rehabil. Hosp., Washington, DC; [4]George Mason Univ., Fairfax, VA

Abstract: Stroke affects over 610,000 people in the United States every year (1) and many are left permanently disabled (2). Chronic post-stroke arm impairment is particularly disabling and existing treatments are of limited efficacy. There are sites in each hemisphere that it may be beneficial to "prime" in order to enhance the effects of a subsequently applied rehabilitation treatment (3; 4). One such region is the dorsal premotor cortex (PMd). Previous research demonstrates that PMd has a role in motor control of the ipsilateral arm, direct ipsilateral and contralateral projections to the spinal cord, and the ability to flexibly compensate for asymmetries in function between hemispheres (5; 6). The role of PMd in post-stroke arm impairment, how it may differ from that of other cortical areas and with severity of post-stroke arm impairment is not known (7). The hypothesis are that nlPMd, not lPMd, has a greater role in recovered reaching function in severe more than mild patients and that nlPMd, but not nlM1, has a greater role in recovered reaching function in severe patients. 30 individuals with (n=15) or without (n=15) active wrist and finger movements after post-stroke arm impairment participated in a reaching task. Participants were asked to reach as quickly as possible with the affected arm to one of the targets in response to a visual 'Go' signal. TMS was applied between the 'Go' signal and movement onset. Double-pulse TMS (ISI 25 ms) was delivered to nlM1, nlPMd and lPMd at 120% of the individual's Resting Motor Threshold (RMT) for unaffected biceps. Change in movement time was greater with TMS applied to nlPMd than to lPMD in the severely impaired but not mildly impaired participants. A trend in the data shows an interaction effect between severity and hemisphere. Within only the severe group, change in movement time was greater with TMS applied to nlPMd but not to nlM1. Data suggest that nlPMd has a greater role in recovered arm reaching in severely impaired patients than lPMd and that this effect is not present in mildly impaired patients. Additionally, data show that this is not an effect of the contralesional

hemisphere as a whole, but a site specific effect to nlPMd as shown through comparison with disruption of nlM1. This study evaluates the role of nlPMd in recovery of arm function. The results of this study lay the foundation to explore nlPMd as a potential site for upregulation as an adjuvant to traditional therapy in severe patients after stroke. Identification of sites to enhance rehabilitation outcomes of severe patients are essential as there are no currently validated treatments and long-term disability is costly to both personal quality of life and national health care costs.

Title: Motor imagery deficits in individuals with post-stroke hemiparesis

Authors: G. CURTIS, *S. JAX;
Moss Rehabil. Res. Inst., Elkins Park, PA

Abstract: Previous research suggests that simulating movement during motor imagery engages the imaginer's own motor system. One test of the validity of this proposal comes from investigating how motor imagery may be disrupted in individuals with motor dysfunction, such as those who have unimanual motor deficits following stroke. To date, results from motor imagery studies in this population have been inconsistent. Several studies suggest that those with motor impairments are subject to different bodily constraints and thus show disrupted performance on motor imagery tasks, which may be related to functional ability. In contrast, other studies have shown that motor imagery is maintained despite abnormal motor function. To examine the effect of motor impairments on motor imagery, we looked at performance of left and right hemiparetic stroke survivors on the Parsons task. In this task, participants were asked to determine if a picture of a rotated hand was a right or a left hand. Reaction time and accuracy were recorded. Results indicated some evidence for an effect of angle of rotation and direction of rotation on accuracy, as is typically seen in performance on the Parsons task. This suggests that participants were engaging in motor imagery for at least a portion of the task. Consistent with

previous research, there was a trend for those with left hemisphere damage to be less accurate than those with right hemisphere damage. Finally, if motor imagery is based on a modeling of one's own body, there should be a relationship seen between motor impairment severity and motor imagery accuracy. However, no correlation between accuracy on the Parsons task and motor impairment (as measured by Fugl-Meyer scores) was found. This would imply that motor imagery is independent of severity of motor impairment. In summary, results from this study indicate that simulation of one's body during motor imagery is not necessarily constrained by one's motor function and execution abilities.

Title: Inter-trial variability during forward reaching differs with severity in people post stroke

Authors: *C. WUTZKE[1], R. M. HARRINGTON[2], E. CHAN[3], S. MOHAPATRA[4], M. L. HARRIS-LOVE[3];
[1]Veterans Affairs Med. Ctr., Washington, DC; [2]Georgetown Univ., Washington, DC; [3]Natl. Rehabil. Hosp., Washington, DC; [4]Physical Therapy, Univ. of Montana, Missoula, MT

Abstract: Studies examining reaching post stroke have primarily focused on people with mild to moderate motor impairment. However, those with the greatest need for improved reaching performance remain under studied. Inter-trial variability of reaching may provide information necessary for the development of individualized rehabilitation protocols. The purpose of this study was to examine inter-trial variability during a seated reaching task between people with different levels of arm impairment severity. We hypothesized that inter-trial variability would be greater in people post stroke with severe impairment (Upper Extremity Fugl-Meyer [UEFM] score <30) versus people with mild or moderate (UEFM score >35) motor impairment. Twenty-eight people post stroke (13 mild/moderate, 15 severe arm impairment) completed 20 forward reaching movements with the paretic arm in response to a visual 'Go' cue to targets located at

80% of their maximum voluntary reach distance. Spatial (movement units (reversals in tangential velocity during a reach)) and temporal (response time, movement time, peak velocity, time to peak velocity) variables were collected with motion capture and a marker placed on the paretic wrist. Coefficients of variation were calculated to determine inter-trial variability of each measure in each participant. The mean coefficient of variation was calculated for participants categorized as mild/moderate or severe. An independent t-test was conducted to identify differences between impairment groups. Compared to participants with mild/moderate motor impairment, severely impaired people had greater inter-trial variability of response time (mild/moderate 0.15, severe 0.30; $p=0.002$) and movement time (mild/moderate 0.19, severe 0.41; $p<0.001$). Inter-trial variability of reaction time however, did not differ between impairment groups (mild/moderate 0.29, severe 0.31; $p=0.799$). Movement units (mild/moderate 0.35, severe 0.61; $p=0.018$), peak velocity (mild/moderate 0.10, severe 0.22; $p<0.001$), and time to peak velocity (mild/moderate 0.19, severe 0.54; $p=0.007$) were also more variable in people with severe motor impairment. These results suggest that people post stroke with severe motor impairment have greater inter-trial variability during a forward reach than people with mild/moderate motor impairment. This increased variability may be influenced by reduced control of paretic arm movement due to reduced integrity of the corticospinal tract. Strokes that include the internal capsule, for example, compromise the relay of motor commands to the paretic arm potentially leading to difficulty controlling the movement.

Title: Toward robotic assessment of proprioception in 3d space

Authors: *J. D. KLEIN[1,2,3], B. WHITSELL[4,1], P. ARTEMIADIS[4,1], C. A. BUNEO[5,1]; [1]ASU, Tempe, AZ; [2]Interdisciplinary Grad. Program in Neurosci., Tempe, AZ; [3]Alliance for Person-centered Accessible Technologies IGERT Program, Tempe, AZ; [4]Sch. of Engin. of Matter, Transport, and Energy, IRA A. Fulton Sch. of Engin. Arizona State Univ., Tempe, AZ;

[5]Sch. of Biol. and Hlth. Systems Engineering, Ira A. Fulton Sch. of Engin. Arizona State Univ., Tempe, AZ

Abstract: Proprioception is the sense of body position, movement, force and effort. Loss of proprioception can affect planning and control of limb and body movements, negatively impacting activities of daily living and quality of life. Proprioceptive assessment is typically performed in the clinic by human examiners, who can potentially provide tactile cues to the subject and who are typically unable to precisely reproduce test positions across trials. Assessments employing planar robots can overcome these limitations but constrain movement and arm configuration within a 2d plane. We have developed a novel paradigm which enables reliable testing of arm proprioception along arbitrary paths in 3d space while also allowing for testing of different arm configurations for the same end point path. A 7-DoF anthropomorphic robot arm (LWR4+, KUKA Inc.) is used for the robotic assessment. Participant's arm is coupled through a trough that stabilizes the wrist and forearm allowing for control of arm posture at the elbow and shoulder. Sensitivity to imposed displacements of the endpoint of the arm are evaluated using a "same-different" task, where subjects are asked to identify if a particular endpoint as the "same" or "different" than a previously visited reference position. The proportion of trials where subjects respond "different" when the stimuli are different ("hit rate"), and where they respond "different" when the stimuli are the same, ("false alarm rate"), are used to calculate d', a measure of sensitivity derived from signal detection theory. Percent correct trials are also calculated. Preliminary data from 4 subjects comparing sensitivity to displacements along a single, vertical axis showed that sensitivity was remarkably consistent across subjects, showing little change in slope for differences in endpoint positions from 1-2 cm, and increasing rapidly in slope thereafter. Across subjects performance reached 75% correct (a standard threshold for discrimination) at a difference slightly greater than 3 cm, consistent with previous studies. The results suggest that the paradigm is suitable for assessment of proprioception in 3d space, which may allow for a more complete characterization of proprioceptive function following nervous system damage. Moreover, the ability to assess multiple joint configurations has the potential to provide a deeper understanding of proprioception with respect to different coordinate systems and a clearer.

Title: Employing a binary decision tree algorithm to identify the abduction load threshold at which loss of independent joint control arrests reaching motion in stroke

Authors: *M. D. ELLIS, C. J. LIANG, M. E. RICHARDSON, K. R. SIPPLE, D. O. TAFELSKI, J. P. A. DEWALD;
Dept. of Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Quantitative measurements with the ACT^{3D} robotic device have been used to evaluate the impact of loss of independent joint control, or abnormal coupling of shoulder abduction with elbow flexion, on reaching function. The haptic device quantifies the deleterious effects of increasing abduction loads up to and beyond the weight of the arm on planar reaching range of motion. Prior work has validated a laboratory-based protocol, reaching work area, however it is time-inefficient and produces several variables. Here we have reduced the original method by employing a binary decision tree algorithm and targeting the threshold where abduction loading and the associated loss of independent joint control minimizes reaching to zero. The newly developed metric results in a single value. The criterion validity was assessed and we hypothesized that the Maximum Reaching Abduction Load, the shoulder abduction load at which reaching is reduced to zero, would have a strong and significant correlation with a gold standard clinical evaluation of arm function. Ten participants (7 men, 3 women) age 48-69 with chronic stroke (4-29 years post-stroke) scored 16-36/66 on the arm motor Fugl-Meyer Assessment and 3-4/7 on the Ranchos Los Amigos Functional Test for the Hemiparetic Upper Extremity. Maximum Reaching Abduction Load was identified using a protocol that began first by finding the maximum isometric abduction strength using the ACT^{3D} robot. Reaching performance was then assessed with the ACT^{3D} robot using shoulder abduction loads standardized to maximum strength employing a binary decision tree algorithm to quickly identify the Maximum Reaching Abduction Load. Correlation analysis was performed for the robotic and clinical measure using a Spearman rank correlation coefficient with a 2-tailed t-test and alpha level of 0.05. There was a strong and significant correlation ($r_s = 0.685$, $p = 0.029$) between Maximum Reaching Abduction Load (absolute force) and the Arm Motor Fugl-Meyer Assessment. Criterion validity was supported. Importantly, the efficiency of the protocol was reduced substantially from prior reports of 1.5 to 3 hours for the original laboratory-based measure of reaching work area. Further research should be conducted using a larger, more diverse sample size to increase generalizability and establish this metric as the gold standard for quantifying loss of independent joint control following stroke.

Title: Role of stretch and startle reflexes in falls following stroke: insights from treadmill induced balance perturbations

Authors: *D. CELINSKIS[1], M. D. GRABINER[2], C. F. HONEYCUTT[1];
[1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [2]Dept. of Kinesiology and Nutr., Univ. of Illinois, Chicago, IL

Abstract: Stroke is the leading cause of disability with falls being a major risk factor for stroke survivors. The lack of understanding of the mechanisms leading to the high prevalence of falls in this population degrades the efficacy of existing rehabilitation interventions. The long-term goal of the present work is to expand our understanding of factors contributing to falls and establish predictors for the identification of fall-prone individuals. Reflexive compensatory movements (e.g. taking a step during a balance disturbance) play a major role in maintenance of balance and recovery during a fall. Stroke survivors are known to exhibit heightened reflexes. We hypothesized that abnormally expressed stretch and startle reflexes contribute to falls. Studies on these reflexes in stroke survivors have been previously reported, but we are first to investigate these involuntary responses in full-body postural perturbations large enough to provoke a fall. To test our hypothesis, sixteen unilateral stroke survivors were recruited. These individuals were exposed to backward perturbations, evoking a forward step. This resulted in 16 falls out of 86 trials. We characterized performance of fallers and non-fallers using EMG and kinematic data. The implication of stretch reflex in falls was evidenced by the presence of abnormal early EMG activity in the reflex time window of 50-110 ms. In addition to having early onset, this activity exhibited significant perturbation level dependency. This translates directly to velocity dependent nature of spastic stretch reflexes commonly present in stroke survivors. Most notably, this activity was increased with falls and in fallers. These observations support our hypothesis and form the basis for future research on abnormal stretch reflex as potential predictor for falls in stroke population. The role of startle reflex in falls was more complex. Startle trials were observed to involve shorter latencies and increased magnitudes of pre-stepping EMG activity in all monitored muscles. Importantly, these changes were shown not to be beneficial for recovery from falling. This was evidenced by the similarly faster and stronger muscle activity present in

falls. Prevalence of startle was observed to be insignificantly higher in the trials resulting in falls and almost equal between fallers (65%) and non-fallers (63%). All these observations suggest that startle cannot be the main mechanism neither impairing compensatory movements nor facilitating them. In conclusion, our results indicate that heightened stretch responses may contribute to falls, but further research is required to understand the role of startle reflex in these responses.

Title: Effects of post-stroke extension/adduction coupling in the lower extremity during gait initiation: preliminary results

Authors: *N. SANCHEZ[1], A. C. DRAGUNAS[2], J. P. A. DEWALD[1], K. E. GORDON[1]; [2]Biomed. Engin., [1]Northwestern Univ., Chicago, IL

Abstract: Introduction: Previous research by our group has demonstrated that during hip extension tasks, post-stroke individuals generate spontaneous grouped extension/adduction torques in both legs, referred to as an extensor synergy. Specifically, in isometric conditions, when individuals were instructed to generate a hip extension torque a concurrent abnormal hip adduction torque was observed. This pattern was identified in both the paretic and non-paretic extremity. In the present study, we quantified how these hip joint torque coupling constraints translate to gait initiation, a dynamic task. During gait initiation each limb has a very specific role: the leading leg is in charge of foot placement while the supporting leg generates forward propulsion and lateral stability. In order to accomplish these tasks, the supporting leg simultaneously generates hip extension and abductions torques. Given the known extensor synergy, we propose to assess how individuals post-stroke accomplish a dynamic task requiring simultaneous generation of hip extension and abduction torques. We hypothesize that the extension/adduction constraint at the hip observed isometrically will affect gait initiation given

the inability to combine hip extension with hip abduction. Methods: Two chronic stroke individuals and two age-matched controls performed a gait initiation task. A motion capture system and force plates recorded kinematics and kinetics. With the aid of visual feedback, subjects began each trial with their body weight equally distrusted between their two limbs. When the weight distribution was held stable for three seconds, a "GO" cue appeared on the screen. Individuals initiated gait leading with either the paretic or non-paretic extremity five times. The leading leg was determined randomly before each trial. Data was processed and used to calculate internal moments about the hip joint. Results: Post-stroke individuals generated a hip adduction torque offset before gait initiation on both extremities. As soon as an extensor moment was generated, this adduction moment increased as a function of hip extension; no net hip abduction torque was generated. In contrast, control individuals began the trial with a slight hip abduction moment. Once hip extension was generated on the support leg, no changes in hip abduction torque were observed, indicating that hip abduction and hip extension moments were controlled independently. Implication: The abnormal joint torque coupling pattern observed during gait initiation may help explain the underlying mechanisms for increased pelvic instability in the transverse plane reducing balance in post-stroke individuals.

Title: Reduced pedaling-related brain activation volume post-stroke does not depend on task performance

Authors: *B. CLELAND, S. SCHINDLER-IVENS;
Marquette Univ., Milwaukee, WI

Abstract: Numerous studies have shown that movement-related brain activation, as measured with functional imaging, is altered after stroke. These observations are suggestive of injury-related and/or recovery-related neuroplasticity. However, stroke is also associated with altered task performance, which confounds the interpretation of imaging data. Our laboratory recently

encountered an example of this performance confound when we discovered that pedaling-related brain activation volume during fMRI was reduced in stroke survivors as compared to controls. Reduced volume could be due to neuroplasticity, or it could be the result of altered pedaling performance. Here, we examined this issue by using passive pedaling to minimize between-group differences in performance. We hypothesized that, if reduced volume of brain activation post-stroke was due to altered pedaling performance, then between-group differences would be reduced or eliminated during passive pedaling. Stroke (n=6, 66 ± 8 yrs) and control subjects (n=5, 61 ± 4 yrs) performed passive and volitional pedaling during fMRI. During passive pedaling, subjects relaxed their limbs while an investigator moved the pedals. Volitional pedaling was performed with no investigator intervention. We used a block design consisting of 3 runs each of passive and volitional pedaling at 2 workloads. Each run consisted of 20 sec of pedaling followed by 20 sec of rest, repeated 5 times. To identify significantly active voxels, general linear modeling was used to fit blood-oxygenation-level-dependent (BOLD) signals to a canonical function. A family-wise error rate of $p<0.05$ was achieved through Monte Carlo simulation. Volume of activation was extracted from active regions in the sensorimotor cortex, namely primary motor cortex (M1), primary sensory cortex (S1), and Brodmann's area 6. Results show that, regardless of condition (passive, volitional), brain activation volume was lower in stroke subjects as compared to controls ($F=4.96$, $p=0.053$). Mean ± SD values for passive and volitional pedaling were 12959 ± 9650 μL, 10791 ± 5994 μL (load 1), and 10378 ± 10800 μL (load 2) in the stroke group and 20633 ± 11333 μL, 23591 ± 8518 μL (load 1), and 23355 ± 7792 μL (load 2) in controls. There was no main effect of condition ($F=0.027$, $p=0.973$) and no group*condition interaction ($F=0.835$, $p=0.469$). Our observations suggest that reduced pedaling-related brain activation volume post-stroke does not depend on task performance, as reduced volume was apparent during passive pedaling when performance differences were minimized. Hence, other explanations for reduced volume, including neuroplasticity, should be considered.

Title: Grey and white matter changes associated with periodic leg movement during sleep: a magnetic resonance imaging study

Authors: ***M.-A. D. GAREAU**, A.-A. BARIL, D. GILBERT, N. GOSSELIN, A. DESAUTELS;
Hôpital Du Sacré Coeur De Montréal, Montreal, QC, Canada

Abstract: INTRODUCTION: Periodic leg movements during sleep (PLMS) are repeated and stereotyped motor activity characterized by extension of the hallux and dorsiflexion of the ankle, with occasional flexion of the knee and hip. Recent studies showed a temporal association between PLMS and activation of the sympathetic nervous system, characterized by an important increase in blood pressure and heart rate. Chronic high blood pressure may impair the cerebral microvasculature and compromise the cerebral white matter (WM) integrity, which could also lead to grey matter (GM) damage. In this study, we investigated the presence of WM and GM changes using magnetic resonance imaging (MRI) in subjects presenting PLMS. METHODS: MRI sequences (T1-weighted Multi-Echo MPRAGE; Diffusion tensor imaging (DTI) with 64 directions) were acquired for 26 subjects (6 Females; 64.0 ± 6.6 years old) presenting varying levels of PLMS severity (PLMS index: 20.8 ± 22.5 events/h, range: 0.0 to 79.3 events/h). GM density was measured using voxel-based morphometry and DTI was used as a correlate of the WM integrity using track-based spatial statistics. Maps of DTI metrics were calculated for each subject and included fractional anisotropy, mean diffusivity, axial diffusivity and radial diffusivity. Correlational analyzes were performed between PLMS characteristics (index, association with arousal, duration, inter-movement interval) and neuroimaging variables with a height threshold of $p<0.001$ uncorrected for multiple comparisons and an extended threshold of 50 contiguous voxels. RESULTS: No correlation was found between DTI metrics and PLMS characteristics. However, a higher PLMS index was correlated with reduced GM density in three regions, namely the right supramarginal gyrus, the right mid-cingulate area and the left middle temporal gyrus. longer inter-movement intervals were associated with reduced GM density in a large cluster extending from the left cerebellum to the left lingual gyrus. Finally, a longer duration of PLMS was associated with reduced GM density in the left cerebellum and the left inferior parietal lobule. CONCLUSIONS: PLMS characteristics that reflected higher severity, i.e. higher index, longer PLMS duration and longer inter-movement interval, were associated with reductions in GM density in the parieto-temporal areas, the cerebellum and the cingulate gyrus. However, no changes were found in WM integrity. Although the pathophysiological substrate and clinical significance of these findings are unclear and results need replication, the association observed in our cohort suggests that PLMS may alter brain structure.

Title: Neuromuscular control bandwidth at the elbow following stroke

Authors: M. C. BENGTSON[1], T. STOECKMANN[2], L. A. MROTEK[3], C. GHEZ[4], *R. A. SCHEIDT[1,5];
[1]Biomed. Eng, [2]Physical Therapy, Marquette Univ., Milwaukee, WI; [3]Kinesiology, Univ. of Wisconsin, Oshkosh, Oshkosh, WI; [4]Physiol. & Cell. Biophysics, Columbia Univ. Med. Ctr., New York, NY; [5]Physical Med. and Rehabil., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Motor deficits after stroke may reflect changes in the timing of muscle initiation and termination, which can degrade joint torque production and impede motor coordination. Better understanding of these deficits may guide development of rehabilitative strategies to restore functional movement post-stroke. Here, we quantified deficits of control bandwidth in 4 hemiparetic stroke survivors (HS) and 4 age-range matched, neurologically intact controls (NI) during 2 isometric torque-tracking tasks. The affected (HS) or preferred (NI) arm was positioned horizontally with the elbow flexed to 90° and the forearm attached to a custom handle that measured elbow joint torque. Surface electromyograms (EMG) were recorded from elbow flexors and extensors. Maximal voluntary contractions (MVCs) were collected for elbow flexion and extension. Subjects viewed a computer screen that cued either an oscillating 'chirp' torque-tracking target (oscillation frequency increased linearly from 0.1 to 20 Hz within each 120 s trial) or discrete, step changes in desired elbow torque, transitioning pseudorandomly between flexion and rest or extension and rest. Real-time feedback of torque at the elbow was also provided. Torque target magnitude was defined as 20% of that measured during MVC. EMGs were zero-meaned and notch filtered (60 Hz), rectified, low-pass filtered (20 Hz) and normalized to MVC. Muscle pairs were used to calculate 2 measures of joint coordination at the elbow: agonist / antagonist co-activation (CoA) and reciprocal activation (ReA). Control bandwidth was defined as the tracking frequency for which torque-tracking amplitude dropped below 71% of baseline performance. HS demonstrated reduced torque-tracking bandwidth relative to NI controls (0.34±0.02 Hz vs. 1.28±0.58 Hz, respectively). This performance deficit was coincident with a two- to three-fold increase in flexor / extensor CoA at failure, but no consistent group-wise

change in ReA. In step tracking, reaction times were greater post-stroke (HS: 361±125 ms; NI: 161±70 ms) as were torque development times (HS: 697±163 ms; NI: 405±88 ms) and torque relaxation times (HS: 651±112 ms; NI: 415±85 ms). Surprisingly, we did not find a consistent inability to produce coordinated reciprocal activations during the step transitions post-stroke. Instead, performance deficits appeared to be related to increased flexor / extensor CoA. A computational model of performance in the chirp-tracking task suggests that neuromuscular control bandwidth is limited by deficits in the temporal activation and deactivation of individual muscles, thus contributing to deficits in muscular coordination.

Title: A model identifiability analysis for separating the relative neural and muscular contributions to weakness after stroke

Authors: *P. COOMAN, F. HUANG, J. L. PATTON;
Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Weakness is the most common motor deficit following stroke, yet current diagnostic tools do not elucidate its underlying neuromuscular impairments. Researchers have attempted to diagnose these impairments by comparing biomechanical models to experimental data. However, experimental data tend to be sparse and noisy, while there are often many model parameters to be estimated. Since experiments in human motor control are often time consuming and laborious, there is a need for a single test that provides sufficient information to unambiguously estimate all of the free model parameters. Using a simplified biomechanical model of the human elbow dynamics, we tested whether kinematic data contains sufficient information to recover a known combination of muscle atrophy and decreased motor commands. Our model consisted of a single arm segment corresponding to the forearm, restricted to move in the horizontal plane by rotating about a hinge joint representing the elbow. The joint was actuated by one antagonistic muscle pair consisting of the biceps and triceps, each described by a Hill-type muscle model. The free

model parameters were: 1) the optimal biceps force (F_(opt,biceps)=800[N]), 2) the optimal triceps force (F_(opt,triceps)=600[N]), and 3) a proportional decrease in motor commands (α=0.75). We fitted these three model parameters 100 times, minimizing the residual error between the model predictions and the simulated output kinematics. For each model regression, the optimization algorithm was initialized with a different randomized population. This resulted in 100 sets of fitted model parameter values. We found that these calibrated parameters were functionally related to each other, meaning that there are an infinite number of parameterizations that explain the simulated kinematics equally well. Further analysis showed that including EMG measurements allowed us to unambiguously recover the true, unique solution. In future work we will build on these initial results by analyzing more complex human arm models and fitting them to experimental data obtained from both neurologically intact individuals and stroke survivors.

Title: Relationship between skilled reach performance and corpus callosum integrity in individuals with mild motor impairment after stroke

Authors: *J. C. STEWART[1], M. O'DONNELL[1], K. HANDLERY[1], C. J. WINSTEIN[2]; [1]Univ. of South Carolina, Columbia, SC; [2]USC, Los Angeles, CA

Abstract: Changes in white matter pathways can occur after stroke due to both direct and remote effects of the lesion that correlate with motor impairment. While deficits in skilled reaching after stroke have been well documented, the relationship between white matter structural integrity and measures of skilled reach performance are not currently known. The purpose of the current study was to examine the correlation between reach kinematics and the integrity of two white matter pathways: the corticospinal tract and the corpus callosum. Eleven individuals with mild motor impairment due to stroke (mean UE FM motor score 54.2±7.6; months post-stroke 62.5±42.4) and no lesion in the cerebral peduncle or the corpus callosum reached to targets displayed in two

directions (ipsilateral, contralateral). Mean movement time, peak velocity, peak acceleration, and endpoint error were extracted for reaches with both the paretic and nonparetic arms. Fractional anisotropy (FA) was calculated from diffusion tensor images and used to determine structural integrity of the corticospinal tract in the cerebral peduncle and the motor and premotor sections of the corpus callosum. Reaches with the paretic arm had significantly lower peak velocity, lower peak acceleration, longer movement times and greater endpoint error than reaches with the nonparetic arm ($p<0.02$). The premotor section of the corpus callosum showed a significant correlation with movement time ($r=-0.64$) and peak acceleration ($r=0.61$) for reaches with the paretic arm and movement time ($r=-0.75$) and peak acceleration ($r=0.77$) for reaches with the nonparetic arm. No measures of reach performance correlated with FA in the motor section of the corpus callosum or the corticospinal tract. Additionally, there was no correlation between UE FM motor score and SIS hand domain score and FA in any of these brain regions. The structural connections between the two premotor cortices, areas commonly reported to support motor recovery after stroke, may play an important role in the control of skilled reach behavior in individuals with mild motor impairment. These results may have implications for interventions that target skilled reaching or include brain stimulation in combination with functional task training.

Title: Improvement of voluntary control of post-stroke paretic hands using a novel assistive system - Rein Hand: preliminary findings

Authors: *J. YAO[1], C. CARAMONA[1], J. SULLIVAN[1], K. WILKINS[1], E. LEE[1], A. MOORE[1], N. PARMANN[1], S. WOJTON[1], Z. GARCIA[2], J. P. A. DEWALD[1];

Abstract: Purpose: Approximately, 75% of survivors with moderate to severe stroke (i.e., our target population) lose hand function. Neuromuscular electrical stimulation (NMES) has been shown to be successful in improving wrist muscle strength and reducing muscle tone. Unfortunately, no methods to date have proven to be effective in improving voluntary functional hand control in our target population, partially because the previous NMES in not employed in a functional context requiring changes in shoulder abduction loading and reaching and retrieval activities. In order to address this gap in functionality, this study tests a newly developed electromyography-triggered NMES system - ReIn-Hand - to regain voluntary hand opening in this population during functional activities. We hypothesize that using the ReIn-Hand system during functional activities will help our target population to improve voluntary hand opening function. Methods: Two individuals with moderate to severe chronic stroke completed a total of 15-22 sessions, 3 sessions per week. In each training session, subjects used the paretic arm to perform 20-30 trials of tasks involving reaching, grasping, and releasing with the assistance of ReIn-Hand and various levels of shoulder abduction loading. Active range of motion, Chedoke MacMaster (CMcM) (stroke-assessment hand portion), Semmes-Weinstein monofilament test, the Nottingham Assessment (stereognosis portion), and grip strength were assessed before and after the intervention. Additionally, S2 was assessed with the box and block test (BB). Results: Pre-intervention, both subjects demonstrated decreased voluntary hand control, and the expression of shoulder abduction with elbow/wrist and finger flexion. Additionally, Subject 1 (S1) had sensory impairment and increased muscle tone, while subject 2 (S2) had muscle weakness, mild sensory impairment, and mild increase in muscle tone. By the end of the intervention, both subjects had improved sensation, grip strength and increased voluntary index finger extension at the metacarpal-phalangeal joint. S2 demonstrated improvements in CMcM, and increased gross manual dexterity (BB from 0 to 3-6 blocks during the last week of intervention). Conclusions: These preliminary results suggest that using the ReIn-Hand during functional reach/grasp activities is effective in improving voluntary hand control and sensory perception in individuals with moderate to severe chronic stroke. Further investigation is needed to evaluate the effectiveness of the ReIn-Hand system in larger populations and using additional quantitative measurements.

Title: Feasibility of transcranial Random Noise Stimulation combined with repetitive reaching practice in stroke survivors with chronic and severe paresis: A triple blind pilot RCT

Authors: *K. S. HAYWARD[1,2,4], K. L. RUDDY[5], D. LLOYD[3], S. G. BRAUER[2], R. N. BARKER[4,6], R. G. CARSON[7,8];

Sci. and Technol., Swiss Federal Inst. of Technol., Zurich, Switzerland; [6]Community Rehab northern Queensland, Townsville Mackay Medicare Local, Townsville, Australia; [7]Trinity Col. Inst. of Neurosci. and Sch. of Psychology, Trinity Col., Dublin, Ireland; [8]Sch. of Psychology, Queens Univ., Belfast, United Kingdom

Abstract: Background: Reaching training can promote functional recovery in stroke survivors with severe arm paresis. To amplify cortical activity and enhance functional benefits, non-invasive brain stimulation (eg transcranial-direct current stimulation) has been combined with training, but with limited success in people with severe paresis. An alternative approach is transcranial random noise stimulation (tRNS). Here, it is thought that by adding random noise, the detection of weak stimuli (or the information content of a signal) will be enhanced and thus, boost the adaptive potential of the stimulated cortical area. Aim: Investigate the feasibility of combining reaching training with tRNS timed to coincide with the generation of a voluntary motor command in stroke survivors with chronic and severe arm paresis. Methods: A triple-blind pilot RCT was completed. Four stroke survivors were randomly allocated to 4-weeks of reaching training with active (n = 2) or sham (n = 2) tRNS delivered over C3/C4. tRNS delivery was triggered by a 'go' signal so as to coincide stimulation with a voluntary movement attempt and ceased after 5-seconds. At this point, electrical stimulation to triceps brachii could be triggered to enable full range reaching. To determine feasibility we considered 1) ability to complete repetitive training, 2) improvement in clinical outcomes between time-points (pre-, post-training, follow-up) and 3) adverse events. To determine if ability to engage in training was contingent upon structural integrity of descending white matter projections, diffusion weighted imaging of the posterior limb of the internal capsule (PLIC) was undertaken. The asymmetry index (AI) between lesioned and non-lesioned hemisphere PLIC projections was calculated, with an AI >0.15 classified as loss beyond the point of no return (PNR). Results: All participants completed all training sessions, engaged in repetitive practice and demonstrated some clinical improvements, irrespective of tRNS group and PNR classification (Table 1). There were no

adverse events. Conclusion: Reaching training that includes tRNS timed to coincide with the generation of voluntary motor commands is feasible. Table 1: Characteristics & outcomes.

Title: Mobility rehabilitation in acute stroke using a wearable ankle robot

Authors: *D. JIN[1], Y. REN[1], K. CHEN[1], R. HARVEY[1], E. ROTH[1], S. PRABHAKARAN[2], L.-Q. ZHANG[1];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Inst. for Publ. Hlth. and Med. (IPHAM),Northwestern Univ. Clin. and Translational Sci. Inst. (NUCATS), Chicago, IL

Abstract: Background and Purpose: Over 7 million individuals currently in the US with stroke-related disabilities, joint impairments of paretic limb is a prevalent symptom and closely associated with limitation in ambulation post stroke. In acute stroke, 50-70% of stroke survivors regained functional independence, it was reported that the first few months post stroke is critical in neuroplasticity and motor recovery. Presently, effective treatment options for ankle impairment and mobility are limited; there is a lack of devices and protocols for in-bed acute stroke rehabilitation. In treating with joint impairments post stroke, stretching has been commonly used to reduce joint stiffness and increase range of motion. However, there is a lack of convenient and effective ways in regular treatment to conduct controlled passive stretching and motivating active movement training with quantitative outcome evaluation. In this study, in-bed wearable robot training involving stretching and active movement training was investigated. Methods: Fifteen patients with acute stroke participated in the combined passive stretching and active movement training using a wearable robot in an in-patient setting (45 minutes/session, 3~5×/week, total 18 sessions). They continued receiving standard of care during the study. One way repeated measures ANOVA with repeated measures was used to compare clinical and biomechanical outcome measures. Results: Results showed improvements after the multiple sessions of training with Fugl-Meyer Lower Extremity (LE) increased from 16.0 ±8.4 to 18.6 ± 7.1 ($p<0.01$), STREAM total score from 50.0±31.2 to 59.7±30.6 ($p<0.05$), Berg Balance Score from 23.0±19.5 to 28.7±20.1 ($p<0.05$). The ankle modified Ashworth Scale decreased from 2.8±0.8 to 2.0±0.9 ($p=0.05$). Ankle dorsiflexion active range of motion increased from -0.9±7.4 to 4.1 ± 7.6°(- means it was still in plantar flexion, $p=0.004$). Dorsiflexor strength increased from 1.8±5.6 Nm to 4.4±8.1 Nm ($p=0.05$). Plantar flexor strength increased from 9.1±12.7 to 13.1±13.2 Nm ($p<0.05$). Conclusions: Robot-aided acute stroke rehabilitation demonstrated improvements in terms of biomechanical and clinical outcomes. The results supported clinical use of this novel device coupled with clinical therapy to promote sensorimotor outcomes for the acute stroke survivors. Limitations of this study include small sample and lack of a control group.

Title: Designing myoelectric computer interfaces to improve arm function in chronic stroke

Authors: *M. W. SLUTZKY, E. M. MUGLER, E. W. LINDBERG;
Neurol., Northwestern Univ., Chicago, IL

Abstract: Stroke causes the most disability of any disease. In addition to weakness and impaired sensation, a stroke can also affect arm function by impairing muscle activation patterns. This abnormal co-activation can prevent subjects from fully participating in standard physiotherapy. We have designed a myoelectric-computer interface (MCI) paradigm that maps activations of a pair of abnormally coupled muscles to orthogonal components of computer cursor movement (Wright et al., Neurorehabilitation and Neural Repair 2014). Stroke subjects learn to decouple these muscle activations by moving the cursor to targets along the mapping directions in a computer game. In this study, we are investigating which aspects of MCI design contribute most to arm function improvement. Chronic stroke survivors use the MCI to decouple 3 muscle pairs in the upper arm over 18 sessions. We are evaluating the effects of duration of training (either 60 or 90 minutes per session) and isometric vs. movement-based muscle activations to control the MCI. We have also improved game design and level of difficulty to enhance motivation. We measure the following outcome metrics at weeks -2, 0, 2, 6, and 10 relative to the start of training: level of co-activation and arm joint kinematics during free reaching, Fugl-Meyer Assessment (FMA), Wolf Motor Function Test (WMFT), Motor Activity Log (MAL), and Modified Ashworth Scale (MAS). Our early results, in 4 subjects, demonstrated improvement from baseline to the end of training. Co-activation levels declined in all subjects in the targeted muscles, and elbow extension improved substantially in all subjects. Less-sensitive functional and impairment scores showed modest improvement (FMA +2.1, Wolf -25.6 s, MAL +12.5), and spasticity decreased by 5.8 points. We expect further testing will reveal more detailed effects of dose and movement-based training on functional outcomes. These results suggest that MCI training can reduce abnormal co-activation and spasticity and improve upper arm function in chronic stroke survivors. If successful, this paradigm could have a broad impact, since it could be made into an inexpensive and portable device that many survivors could incorporate into their daily routine.

Title: Testing the feasibility of way-finding combined with aerobic activity after stroke

Authors: ***L. WILLIAMS**[1], A. TRINH[1,2], A. MANSFIELD[3,4,2], D. BROOKS[4,3,2], N. ANDERSON[5], W. E. MCILROY[1,4,2];

Abstract: Stroke is one of the leading causes of long term disability in North American adults, leading to deficits in motor function, cardiovascular capacity and cognitive impairments. Exercise interventions have demonstrated positive impacts on brain health in various populations, and therefore may aid in the rehabilitation of cognitive, sensorimotor and cardiovascular impairments in a stroke population. However, current protocols challenge physical capacity but do not concurrently challenge executive function. We propose that stroke patients are capable of more fully engaging in executive tasks while performing aerobic activity. Specifically, we challenged executive function by having participant's way-find through the rendered version of street view within Google Earth™. Way-finding was chosen because it is a complex cognitive task, and is considered an ecologically valid task with natural links to locomotion. The objective of this study was to determine the feasibility of combining aerobic activity and way-finding in a stroke population, to examine if there were group differences in dual task performance. Four stroke patients and 3 healthy adults performed aerobic activity on a semi-recumbent stepper. Participants completed 4 five minute blocks of aerobic activity with approximately 2 minutes between blocks. Participants were asked to step at a self-selected cadence. Tasks alternated between activity alone and activity coupled with way-finding. Cadence, heart rate (HR), and rate of perceived exertion (RPE) were recorded as well as geographic coordinate data from Google Earth™ in order to determine performance of the way-finding task. Stroke patients displayed the same behavioral characteristics as control subjects in

both conditions. Both groups showed decreases in cadence when executive function was simultaneously challenged with way-finding. All participants were able to maintain or increase target power output and HR throughout activity. This sample of stroke patients demonstrated the capacity to couple aerobic activity with the executive task of way-finding without sacrificing workload. Ongoing work is implementing this protocol as a training program in a stroke population. Funding support: Canadian Partnership for Stroke Recovery

Title: Assessment of tissue using high resolution MRI following intracortical multi-shank microelectrode array implantation

Authors: *A. J. WOOLLEY[1,3], A. BONGERS[2], N. H. LOVELL[1], J. W. MORLEY[3]; [1]Grad. Sch. of Biomed. Engin., [2]Biol. Resource Imaging Laboratory, Mark Wainwright Analytical Ctr., Univ. of New South Wales, Sydney, Australia; [3]Sch. of Med., Univ. of Western Sydney, Sydney, Australia

Abstract: Brain penetrating, multi-shank microelectrode arrays, like the 'Utah Array' (Blackrock Microsystems), are invaluable tools for neurophysiologists. They are also potentially ground-breaking medical devices, holding great promise as neuroprosthetic implants. However the acute and long-term tissue impact of these devices on surrounding cerebral cortex is difficult to fully characterize using the histological methods that are typically employed. Work presented here describes results from utilizing a high resolution MRI system (9.4 Tesla) to assess brain tissue following implantation of intracortical, 100-shank electrode arrays. Imaging was performed on blocks of fixed feline brain tissue (Fig.1A). Areas of sub-surface hemorrhaging were visible in the MRI data in tissue collected 2-days following surgery (Fig.1B,1C,1D). These hemorrhages and micro-hemorrhages were not visible at all depths in the tissue, and could be found in cortical layers below the implant shanks, an area easily overlooked by investigators using typical histological analysis methods. Electrode tracks were clearly visible within tissue in

which the device was explanted, provided a reasonable guide to the depth of device implantation upon tissue collection and fixation. MRI data collected with arrays *in situ* demonstrates that similar methods may be employed at the termination of future, long-term studies to potentially document dural encapsulation and retraction of devices from brain tissue. Overall, high resolution MRI is demonstrated to be a promising method to assess important 'wide view' features of the tissue response to implanted microelectrode arrays, and may be utilized to fill an important gap in our understanding of how multi-shank implants impact surrounding brain tissue.

Abstract: Although fibrillar collagen is not commonly found in the brain parenchyma, complex networks of fibrillar collagen can be observed around neural devices, including but not limited to implanted electrodes. Previous studies in the central nervous system have implicated microglial and astrocytic mediated responses to device implantation as primary factors in implant failure. The role of the extracellular matrix (ECM) that encompasses these cells however, is not well understood. Collagen deposition and remodeling throughout the ECM in tumor models has shown a potentiation of invasive cancer cells migrating along collagen fibers. It would therefore follow that the collagen fibers that form within a wound site could provide the pathway necessary for the reactive immune response observed following neural device implantation, and may be critical to understanding the biological mechanisms underlying device failure. It may also have implications for the logical design of devices for longer lasting brain-machine interfaces. This study used second harmonic generation (SHG) imaging on a multiphoton microscope to observe the extent to which fibrillar collagen is involved in the ECM of neural wounds. SHG imaging is attractive to neuroscientists not only because the number and orientation of detectible collagen fibers can be quantified, but also because the imaging takes advantage of an intrinsic property of collagen fibers without the addition of extrinsic dyes or fluorophores. Thus, SHG imaging has great potential for further neurosurgical applications.

Abstract: The transparent, graphene-based micro-electrocorticography (μ-ECoG) electrode array is an implantable device that is capable of advanced *in vivo* neural imaging, electrophysiological recordings, and optogenetic stimulation. Previous *in vivo* studies with conventional metal electrode were limited to monitoring the tissue surrounding μ-ECoG electrode sites due to the opaqueness of the metal. Optical stimuli through the electrode sites and traces were also impossible with metal electrode arrays. Graphene, a novel material made of carbon atoms, has broad wavelength transparency from ultraviolet (UV) to infrared (IR). In addition, electrical conductivity, mechanical flexibility, and biocompatibility of graphene make it a promising material for the next-generation neural electrode. The transparent graphene μ-ECoG array placed under a cranial window implanted over the cerebral cortex in rodents allows for chronic investigations of the underlying neural tissue while simultaneously performing electrophysiology and optogenetic experiments. In this work, *in vivo* imaging of the cortical vasculature through the transparent electrode sites has been shown via fluorescence microscopy and 3D optical coherence tomography. Optogenetic activation of focal cortical areas directly beneath electrode sites has been demonstrated in transgenic Thy1::ChR2 mice. The graphene remains electrically viable for chronic recording for extended time periods (months). For the fundamental understanding of the graphene μ-ECoG, electrochemical impedance spectroscopy (EIS) has been performed and an equivalent circuit has been modeled. The result shows that the graphene device is capacitive at lower (<10 Hz) or higher (>1000 Hz) frequency, and rather faradaic near 100 Hz. This study demonstrates an array of interfacing abilities of the graphene μ-ECoG and its utility for neural applications.

Title: A mesh structure based polyimide microelectrode for long-term epidural-ECoG recording

Authors: *D.-H. BAEK[1,3], S. K. BRODNICK[1], D.-W. PARK[2], H. KIM[2], S.-H. LEE[3], J. C. WILLIAMS[1];
[1]Dept. of Biomed. Engin., [2]Dept. of Electrical and Computer Engin., Univ. of Wisconsin-Madison, Madison, WI; [3]Sch. of Biomed. Engin., Korea Univ., Seoul, Korea, Republic of

Abstract: Epidural electrocorticography (ECoG) activity may be more reliable and stable than single-unit recordings such as are found with intracortical implantable devices. These devices are limited by mechanical mismatching and cellular reactive responses due to differences in the elastic modulus and immune response. Consequently, we evaluated the feasibility of long-term recording of epidural ECoG activity by developing flexible and mesh structured polyimide (PI) based multi-electrode arrays. We designed a multi-channel electrode array with a mesh structure for more conformal contact with a curved surface such as the surface of the cortex. We compared the contact capability of mesh PI electrodes with conventionally used sheet PI electrodes. The electrical properties of the mesh PI electrode were evaluated for 4 weeks *in vitro*. We recorded the epidural ECoG activity on the surface of rhesus macaque cortex while they performed a saccadic task. The mesh PI electrode showed good contact with the brain surface, as evaluated by visual inspection and an electrical contact test with an agarose brain model. Classification analysis of left and right saccadic movements showed accuracies of about 87 % for predicting the direction of saccade eye movement during two sessions. These studies demonstrates that the mesh PI electrode was flexible, contactable and can record epidural ECoG activity while maintaining close contact to the dural layer without serious biological damage and degradation of signals, which was proved by *in vivo* and *in vitro* test. And this work exemplifies the future application of for minimally invasive BCI electrode arrays based on thin film electronic approaches.

Abstract: Currently, clinical therapies such as deep brain stimulation for Parkinson's disease and stimulation to decrease epilepsy symptoms exist without much knowledge of how the therapies work. The mechanisms by which electrical stimulation of the central and peripheral nervous system work are still poorly understood, and need to be further investigated in order to increase effectiveness in clinical studies. Electrode arrays stimulate the cortex and deeper brain structures to lessen physiological symptoms, but the extent of which brain regions are affected by the stimulation and how it propagates has not been well studied because of the previous lack of imaging and recording tools. The volume of stimulated tissue has been estimated with computer modeling, fMRI imaging, or functional behavioral tests, but not quantitatively known. We have taken advantage of the recently developed genetically modified mouse which has the green fluorescent calcium indicator GCaMP6f in subsets of excitatory neurons. This mouse line has especially fast response kinetics and therefore is an excellent model for imaging precise neuronal activity *in vivo*. We have combined our graphene based CLEAR microECoG electrode array with chronic fluorescent *in vivo* imaging of GCaMP6f mice through a cranial window. Our investigations start to characterize the extent of the volume of neural tissue that is activated through various stimulation parameters by simultaneously imaging neural activity in real-time. By using already developed computer models and data analysis techniques, these data may also be used to tease apart the various contributors to electrical stimulation effects, such as volume conduction and synaptic propagation. Further combining this with other advanced imaging techniques (OCT, multiphoton), optogenetics, and different animal disease models will create a multi-model platform for investigating the mechanisms of action of neuromodulation on various neurological disorders.

Abstract: Peripheral nerve stimulation has been shown to have the potential to restore sensory feedback after amputation in humans. However, incomplete long term stability assessment of current intraneural electrodes limits their potential for clinical applications. An ensemble of four key criteria defines the success of a stimulating peripheral nerve electrode - stability, selectivity, functionality, and biocompatibility. Here we evaluated these pivotal features for a newly developed self-opening intra-neural electrode (SELINE) using a chronic rat model. A SELINE electrode was implanted in the left sciatic nerve of 5 female Lewis rats, which also received bipolar electrodes into ankle muscles to record electromyographic activity. Weekly evaluations of muscle recruitment curves in response to electrical stimulation through each of the ten active sites of the SELINE implant demonstrated the stability of charge delivery and muscle recruitment selectivity after three to four weeks post-implantation, and for a duration of 4.5 months. The selectivity of the electrodes allowed the preferential recruitment of flexor versus extensor muscles in all the implanted rats. To demonstrate the functionality and controllability of this selective muscle activation, we developed a closed-loop control system whereby real-time adjustment of stimulation frequency through selective electrodes achieved high fidelity control of ankle kinematics and the produced force. Immunohistochemistry of the chronically implanted

nerves revealed a loss of myelin and axons around the implant site. In all 5 rats, we also observed a layer of fibroblasts and an accumulation of multi-nucleated cells that encapsulated the implant. The high degree of muscle activation selectivity and functionality of the long term SELINE implants provides promising perspectives for chronic therapeutic applications. In light of the stability of these results, the impact of chronic intraneural implants on the surrounding neural tissue is undergoing further evaluations to understand the relationship between tissue response and electrode functionality and thereby aid a translation into clinics.

Title: A new ECOG-based BCI system based on WIMAGINE® a fully implantable recording device for human applications

Authors: *F. SAUTER-STARACE, G. CHARVET, C. MESTAIS, M. FOERSTER, A. LAMBERT, N. TORRES-MARTINEZ, T. COSTECALDE, D. RATEL, T. AKSENOVA, A.-L. BENABID;
DRT/CLINATEC, French Alternative Energies and Atomic Energy Comm, Grenoble Cedex 9, France

Abstract: Our team has developed a fully implantable device called WIMAGINE®[i] to record ElectroCorticoGrams (ECoG) as a part of a Brain Computer Interface (BCI) platform to be used

by quadriplegic subjects[ii] to control effectors with a large number of degrees of freedom, such as a 4-limb exoskeleton. Innovative ECoG signal decoding algorithms will allow self-paced control of the exoskeleton by decoding the subject's brain activity. The implant consists of an array of 64 biocompatible epidural electrodes fixed under a titanium housing the electronic boards, and two antennae for wireless transmission of data and remote power supply. For this purpose, our team designed and handled the implant manufacturing according to ISO 13485, as well as qualification tests according to the European directive 2007/47/EC and ISO standards (risk analysis ISO 14971, ISO 45502 for electrical and mechanical safety of implantable devices and EN 60601-1 for electrical safety and electromagnetic compatibility of the external unit). Long-term biocompatibility abides by the ISO 10993 requirements, in particular the local tolerance and systemic effects after 26 weeks contact duration in animals. The clinical procedure and the investigator files were submitted to the French authorities (ANSM) and Ethical committee to get approval for the BCI clinical trials with quadriplegic subjects. Other neurological applications requiring wireless ECoG recording such as epilepsy or post stroke rehabilitation can be addressed. The project is partially supported by French National Research Agency (ANR-Carnot Institute), Fondation Motrice, Fondation Nanosciences, Fondation de l'Avenir, and Fondation Philanthropique Edmond J. Title: Additional information from connectivity may improve classification in ECoG based Brain-Computer Interfaces

Authors: *E. J. AARNOUTSE, S. BROLSMA, Z. V. FREUDENBURG, N. F. RAMSEY; Brain Ctr. Rudolf Magnus, Utrecht, Netherlands

Abstract: In a permanent, implanted Brain- Computer Interface (BCI), classification of users intent must be held to a higher standard than in a laboratory setting. For example, the minimization of false positives is as important as detecting true positives (Torres Valderrama et al. 2012). We investigated whether information on the communication between two areas with distinct brain function can improve classification. Two brain functions were evaluated for BCI, in six patients scheduled for epilepsy surgery: working memory (activates dorsolateral prefrontal cortex; DLPFC) and motor (activates motor cortex; M1) BCI. A week before resection ECoG grids were implanted. In the following week they performed two screening tasks to locate DLPFC and M1: a counting back task (steps of 7) and a fingertapping task. All trials alternated with rest trials. They also performed a BCI task with visual feedback: moving a cursor in the vertical direction by either counting backwards or fingertapping for up, and active resting for down. We selected bipolar electrodes over DLPFC and M1 on the basis of significant covariance with the appropriate screening task. We than calculated Granger causality (GC) in the high gamma band between DLPFC and M1 electrodes for each of the tasks. Significance was tested with a bootstrap method. During the working memory BCI task GC was found from DLPFC to M1, whereas during the working memory screening task no GC was found. Both during the motor screening task and the motor BCI task GC from M1 to DLPFC was found, but only during motor BCI GC from DLPFC to M1 was found. Thus, we find that feedback of brain signals increases GC from DLPFC to M1, for both WM and motor BCI, as compared to the screening tasks. These results point in the direction of feedback causing a general top down effect, for example from a third frontal area. The results suggest that the activity of two areas with distinct function combined may improve BCI classification, notably reducing false positives. These results may inspire strategies for better classification in BCIs using one extra bipolar electrode.

Title: A cost-efficient method for impedance reduction of neural microelectrodes by nanostructured platinum

Authors: *C. BOEHLER, M. ASPLUND;
Dept. of Microsystems Engin. (IMTEK), Albert-Ludwigs-University, Freiburg, Germany

Abstract: Micro-sized electrodes enable highly sensitive communication at the neural interface with superior spatial resolution and thus provide excellent possibilities for the exploration of basic neurological functions *in vivo*. Such small electrodes however suffer from high electrical impedance and low signal to noise ratio which results in adverse effects on their recording/stimulation performance. In order to overcome this problem, a nanostructured platinum coating with superior porosity was introduced as add-on functionalization for impedance reduction of small electrodes. In contrast to the fabrication process of platinum black our approach does not rely on the usage of cytotoxic components thus making it suitable for biomedical applications. The realization of the Pt-grass coating is performed via a chemical reduction process using chloroplatinic/formic acid and allows batch fabrication as well as individual site modification on larger electrode arrays. Electrochemical impedance spectroscopy (EIS) of the grass-like nanostructure displayed a reduction in impedance by almost two orders of magnitude compared to untreated platinum samples. Similarly, the charge storage capacity (CSC) and the charge injection capacity (CIC) could be substantially increased by factor 40 and 20, respectively, by implementing the Pt-nanograss coating. Biocompatibility of the nanostructured film was assessed by elution and direct contact tests using the human neuroblastoma cell line SH-SY5Y and results proved that the nanostructures were non-toxic. With the herein proposed nanostructured platinum, we were able to reduce the impedance of microelectrodes to limits below what could be reached for electrode materials like IrOx or PEDOT. This allows for a reduction of the electrode area to 1% of the untreated electrode site, while retaining equal electrical properties, which consequently offers substantially improved spatial resolution in neural recordings. The simple deposition technique further provides the opportunity to apply the impedance reduction coating to virtually any possible electrode type and correspondingly shows great potential as a universal impedance reduction strategy. The high

CSC in combination with the strong adhesion further show the potential for use in chronic stimulation and finally demonstrate the relevance of Pt-nanograss for improving the performance of geometrically small neural electrodes.

Title: PEDOT electroplating improves tetrode impedance stability

Authors: *B. A. GROSS[1], D. BAUER[1], G. R. POE[1], N. B. LANGHALS[2];
[1]Anesthesiol., [2]Section of Plastic Surgery, Dept. of Surgery, Univ. of Michigan, Ann Arbor, MI

Abstract: Micro-wire electrodes for use in single unit electrophysiology experiments are relatively affordable in comparison with fabricated electrodes (e.g., silicon-based electrodes). Tetrodes, consisting of four electrically-isolated micro-wires bound together, are used by many researchers due to their ability to identify and classify action potentials arising from several individual neurons in densely populated neural regions, such as the hippocampus. When the target population of neurons is in a small volume of brain tissue, several individual neurons can be recorded from even if only a couple of tetrodes in a bundle reach their target. Tetrodes are commonly constructed using polyimide-insulated nichrome wire that is electroplated with gold at the recording sites before implantation into the brain. The impedance values after initial gold-plating vary greatly across several sites in the fabrication of a given batch of tetrodes and increases significantly over hours to days prior to implantation. Our goal was to produce tetrodes with lower, more uniform, and more stable impedance values than the standard gold-plated nichrome micro-wire tetrodes without significantly increasing the labor involved in fabrication. Based on several studies demonstrating the advantages of coating poly(3,4-ethylenedioxythiophene) (PEDOT) onto implantable micro-electrodes, we chose to electroplate this conducting polymer onto the gold-plated recording sites of our micro-wire tetrodes. Arrays of 8 to 16 tetrodes (32-64 electrode sites) were constructed using nichrome wire. Electrode sites were individually electroplated by placing in a gold ionic solution and applying a potential to the individual electrodes sites for 5 seconds. Then sites were connected to a Gamry potentiostat to

polymerize an EDOT monomer solution containing poly(styrenesulfonate) counter-ions using a 500 pA current for 250 seconds per site. Impedance measurements immediately after plating were significantly lower and less variable than gold-plating alone when compared at several electrophysiologically-relevant frequencies between 1 Hz and 10 kHz (p values < 0.0001). In addition, PEDOT improved the stability of the impedance at each site as compared to gold-plating alone. Our results suggest that PEDOT can provide significant stability and consistency improvements to standard gold tetrode sites. With little additional effort in fabrication, these improvements should lead to easier separation of spikes from individual neurons due to more consistent electrode-tissue interfaces.

Title: The foreign body response to the Utah Slant Electrode Array in human peripheral nerve

Authors: ***M. B. CHRISTENSEN**[1], H. A. C. WARK[1], D. T. HUTCHINSON[2], P. A. TRESCO[1];
[1]Bioengineering, [2]Orthopaedics, Univ. of Utah, Salt Lake City, UT

Abstract: Microelectrodes have been investigated for stimulation and recording of peripheral nerves for well over half a century. Research with peripheral nerve electrodes has resulted in a number of clinical applications, including respiratory pacing, sacral nerve stimulation for urinary and fecal management, and peroneal nerve stimulation for the treatment of foot-drop. More recently, microelectrodes, including the Utah Slant Electrode Array (USEA), have been investigated for the control of neuroprosthetic devices. However, studies evaluating the foreign body response (FBR) to penetrating arrays in humans have yet to be conducted. Therefore, we evaluated the FBR to USEA implantation in median and ulnar nerves. To this end, USEAs (Blackrock Microsystems, Salt Lake City, UT) were implanted into the ulnar and/or median nerves of two patients with previous amputations. Following a 28-day implantation period, nerves were removed from the patients and immersion fixed in 4% paraformaldehyde in PBS. Electrodes were then dissected free from the nerves which were then equilibrated in a 30% sucrose solution and sectioned through the implantation site using a crysostat. Sections were placed in blocking solution overnight, and incubated overnight with primary antibodies against

MAC387 for macrophages or NF200 and S-100β for axons and myelin identification, respectively. Sections were then washed, incubated with the appropriate secondary antibodies plus DAPI, and washed again before mounting. Retrieved arrays were stained using similar methods for antibodies against MAC387. Final images were obtained by montaging multiple image fields. MAC387+ cells were observed covering the surface of all retrieved devices, similar to previous studies examining USEAs implantation in animals. Longitudinal sections showed minimal disruption of nerve fibers around electrode tracks, with no evidence of any significant loss of nerve fibers or demyelination in the implantation area other than those damaged initially at the time of insertion. Sagittal and cross-sections revealed that a relatively small percentage of the nerve was penetrated by the array. Further, cross-sections provided evidence that the array, particularly the side of the array with longer electrodes, may have migrated out of the endoneurial tissue over the indwelling period. These results suggest that while the USEA can effectively penetrate into endoneurial tissue without significant loss of axons or demyelination to function as a neuroprosthetic controller, further efforts should be made to maintain implant location over time in order to enhance its effectiveness as a neuroprosthetic interface device.

Title: ECM coatings reduce the FBR to chronically implanted microelectrode arrays

Authors: ***M. POLEI**, R. OAKES, J. SKOUSEN, P. A. TRESCO;
Bioengineering, Univ. of Utah, Salt Lake City, UT

Abstract: Microelectrode recording arrays have provided volitional control of prosthetic devices by using recorded neuronal activity from single or small populations of isolated neurons. However, such devices perform inconsistently over long indwelling periods, presumably due in part to the foreign body response (FBR). Specifically, we have shown that blood-brain barrier (BBB) leakiness and astrogliosis correlate with reduced recording performance.1 To improve biocompatibility, we have been examining the utility of hemostatic coatings to limit the initial

blood loss and reduce the FBR. To test this hypothesis, we have coated single-shank and high-density electrode arrays with Avitene™, an FDA-approved collagen hemostat, or cell-derived extracellular matrix (ECM), and examined the tissue damage and FBR following implantation into the motor cortex of male Sprague Dawley rats.open-cell polyurethane foams were fabricated, pretreated with fibronectin, seeded with primary astrocytes and cultured for several weeks.2 The cells and polymer were removed using a weak aprotic solvent and the remaining cell-derived material was rinsed in DI water and lyophilized. Planar single shank Michigan type electrodes or 4x4 UEAs were coated with acid solubilized ECM solutions by repetitive dip coatings using a sterile process. Coated electrodes and uncoated controls were implanted stereotactically in the motor cortex of adult male Sprague-Dawley rats. After a chronic indwelling period, animals were transcardially perfused and fixed with 4% paraformaldehyde. The brains were then sectioned and FBR characterized using biomarkers for macrophage activation (CD68), blood-brain barrier dysfunction (IgG), gliosis (GFAP) and implant-associated neuronal death (NeuN).3Eight weeks after implantation, Avitene™ and ECM coated single-shank electrodes showed reductions in the intensity and spatial distribution of glial fibrillary acid protein (GFAP) and IgG immunoreactivity but not CD68. More extensive analysis is ongoing and will be reported at the meeting.Our results show that such ECM coatings may be a useful tool for reducing some elements of the FBR to these and other such devices chronically implanted in the central nervous system. Current research is focused on investigating underlying mechanisms of action. References: 1. Nolta, N., Tresco P.A, et al., Biomaterials, 2015, 53, pp. 753-762 2. Title: Artifacts reduction with a simple filter for multichannel implantable neural interfaces

Authors: *O. FUKAYAMA, K. MABUCHI;
The Univ. of Tokyo, Tokyo, Japan

Abstract: Implantable neural interfaces have become a powerful tool to observe information flow inside the body both for scientific purposes and clinical uses. However, they have suffered from artifacts caused by body movements or noise sources nearby the recording site. Although many sophisticated noise reduction methods have been proposed, methods extracting components such as PCA or ICA may prejudice a physical context of the recorded signals, while machine learning methods such as ANN or GA tend to cause unintended effect on the information that the signal conveys. In this work, we propose a simple temporal filter design for multichannel implantable neural interfaces based on frequency bands limitation preserving the signal properties. The basic idea of our method is to remove common-mode components caused by signals in non-target channels from the signals observed in the target channel. First, by-channel immediate weights are determined according to a ratio of a cross-correlation coefficient between the target and non-target channels and an auto-correlation on the target channel. Then, we formed an estimation of the true source as a convolution of the weighted summation of the non-target signals and a finite impulse response (FIR) by solving a Wiener-Hopf equation. The method was tested with the extracellular neural signals recorded in the cortical brain and the sciatic nerve fibers of a behaving rat, and the vagal nerve of an anesthetized goat which had an artificial heart device implanted in its chest cavity. In the case of recording the cortical brain of a rat, the method has reduced motion artifacts contaminating the neural signals recorded with wire electrodes. Another application to the sciatic nerve signals has suppressed the influence of EEG signals caused by muscles near the chronically implanted cuff electrodes during the free movements. The method was also applied to an acute recording of the vagal nerve signals of a goat with an artificial heart (AH) device, which enabled an observation of a neural-oriented signals in spite of the presence of strong AH motor noises.

Title: Wireless floating microelectrode array (WFMA)for neural stimulation

Authors: *P. TROYK[1,2], S. COGAN[3], M. ROMERO-ORTEGA[3], M. BAK[4], S. BREDESON[1]; [1]Illinois Inst. Tech., Chicago, IL; [2]Sigenics, Inc, Chicago, IL; [3]Univ. of Texas, Dallas, TX; [4]MicroProbes for Life Sci., Gaithersburg, MD

Abstract: Neural interfaces for stimulation of the central and peripheral nervous system are being proposed for numerous research and neural prosthesis devices. Wires and cables that connect to electrode arrays, and other structures placed on or near neurons and axons, often cause short-lived viability. For chronically-implanted devices, wires and transcutaneous connectors are often the primary cause of failure. Functionally, placing stimulation electronics physically close to the stimulating electrodes avoids crosstalk between adjacent electrodes. Called the Wireless Floating Microelectrode Array, (WFMA) this self-contained implantable stimulation device contains 16 iridium metal wire electrodes within a ceramic platform. An application-specific-integrated-circuit (ASIC), and power/communication coil, are placed on the top side of the ceramic platform, resulting in an assembly of 5mm diameter x 0.5mm thickness. Powering and communication with the ASIC takes place through a transcutaneous inductive link, without wires or connectors, via an extracorporeal telemetry controller (TC) that provids the magnetic power and the computer-based command/telemetry interface. The area and length of the electrodes are independently configurable. The first generation of WFMA is being tested in rodent sciatic nerve experiments. WFMAs implanted on the sciatic nerve have been stable and shown to produce differentiated stimulation of limb muscles over a period of greater than 150 days (experiment ongoing), with 3cm of separation between the implanted WFMA and the external TC. Stimulation thresholds and reverse telemetry of electrode waveshapes have been documented. In contrast, for the same animal model, wired arrays with percutaneous connectors remained fully functional for less than one month.

Title: Evaluation of systemic and histological changes using accelerated failure studies in mice implanted with intracortical device

Authors: J. GAIRE, *K. J. OTTO;
Univ. of Florida, Gainesville, FL

Abstract: Intracortical microelectrode devices provide a brain machine interface capable of targeting very small populations of neurons with a potential to treat many neurological disorders. These penetrating devices generally perform well for a short duration but fail to record or stimulate reliably for chronic time putatively due to reactive tissue response (RTR). The RTR though suggested to be one of the major failure modes, has not been yet firmly established as a cause for device failure. In this study, we evaluated the changes in systemic markers of inflammation and histological changes in animals implanted with silicon microelectrodes and received either lipopolysaccharide (LPS) or Dexamethasone (Dex). We dip-coated implanted devices with LPS, a bacterial endotoxin, and injected Dex systematically. The panel of pro-inflammatory markers were analyzed using multiples plates (Mesoscale Discovery) and histological changes using device capture histology (DCHIST) [1, 2]. In our preliminary results, we did not see any significant increase at the systemic levels of pro-inflammatory marker in implanted animals after one week. This observation could be due to 1) the longevity of the 1 week time point as opposed to acute time points (hours) after implantation, 2) the systemic method of assessment instead of local assessment, and 3) small number of animals used. We chose to measure the cytokines systemically so that the histological assessment of the tissue surrounding the implant can be performed from the same animal. The group of animals that received both the implant and LPS showed increased levels of pro-inflammatory marker as compared to group that received the implant only. However, the increase was minimal and could be due to a small amount of LPS that went into the brain. In conclusion, our study indicates that collecting blood samples at multiple time points from the same animal will be useful in gathering data that can be corroborated with histological and electrophysiological findings to make meaningful conclusions from the same subject. The use of pro- and anti-inflammatory substances, like LPS and Dex, in tandem with new imaging techniques will help to discern if the causality between inflammation and device performance exists.

Title: Does precise pulse timing affect the perception of intracortical microstimulation?

Authors: ***T. CALLIER**[1], H. P. SAAL[1], E. W. SCHLUTER[1], F. V. TENORE[2], S. J. BENSMAIA[1];
[1]Univ. of Chicago, Chicago, IL; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Intracortical microstimulation (ICMS) can be used to deliver naturalistic and intuitive sensory feedback in upper-limb neuroprostheses. One way to evoke graded sensations is to vary the stimulation amplitude. Another way is to vary the timing of the stimulation pulses. Indeed, the precise spiking timing of neuronal responses has been shown to carry information and shape perception. For example, skin oscillations, such as those evoked when touching a textured surface, are encoded in primary somatosensory cortex (S1) in two ways: the strength of the response (firing rates) tracks the amplitude of the vibrations, while the precise spike timing of the response signals their frequency composition. In theory, varying ICMS pulse frequency and amplitude should thus have distinct perceptual consequences. In a landmark study, Romo and colleagues have shown that monkeys are able to distinguish changes in ICMS pulse frequency at low frequencies (< 50 Hz). However, the timing of cortical responses has been shown to carry information up to much higher frequencies. In the present study, we ask whether changes in ICMS frequency produce distinguishable percepts across a wide range of frequencies. To this end, we train Rhesus macaques to discriminate the frequency of vibrations delivered to the hand, with frequencies ranging from 50 to 400 Hz. The vibratory amplitude varies randomly from trial to trial so that the animals cannot rely on intensity cues to make the frequency discrimination judgments. Once the animals are trained on the task, we have them perform the same task based on ICMS delivered to S1 through chronically implanted electrode arrays. We then assess the animals' ability to generalize from the mechanical to the electrical version of the task to infer the degree to which the two tasks are perceptually analogous. Our preparation allows us to probe causally the importance of precise spike timing in S1, and to determine the limits of ICMS with respect to pulse timing.

Title: Effects of stimulation frequency on the excitability of central nervous system during functional electrical stimulation

Authors: *H. SUZUKI[1], T. ONO[4], E. YAMADA[4], S. KASUGA[2], J. USHIBA[3];
[1]Grad. Sch. of Sci. and Technol., Keio Univ., Kanagawa, Japan; [2]Dept. of Rehabil. Med., Keio Univ., Tokyo, Japan; [3]Dept. of Biosci. and Informatics, Fac. of Sci. and Technol., Keio Univ., Kanagawa, Japan; [4]Saiseikai Kanagawa-ken Hosp., Kanagawa, Japan

Abstract: Functional Electrical Stimulation (FES) to the paralyzed limb after stroke is considered to induce adaptive plasticity in the motor system through exciting afferent and efferent pathways. The stimulation frequency most commonly used in studies investigating FES-based rehabilitation of paralysis is relatively low (20-80 Hz; Fujiwara et al. Neurorehabil Neural Repair 2009), while higher frequency (100 Hz) stimulation is suggested to excite central nervous system (Collins et al. J Neurosci 2001). In order to clarify optimal stimulation frequency for clinical purpose, relationships between stimulation frequency and the excitability of central nervous system need to be investigated. In this study, we sought to identify a stimulation parameter adequate to excite afferent and efferent pathways by comparing high-frequency-FES (HF-FES) and low-frequency-FES (LF-FES). In eight neurologically normal participants, we acquired functional magnetic resonance images during HF-FES (100 Hz) and LF-FES (20 Hz) whose intensities are adjusted to produce 45-degree of wrist dorsiflexion. Only HF-FES significantly activated contralateral primary motor cortex (M1) and contralateral primary somatosensory cortex ($P < 0.001$ unc.). To test whether this M1 activation results in the excitation of the exact efferent pathways, in the next experiment we investigated cortical excitability during HF-FES and LF-FES by using transcranial magnetic stimulation (TMS) in ten neurologically normal participants. We identified TMS intensities evoking more than 2-degree change of wrist dorsiflexion while applying HF-FES and LF-FES whose intensities are adjusted to produce 30-degree of wrist dorsiflexion. The identified TMS intensities during both HF-FES and LF-FES were lower than those during rest ($P < 0.001$), and the intensities during HF-FES

were lower than those during LF-FES ($P < 0.05$) in all subjects. Our results suggest that HF-FES activates both the afferent and efferent sensorimotor pathways, therefore this frequency might be useful in FES-based interventions which aim to improve the excitability of central nervous system. The current findings may also be applicable to electrical stimulation as sensory feedback of Brain-Machine Interface-based stroke rehabilitation.

Title: Large scale group analysis of spectral features in electrocorticography

Authors: ***Z. V. FREUDENBURG**[1,2], R. VAN DER SPEK[2], M. J. VANSTEENSEL[2], E. J. AARNOUTSE[2], N. F. RAMSEY[2];

Abstract: Spectral features in human brain electrophysiology have been extensively studied in relation to human brain function, and have proven robust enough for use in clinical diagnostic practices and online closed-loop direct cognitive control of a computer. Lower frequency bands have been associated with various functions in EEG, such as the alpha, theta and mu bands for visual attention, working memory and motor action respectively. Functional significance of these bands appears to be confined to specific regions of the brain, but the exact source and extent of involved cortex is unclear due to the limited sensitivity of EEG. Electrocorticography (ECoG) allows for detailed mapping of electrophysiological signals across the human cortex with high topographical precision since each electrode measures from only the cortical tissue with which it is in direct contact. ECoG has the added benefit of being sensitive to high gamma frequencies, which have been closely linked to increased neuronal spiking and BOLD signal increases [Nir et al. 2007, Goense et al. 2008], allowing ECoG to relate low frequency patterns to these other domains. In this study we addressed the question whether the cortex exhibits a topographical distribution of function-related low frequencies. For this we studied ECoG data from 11 patients

who performed multiple cognitive and motor tasks. Each subject had 64-117 non-noisy electrodes, and performed up to 12 tasks, bringing the total number of datasets to 151 and ECoG measurements to 14,154. ECoG was recorded with the standard clinical grids used in pre-resection epileptic focus localization. Anatomic localization of electrodes was done with the help of pre-surgical MR and post-implant CT scans. Amplitude variance during the tasks was used as an indication of the functional significance. For each electrode measurement PCA was performed on the amplitude response of 66 frequencies exponentially sampled from 1-135Hz and the top 2 components were used as its canonical spectral feature. The measurements were then clustered using a variant of Affinity Propagation [Frey et al. 2007] into 13 groups of similar canonical features. The results show that 1) despite being defined naively without task labels, the canonical features that bind each cluster display bands responses highly comparable to those defined using functional contrast, 2) the clusters of like spectral features are anatomically specific but not subject or cognitive task specific. This suggests that different regions exhibit functionally relevant different spectral features. It remains to be seen how this distribution relates to anatomical differences between regions.

Title: Investigating the effect of current flow on cortical excitability using bipolar tDCS

Authors: *V. RAWJI[1], J. C. ROTHWELL[1], S. BESTMANN[1], M. CIOCCA[2], A. ZACHARIA[3], M. BIKSON[4];
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London, Birmingham, United Kingdom; [2]Dept. of Pathophysiology and Transplantation, Univ. of Milan, Milan, Italy; [3]Clin. of Neurology, Dept. of Clin. Neurosci., Geneva Univ. Hosp. and Fac. of Med., Geneva, Switzerland; [4]Dept. of Biomed. Engin., The City Col. of New York, New York, NY

Abstract: Question TDCS over M1 conventionally has the cathode/anode directly over M1 with a remote return electrode. However, calculations suggest that field intensity is max between the two electrodes.1 Here we ask whether tDCS to an area between two electrodes has different effects depending on the orientation of the applied field. We conducted experiments on the FDI hand area of M1 since previous work has shown that stimulation here with TMS is directionally dependent.2 Methods TMS intensity was adjusted to produce MEPs of approximately 1mV peak-to-peak amplitude. Twenty MEPs from the right FDI were collected before and after conditioning the cortex with 10min 1 mA TDCS with the TMS coil 45o to the midline. HD-tDCS (Neuroelectrics, Spain; 1mA, 10min) was delivered via circular electrodes (3.14cm2), each placed 3.5cm from the FDI hotspot. Two were positioned parallel to the TMS coil to induce either a posterior-anterior (PA-tDCS) or anterior-posterior (AP-tDCS) current across the hotspot. Two perpendicular to the coil induced a mediolateral current (ML-tDCS). This protocol involved three sessions: (1) ML-tDCS, (2) PA-tDCS and (3) sham stimulation, all with PA TMS (n=15). In experiment 2 (n=20), we reversed the polarity of PA-tDCS (AP-tDCS) and repeated parameters from experiment one. Experiment 3 (n=14) investigated the effects of PA-tDCS on PA and AP TMS. To complete the permutations, we tested the effect of AP-tDCS on AP TMS pulses (n=14). Results Modelling: We found clear differences between electrical fields induced by PA and ML tDCS Experiment 1: PA-tDCS significantly reduced M1 excitability compared to ML (p=0.006) and sham stimulation (p=0.005) but ML stimulation showed no significant change in M1 excitability compared to sham (p=0.46). These were all under PA TMS. Experiment 2: Comparison between PA-tDCS and AP-tDCS, using PA TMS showed no significant difference. Experiment 3: Using PA-tDCS, we showed a significant difference between post-stimulation effects between PA and AP TMS (p=0.024). Experiment 4: Using AP-tDCS, we found no significant difference between post-stimulation effects between PA and AP TMS. Variability: We tested PA-tDCS with PA TMS in 22 subjects, with 15 of these being tested twice. The interclass correlation was found to be 0.68, indicating moderate-strong reproducibility. Conclusions We show that tDCS displays a clear element of anisotropy, with particular emphasis on the PA-tDCS orientation. Further investigations are needed to elucidate the physiological mechanisms of this anisotropy.

Title: Direct current stimulation modulates bidirectional synaptic plasticity

Authors: *G. KRONBERG[1], M. BRIDI[2], T. ABEL[2], L. C. PARRA[1];
[1]Biomed. Engin., The City Col. of New York, New York, NY; [2]Biol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Transcranial direct current stimulation (tDCS) is an emerging therapeutic technique being explored for the treatment of a wide range of neurological disorders. Despite its rapid adoption, little is known about the cellular mechanisms that underlie long-term tDCS outcomes. To elucidate these mechanisms, we applied direct current stimulation (DCS) during synaptic plasticity induction in rat hippocampal slices. DCS biased synaptic plasticity towards potentiation, i.e. enhanced long-term potentiation (LTP) and attenuated long-term depression (LTD), when applied during plasticity-inducing synaptic activity. However, if concurrent synaptic activity was too weak to induce plasticity, DCS had no effect on the strength of synapses. Our results provide a mechanism for tDCS to enhance memory storage, by facilitating LTP when applied during synaptic plasticity induction, as presumably occurs during the performance of a cognitive task. Moreover, these results provide a mechanism for tDCS to be functionally specific, selectively affecting synapses that are undergoing plasticity. We show further that the effects of DCS vary with the dendritic location of synapses (i.e. apical or basal) and are NMDA receptor dependent, supporting the notion that DCS modulates synaptic plasticity by modulating dendritic membrane potential. Taken together, our results motivate the application of tDCS during plasticity-inducing cognitive tasks and draw attention to the influence of dendritic membrane polarization in determining long-term tDCS outcomes.

Title: Different learning processes of multichannel versus small channel configuration for online brain-computer interface

Authors: *J. MENG, S. ZHANG, A. BEYKO, T. HANSON, B. HE;
Univ. of Minnesota, Minneapolis, MN

Abstract: Motor imagery based brain computer interfaces (BCI) using electroencephalography (EEG) have shown promising results in the control of virtual or real objects, during which subjects can learn to modulate brain rhythms. BCI studies commonly employ a small channel configuration, known as a large Laplacian, which uses the same two electrodes/channels together with surrounding channels. A more recent approach is the multichannel configuration, which can utilize more EEG electrodes than the small channel configuration. With additional electrodes and different online decoding algorithms, better performance and new learning processes may be expected. One challenge is that additional channels lead to higher inclusion of both task-related and -unrelated information, and thus may obfuscate the task-related information and affect the efficiency and stability of learning processes. This study aimed to compare the learning processes between the two configurations (multichannel vs. small channel) by evaluating the average online performance across several sessions. BCI naïve subjects were recruited to participate in the experiments and were randomly distributed into two groups. Each group performed 1D online cursor control with one configuration for 3 sessions and then crossed over to the other configuration for the remaining 2 sessions. The experimental results revealed that the multichannel configuration exhibited significantly better performance initially within naïve subjects, though it did not lead to a congruent improvement in long-term learning. In contrast, the small channel configuration displayed a slow and steady improvement on average across all sessions. The results indicate that learning may initially involve a larger brain area and multichannel configuration and corresponding algorithm can use information from a broader range of brain regions to achieve a better initial performance; whereas, as learning progresses, both methods approach equivalent performance level and the two electrodes (C3 and C4) above the motor cortex becomes sufficient for the subjects to learn to control the cursor or objects. This might explain why the multichannel configuration can decode motor imagination better initially, while small channel improved after a long-term learning period. This work was supported in part by NIH EB006433.

Title: Methods for detecting speech articulation events from single channel recordings of the speech cortex

Authors: M. MCCURRY[1], P. KENNEDY[2], *M. CLEMENTS[1];
[1]777 Atlantic Drive, Georgia Inst. of Technol., Atlanta, GA; [2]Neural Signals Inc., Duluth, GA

Abstract: Identifying speech articulation from electrode recordings of individuals with restricted articulation is an area of ongoing research. Acquiring data for this task can be difficult and the amount is often quite small. Additionally, comparisons across patients with different conditions is often nearly non-existent. To provide a point of comparison an unimpaired individual (PK) was implanted with 4 electrodes in his speech motor cortex. Over 15 days recordings were made using this set of electrodes in an effort to observe activity during articulation. These recordings focused on creating a series of sections of rest, vocalization, subvocalizations, and coarse muscle movement in the mouth. This work focuses on identifying the characteristics of vocalization events within these recordings and finds that highly statistically significant markers can be found and extracted from the local field potentials. These markers generally occur either during a vocalization event or very shortly after the termination of the audible speech. Each marker was extracted from single electrode recordings and matched with speech recorded from a time synchronized microphone. In order to extract these events from the raw electrode signal a series of non-linear processing steps were sequentially applied. First a 3788Hz recording was converted into a spectrogram with 90% overlap and half second windows. Then areas corrupted by recording noise were removed by limiting the region of interest and eliminating the 0-64Hz band. At this stage the events could be visibly observed due to their excitatory nature, though peppering noise made extraction difficult. To correct for this a combination of median filtering and thresholding was used to denoise the signal. At this point the events were extracted via gating the overall energy and observing the central frequency at each frame of time. Some artifact elimination was performed on this representation and then the events were compared to their distance from the nearest previous audible vocalization. In recording with word and phrase based utterances the event markers appeared to coincide with audible articulation events 77%+-11.6% of the time when the chance rates were 30.2%+-7.4%. In phoneme based files, event markers appeared at chance levels. In addition to these classification rates, there were some noteworthy differences between the characteristics of the event markers when used in different words which may indicate some word or phrase specific structure. This preliminary work shows promise in extracting articulation events from the speech motor cortex, though further datasets would be required to fully characterize and utilize them.

Title: Characterization of gamma electrophysiological response over sensorimotor cortex

Authors: ***M. P. BRANCO**, Z. V. FREUDENBURG, E. J. AARNOUTSE, M. J. VANSTEENSEL, N. F. RAMSEY;
Brain Ctr. Rudolf Magnus, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Gamma power activity has been recently considered as a feature for electrocorticography(ECoG)-based brain-computer interface (BCI) control. This activity (30-150 Hz) is known to be involved in several fundamental brain functions, in particular during motor execution or attempted movement. Gamma responses typically emerge as a spiky transient response time-locked to cognitive events and are commonly anatomically specific [1,2]. Wavelet-based signal analysis has been shown to be appropriate for power extraction, particularly when gamma responses are expected to show dynamics on a short temporal scale [3]. Typically, spectral analysis of the neuronal signals involves the use of a Morlet wavelets dictionary, the computational implementation of which requires the specification of at least two parameters: temporal resolution and smoothing. By varying these in a controlled manner, we can access important properties of the gamma response, such as the duration or sharpness of the gamma peaks and its smoothness or noise morphology. The characterization of such response could help to better understand the electrophysiology behind gamma responses, as well as to improve decoding strategies. We used data from 12 epilepsy patients who were implanted either with clinical or high-density ECoG grids over the sensorimotor cortex. Both impulse (button press or stimulation) and sustained (complex gestures or phonemes execution) gamma power (65-125 Hz) responses, were obtained through different combinations of temporal resolution (sampling every 0.002 to 0.1 s) and smoothing (window 0 to 3 s). The results revealed that both impulse response, characterized by maximum R2 values, and sustained cortical tasks, characterized by decoding classification accuracy, show an optimal range for gamma temporal sampling and smoothing. This range indicates that motor gamma response classification improves with a particular combination of higher temporal resolution and smoothing. Hence, we propose that in the analysis of ECoG gamma power the temporal response should be sampled at a high rate (> 1 sample/0.02s) and smoothed with a window of approximately 0.5 s. Given that

sensorimotor gamma responses tend to be quite variable and noisy, suboptimal sampling and smoothing may affect the interpretation in terms of the anatomic and temporal characteristics of underlying neuronal response. Therefore, optimization of wavelet-based power extraction methods will not only enable better decoding for BCI purposes, but also give a better understanding of the electrophysiological events underlying the gamma response. Title: Dynamic iterative brain-computer interface for dexterous hand movements

Authors: ***J. WU**[1,2], N. R. WILSON[2], D. SARMA[2], V. KUMAR[3], T. M. BLAKELY[2], F. DARVAS[4], B. W. BRUNTON[5], J. G. OJEMANN[4], R. P. N. RAO[3];

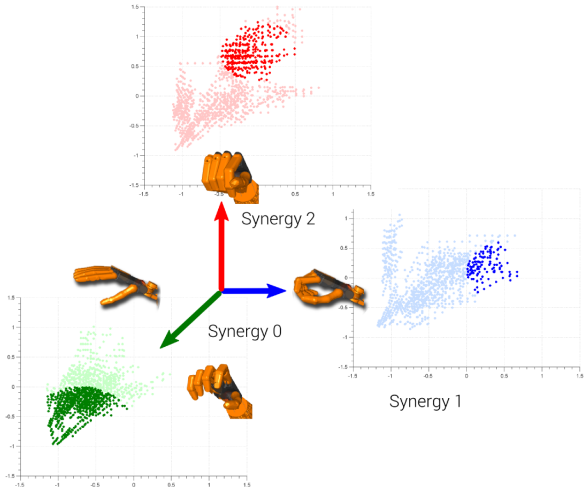
Abstract: Electrocorticography (ECoG)-based control systems for dexterous upper-body robotic prostheses have demonstrated potential to fulfill a role as implanted brain-computer interfaces (BCI) for volitional control of assistive devices. However, hand movement BCIs based on ECoG data primarily rely upon epoch-based end-point postural interpretation. One improved model of closed-loop BCI for hand prosthetics would be the incorporation of natural human control and feedback; this may be accomplished by dynamically decoding the velocity of underlying "movement primitives" multiple times a second to allow for real-time correction and adaptation.

Here we demonstrate preliminary performance of iteratively decoding ECoG sensorimotor recordings into dimensionality-reduced correlates of hand movement primitives. A variety of multi-spectral-band decoding strategies are experimentally tested on both imagined and overt movement paradigms in order to better understand the dynamics of human hand control in epileptic patients implanted with clinical (10mm spacing) and high-resolution (3mm spacing) platinum subdural ECoG grids, with differing spatial control patterns and control timing. Initial decoding tests in one implant patient (age 33, 8×8 lateral temporalparietal clinical grid) during a dynamic dwell task of a software robotic hand in three target postures (ball, handle, and pinch) in a closed loop imagined movement BCI achieved decoding accuracies of 70%, 20%, and 10% respectively, as compared to the chance at 40%, 10%, and 10%. These recordings suggest the presence of movement primitives during overt coordinated grasping and virtual hand control, and the capacity for real-time decoding of grasps from ECoG activity. Further, subject BCI performance reveals potential capability for real-time closed-loop error correction of the end-user in using decoded movement velocities to perform simulated motor tasks. We hope to significantly advance our computational understanding of human neural control of manipulation as well as ECoG-based dynamic hand prosthetics.



Dynamic decoding performance of overt movements in a two-dimensional synergy space; each dot represents a postural position every 100ms.

Title: Initial performance is better in altered BMI decoders that preserve muscle synergies

Authors: *S. N. NAUFEL, L. E. MILLER;
Northwestern Univ., Chicago, IL

Abstract: Our lab has developed a neuroprosthetic system with potential application to spinal cord injury that uses recordings from motor cortex (M1) to "decode" intended muscle activity (EMG). We can in turn control muscle stimulation to restore voluntary grasp. Understanding the limits of a patient's ability to adapt to these imperfect decoders has become a central question in the field of Brain Machine Interfaces (BMIs). We used our unique BMI to study a monkey's ability to adapt to two types of altered decoders: one that preserved the natural synergies between muscles, and one that didn't. Ultimately the monkey was able to use the synergy-preserving decoders much more successfully than those that disrupted natural synergies. We first trained a rhesus macaque to apply isometric wrist torque, with its forearm held in the mid-prone position, to place a cursor within one of 8 targets. We recorded multi-unit activity from a 96-channel microelectrode array implanted in the hand area of M1, as well as EMG from the major wrist muscles: extensor carpi radialis (ECR), extensor carpi ulnaris (ECU), flexor carpi radialis (FCR), and flexor carpi ulnaris (FCU). We computed a "cascade" decoder made of two multiple-input, linear filters: one to decode EMG from neural activity, and a second to decode force from EMG. We designed a synergy-preserving, "rotated" decoder by substituting an EMG-to-force decoder that was trained on data collected with the monkey's forearm rotated 90 degrees to the pronated position. We also designed a "reflected" decoder in which ECR and FCR were swapped, "reflecting" their lines of action across their insertions at the wrist, and simulating an anatomically impossible configuration. In a given session we alternated blocks of the normal decoder and one of the altered decoders. The rotated decoder was the more intuitive of the two altered decoders, as the animal could initially reach three times as many targets as in the reflected case. Furthermore, after 10 days, the monkey still had not learned to reach all targets using the reflected decoder. At this point, his performance in the rotated case was similar to that during normal decoder use, and nearly five times better than the reflected performance. Notably, with the reflected decoder, the monkey could most reliably reach the target that required only ECU and FCU activity. These two muscles were unaffected by the decoder transformation. These results suggest that the user can adapt to neuron-to-muscle decoders that preserve muscle synergies much more readily than those requiring completely new synergies. However, we don't know whether even longer-term adaptation may allow non-synergistic control to be learned.

Title: Distinct motor cortical representations for grasp kinematics and kinetics

Authors: *R. D. FLINT, III[1], E. W. LINDBERG[1], E. M. MUGLER[1], J. M. ROSENOW[2], M. C. TATE[2], M. W. SLUTZKY[3,4];
[1]Neurol., [2]Neurolog. Surgery, [3]Neurology, Physiology, and Physical Med. & Rehabil., Northwestern Univ., Chicago, IL; [4]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Grasping an object requires continuous control over two motor activities: isotonic movement and isometric force. The transition between these two activities has been shown to be nonlinear in terms of the muscle activity causing finger flexion. This nonlinearity suggests that movement kinematics and force may have different cortical representations, despite their common muscle origins. By contrast, cortical networks in non-human primates have been shown to be capable of rapid, task-related modulations during arm movements. The extent to which cortical representations may shift during a motor act is a question of primary interest in neuroscience. It could also inform the design of brain-maching interface (BMI) technology for restoring function to the disabled. To investigate the nature of kinematic and kinetic grasp representations in human cortex, we recorded the electrocorticogram (ECoG) of subjects from two populations: 1) patients who were undergoing monitoring for treatment of intractable epilepsy; and 2) patients who were undergoing an awake craniotomy procedure for functional mapping during tumor resection. The subjects performed both kinematic and kinetic grasp tasks involving a precision pinch movement. We decoded the continuous kinematics of the thumb and index finger joints, as well as the continuous isometric force, at each ECoG electrode using a Wiener cascade decoder of spectral features (0-300 Hz). We then represented each electrode by its cross-validated decoding accuracy for joint kinematics or force. This produced maps of cortical activation associated with the movement of each joint, and with the regulation of force. In each subject we evaluated, the kinematic representations were highly conserved across the different joints of the thumb and index finger. However, those representations were distinct from

the representation of isometric pinch force. This occurred even in a grasp task that placed an index finger pinching motion and force application directly in series. These results suggest that the kinematic and kinetic phases of hand grasp are encoded differently in the cortex.

Title: Nerve-muscle graph chamber for amputee control of powered prostheses

Authors: *R. R. RISO[1], M. J. CARTY[2], S. G. TALBOT[2], H. M. HERR[1];
[1]Biomechatronics, MIT Media Lab, Biomechatronics Dept., Neural Interfaces Group, Cambridge, MA; [2]Plastic and Reconstructive Surgery, Brigham and Womans Hosp., Boston, MA

Abstract: Powered prostheses require reliable and intuitive means for users to control the joint movements simultaneously and with minimal effort. An ideal solution is to derive the control from the user's peripheral nerves since amputee's can initiate and coordinate the requisite neural activity according to volitional intent. Moreover, sensory input (e.g. vision, vestibular, joint and cutaneous forces) can be applied automatically for corrective adjustments with minimal delays. Developers of neural interfaces still struggle with issues of stability, low recorded signal amplitudes and motor nerve selectivity. Our studies aim to mitigate these issues by developing a "nerve-muscle graft chamber" (NMGC) where the stump of an amputated nerve is grafted to a piece of autologous muscle (ca. 4mm2 x 20mm) that is placed into an isolated compartment of the NMGC. This strategy modifies the Targeted Muscle Re-Innervation (TMR) technique [Kuiken et.al., JAMA 301(6), 2009] to afford several benefits: The major advantage of transforming the neural activity into higher amplitude EMG activity to facilitate recording is retained, but the need to sacrifice the original function of a healthy host muscle to accept the grafted nerve can be eliminated by salvaging the needed muscle tissue from the amputated limb. In addition, NMGCs can be installed at the existing locations of the nerves to eliminate mobilizing nerves over long distances. With TMR, depending on the complexity of the grafted nerve, the muscle may be innervated by a mix of nerve fascicles originally targeted to multiple

other muscles. By fabricating NMGCs in a variety of sizes and numbers of muscle compartments, fascicles from a complex nerve can be mechanically divided by function and then each isolated functional group can be directed to a separate NMGC compartment. Preliminary studies at InnerSea Tech., Inc. used a dual compartment NMGC with transgenu amputated rabbits: The transected tibial and peroneal nerves were each introduced to one of the muscle slice compartments. Tri-polar electrodes in each compartment recorded independent activity from the tibial and peroneal nerves elicited by postural disturbances and volitional movements. Recorded EMG signals were robust (>100uv) and well modulated suggesting they would be adequate for graded prosthesis control. Continuation studies in our MIT laboratory involve NMGCs applied to the transected tibial n. in Ferrets. Neural activity is assessed during treadmill walking and standup tasks. NMGC designs anticipate the future addition of micro-channel nerve regeneration arrays applied proximally to allow for sensory stimulation and additional command signal acquisition.

Title: Non-invasive BMI and Neuroprosthesis in spinal cord injury

Authors: R. RUPP[1], *G. R. MUELLER-PUTZ[2];
[1]Univ. of Heidelberg, Heidelberg, Germany; [2]Graz Univ. of Technol., Graz Univ. of Technol., Graz, Austria

Abstract: For individuals with high spinal cord injury (SCI), restoring missing grasping function is a high priority. Neuroprostheses based on functional electrical stimulation (FES) can partly compensate the loss of upper extremity function in people suffering from tetraplegia. With non-invasive, multichannel neuroprostheses a pinch and power grasp can be accomplished for everyday use [Rupp et al. 2012]. Hybrid systems combining FES with active orthoses hold promise for restoring a completely lost arm function. Novel control interfaces are needed to

make full use of the many degrees of freedom of complex hybrid neuroprostheses. Non-invasive electroencephalogram (EEG)-based brain-computer interfaces (BCIs) [Millán et al. 2011] are an emerging technology that may serve as a valuable adjunct to traditional control interfaces for neuro-prosthetic control. Shared control and context-specific autonomy are most effective for reducing the users' workload. The modularity of upper extremity neuroprostheses as well as their associated control interfaces enable customization of the systems to adapt to the impairment and needs of each individual end user. This work provides an overview of the application of noninvasive hybrid BCI [Müller-Putz et al. 2015]-controlled upper extremity neuroprostheses in individuals with high SCI [Rupp et al. 2015]. We start with single use cases on basic hand function control with non-invasive and invasive neuroprosthesis. We continue with the use of an non-invasive hybrid BCI for the control of hand and elbow function and further with the continuous control of an elbow/hand neuroprosthesis in spinal cord injury. These are results from the European Integrated Project Tools for Brain-Computer Interaction. Additionally, we also present latest results from non-invasive movement trajectory decoding [Ofner et al. 2012, Ofner et al. 2014]. Further on, we will describe the challenges and promises for the future, which will be partly covered by the European Horizon 2020 project MoreGrasp.

Title: Wavelet analysis on electroencephalographic time series to identify key patterns corresponding to arm movements

Authors: *L. GOODMAN, B. DE CELIS ALONSO, E. MORENO BARBOSA;
Facultad de Ciencias Físico Matemáticas, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: Electroencephalography (EEG) is the recording of electric fields produced by neuronal activity within the cerebral cortex by placing electrodes on specific locations of the scalp and measuring evoked potentials. The signals captured by EEG, commonly known as brainwaves, are time series of voltages in the range of 0.1-200 μV. Traditionally, band-pass filters are applied to these signals to break them into δ, θ, α, β and γ frequency bands, each of which has been found to be associated with specific brain activities. *We hypothesize that for each*

of the arm movements performed during our experiment, certain identifying patterns can be found in the corresponding brainwaves which are consistent among all individuals. In our research, twenty right handed male and female subjects perform real and imaginary movements of their right arm as EEG signals are recorded. Our experiment consists of twelve 30-second tests, each composed of 5 repetitions of two opposite movements. Indications on timing, speed, and type of movement are provided by a computer program during the experiment. The 12 tests include two base lines with open and closed eyes, four tests covering all degrees of freedom of the shoulder and elbow, and one for hand movement, as well as imagination of all five movements. We use the Continuous Wavelet Transform to identify how characteristic frequencies change over time, and Wavelet Coherence to determine (a) connections between different brain regions and (b) the degree of similarity between signals from different subjects or tests. We introduce a novel pre-processing technique for phase-independent multiscale addition and subtraction of signals. Preliminary results comparing a single electrode of two subjects performing horizontal arm movement indicate wavelet coherence in the gamma-beta range. Similar studies suggest that motor activity can be deciphered from brainwaves, but to the best of our knowledge, it has yet to be accomplished with a high rate of success. The information obtained in this study regarding the frequencies and brain regions involved in each movement has applications in non-invasive Brain-Computer Interfaces for natural movement of prosthetic or virtual limbs.

Title: Adaptive decoder training for FES neuroprosthesis

Authors: *C. ETHIER[1], D. ACUNA[2], S. SOLLA[1], K. KORDING[2], L. MILLER[1];
[1]Dept Physiol., Northwestern Univ., Chicago, IL; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Brain-machine interfaces (BMIs) can be used to restore voluntary grasp function after paralysis, through the control of functional electrical stimulation (FES). We have used neuron-to-EMG decoders in the past, to generate muscle activity (EMG) predictions for use as FES control

signals. This approach has the potential to control a large number of degrees-of-freedom, and the flexibility for the user to compensate voluntarily, for external load and muscle fatigue. However, training EMG decoders in paralyzed individuals is challenging because no output signal is available for direct decoder calculation. Kinematic decoders have been trained using observed cursor or robot arm movements, but there is no corresponding way to use a high-dimensional target EMG signal. However, we can estimate the EMG patterns required to produce a given force under simple isometric conditions. Here we present a method that we developed in monkeys, which allows us to compute the relationship between intracortical activity and intended EMG adaptively, without using any recordings of motor output. We trained monkeys at a 2D isometric wrist force task, in which they controlled a computer cursor by applying wrist force in the flexion, extension, ulnar and radial directions. Each trial required the monkeys to move to and hold briefly in a central (zero force) target, followed by one of eight outer targets to obtain a juice reward. We used a muscle-to-force model to relate each target to a muscle activity pattern, by identifying the optimal muscle combination minimizing overall activity. The model was based on generic muscle pulling directions obtained from a stimulation study in humans. We then trained EMG decoders during the target hold periods, with a gradient descent algorithm that compared the EMG predictions to the optimal EMG patterns. We tested this method both offline and online, by feeding the EMG predictions to the generic muscle-to-force model, and quantifying the resulting force prediction accuracy. Our results suggest that this adaptive approach can be used to train neuron-to-EMG decoders suitable for FES control, at least within the constrained biomechanical paradigm of this wrist force task. We plan further developments involving a muscle-to-force model obtained from stimulation that also includes temporal dynamics. We also intend to include multiple grasping tasks, each with it's own muscle-to-force model, to expose the neuron-to-EMG decoder training process to a wider repertoire of actions. We believe that these improvements could lead to EMG decoders that are accurate across tasks, and trainable in paralyzed patients.

Abstract: Objective: Brain-machine interfaces (BMIs) may provide new communication channels and motor function to individuals with severe neurodegenerative diseases, but little is known about their interests in such devices. We investigated the interests of severely affected ALS patients in BMIs, and examined factors that might influence these interests. Methods: We conducted an anonymous, mail-back questionnaire survey of severely disabled ALS patients diagnosed using the revised El Escorial criteria. Results: Thirty-seven patients responded to the questionnaire. Twenty-nine patients (78.4%) had undergone tracheostomy positive pressure ventilation. More than 80% of the patients were interested in communication support. Thirty-three patients (89.2%) felt stressed during communication. Among those using assistive communication devices (17 patients), 15 (88.2%) were not satisfied with these devices. More than 50% of the patients expressed an interest in BMIs. Their expectations of BMIs ranged widely from emergency alarm to postural change. The frequent use of personal computers tended to be correlated with an interest in invasive BMIs ($p = 0.07$). Conclusions: This is the first questionnaire survey demonstrating that severely affected ALS patients have broad and high expectations for BMIs. Communication was the most desired support from BMIs for such patients. We need to meet their widely ranging expectations of BMIs.

Title: Decoding of limbs movement from magnetoencephalography for BCI applications

Authors: *T. AKSENOVA[1], M.-C. SCHAEFFER[1], V. ROHU[1], N. TARRIN[1], E. LABYT[1], I. VERGARA[1], B. MORINIERE[2], A. ELISEYEV[1], C. MESTAIS[1], A.-L. BENABID[1]; [1]CLINATEC, CEA-LETI MINATEC, Grenoble, France; [2]CLINATEC, CEA-LIST, Grenoble, France

Abstract: Chronic clinical Brain Computer Interface (BCI) is the challenge of BCI project at CLINATEC®/LETI/CEA. The goal of the project is to improve tetraplegic subjects' quality of life by allowing them to interact with their environment through the control of effectors with multiple degrees of freedom after training. The project includes the chronic wireless ECoG recording implant WIMAGINE®, a 4-limb exoskeleton EMY, a software platform and signal decoding algorithms. A pre-clinical study yielded satisfying movement reconstructions from neural activity on ECoG non-human primate data. To prepare BCI clinical application, preliminary studies on human data were carried out using non-invasive MagnetoEncephaloGraphy (MEG). Clinical trials have been agreed by Ethical Committee and ANSM. The brain activity of control subjects was recorded by a MEG acquisition system while they were executing real or imagined limbs movements: (A) 3D hand trajectory reconstruction was studied on 5 control subjects. Two 4-min sessions were performed for the paradigms: cue-paced execution of stereotypical movements (1), self-paced execution of stereotypical movements (2), execution of self-paced free hand movements (3). Predefined stereotypical movements consisted in rectilinear trajectories of the hand from an idle position along the axis x, y, z. Execution of movements was randomized in time. Hand coordinates were tracked using a MEG compatible tracking system. (B) Imagination of stereotypical movements (see A) was performed by 2 subjects in different paradigms. (C) Preliminary study of real alternative multi-limbs 1D trajectory decoding was performed in 1 control subjects (2 hands, 2 hands+1 leg correspondingly). In all the cases, 36 sensors (12 magnetometers and 24 gradiometers) facing the subject's sensorimotor area were selected by an expert for the decoding purpose. Time-frequency

features were extracted using continuous wavelet transforms. A decoding model was identified using Partial Least Squares combined with Generalized Linear Model [1]. 8-fold cross-validation was performed to assess the accuracy. Preliminary results for 3D hand trajectory reconstruction (A) yield Pearson Correlation Coefficient (PCC) in the range of 0.2 to 0.7, depending on paradigm (1-3) and axis (average PCC = 0.42±0.11 for 3 coordinates, 3 paradigms, 2 sessions per paradigm, 5 subjects). An average PCC = 0.31±0.13 was found for 3D cued-paced imagined movements (B) (3 coordinates, 2 sessions, 2 subjects). PCCright hand = 0.55, PCCleft hand = 0.42 and PCCfoot = 0.26 were found for multi-limb movement (C) (2 sessions, 1 subject).

Title: Real-time myoelectric control of a virtual upper limb prosthesis via lower leg gestures: Preliminary results

Authors: *K. R. LYONS, S. S. JOSHI;
Mechanical and Aerospace Engin., UC Davis, Davis, CA

Abstract: Few options are currently available for high-level upper limb amputees to control a powered prosthetic arm. Existing techniques are either invasive, requiring surgery and recovery time (approximately one year), or are complex, requiring significant training time (several weeks). We have developed a noninvasive technique where lower leg and foot gestures recognized by surface electromyography (EMG) map to homologous movements of the prosthetic arm and hand. The mapping is based on the alignment of the degrees of freedom of the wrist and ankle in addition to the similarity of finger and toe movements (grasps), so each of the mapped gestures are intuitive and the entire mapping takes less than five minutes to learn. Our previous work has demonstrated that 10 or more lower leg and foot gestures can be recognized offline via surface EMG, and we now present the results of a real-time experiment in which subjects controlled a simulated prosthetic arm using this technique. The Target Achievement Control (TAC) test was used as an experimental task to evaluate subjects' ability to move the

virtual arm to target postures offset from the neutral posture in several degrees of freedom. Common performance metrics for this task are presented and compared to the case in which subjects used arm gestures, recorded via an analogous surface EMG configuration on the arm, to perform the same task.

Title: Contralateral and ipsilateral gesture decoding in epilepsy patient using electrocorticographic signals

Authors: *Y. JIN[1,2], X. WANG[1], M. LU[1,2], S. ZHANG[1,2], J. ZHU[1,3], X. ZHENG[1,2]; [1]Qiushi Acad. For Advanced Studies, Zhejiang Univ., Zhejiang, China; [2]Dept. of Biomed. Engin. and Instrument Science, Zhejiang Univ., Zhejiang, China; [3]The Second Affiliated hospital of Zhejiang Univ. Sch. of Med., Zhejiang, China

Abstract: Ipsilateral decoding is a hot topic in Brain-machine interface (BMI) nowadays, which can extend the application of BMI to help the patient whose contralateral brain was injured to restore their motor function. Electrocorticography (ECoG) signals are proved available signal source in BMI with high spatial resolutions. In our study, two participants undergoing invasive electrocorticographic monitoring for seizure localization were asked to perform three types of

gestures following visual cues. The two participators completed the task with their left hand and right hand respectively. Subdural electrodes were placed over their sensorimotor cortex to collect the ECoG signals. Power spectrum of high gamma frequency components (80-120Hz) of ECoG signals was extracted to decode their hand gestures. The best accuracy of contralateral decoding and ipsilateral decoding were 60% and 64% for participator 1 and 64% and 68% for participator 2. There was no significant difference between the performance of contralateral decoding and ipsilateral decoding ($p>0.05$, $p=0.50$ for participator 1 and $p=0.76$ for participator 2). Our result exhibited that ipsilateral decoding using electrocorticographic signals was available, whose performance was not worse than the contralateral one.

Title: Real-time decoding of individual and combined finger movements from macaque area AIP, F5, and M1

Authors: ***W.-A. SHENG**, A. AGUDELO-TORO, H. SCHERBERGER;
Neurobio., German Primate Ctr., Goettingen, Germany

Abstract: Recent neuro-prosthetic studies have allowed patients to control artificial arms and hands, but these devices have been largely restricted to reaching and simple hand closure commands. Offline studies have demonstrated high accuracy decoding of individual and combined finger movements but real-time decoding studies have been restricted to grip types or individual finger movements. We report the decoding of individual and combined finger movements online from three areas in macaque cortex reaching up to 91% accuracy. A macaque monkey was trained in a delayed finger task with visual cues, in which the thumb (f1), index (f2) and middle (f3) finger were flexed and hold individually or in combination with neighboring fingers (5 conditions). A micro-switch manipulandum detected flexion movements and provided tactile feedback. The task consisted of several epochs, in which “fixation”, “cue”, “go”, and “hold” were used for decoding. We acquired single-unit activity simultaneously from the left

anterior intra-parietal area (AIP), area F5 of the ventral premotor cortex, and the hand area of primary motor cortex (M1) using two 32-channel floating microelectrode arrays for each area (total 192 channels). Spikes were sorted online, counted in 40ms bins, and fed in real-time to a Naïve Bayesian classifier. Over 8 days, 17 decoding runs were performed. In each, the decoder was trained online with ~10 correct trials per condition before real-time decoding. Finger classification performance over 17 runs ranged from 68% to 91% (mean 80%) for the hold epoch using all areas (fixation: 21%, cue: 52%, go: 66%; chance level 20%). During the hold epoch, movements were best decoded using all areas combined (M1 75%, F5 59%, AIP 47%) but M1 alone was not significantly worse (ANOVA, $p<0.05$). Among the five single and combined finger movements, f1 could be best decoded (86%), followed by f3 (85%) and f2 (78%), while decoding of f2+f3 performed least (72%). The important combination f1+f2 was correctly decoded 78% of the time. On average, 154 online spike-sorted units (M1 61, F5 62, AIP 30) were used for decoding, from which 56% of the M1 units were tuned to the task (F5 49%, AIP 30%, ANOVA, $p<0.05$). Previous offline studies demonstrated that, in contrast to individual fingers, it is intrinsically hard to decode combined finger movements due to the non-linearity of the neuronal response. Here, we decoded individual and combined finger flexion simultaneously from M1, F5, and, AIP in contrast to previous studies that were limited to individual movements and to M1. We could determine possible cortical area combinations for decoding, which may be useful for future neuro-prosthetic device developments.

Title: Functional testing of a soft-synergy based artificial prosthetic hand

Authors: *A. GAILEY[1], S. GODFREY[2], R. BREIGHNER[3], K. ANDREWS[3], K. ZHAO[3], A. BICCHI[2,4], M. SANTELLO[1];
[1]Arizona State Univ., Tempe, AZ; [2]Inst. Italiano di Tecnologia, Genoa, Italy; [3]The Mayo Clin., Rochester, MN; [4]Ctr. Interdipartimentale "E. Piaggio", Univ. of Pisa, Pisa, Italy

Abstract: The loss of a hand can dramatically affect the ability to perform activities of daily living, and thus quality of life. Although many commercially-available prosthetic hands exist, rejection rates remain high in part due to their limited function. To address these limitations, the University of Pisa and the Italian Institute of Technology have created a myoelectric artificial hand, the SoftHand, whose design combines soft robotics and the concept of hand synergies. The hand consists of 19 joints. Motion occurs along the 1st principal component of kinematic hand synergies and is generated by a single motor. The user controls the SH via electromyographic (EMG) signals from two antagonistic wrist muscles. The present study was designed to quantify grasp performance of the SH in able-bodied subjects. We asked subjects (n = 19) to grasp and lift an object while recording forces on the object, object kinematics, and EMG signals. We measured the contact-to-lift time, hold, and object placement (total task duration), changes in total grip force as a function of practice, and native hand performance (20 trials). SoftHand trials were performed at two different weights (667 g and 1067 g) 30 trials each to assess grip force modulation in response to object weight. We also assessed effects_on grasp performance_of training exercises consisting of tracking a cursor on a computer monitor by opening and closing the SH. Subjects were randomly divided into four experimental groups, with each given a 10-15 minute familiarization period with the SH plus the experimental training and then tested on the grasp-and-lift task the next day. Group 1 underwent training as described above; Group 2 had 45 minutes of exploratory practice; Group 3 received half-doses of both training and exploratory practice; and Group 4 had no training beyond the familiarization period. The type of practice did not systematically affect our behavioral measures. After pooling data across all groups we found that, even though total task duration was longer when using the SH vs. the native hand (mean across all trials ±S.E.: 7.06 ±1.25 s and 2.17 ±0.1), subjects' performance with the SH improved with practice. Specifically, average total task duration decreased from 10.13 ±1.91 s on the first 10 trials to 5.94 ±0.88 s on the last 10 trials. Greater object weight caused a larger grip force in both native hand and SH; the difference was larger for the native hand (~5.5 N vs. ~1.5 N, respectively). Although preliminary, these data suggest that the SH has promising potential for prosthetic use. Current work is examining design modifications to improve the function of the SH. Grant support: NIH R21 HD081938 and The Grainger Foundation.

Abstract: Brain-machine interfaces (BMIs) are a promising technology for enabling the effective control of advanced prosthetic limbs. However, the ability of BMIs to reproduce hand-level fine motor skills is still relatively lacking. Here, we investigate the feasibility of extracting finger-level motor information from both cortical and peripheral neural sources. We trained two rhesus macaques to perform index finger movements to acquire virtual targets on a monitor, recording finger position via a flex sensor on the index finger. In one monkey, we implanted two intracortical electrode arrays in M1, one 96-channel Utah array (Blackrock Microsystems) and one 16-channel FMA (Microprobes). In a second monkey, we recorded signals from the median and radial nerves in the forearm via three Regenerative Peripheral Nerve Interfaces (RPNIs). The RPNI is a novel interface consisting of a free muscle graft implanted on the end of a transected nerve fascicle. After implantation, the nerve fascicle re-innervates the graft, which then acts as a bioamplifier for the efferent signals. To record these signals, we implanted one bipolar intramuscular EMG electrode (Ardiem Medical) in each RPNI. We performed two decodes for each signal modality, using neural spikes (thresholded at -4.5*RMS) as the cortical data feature and waveform signal power and line length as the EMG features. First, we predicted continuous 1D finger position and velocity (as a percent of flexion) via a linear Kalman filter, using 100ms bins and including 5 bins of neural history for the cortical decode. Second, we used linear discriminant analysis to classify movement type (flexion vs. extension vs. rest) for a variably-sized window centered on the manually-labeled movement onset. For the continuous cortical decode using 10-fold cross-validation, the predicted and true finger positions had a correlation coefficient (ρ) of 0.88, and a root mean squared error (RMSE) of 0.12 (an average error of ~12% of the full range of movement). For the continuous EMG decode using 10-fold cross-validation, $\rho = 0.82$ and RMSE = 0.13. For the discrete classifications, we lowered the window size to 50ms for EMG and 200ms for cortical without losing significant performance. Using leave-one-out cross-validation, the EMG decode was 97.7% correct and the cortical decode was 95.3% correct (out of 261 and 342 movements, respectively, with chance at ~33%). These results demonstrate that accurate finger kinematics can be extracted from both cortical and peripheral sources. It remains to be seen whether the presented decodes can be used effectively in a closed-loop setting. This could, in the future, allow BMIs to reproduce dexterous hand movements.

Title: Measuring the influence of EMG control on feedforward uncertainty

Authors: ***R. JOHNSON**[1,2], K. KORDING[1,2], L. HARGROVE[1,2], J. SENSINGER[3,2]; [1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Northwestern Univ., Chicago, IL; [3]Univ. of New Brunswick, Fredericton, NB, Canada

Abstract: Movements with powered upper limb prostheses are currently imprecise and unpredictable, which degrades the ability to perform everyday tasks. The movement unpredictability, or feedforward uncertainty, may be caused in a large part by the use of EMG control, which is highly variable and is shown to increase errors relative to able-bodied joint angle or torque control. To reduce movement uncertainty, we first need to understand the sources of uncertainty during prosthesis control. However, uncertainty is typically inferred through observing behavior, or assumed to be represented by variability or error. In this experiment we dissociate error and uncertainty by explicitly quantifying feedforward uncertainty. We compare feedforward uncertainty during the use of EMG control, torque control, and torque control with added noise. The torque+noise condition was meant to create a wider range of movement performance, which allowed us to analyze uncertainty as a function of mean absolute error. Feedforward uncertainty was quantified by measuring the just noticeable difference of a visual perturbation. We found that for equal errors, EMG resulted in higher feedforward uncertainty than both torque and torque + noise.

Title: EEG-controlled functional electrical stimulation of paralyzed hand muscles in subjects with chronic, complete, cervical spinal cord injury for grasp and release

Authors: *K. GANT, L. ZIMMERMAN, Z. XIE, J. C. SANCHEZ, A. PRASAD;
The Univ. of Miami, Miami, FL

Abstract: Over 33,000 people in the United States are living with complete tetraplegia caused by cervical spinal cord injury (SCI), which results in paralysis of hand muscles. This population relies heavily on caregivers and family, due to an inability to perform activities of daily living. In these individuals, the options for hand function rehabilitation are limited since improvements are not expected during the chronic phase. People with complete tetraplegia rank restoration of arm and hand function as most important to them, as it would increase independence and improve their quality of life. In this study, we show that subjects with chronic C5/C6-level, motor-complete SCI are able to control a brain computer interface-functional electrical stimulation (BCI-FES) system to perform a grasp and release task. The subjects (SCI and uninjured controls) participated in 6 days of BCI-FES training over a period of 3 weeks, consisting of 120 closed-loop trials each day. Visual cues were presented to the subject on a computer screen, instructing them to either relax or imagine movement of their right hand. Electroencephalographic (EEG) signals were acquired using a wireless 20-channel EEG system at 256 Hz sampling rate and 16-bits resolution (X24 headset, Advanced Brain Monitoring, Carlsbad, CA). We extracted average power in 5 Hz bins (6-35 Hz) from C3, C1, Cz, C2, and C4 electrodes and input as features to a Support Vector Machine (SVM) classification algorithm. When “movement” was classified correctly from the EEG motor imagery, a custom-designed stimulation sequence was delivered to the forearm muscles (extensor digitorum profundus, extensor digitorum superficialis, and extensor pollicis longus, flexor digitorum superficialis, flexor digitorum profundus, 200 μs pulse width, 35 Hz) to enable opening and closing of the hand for grasp and release. Although classification accuracies started off low during the first day of training (49% for control, 52% for SCI), they improved over the training period. By day 6, overall accuracy for the control subject averaged 73% (± 2.2%), while the SCI subject achieved 80% (± 1.8%) accuracy. This study shows that subjects with motor complete, cervical SCI were able to control a BCI-FES system after a brief training period. BCI-FES systems may have the potential to restore hand function in

people with motor-complete SCI, which would increase independence and improve quality of life.

Title: Restoration of hand function in daily life using a brain/neural interface controlled hand-exoskeleton

Authors: ***M. WITKOWSKI**[1], M. CEMPINI[2], M. CORTESE[2], N. VITIELLO[2], N. BIRBAUMER[3,4], S. R. SOEKADAR[1];
[1]Applied Neurotechnology / Univ. Hosp. Tübingen, Tübingen, Germany; [2]Scuola Superiore Sant'Anna, The BioRobotics Inst., Pontedera, Italy; [3]Inst. for Med. Psychology and Behavioural Neurobio., Tübingen, Germany; [4]Ospedale San Camillo, Inst. di Ricovero a Cura a Carattere Scientifico, Venice, Italy

Abstract: Background: High-level spinal cord injuries (SPI) are often associated with complete loss of hand function. While the majority of individuals with SPI have sufficient shoulder and arm function to perform reaching movements, severe or complete finger paralysis incapacitates them to grasp, hold or manipulate daily life objects. Here we tested whether a non-invasive autonomous brain/neural-computer interaction (BNCI) system that translates neuronal activity and eye movements into grasping motions of a hand-exoskeleton can restore hand function to grasp and manipulate daily life objects. Method: Two individuals (one male, 26.0±8.48 years)

with complete (Asia Impairment Scale A) and incomplete (Asia Impairment Scale B) chronic SPI and severe loss of hand function participated in the study. All participants performed the Toronto Rehabilitation Institute Hand Function Test (TRI-HFT) to assess their ability to grasp and manipulate daily life objects without (baseline) and with the BNCI system. Results: After calibration and familiarization, participants were able to control the BNCI hand-exoskeleton system. TRI-HFT scores increased from 42.75±25.1 at baseline to 109.5±16.26 (max. score: 133) under BNCI hand-exoskeleton control documenting hand function close to normal. Conclusion: Non-invasive brain/neural hand-exoskeleton systems are powerful tools to restore autonomy and independence of individuals with high-level SPI. Integration of such systems and fusion with other assistive tools may significantly improve paralyzed individual's quality of life and accessibility.

Title: Changes in LFP power during motor learning in brain-machine interface

Authors: R. JIE CUI, M. ARMENTA SALAS, *S. I. HELMS TILLERY;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: The study of the neural correlates of motor learning is a primary focus of neuroscience. Previous studies have shown that local field potentials (LFPs) measured at the motor and premotor cortices can encode a variety of parameters, from behavioral states to motor execution. However, quantitative information about LFPs and motor learning is lacking. Here we study the changes of the band-limited power (BLP) of LFPs recorded in motor cortical areas while a monkey learned to control a computer cursor in a 3D center-out task via brain-machine interface. In this task, the control of the cursor was initially learned using a population vector algorithm. The animal was then challenged by introducing perturbations in the control mapping between neural signals and movement. We changed the control algorithm either by using a visuomotor rotation or by using a decorrelation approach, in which pairs of neurons that were

normally highly correlated were required to be uncorrelated in the control algorithm. We found that, in general, the power of beta-band (15-30 Hz) activity was significantly elevated during the sessions of perturbation. Moreover, the spectra of LFPs indicate differences between the two types of perturbation. Finally, our preliminary results suggest a linear correlation between BLP of very low frequency bands (1-8 Hz) and success rate of trials, implying a potential role of LFP in motor learning

Title: Radio-transparent enclosures for enabling wireless home-cage recordings of non-human primates

Authors: ***M. POWELL**[1], D. XING[1], R. DARIE[1], A. GREGOIRE[2], J. B. ZIMMERMANN[2,4], W. BRITZ[5], J. S. HARPER, III[3], D. A. BORTON[1,4];

Abstract: Studies of the non-human primate (NHP) motor system generally involve a head-fixed animal performing a limited set of learned motions. Such motions represent only a subset of the complex movement repertoire. Recently, a wireless neurosensor capable of recording neural activity during unconstrained movements has become commercially available. With the introduction of this small, lightweight, wireless neural recording technology, experiments no longer require animals to be head-fixed or otherwise restrained during recordings. For example, long-term recordings in the animal's home-cage become possible, enabling scientific exploration of social behavior, adaptation, and learning. Current wireless solutions use radio frequency (RF) far-field transmission to stream data. Traditional metal cages block this signal from leaving the enclosure's boundary. To address this issue, we developed a non-metallic, dielectric cage that is transparent to RF radiation. We show that broadband neural data can be wirelessly transmitted and recorded from a naturally behaving animal to external receiving equipment for further processing and interpretation. Using a neural signal simulator, the cage was validated to ensure that data could be successfully retrieved from inside the enclosure. Components constructed from a thermoplastic laminate, as well as polycarbonate and a fiberglass, thermoset polyester

composite, were used as strong, non-conductive alternatives to steel preventing absorption or scattering of the radio signals. The final construct contains less than 5% electrically conductive components. The transparent home-cage system is not limited to studies of the motor system. As animals perform daily tasks in their home environment, neural systems can be interrogated with contextual relevance, for instance during sleep. Complex social interactions can be studied, as animals may be left undisturbed to socialize with their peers while researchers observe remotely. As new neural recording technologies are developed, they can be seamlessly integrated into the new housing system. Using this tool, neural signal collection can now be performed throughout an animal's daily routine enabling researchers to ask new and interesting questions about the nervous system.

Title: Myoelectric pattern recognition control of a wearable exoskeleton hand

Authors: **Z. LU**[1], K.-Y. TONG[2], *P. ZHOU[1];
[1]PM&R, Univ. of Texas Hlth. Sci. Ctr. At Houst, Houston, TX; [2]The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Robot-assisted training is an effective approach to neurologic injury (such as stroke, spinal cord injury or cerebral palsy) rehabilitation. Compared with passive training, the active or voluntary implementation of tasks with the user's intention input can enhance therapeutic effect and promote motor learning as well. Active myoelectric control has been developed for robot-aided therapy, primarily based on an "on-off" or proportional strategy. On the demand for the mobility of assistive devices, a more advanced myoelectric control strategy is required (to overcome the limitation of the one-to-one mapping between a muscle and a degree-of-freedom).

This is particularly important for a hand exoskeleton or robot due to hand dexterity. To meet this need, a myoelectric pattern recognition framework was implemented in this study to control a wearable exoskeleton hand (Hand of Hope, Rehab-Robotics Company Ltd, Hong Kong) in real time. The framework used four channels' surface electromyogram (EMG) acquired from the flexor carpi radialis, flexor carpi ulnaris, extensor digitorum, and abductor pollicis brevis muscles, respectively. A pattern recognition algorithm based on a RMS +WL+AR feature set (i.e. a combination of root mean square amplitude, waveform length, and 4th order auto regressive coefficients) and a Bayes classifier was implemented on 200 ms analysis windows (with 100 ms overlapping). This was used to identify 6 different hand patterns: hand closing and opening (HC & HO), thumb, index and middle finger closing and opening(TIMC & TIMO), middle, ring and little finger closing and opening (MRLC & MRLO). Once a motion intention was detected, the exoskeleton hand performed the motion task. Five neurologically intact subjects (32.0 ± 6.0 years, 1 female, 4 male) participated in the study. For each subject, at least 300 analysis windows were recorded for each hand pattern to train the classifier. Then, performance of the myoelectric pattern recognition control for the exoskeleton hand was tested. Across different hand patterns, the overall control accuracy was 98.4 ± 3.6% with an algorithm delay approximately 38 ms (Intel Core i5 4690S, 8GB RAM). The average completion time for each hand pattern was 6.4 ± 1.7s, including 2.3 ± 1.6 s waiting period. Current experimental results demonstrated the feasibility of applying myoelectric pattern recognition for controlling the exoskeleton hand, which will be further tested with neurological injury patients for hand function restoration.

Title: Time course of photoperiodic responses in the hypothalamus of a seasonally breeding songbird

Authors: *S. EDWARDS[1], R. A. ALDREDGE[2], A. M. IANCU[1], N. P. JAMES[1], K. W. SOCKMAN[2,3], D. L. MANEY[1];
[1]Psychology, Emory Univ., Atlanta, GA; [2]Biol., [3]Curriculum in Neurobio., Univ. of North Carolina, Chapel Hill, NC

Abstract: Seasonally-breeding birds use day length as an initial predictive cue to time gonadal recrudescence and the onset of reproduction. The neural response to photostimulation culminates in the release of gonadotropin-releasing hormone (GnRH) from the median eminence of the hypothalamus. We previously showed that in white-throated sparrows (Zonotrichia albicollis), a North American seasonal breeder, GnRH neurons in the preoptic area express the immediate early genes Egr-1 and FOS by the morning following the first long day. It remains unclear, however, when during the night the GnRH neurons begin responding to the long day, and whether other neural responses precede or follow GnRH responses. In this study, photosensitive male white-throated sparrows in non-breeding condition were housed on short days (8L:16D), then half were exposed to a single long day (16L:8D). We collected brain tissue at three intervals: 10-14 hours, 18-20 hours, and 24-26 hours after dawn of that long day. Using immunohistochemical labeling, we found that Egr-1 expression was not induced in GnRH neurons until 26 hours after dawn. In contrast, Egr-1 was induced elsewhere in the brain at earlier time points. For example, we noted considerable induction of Egr-1 throughout the mediobasal hypothalamus (MBH), including the lining of the third ventricle, in long-day birds by 18 hours. This response persisted until at least 26 hours. Immunohistochemical co-labeling of tyrosine hydroxylase showed that a subset of the responding cells belonged to dopaminergic cell groups in the ventral and caudal portions of the MBH. These findings led us to do a follow-up study to determine exactly when during the night the Egr-1 response begins. Using tissue collected from males between 13 and 18 hours after dawn on the first long day, we noted Egr-1 induction in the infundibular nucleus of the MBH as early as 15.2 hours after dawn, and in the lining of the third ventricle one hour later. The Egr-1 response in the dopaminergic cells of the MBH increased significantly by 16.5 hours. Egr-1 expression throughout the MBH was robust in all birds by 17 hours after dawn. Our results indicate that compared with neural responses in the MBH, the GnRH cell population responds to photostimulation relatively late in the cascade of events. Induction of immediate early genes in GnRH neurons may reflect new synthesis related to GnRH depletion rather than stimulation by light cues.

Title: Gonadal regression elicited in Pekin duck drakes and hens associated with a drop in light intensity

Authors: *G. S. FRALEY;
Hope Col., Holland, MI

Abstract: Many studies have focused on the neural mechanisms associated with seasonal reproduction in birds and the light intensity necessary to initiate gonadal recrudescence. However, few studies have examined the drop in light intensity that initiates gonadal regression. The Pekin duck is an excellent model for the study of seasonal reproduction and the question regarding the neurobiology of gonadal regression is important in the US duck poultry industry. To more fully understand the relationship between light intensity and gonadal regression we housed adult (45 week old) drakes and hens were housed in the Hope College aviary as 4 drakes:20 hens in each of 3 floor pens (density = 0.24 m2 per duck). Light conditions were divided into the following: 1) to simulate summer, 14 hrs 75 Lux with 10 hrs 1 lux; 2) to simulate winter, 8 hrs 75 lux with 16 hours 1 lux; 3) winter augmented, 8 hrs 75 lux with 16 hours with 25 lux. Daily, total number of eggs laid and a daily average of eggs laid calculated for each week of the study. Weekly, eggs were weighed and the perivitilline membrane was assayed for number of sperm holes as an indirect measure of drake fertility. As expected, winter conditions caused a significant ($p < 0.01$) reduction in the percent of eggs laid and a significant ($p < 0.001$) reduction in the number of fertilized eggs compared to the summer light conditions. The augmented winter light conditions prevented the loss in the percent eggs laid and fertilized eggs. Surprisingly, even after 5 weeks of the study, the winter conditions did not cause a complete loss of fertility in the Pekin ducks. Although a minimum (1 lux) of light is capable of maintaining some fertility, commercial Pekin duck barns might want to increase the augmented light to 25 lux in order to maintain fertility during winter months. Furthermore, it appears that the drakes may be more sensitive to environmental light conditions than are hens.

Title: Increased hypothalamic GnIH-ir and decreased reproductive behaviors in an inbred line of Single Comb White Leghorn egg-layers, GHs6

Authors: *H. M. POTTER[1], E. ALENCIKS[2], L. PORTER[2], M. SHANNON[2], G. S. FRALEY[2]; [2]Biol., [1]Hope Col., Holland, MI

Abstract: An inbred line of White Leghorn chickens has been housed at the University of Wisconsin for decades. This line of birds could only be propagated by artificial insemination despite that researchers in the past demonstrated that the hens laid eggs at a typical leghorn rate, and the roosters produced good quality semen, though of slightly, but significantly lower sperm count compared to controls. Thus we hypothesized that the lack of fertility in these birds was due to deficits in reproductive behaviors. To test this hypothesis, a remote surveillance system was was set up over the floor pens (n = 3) that contained roosters and hens (1:4 ratio) housed on 18 hrs of daylight. Constant remote monitoring continued for 6 months, and reproductive and aggressive behaviors were assayed once per week for 3 hours after lights-on. Controls were standard white leghorns (SWLR) housed in a similar fashion with remote surveillance in the Hope College aviary (n = 3 pens). We focused on the roosters' behaviors and found no differences in thrusts or pecks between the inbred and standard leghorns. However, unlike the SWLR the GHs6 roosters showed zero courtship or mating behaviors. Gonadotropin inhibitory hormone has been described in birds to stimulate food intake, and to inhibit both the HPG axis and reproductive behaviors. Thus we hypothesized that the lack of reproductive behaviors in GHs6 roosters may be due to an overexpression of GnIH. To test this hypothesis, 45 week old GHs6 and SWLR (n = 4 per strain) roosters were euthanized and pericardially transfused with 4% paraformaldehyde. Brains were processed for immunocytochemical analyses of GnIH-immunoreactivity (ir). A significant ($p < 0.05$) increase in the number of GnIH-ir perikarya were observed in the paraventricular nucleus of the hypothalamus in GHs6 roosters compared to SWLR controls. The increased GnIH protein expression may be related to the loss of reproductive behaviors in the Single comb white Leghorn roosters.

Title: Lack of effects on growth and body weight gain after elimination of the leptin receptor from the brain of immature Pekin drakes

Authors: *L. M. PORTER, E. ALENCIKS, K. FRAZIER, A. PORTER, G. S. FRALEY; Biol., Hope Col., Holland, MI

Abstract: The presence of the hormone leptin (LEP) is a controversial topic in the field of avian physiology. While LEP is well understood in mammals, the hormone has not been definitively verified in avian species. Although the hormone remains elusive, the leptin receptor (LEPR) has been identified and sequenced in multiple avian species. Its role, however, remains unclear. To attempt to deduce the role of the leptin system in birds, we focused on altering the leptin receptor expression in the brain of immature Pekin ducks. We hypothesized that eliminating the LEPR-expressing neurons of the hypothalamus would elicit an increase in body weight, as is the case for mammals. To test this hypothesis, we injected stereotaxically 3 µl of a solution containing a monoclonal antibody (anti-LEPR) conjugated to saporin (LSAP, 100 ng/µl) was injected into the lateral ventricle of 10 day old Pekin ducks (LSAP, N = 10). Control group animals (SAP) were injected with unconjugated antibody and saporin at equimolar concentrations to the LSAP. Ducks were weighed weekly starting at 3 days of age. After a final weight was obtained at 50 days of age, ducks were euthanized and a blood sample was collected and sent out for an avian panel to assay serum glucose and free fatty acids. We found that the elimination of LEPR had no significant effect on the body weights of the ducks ($p>0.05$). In addition, The CBC panel did not reveal any significant differences in the overall health of the ducks in each treatment group. Our data indicates LEPR may not play a significant role in the regulation of body weight or growth in juvenile ducks.

Title: Immunolesions of melanopsin receptive neurons attenuates the hormonal reproductive axis in the adult but has no effect on growth in immature Peking ducks

Authors: *E. ALENCIKS[1], K. FRAZIER[2], A. PORTER[2], G. FRALEY[2];
[2]Biol., [1]Hope Col., Holland, MI

Abstract: Several light sensitive receptors have been described in the avian brain that are thought to regulate the reproductive axis independently from the eyes and pineal gland. Recently, our lab has described the presence of 3 photoneuroendocrine systems in the Pekin duck: rhodopsin, opsin 5, & melanopsin. We set out to test the hypothesis that melanopsin receptive neurons are necessary to maintain seasonal reproductive status along with growth and development in the Pekin drake. To accomplish these goals we first investigated 50-week-old Pekin drakes that were housed in the aviary at Hope College under long day length (18 hrs lights on) conditions in floor pens. To specifically lesion melanopsin-receptive neurons, 3 µl of an anti-melanopsin-saporin conjugate (MSAP, 100 ng/ul) was injected into the lateral ventricle (n = 10). Control drakes were injected with 3 ul of equimolar unconjugated anti-melanopsin and saporin (SAP, n = 10). The drakes were returned to the aviary after complete recovery. Reproductive behaviors were analyzed weekly in a test pen with adult hens. After 4 weeks, birds were euthanized and body weights were measured, and brains, pituitaries, and testes collected and stored for analyses. To test melanopsin's effect on immature ducks the same surgery was performed on a group of 10 day old ducks (n= 10). Ducks were weighed weekly starting at 3 days of age. After a final weight was obtained at 50 days of age, ducks were euthanized and a blood sample was collected and sent out for an avian panel. Mature MSAP-treated drakes had significantly ($p< 0.001$) reduced relative teste weights compared to SAP controls. qRT-PCR analyses (n= 3 per treatment) of anterior pituitary showed a significant reduction ($p< 0.001$) in both LH-beta and FSH mRNA's. Immunoctyochemical analyses (n= 3 per treatment) showed a significant reduction in melanopsin and GnRH-immunoreactivities. Immature drake BW did not differ significantly between MSAP and SAP animals at any of the measured days. The data appeared to drift toward significance near the end of the sampling period ($p = 0.297$). Blood panel results revealed no significant differences between MSAP and SAP animals in any CBC component. Serum glutamic-oxaloacetic transaminase (SGOT) ($p= 0.022$) and creatine phosphokinase (CPK) values were significantly elevated ($p = 0.006$) in MSAP animals compared to controls. Although melanopsin neurons in the PMM appear to have an important role in adult drakes, their importance in the growth of immature ducks is still unclear. However, these data underscore the importance of the photoneuroendocrine system in maintaining the reproductive axis along with growth and development in seasonally breeding birds.

Title: The neonatal sensorial denervation induced by capsaicin increases the dendritic arborization in the hippocampus of the adult male rat

Authors: C. CORDERO[1], G. HERNANDEZ[1], E. BIVIANO[1], G. FLORES[2], R. REYES[3], U. QUIROZ[1], *C. MORAN[4];
[1]Lab. de Histofisiología, Escuela de Biología, [2]Lab. de Neuropsiquiatría, Inst. de Fisiología, [3]Lab. de Biología de la Reproducción, Escuela de Biología, Benemerita Univ. Autonoma de Puebla, Puebla, Mexico; [4]Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: It has been previously shown that sensorial denervation induced by capsaicin (Caps) decreases the total number of sperm, the motility and viability of the rat. This decrease was higher in the right testis. The participation of the neural mechanisms controlling the spermatogenesis is still unknown. There are neural connections between testicles and central nervous system. Some nuclei that have/use this route are the amygdala and hippocampus. The aim of the present study was to analyze the effects of the sensorial denervation induced by capsaicin on the dendritic morphology in the neurons of amygdala (basolateral nucleus) and hippocampus (CA3). Newborn male rats of the CIIZ-V strain were injected with 50 mg/kg Caps dissolved in vehicle: 10 % ethanol, 10 % Tween 80, and 80 % saline solution, or vehicle only (Control group): The animals were sacrificed at 90 days of age. Dendritic morphology and characteristics were measured by using the Golgi-Cox procedure followed by Sholl analysis. The dendritic morphology did not affect the amygdala. Interestingly the dendritic length and order was higher in the right hippocampus in the denervated animals. Our results suggest that the lack of the sensorial innervation in the testicles leads to asymmetrical response in the dendritic morphology. This response is higher in the right hippocampus and may explain the changes observed in the spermatogenesis of left testicle.

Title: Interaction of leptin, nitric oxide and neuropeptide Y to control the female reproductive function: modulation by estrogen and food condition

Authors: *L. OLIVEIRA, C. R. FRANCI;
Ribeirão Preto Med. School, Univ. of São P, Ribeirão Preto, Brazil

Abstract: Leptin action on hypothalamus-pituitary-gonad axis is mediated by nitric oxide (NO) and neuropeptide Y (NPY). NPY action to control food intake may also be mediated by NO. The control of reproductive function and food intake involves medial preoptic area (MPOA) and arcuate nucleus (Arc), in which were identified neurons that co-express NOS (nitric oxide synthase)-leptin and NOS-NPY. Our aim was assess whether leptin action on reproductive function may be controlled by interaction between NPY and NO as well the effect of different metabolic conditions, and of estrogen. **Methods:** Wistar rats were subjected to ovariectomy and stereotaxic implantation of intracerebroventricular (icv) cannula, a week before the experiment. From the fifth day, they were treated with estradiol cypionate (10 µg / rat) or vehicle (vegetable oil, 0.1 ml / rat). One group was kept fasting for 48 hours before the experiment and the other normally fed. On the day of experiment the animals received icv microinjection of L-NAME (500µg/1µl; Sigma) or vehicle, and an hour later received isotonic saline (control) or leptin (3µg/1µl) icv microinjection. After two hours they were perfused to remove the encephalon. MPOA and Arc were microdissected to assess the NPY and FOS expression by immunohistochemistry. **Results**: We found that in fasting state, the number of active NPY neurons (coexpression FOS-NPY) increased in the ARC and the MPOA, being more evident in Arc, mainly in animals treated with estrogen. In the normal feeding occurs a similar response to the fasting, but the effect of blocking of the NO activity seems to be less pronounced. Leptin treatment caused a considerable decrease in that number, especially in animals without estrogen replacement. The same happened in the treatment with L-NAME, but more evident in animals with replacement, even in fasting, when leptin is low, the number of active NPY neurons decreases, indicating the participation of NO neurons in this communication, mostly in the presence of estrogen. In the treatment with L-NAME and leptin, the number of active NPY neurons also decreased mainly in animals treated with estrogen. This suggests that leptin icv could be influencing this activation through other pathways in the presence of estrogen, moreover in treatment with L-NAME, low leptin has not been able to activate a large number of NPY neurons with blockade NO neurons. Therefore, in fasting situation seems to exist a communication line leptin - NO - NPY, in the MPOA and mainly in Arc, regions involved in the control of reproductive function and food intake, especially in estrogen presence.

Title: RFRP-3 stimulates the male mouse reproductive axis

Authors: ***C. ANCEL**, J. S. KIM, M. INGLIS, G. M. ANDERSON;
Dept. of Anat., Ctr. For Neuroendocrinology, Dunedin, New Zealand

Abstract: In 2000, gonadotrophin-inhibitory hormone (GnIH) was discovered in birds and shown to inhibit gonadotrophin secretion (Tsutsui et al. 2000). The mammalian ortholog was concurrently discovered in humans and rats and termed RFamide-related peptide-3 (RFRP-3) (Hinuma et al. 2000). Since then, a number of studies have aimed at determining the involvement of RFRP-3 in the regulation of reproduction in various mammalian species, including rats (Johnson et al. 2007, Murakami et al. 2008, Pineda et al. 2010), hamsters (Kriegsfeld et al. 2006, Ancel et al. 2012, Ubuka et al. 2012), sheep (Clarke et al. 2008, Sari et al. 2009, Caraty et al. 2012), and cattle (Kadokawa et al. 2009). This plethora of results has underlined the species- and sex-specific effects of RFRP-3 on the reproductive axis, through the analysis of LH section in most cases. However, a comprehensive investigation of the role of RFRP-3 in the regulation of the mouse gonadotrophic axis remains to be carried out, in part because of the difficulty in taking repeated LH measurements from this species. In this study, we performed an extensive analysis of the effects of RFRP-3 on LH secretion in male C57BL/6 mice. Using a repeated tail tip blood sampling method combined with a highly sensitive ELISA, RFRP-3 dose-dependently stimulated LH secretion in mice when injected centrally (0.5-5 nmol/mouse), but had no effect when administered peripherally (5-50 nmol). In cultured HEK293 cells transfected with the human KISS1R, RFRP-3 showed some affinity to KISS1R and was able to potentiate the effects of kisspeptin, but did not show agonism alone. This potentiating effect may occur through allosteric modulation, although further studies are required. To conclude, our results show that RFRP-3 can stimulate the reproductive axis in male mice, as has been shown in hamsters (Ancel et al. 2012, Ubuka et al. 2012). Thus, the idea that RFRP-3 and kisspeptin exert opposing effects is likely to be overly simplistic.

Title: Winter is coming: Linking seasonal cues to reproduction in the mouse

Authors: *M. J. BEYMER[1], C. SÁENZ DE MIERA[1], D. HAZZLERIG[2], V. SIMONNEAUX[1]; [1]Inst. des Neurosciences Cellulaires et Intégratives, Univ. of Strasbourg, Strasbourg, France; [2]Dept. of Arctic and Marine Biol., Univ. of Tromsø, Tromsø, Norway

Abstract: The proper timing of reproduction is an essential factor for the continuation of a species. The Arginine-Phenylalanine-amide (RF-amide) family of peptides is a class of hypothalamic neuropeptides that have been implicated in many physiological regulatory processes, including nociception, stress response, energy metabolism, as well as reproduction. Two members of this family, in particular, have been shown to regulate the hypothalamic-pituitary-gonadal (HPG) axis. Kisspeptin, is expressed by neurons in the arcuate (ARC) and medial preoptic (MPN) nuclei. Release of kisspeptin from these neurons can strongly activate the HPG axis. RF-amide related peptides (RFRP-1 and -3), are expressed in neurons located in and around the dorso- and ventro-medial hypothalamic nuclei. RFRP neurons were original discovered in birds as a potent inhibitory factor of the HPG axis; however this role seems to be less the case in mammalian species where the specific actions of RFRP-3 are species-, sex-, and photoperiod-dependent. The central pathways through which seasonal cues are able to regulate reproductive capacity are still mostly unknown; however recent findings suggest that RFRP and kisspeptin may be involved in this process. In order to fully elucidate the photoperiodic pathways involved in the transduction of seasonal cues onto the reproductive axis we are using several strains of mice with different melatonin profiles: C57BL/6J, which are melatonin-deficient, CBA, which are melatonin-proficient, and MSM/Ms, which are also melatonin-proficient. We placed male mice of all genotypes in either short day (LD 8:16) or long day (LD 16:8) conditions to determine the effect of the presence or absence of melatonin on RF-amides. Both CBA and C57 males showed no significant changes in body weight, paired testes weight, or seminal vesicle weight in response to different photoperiodic conditions. Interestingly, in short day adapted CBA males there was a decrease in *Rfrp* expression as compared to long day adapted CBA males, whereas there was no change in *Rfrp* expression in C57 males in response to either photoperiod. This is in concordance to what is found in classical seasonal breeders adapted to short day conditions where there is a reduction in hypothalamic *Rfrp* expression. It is clear from

these findings that the RFRP system in mice is still sensitive to seasonal cues in the form of melatonin secretion. Furthermore, since we do not see a response of the testes in CBA mice due to changing photoperiods, it is tempting to conclude that there is another central factor, a likely candidate being kisspeptin, in non-seasonal breeders blocking the full transduction of seasonal cues onto the HPG axis.

Title: KNDy neurons are activated by estradiol during the preovulatory surges of luteinizing hormone and prolactin in female rats

Authors: ***R. E. SZAWKA**[1], R. ARAUJO-LOPES[1], R. G. L. BERNARDES[1], F. L. M. BELLO[1], P. C. HENRIQUES[1], N. S. S. AQUINO[1], C. R. FRANCI[2];

Abstract: Central kisspeptin is critical for luteinizing hormone (LH) secretion and fertility in mammals. Kisspeptin, neurokinin and dynorphin (KNDy) neurons in the arcuate nucleus of hypothalamus (ARC) are involved with LH and prolactin (PRL) secretion, but their functional roles in the secretion of these hormones remain poorly understood. Here we used dual label immunohistochemistry to investigate the activity of KNDy neurons associated with changes in LH and PRL secretion in male and female rats under different hormonal conditions. Cycling rats were perfused on the days of diestrus (n = 6), morning of proestrus (n = 6), late afternoon of proestrus (n = 5), and estrus (n = 6). The number of kisspeptin-immunoreactive (ir) neurons in

the ARC was lower on proestrus and estrus compared with diestrus ($P < 0.01$). Conversely, the percentage of kisspeptin-ir neurons expressing c-Fos (anti-c-Fos Ab-5, Calbiochem) was 45% higher on the afternoon of proestrus ($P < 0.05$), when the preovulatory surges of LH and PRL occur. These results were further confirmed in an additional analysis using a different c-Fos antibody (anti-c-Fos K-25, Santa Cruz Biotechnology), which showed the same response of increased activity of KNDy neurons on proestrous afternoon ($P < 0.01$). In male rats ($n = 6$-8), the number of kisspeptin-ir neurons in the ARC was lower than in diestrous females and c-Fos expression in KNDy neurons was low and unchanged between morning and afternoon ($P = 0.68$). Ovariectomized (OVX) rats were treated with oil (OVX; $n = 8$ per group), estradiol (OVX+E; $n = 7$ per group) or estradiol and progesterone (OVX+EP; $n = 6$-7) and perfused in the morning or late afternoon. The number of kisspeptin-ir neurons in the ARC was reduced in OVX+E and OVX+EP rats compared with OVX rats at all time points evaluated ($P < 0.05$). On the other hand, associated with the estradiol-induced afternoon surges of LH and PRL, the expression of c-Fos in KNDy neurons was increased by approximately 50% at 12:00 h ($P < 0.01$) and 18:00 h ($P < 0.05$) in OVX+E rats and only at 12 h ($P < 0.01$) in OVX+EP rats. We provide evidence of a dual effect of estradiol on the regulation of KNDy neurons. Estradiol reduces the expression of kisspeptin in the ARC as part of the negative feedback effect on LH secretion. Concurrently, however, estradiol induces an afternoon rise in the activity of the remaining population of KNDy neurons, suggesting an increase of kisspeptin release at specific synapses by the time of the estradiol-induced surges of LH and PRL. Thus, our findings reveal a novel aspect of the estrogen regulation of KNDy neurons, which expands our knowledge of the neural control of gonadotropin secretion and fertility.

Title: Colocalization of substance P receptor and gonadotropin-releasing hormone (GnRH) in hypothalamic mice neurons

Authors: *R. DÍAZ ESCÁRCEGA[1], A. E. SOSA-ESCALANTE[1], M. L. LOPEZ-MERAZ[2], L. BELTRAN-PARRAZAL[2], C. MORGADO-VALLE[2];

Abstract: The participation of substance P (SP) in the modulation of the Hypothalamic-Pituitary-Gonadal (HPG) axis has been already documented. However, is still incompletely understood whether SP modulation occurs at hypothalamic, pituitary and/or gonadal levels. The HPG axis is driven by the pulsatile secretion of gonadotropin-releasing hormone (GnRH). GnRH is synthesized by a diffuse group of hypothalamic neurons (GnRHergic neurons) terminating in the median eminence (ME). Previously, we have shown *in vitro* that SP increases the firing frequency of GnRHergic immortalized hypothalamic neurons. Furthermore, histological studies in the human hypothalamus show the presence of fibers immunoreactiveto SP juxtaposed with cell bodies of GnRHergic neurons. In this study we tested the hypothesis that the SP receptor, i.e., the neurokinin 1 receptor (NK1R)colocalizes with GnRH inhypothalamus neurons. We performed double immunofluorescent staining against NK1R and GnRH in coronal slices of mouse hypothalamus. Our results suggest that thestimulation exerted by SP on GnRHergic neurons is probably mediated by NK2 or NK3 receptors and not through the NK1R.

Title: Neuromedins U and S differentially regulate pulsatile LH and prolactin secretion and are expressed in the supraoptic and paraventricular nuclei in ewes

Authors: *P. GRACHEV, M. VALENT, R. L. GOODMAN;
Dept. of Physiol. and Pharmacol., West Virginia University, Sch. of Med., Morgantown, WV

Abstract: Prolactin (PRL) secretion is elevated annually during long days and is stimulated by estradiol, while pulsatile LH secretion is subject to negative feedback effects of gonadal steroids and photoperiodic suppression. We have recently demonstrated the biphasic effect of central administration of NMU-8, a synthetic peptide the sequence of which resembles the receptor-binding portion of endogenous ovine neuromedins U and S, on LH pulse amplitude in ewes - stimulatory in ovary-intact and inhibitory in ovariectomized sheep. In light of the differential regulation of prolactin and LH, we proposed that NMU-8 would have converse effects on PRL pulse amplitude. To test this hypothesis, we examined the effects of intracerebroventricular administration of NMU-8 on PRL levels in frequently sampled blood from anestrous or ovariectomized ewes. Immunohistochemistry, utilizing a polyclonal antibody raised in rabbit against NMU-8, was performed as a first step in exploring the localization of endogenous ovine neuronal populations expressing neuromedins U and S. Contrary to our hypothesis, NMU-8 failed to affect PRL pulse amplitude in either anestrous or ovariectomized ewes, but did exert significant biphasic influence over PRL pulse frequency: inhibitory in ovary-intact anestrous and stimulatory in ovariectomized ewes. Discrete populations of neuromedin U/S-immunoreactive soma were localized to the supraoptic (including auxiliary supraoptic) and paraventricular nuclei. These are the first data in sheep that detail effects of central neuromedin U/S signaling on pulsatile PRL secretion and the hypothalamic expression of endogenous ovine neuromedins U and/or S.

Title: Comparative study of the RFRP system in male and female Syrian hamster

Authors: *J. B. HENNINGSEN[1], V. SIMONNEAUX[2], J. D. MIKKELSEN[3], V.-J. POIREL[2], F. GAUER[2];
[2]Melatonin and Seasonal Rhythms, [1]Inst. of Cell. and Integrative Neurosci., Strasbourg, France; [3]The Neurosci. Center, Rigshospitalet, Neurobio. Res. Unit, Copenhagen, Denmark

Abstract: Hypothalamic RF-(Arg-Phe) related peptides (RFRP-1 and -3) are considered to play a role in the (seasonal) regulation of reproduction and their expression is strongly down-regulated by the pineal hormone melatonin in short photoperiod. RFRP-3 stimulates reproductive activity in male Syrian hamsters; however the effects of the peptides depend on species and gender. This study aimed at comparing the RFRP system in male and female Syrian hamsters in long and short photoperiod in order to investigate the neuroanatomical basis of these differential effects. Moreover, we evaluated the effects of intracerebroventricular administration of RFRP-3 in female Syrian hamsters. The neuroanatomical distribution of RFRP neurons and fibers, revealed using an antiserum recognizing RFRP-1 and -3, as well as GPR147 mRNA, are similar in male and female Syrian hamsters. RFRP neurons are mainly found in the dorso/ventromedial hypothalamus while RFRP projections and GPR147 mRNA are observed in the preoptic area, anteroventral-periventricular nucleus, suprachiasmatic nucleus, paraventricular nucleus, bed nucleus of stria terminalis, ventromedial hypothalamus, habenular nucleus and the arcuate nucleus. The number of RFRP neurons is higher in females than in males, and in both sexes, the number of RFRP neurons is reduced in short as compared to long photoperiod. GPR147 mRNA levels are higher in females than in males and is down-regulated in short photoperiod, with a stronger decrease in females than in male. Interestingly, the number of RFRP-positive fibers in the anteroventral periventricular nucleus is higher only in females adjusted to short photoperiod. Chronic intracerebroventricular administration of RFRP-3 decreases the gonadal size of sexually active female hamsters, whereas in SP-adapted females, RFRP-3 potently stimulates gonadal size despite photoinhibitory conditions. RFRP and its receptor GPR147 are down-regulated in short photoperiod in both male and female Syrian hamster. Moreover, our results suggest that the RFRP system is particularly important in females with a distinct role in the anteroventral-periventricular nucleus, possibly in the regulation of the pre-ovulatory LH surge via kisspeptin neurons. The effect of RFRP-3 in female Syrian hamsters depends on the reproductive state of the animal and interestingly, RFRP-3 reactivates the reproductive axis in sexual inactive animals despite photoinhibitory conditions.

Title: A transcriptomic analysis of the estrous cycle in 4 regions of the mouse brain

Authors: *L. M. DICARLO, C. M. VIED, R. S. NOWAKOWSKI;
Biomed. Sci., Florida State Univ. Col. of Med., Tallahassee, FL

Abstract: For many years biomedical research, and in particular neuroscience research, has often focused on male subjects. Female subjects have frequently been excluded due to the perceived complications of the hormonal changes across the estrous cycle and the potential need to include the appropriate control groups. We utilized transcriptomic analysis of the hypothalamus, hippocampus, neocortex, and cerebellum of female C57BL/6J (B6) mice to examine changes in gene expression in the female mouse brain. The changes in gene expression between brain regions (n=12/brain region) and changes in gene expression within each brain region as a result of the estrous cycle (n=3/stage/tissue) were performed using the same animals. Not surprisingly, there are ~10,000 differentially expressed genes (DEGs) between the hypothalamus, hippocampus, neocortex, and cerebellum at a false discovery rate (FDR) less than 0.05. The hippocampus vs. cerebellum (n=10,610) and neocortex vs. cerebellum (n=10,464) comparisons have the most DEGs and the hippocampus vs. neocortex (n=9,166) comparison has the least. In contrast to the ~10,000 DEGs between brain regions, within each brain region there are fewer than 70 stage-specific DEGs (FDR<0.05) as a result of the estrous cycle. The hippocampus has the most DEGs (n=67), followed by the neocortex (n=55), hypothalamus (n=53), and cerebellum (n=20). Genes encoding hormones or hormone precursors that are significant DEGs in only the hypothalamus are potential candidates to be the source of changes in downstream gene expression. Six genes in the brain region-specific comparisons (Oxt, Pomc, Esr1, Ghrh, Hcrt, Trh) and five genes in the stage-specific comparisons (Oxt, Hcrt, Gh, Prl, Pitx2) fulfill these criteria. The interactions of potential candidate genes on downstream processes within the hypothalamus and between the 4 brain regions are part of ongoing analyses. This dataset demonstrates that the differences between brain regions overwhelm changes in gene expression as a result of the estrous cycle. We expect that our results will be a useful guide for researchers in the field of neuroscience in incorporating females in future experiments as well as shedding light on the interactions of hormones and gene expression in different brain regions.

Title: Induction of the rat luteinizing hormone (LH) surge activates pubertally born cells whereas blocking cell proliferation during puberty or adulthood blunts the LH surge

Authors: *M. A. MOHR[1], L. L. DONCARLOS[2], C. L. SISK[1];
[1]Neurosci., Michigan State Univ., East Lansing, MI; [2]Loyola Univ. Chicago, Maywood, IL

Abstract: The female rodent brain goes through extensive remodeling during puberty, adding new neurons, glia, and microglia to the anteroventral periventricular nucleus of the hypothalamus (AVPV). The AVPV regulates the preovulatory surge of gonadotropin hormone releasing hormone (GnRH) and thus the pituitary surge in luteinizing hormone (LH), the primary trigger of ovulation, and a pivotal event in reproduction. We asked whether cells added to the AVPV during puberty are among those cells active during the LH surge, and whether cells added to the AVPV during or after puberty are necessary for generation of an LH surge. Expt 1: Postnatal day (P) 28 female Sprague-Dawley rats received 4 wks of bromodeoxyuridine (BrdU; 4.5 µg/l in artificial cerebrospinal fluid, aCSF; via ICV cannulas & minipumps) to identify newly born cells. On P56, all females were OVX'd and 1w later a surge was induced with sc injections of estradiol benzoate (EB, 40 µg/kg in sesame oil) on 2 consecutive days followed by progesterone (P, 2 mg/kg, sc, in sesame oil) the next day. Age-matched controls received oil injections. All rats were perfused ~6 hrs after P, a time when both Fos expression in the AVPV and LH secretion were expected to be high. Immunofluorescence for both BrdU and Fos was performed and the proportion of BrdU-immunoreactive (-ir) cells that were Fos-ir was assessed in the AVPV. In EB+P treated animals, ~32% of pubertally born cells in the AVPV were active during the LH surge, whereas only ~8% were active in the absence of hormones. Expt 2: Both pubertal (P28) and adult (~P60) female rats were treated for 4 weeks with the cell proliferation inhibitor, cytosine β-d arabinofuranoside (AraC; 33 µg/µl ICV in a solution of BrdU in aCSF, as above). Age-matched controls received ICV vehicle. Rats treated during puberty were OVX'd on P55-56; those treated as adults were OVX'd on P92-93. An LH surge was induced ~1-2 wk after the end of ICV infusions. Blood samples were taken every 0.5-1 hr for 8 hr on the day of the surge, and RIA for LH was performed. A week later, another surge was induced and animals were perfused at the time of the expected surge, as above. AraC treatment decreased the total number of BrdU-ir cells by 40% and 81%, rats treated during puberty or adulthood, respectively. AraC treatment also delayed by ~40 min and blunted the LH surge (37% and 62% reduction in the peak [LH] in rats treated during puberty or adulthood, respectively), without changes in body weight or overall health. Remodeling of the AVPV during puberty followed by ongoing turnover of cells during adulthood thus may support hormone positive feedback and the generation of the LH surge.

Title: The trithorax group complex counteracts the repressive effect of the polycomb group at puberty by promoting an active chromatin state at key gene promoters

Authors: *C. A. TORO[1], A. LOMNICZI[1], H. WRIGHT[1], A. SHILATIFARD[2], S. R. OJEDA[1]; [1]Div. of Neurosci., Oregon Hlth. & Sci. Univ. (OHSU), Beaverton, OR; [2]Feinberg Sch. of Med., Northwestern Univ., Chicago, IL

Abstract: The initiation of mammalian puberty requires a diurnal increase in pulsatile gonadotropin releasing hormone (GnRH) secretion from the hypothalamus. This change results from coordinated changes in the activity of gene networks that lead to a synchronized loss of transsynaptic inhibition and gain of transsynaptic/glial excitatory inputs to GnRH neurons. A major regulatory event controlling this process appears to be a mechanism of transcriptional repression. The Polycomb group (PcG) of transcriptional silencers acting within the arcuate nucleus (ARC) of the hypothalamus, has been shown to prevent the premature initiation of female puberty by silencing at least one gene (Kiss1) involved in the pubertal control of pulsatile GnRH release. At puberty, key PcG proteins are evicted from the Kiss1 promoter and this eviction is accompanied by increased abundance of histone post-translational modifications (PTMs) either catalyzed by, or associated to, the Trithorax (TrxG) group of transcriptional activators. To determine if the TrxG complex is an epigenetic component of the transcriptional program controlling puberty we performed a series of studies in female rats. Double fluorescent *in situ* hybridization revealed that key components of the TrxG complex, including the COMPASS genes Set1a and Set1b and the COMPASS-like genes Mll1, Mll2, Mll3 and Mll4 are expressed in ARC kisspeptin neurons. Quantitative PCR demonstrated that the expression of Set1a, Mll1 and Mll3, in addition to the gene encoding UTX, increases in the ARC before puberty. UTX demethylates histone 3 trimethylated at lysine 27 (H3K27me3) and partners with Mll3 to activate distal enhancers. Chromatin immunoprecipitation (ChIP) assays showed that the association of both MLL1 (required for the circadian activation of promoters) and Mll3 (that in conjunction with UTX activates distal enhancers) increase at the regulatory regions of the

puberty-activating genes Kiss1 and Tac2 during juvenile development (PND21-28). We further observed that as the association of these TrxG proteins to the Kiss1 and Tac2 promoters increases, there is an increase in the abundance of histone 3 dimethylated at lysine 4 (H3K4me2), a PTM associated with gene activation. The presence of both a PcG and a TrxG system of epigenetic regulation in ARC kisspeptin neurons, and their opposite pattern of association to the Kiss1 and Tac2 regulatory regions during prepubertal development suggests that a switch from epigenetic repression to activation within these neurons underlies the developmental process by which GnRH release increases by late juvenile development to bring about the pubertal process.

Title: Estradiol is the major ovarian steroid involved in the transcriptional e translational regulation of kisspeptin system in the preoptic area of female rats

Authors: *C. M. LEITE[1], B. KALIL[2], E. T. UCHOA[2,3], J. ANTUNES-RODRIGUES[2], L. L. K. ELIAS[2], J. A. ANSELMO-FRANCI[1];
[1]Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]Sch. of Med. of Ribeirao Preto, Univ. of Sao Paulo, Ribeirao Preto, Brazil; [3]State Univ. of Londrina, Londrina, Brazil

Abstract: Kisspeptin neurons in the antero periventricular region of the preoptic area (POA) are known to be are regulated by ovarian steroids and comprise the major stimulatory input to gonadotrophin-releasing hormone (GnRH) neurons. However, how these ovarian steroids could temporally modulate kisspeptin transcription and translation in the POA is not fully elucidated. Thus, the aim of this study was to determine the time course effects of ovarian steroids on kisspeptin mRNA expression and content in the POA of ovariectomized rats throughout the day. Female Wistar rats were ovariectomized and after 4 days they were treated with oil or oestradiol for 3 days. On the next day, rats treated with oil were injected with oil (OVO), oestradiol

(OVOE) or progesterone (OVOP) and rats treated with oestradiol were injected with oil (OVE) or progesterone (OVEP). In OVO, OVOE and OVOP groups, no changes were observed on kisspeptin mRNA expression and content throughout the day. Compared to OVO group, acute estradiol (OVOE group) or progesterone (OVOP group) treatment did not modify kisspeptin mRNA expression in all time studied, but acute treatment with estradiol or progesterone increased kisspeptin content in the POA at 11 h, 13 h and 17 h. Kisspeptin mRNA expression was not modified throughout in OVE animals, while kisspeptin content in this group was enhanced at 13 h and 15 h. Compared to OVO group, there was an increase in kisspeptin mRNA expression from 10 h to 16 h in OVE group, while POA kisspeptin content increased at 13 h and 15 h. Administration of progesterone in estradiol-primed rats (OVEP) resulted in the same pattern of response for POA kisspeptin mRNA expression and content observed for OVE group. In summary, estradiol treatment for 3 days seems to stimulate the kisspeptin transcript and content in the POA, while acute estradiol only increased kisspeptin content in the POA. On the other hand, progesterone enhanced only kisspeptin content in OVO rats, with no effects in estradiol-primed animals. Thus, these data indicate that estradiol is the major ovarian steroid involved in the transcriptional e translational regulation of kisspeptin system in the POA, while progesterone seems to have minor effects in these responses.

Title: Rapid progesterone signaling in adult female kisspeptin neurons *in vitro*

Authors: *M. A. MITTELMAN-SMITH, A. K. SCOTT, P. E. MICEVYCH;
Neurobio., UCLA, Los Angeles, CA

Abstract: We recently reported the use of immortalized mHypoA51 neurons as a model for anterior hypothalamic (AVPV/RP3V) kisspeptin neurons underlying the LH surge, based on

their estradiol induction of classical progesterone receptor (PR) and kisspeptin (Kiss1). Here, we investigate the role of progesterone (P4) signaling in these cells. P4 synthesized in hypothalamic astrocytes (NeuroP) is critical for normal reproductive function. Blocking local steroidogenesis with aminoglutethimide arrests the estrous cycle and abrogates the LH surge. We hypothesize that E2 and neuroP interact in Kiss1 neurons to induce the LH surge. First, we established a co-culture paradigm with mHypoA51 Kiss1 neurons and primary hypothalamic astrocytes (from adult, female mice). In this co-culture system, media is freely shared, allowing interactive signaling between the two cell types. Following a pretreatment with 1 nM E2, which increases Kiss1 expression, neurons plated on mesh inserts were introduced to primary astrocyte cultures with E2 (astrocytes had no E2 pre-exposure) for a total of 2 hours. During this time, Kiss1 was upregulated dramatically in mHypoA51 neurons, above that seen after E2 (only) treatment. We observed similar results when exposing Kiss1 neurons to astrocyte-conditioned media, confirming that this was a one-way interaction. In order to investigate potential mechanisms through which neuroP might act on Kiss1 neurons, we investigated the activity of Src, a non-receptor tyrosine kinase shown to associate with classical PR localized to the membrane. As assayed by immunocytochemistry, 96.5% of these Kiss1 neurons express Src. A 15 minute exposure to P4 induced phosphorylation of both Src and MAPK in E2-primed Kiss1 neurons. These data indicate one or more functional membrane progesterone receptors in these anterior hypothalamic Kiss1 neurons, which is consistent with western blot data that reveal classical PR and membrane progesterone receptors mPRα and mPRβ in mHypoA51 membranes. Furthermore, these and previous results suggest that E2 primes Kiss1 neurons by inducing both Kiss1 and PR, and that local synthesis of P4 following E2-priming additively stimulates Kiss1 neurons to induce the LH surge.

Title: Estradiol regulation of A-type potassium currents sculpts the membrane potential response to GABA in arcuate KNDy neurons

Authors: *R. A. DEFAZIO[1], M. A. NAVARRO[3], L. S. MILESCU[3], S. M. MOENTER[2]; [1]Mol. and Integrative Physiol., [2]Mol. and Integrative Physiology, Intrnl. Medicine, Obstetrics and Gynecology, Univ. of Michigan, Ann Arbor, MI; [3]Div. of Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: Gonadotropin-releasing hormone (GnRH) is the final central output regulating fertility; steroid feedback controls GnRH release. Estradiol-sensitive arcuate kisspeptin neurons stimulate GnRH neurons and may play a role in estradiol feedback regulation of these cells, since GnRH neurons lack estradiol receptor alpha. GABA strongly depolarizes the membrane potential of arcuate kisspeptin neurons from ovariectomized mice treated with estradiol (OVX+E) but this response was blunted in cells from OVX mice. Native intracellular Cl- concentration (15 mM, reversal potential -55 mV) and baseline membrane potential (-75 mV) were not different between groups, ruling out estradiol-dependent changes in these properties. We hypothesized voltage-dependent potassium channels blunt the response to GABA in arcuate kisspeptin neurons from OVX mice. Whole-cell current-clamp recordings were made from neurons in brain slices from OVX and OVX+E mice using a 15 mM Cl- pipet solution (cut 9 - 11AM, record 11AM - 3PM). Input resistance was the same (OVX 852 ± 113 MΩ n=5; OVX+E 672 ± 52 MΩ n=6). We used dynamic clamp to simulate a synaptic input using model parameters based on GABA postsynaptic currents: 10 nS conductance, 7 msec decay time constant, and -55 mV reversal potential. From a baseline membrane potential of -75 ± 0.4 mV (-70 to -79 mV), the membrane potential response to the dynamic clamp synaptic conductance was blunted by 20% in arcuate kisspeptin neurons from OVX vs OVX+E mice (response to 10 nS: OVX 13.0 ± 1.0 mV n=7; OVX+E 15.9 ± 0.9 mV n=6; $p<0.05$). We next tested the hypothesis that A-type voltage-gated potassium channels diminish the response to the GABA conductance using 4-aminopyridine (4-AP, an A-type channel antagonist). The response to GABA was increased in arcuate kisspeptin neurons from OVX mice in the presence of 4-AP ($p<0.05$), with no effect in neurons from OVX+E mice (response to 10nS + 4-AP: OVX 15.9 ± 0.6 mV n=9; OVX+E 15.1 ± 0.4 mV n=6). Input resistance was greater, however, in OVX vs OVX+E in 4-AP (OVX 1055 ± 93 MΩ n=9; OVX+E 818 ± 52 MΩ n=6, $p<0.05$). We tested the effect of decreasing input resistance in neurons from OVX mice by introducing a 0.44 nS leak conductance via dynamic clamp. Despite a 35% decrease in input resistance, the membrane potential response was decreased by only 6% (n=3), suggesting that input resistance alone is insufficient to explain the effect of 4-AP. Our data support the hypothesis that a strong A-type potassium current in arcuate kisspeptin neurons from OVX mice blunts the depolarizing membrane potential response to GABA. Estradiol suppression of this A-type current may play a role in regulating the output of arcuate kisspeptin neurons.

Title: Bursts-generation mechanisms of AVPV kisspeptin neurons are regulated by the estrous cycle with multiple currents involved

Authors: *L. WANG[1], S. M. MOENTER[1,2,3];
[1]Mol. and Integrative Physiol., [2]Intrnl. Med., [3]Obstetrics & Gynecology, Univ. of Michigan, Ann Arbor, MI

Abstract: Gonadotropin-releasing hormone (GnRH) neurons form the final common pathway for central control of fertility, but lack estrogen receptor alpha (ERα) needed for negative and positive feedback regulation. The anteroventral periventricular area (AVPV) is a likely site of estradiol positive feedback induction of the proestrus GnRH surge. Release of neuropeptides such as kisspeptin is linked with action potential bursts. We tested the hypothesis that burst generation in AVPV kisspeptin neurons differs with estrous cycle stage. AVPV kisspeptin neurons exhibit increased burst firing on the afternoon of proestrus (P, positive feedback) vs diestrus (D, negative feedback). This difference was maintained after blocking fast synaptic transmission, indicating intrinsic mechanisms (bursts/5min, n≥11cells, control, D 17.4±7.4, P 56.4±14.4; blockers, D 0.7±0.3, P 24.8±8.1, $p<0.05$). To study burst-generation mechanisms, depolarizing and hyperpolarizing current injections were done in current-clamp mode. During depolarization, cells fired tonically (instantaneous frequency, IF, 21.4 ± 5.1 Hz, n=25), or fired an initial 3-4 spike depolarization-induced burst (DIB) with a higher IF than tonic cells (113.6 ± 1.0 Hz, n=16, $p<0.001$). Cycle stage did not affect tonic vs DIB firing patterns (tonic vs DIB, D, 69% vs. 31%, n=19; P, 54% vs. 46%, n=22). After hyperpolarizing current injection, most tonic cells (D 62%, n=13; P 75%, n=12) generated rebound bursts (≥2 spikes), but DIB cells only had rebound bursts on proestrus. Ni2+ (100μM), a T-type current (IT) blocker, decreased initial DIB IF (control 106.4±2.8Hz; Ni 46.0±2.4Hz, n=8, $p=0.0008$), and eliminated rebound spikes in most cells (D 7 of 8; P 6 of 7). We used voltage-clamp to study IT. Current density was greater ($p<0.01$) on P vs D from -50 to -30mV with no difference in voltage-dependence between cycle stages, perhaps indicating increased channels in the membrane. This suggests IT may underlie increases in both rebound and depolarization-induced bursts in these cells during positive feedback. All diestrous cells showed IT but only half had rebound bursts, suggesting another channel under cycle regulation plays a facilitatory role to trigger rebound spikes. Voltage ramps

(10mV/s from -80mV) ±TTX (1μM) were used to isolate persistent sodium current (INaP). INaP current density was greater from -52.5 to -42.5 mV ($p<0.01$) on diestrus in cells exhibiting rebound bursts than those without rebound. These observations suggest mechanisms for increased intrinsic bursts in AVPV kisspeptin neurons on proestrus during estradiol positive feedback, and indicate that burst generation is complex, with multiple currents involved.

Title: Arcuate kisspeptin-expressing neurons exhibit steroid-sensitive long-term patterns of episodic firing activity in male mice

Authors: *M. RICU[1], S. M. MOENTER[2];
[1]Dept. of Mol. and Integrative Physiol., [2]Dept. of Mol. and Integrative Physiology, Intrnl. Medicine, Obstetrics and Gynecology, Univ. of Michigan, Ann Arbor, MI

Abstract: Gonadotropin-releasing hormone (GnRH) neurons form the final common pathway for central regulation of fertility via the episodic release of GnRH, which is modulated by gonadal steroid feedback. The episodic nature of GnRH release suggests synchrony among the GnRH neuronal population but where this rhythm arises is unknown. Further, as GnRH neurons do not express the steroid receptors needed for feedback regulation of GnRH release frequency, where steroid feedback acts centrally to regulate this frequency is also unknown. Kisspeptin neurons of the arcuate nucleus are a potential site for both rhythm generation and steroid feedback integration. Kisspeptin neurons are steroid-sensitive and synapse on GnRH neurons. The kisspeptin-expressing neurons of the arcuate nucleus of the hypothalamus are called KNDy neurons because they coexpress neurokinin B and dynorphin, both of which may also affect GnRH release pattern. KNDy neurons have been postulated to be extrinsic drivers of pulsatile GnRH secretion via release of kisspeptin, which increases GnRH neuron activity and release. The objective of this work was to determine the long-term firing pattern of KNDy neurons and test if this pattern is steroid sensitive in male mice. KNDy neurons were identified by expression of green fluorescent protein driven by the Tac2/NKB promoter. Coronal brain slices (400μm)

were made from adult gonad-intact and castrate (5-10 d before slice preparation) male mice. Spontaneous action potential firing activity of single KNDy neurons was monitored for 1-7h with targeted extracellular recordings. Peaks and nadirs in firing rate were analyzed with the Cluster8 algorithm. KNDy neurons showed repeated episodic peaks in firing activity in both intact and castrated mice. Firing rate of KNDy neurons from intact males was episodic with 0.8±0.1 peaks/h (n=12). This frequency was markedly increased ($p<0.004$) in KNDy neurons from castrate males (1.7±0.3 peaks/h, n=6). A corresponding decrease ($p<0.008$) in interpeak interval from 50.7±4.8 min in intact (n=7) to 30.0±4.1 min in castrate mice (n=6) was observed. Peak firing rate was not different between KNDy neurons from intact (5.6±1.3 Hz) and castrate (4.5±1.7 Hz) mice. Of interest, firing peak intervals in KNDy neurons are strikingly similar to those observed in GnRH neurons (Biol Repro 74:931). Together these observations are consistent with the hypothesis that changes in KNDy activity drive changes in GnRH activity and that steroid sensitivity of this episodic pattern may arise in KNDy neurons. Our next steps are to examine if firing activity is coordinated among KNDy neurons and if KNDy neuron activity is coordinated with GnRH release.

Title: Morphometric and myelination changes in ARC kisspeptin neurons underlie activation of HPG-axis during breeding season in the adult male rhesus monkey

Authors: H. ZUBAIR[1], S. SHAMAS[1], H. ULLAH[1], T. HUMA[2], S. KIRAN[1], *R. HUSSAIN[1], M. SHAHAB[1];
[1]Lab. of Reproductive Neuroendocrinology, Quaid-i-Azam University, Islamabad, Pakistan;
[2]Lab. of Reproductive Neuroendocrinology, Islamabad, Pakistan

Abstract: Recently, kisspetin has been observed to enhance the gonadotropin secretion in rodent and primate species by various expression and functional studies. Kisspeptin has also been shown to play a role in seasonal regulation of the HPG-axis in rodents and sheep. Present study was designed to assess the involvement of kisspeptin signaling in regulating the transition between breeding and nonbreeding seasons by comparing the semi-quantitative expression of the kisspeptin like-immunoreactivity, measurement of the kisspeptin cell body size, myelination

status of the kisspeptin axons and number of close contacts between kisspeptin fibers and GnRH cell bodies in the hypothalamus of the adult male rhesus monkey. Hypothalamic tissues were collected from three free ranging breeding season (September) and two nonbreeding season (June) monkeys and fixed, and stored in 30% sucrose solution. Testicular dimensions were noted and a blood sample was obtained for determination of testosterone levels before euthanization from all animals. This study was approved by the Research Ethics Committee of the Quaid-i-Azam University. Twenty µm thick hypothalamic sections were processed for standard immunocytochemistry procedure using sheep anti human kisspeptin, mouse anti human myelin basic protein (MBP) and rabbit anti GnRH as primary antibodies against kisspeptin, MBP and GnRH, respectively. The immunoreactivities were identified by using Alexa Flour 488 (kisspeptin), Cy3 (MBP) and Texas red (GnRH) labeled specific secondary antibodies. Three consecutive sections (mediobasal hypothalamus) were stained from each animal. Primary antibody omitted control sections were used to check the nonspecific binding of the antibodies. Plasma testosterone levels and testicular volumes were found to be significantly higher in breeding season monkeys as compared to that in non-breeding season monkeys. Increased expression of kisspeptin like-immunoreactive cell bodies and higher number of synaptic contacts between kisspetin fibers and GnRH cell bodies was observed in the arcuate nucleus of the breeding season monkeys while increased kisspeptin cell body diameter and increased thickness of myelin sheath around the axons was quantified in nonbreeding season monkeys. In summary, our results indicate enhanced kisspeptin signaling in the hypothalamus of the breeding season monkeys as compared to the non-breeding season monkeys. Further, degree of myelination and diameter of kisspeptin-ir cell bodies is increased during the non-breeding season. Present results suggest that kisspeptin acts as an arbitrator of the seasonal regulation of the reproductive axis in higher primates.

Title: Kisspeptin does not affect excitatory postsynaptic currents in supraoptic nucleus neurons from virgin or pregnant rats

Authors: *A. SEYMOUR, R. PIET, R. E. CAMPBELL, C. H. BROWN;
Dept. of Physiol., Univ. of Otago, Dunedin, New Zealand

Abstract: Supraoptic nucleus magnocellular neurosecretory cells (MNCs) project to the posterior pituitary gland where they secrete oxytocin or vasopressin into the circulation in response to action potential firing. During parturition and lactation, oxytocin is released in pulses to stimulate uterine contraction (in parturition) and mammary gland duct contraction to eject milk (in lactation). Despite the importance of these physiological processes, relatively little is known about what initiates and maintains action potential firing in oxytocin MNCs at these times. Previous *in vivo* electrophysiology experiments in our lab have shown that kisspeptin causes a transient excitation of oxytocin neurons in late pregnant rats but not in virgin or early pregnant rats. This suggests that oxytocin neurons become sensitive to kisspeptin during pregnancy, and hence that this might be involved in preparation for parturition. Here, we have recorded from MNCs in rat hypothalamus coronal slices from virgin and late-pregnant rats to determine the mechanisms of excitation of oxytocin neurons in late-pregnant rats. Using whole-cell voltage clamp recording with a holding potential of -60 mV and constant perfusion of 100 μM picrotoxin to block GABA-mediated events and 0.5 μM tetrodotoxin to block action potential-mediated events, we measured miniature excitatory post-synaptic current (mEPSC) frequency and amplitude in response to kisspeptin. We found that mEPSC frequency was lower in late pregnant rats compared to virgin rats (t-test $P = 0.02$). However, kisspeptin did not change mEPSC frequency ($P = 0.70$, two way repeated measures ANOVA) or amplitude ($P = 0.77$) in MNCs from virgin or late-pregnant rats. Furthermore, kisspeptin did not change the mean baseline current ($P = 0.82$) in virgin or late-pregnant rats suggesting that there was no direct effect of kisspeptin on MNCs. These results suggest that the emergence of oxytocin MNC excitation by kisspeptin in pregnancy probably does not occur locally within the brain slice and is likely mediated upstream. However, it is also possible that kisspeptin causes excitation of oxytocin MNCs by altering GABAergic synaptic transmission. Therefore, we are currently investigating whether changes in inhibitory post-synaptic currents occur during kisspeptin administration to MNCs from virgin and late-pregnant rats.

Abstract: The pulsatile release of gonadotropin-releasing hormone (GnRH) neurons is necessary for reproductive success. Kiss1 neurons provide critical synaptic input to GnRH neurons; however it has yet to be determined whether Kiss1 afferents generate a synchronous patterned input that facilitates GnRH pulsatility. One population of Kiss1 neurons in the hypothalamic arcuate nucleus (ARC) that co-express neurokinin B (NKB), dynorphin (Dyn) and glutamate, may provide synchronized excitatory drive to GnRH neurons. To explore the possibility of synchronization among Kiss1 neurons, we injected an adeno-associated virus (AAV) that allows Cre-dependent expression of channelrhodopsin 2 (ChR2:YFP) in the ARC of *Kiss1*$^{Cre:GFP}$ mice. A short train of blue light (470 nm) stimuli delivered at a frequencies of ≥10 Hz evoked a slow excitatory postsynaptic potential (slow EPSP) in ARC Kiss1 neurons in hypothalamic slices. The slow EPSP was frequency and duration dependent, and was abolished by perfusing low Ca^{2+}/high Mg^{2+} or TTX. The TTX blockade was rescued by the addition of non-selective K^+ channel blockers 4-AP and TEA, suggesting the slow EPSP was dependent on direct synaptic input from neighboring Kiss1 neurons. Furthermore, the slow EPSP was unaffected by the ionotropic glutamate receptor antagonists CNQX and AP5, but was abrogated by an NKB receptor (NK3R) antagonist and occluded by NKB pretreatment, demonstrating that the slow EPSP was mediated by the Gq-coupled NK3R. Taken together, these findings suggest that NKB-mediated slow EPSPs may play a pivotal role in the prolonged excitation and synchronization of ARC Kiss1 neurons which could potentially drive GnRH pulsatile release.

Title: The rapid effects of estrogens in the medial amydgala on social recognition in female mice

Authors: *P. A. SHEPPARD, J. LYMER, T. KUUN, P. PALETTA, E. CHOLERIS; Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: It is becoming well established that estrogens affect different types of learning and memory on a rapid time scale. Specifically, estrogens can affect social recognition in female mice within 40 minutes of drug administration. Improvements in social recognition have been shown with the systemic administration of 17β-estradiol, the estrogen receptor (ER) α agonist, PPT, and the G-protein coupled estrogen receptor 1 (GPER) agonist, G-1, while impairments in social recognition have been shown with the ER β agonist, DPN (Phan et al., 2011; 2012). Although the hippocampus has been shown to mediate these effects, other brain regions are likely involved in the estrogenic facilitation of social recognition. One possible candidate is the medial amygdala, as it has been shown to be necessary for social recognition (Wang et al., 2014), and ER α in the medial amygdala is involved in the estrogenic facilitation of social recognition on a long-term time scale (Spiteri et al., 2010). Thus, we investigated the role of 17β-estradiol, G-1, PPT, and DPN in the medial amygdala in social recognition in ovariectomized female mice. Mice received an infusion (0.5μL/side, rate of 0.2μL/min) of 17β-estradiol (10, 25, 50, 100nM), G-1 (25, 50, 200, 400nM), PPT (25, 50, 100, 150nM), or DPN (25, 50, 100, 150nM) directly into the medial amygdala. Mice were then tested on the social recognition paradigm, consisting of two 5min habituations where two female conspecifics are presented, and one 5min test phase where one of the stimulus mice presented is novel and the other is familiar. The paradigm is completed within 40min of drug administration to investigate the rapid effects of estrogens. Medial amygdala infusions of 50nM G-1 improved social recognition. The experiments with 17β-estradiol, PPT, and DPN are currently underway. Therefore, estrogens, at least via the GPER, in the medial amygdala are involved in the rapid estrogenic facilitation of social recognition in female mice. Supported by NSERC.

Title: Evidence of ligand-independent activation of estrogen receptor alpha in rat hippocampus

Authors: E. M. GRISSOM, *J. M. DANIEL;
Tulane Univ., New Orleans, LA

Abstract: Previous work by us and others indicates that increased levels of hippocampal estrogen receptor alpha (ERα) are associated with enhanced cognition even in the absence of ovarian or exogenously administered estrogens. *In vitro* evidence indicates that under conditions of low levels of estrogens, growth factors, including insulin-like growth factor-1 (IGF-1) can activate ER and regulate ER-mediated transcription through mechanisms that likely involve modification of phosphorylation sites on ER by cellular kinases. The goal of the current work was to investigate a role for IGF-1 in ligand-independent activation of ERα by IGF-1 in rat hippocampus. Ovariectomized rats received a single icv infusion of IGF-1 and hippocampi were collected 1 h later. IGF-1 increased phosphorylation of ERα at serine 118 (S118), but not at S167, as revealed by Western blotting. Activated ERα bound to estrogen response elements (EREs) recruits coactivators, including steroid receptor coactivator (SRC)-1, that stimulates gene transcription. Therefore, we next measured the impact of IGF-1 on the association of ERα and SRC-1 via co-immunoprecipitation. Rats that received IGF-1 infusions had significantly enhanced ERα -SRC-1 interactions in the hippocampus than those that received control infusions. Collectively results indicate that IGF-1 ligand-independently activates ERα in the hippocampus via phosphorylation at S118 resulting in increased association of ERα with SRC-1. To our knowledge, these data are the first *in vivo* evidence of ligand-independent actions of ER and provide a mechanism by which ERα can impact memory in the absence of ovarian estrogens.

Title: Estradiol increases extracellular glucose concentration in the hippocampus of young adult female rats

Authors: *W. WANG, P. E. GOLD, D. L. KOROL;
Dept. of Biol., Syracuse Univ., Syracuse, NY

Abstract: Estrogens promote hippocampus-based learning and facilitate glucose uptake into the brains of ovariectomized rodents. Thus, we hypothesized that estradiol treatments would increase extracellular glucose concentrations in the hippocampus in awake behaving rats. To test this, we used microdialysis to measure extracellular glucose in the hippocampus of three-month-old ovariectomized Sprague-Dawley rats that received either estradiol (4.5 μg/kg) or oil vehicle (s.c.) 24 and 48 hours prior to microdialysis. Microdialysis probes, previously implanted unilaterally in the ventral hippocampus, were used to collect dialysate samples (20 min each) while rats were in a holding container that allowed free movement. Artificial cerebrospinal fluid prepared with six different concentrations of glucose (0.5 mM-3 mM) was infused through the probes while dialysates were collected for off-line assay of glucose concentration. Separate groups of rats were tested for each glucose concentration. The dialysates were later measured for glucose content with an enzymatic assay. Comparisons of [glucose]out vs. [glucose]in for different glucose concentrations in the perfusate generated a Zero-Net-Flux regression line. The concentration where [glucose]in = [glucose]out reflected the extracellular concentration. Rats with estradiol treatment had hippocampal extracellular glucose concentrations of 2.44 ± 0.1 mM whereas extracellular concentrations in oil-treated rats were nearly 25% lower at 1.86 ± 0.16 mM. The higher glucose concentrations associated with estrogens may protect the female hippocampus against glucose depletion during cognitive activity and, by extension, also protect energy availability needed to support cognitive functions during aging. Currently, we are examining whether estrogen treatment to ovariectomized rats protects against experimentally-induced local glucose deprivation in the hippocampus by rapidly providing metabolic substrates such as glucose or lactate to accommodate the depletion. This result would indicate that estrogens create a dynamic energetic state in hippocampus that could protect against metabolic insult. Our findings support a growing literature suggesting that estrogens may benefit hippocampal functioning through modulation of bioenergetics.

Title: Adding reference memory to a working memory maze task alters the pattern of age-related impairment in rats: Associations with choline acetyltransferase activity in discrete brain regions

Authors: *A. V. PRAKAPENKA[1,3,4], R. HIROI[2,3], M. POISSON[2,3], Z. KIRSHNER[5], A. J. CASTANEDA[2], R. B. GIBBS[5], H. A. BIMONTE-NELSON[2];
[2]Dept. of Psychology, [1]Arizona State Univ., Tempe, AZ; [3]Arizona Alzheimer's Consortium, Phoenix, AZ; [4]Barrow Neurolog. Inst., Barrow Brain Tumor Res. Ctr., Phoenix, AZ; [5]Dept. of Pharmaceut. Sci., Univ. of Pittsburgh Sch. of Pharm., Pittsburgh, PA

Abstract: Rodent studies demonstrate that age-related detriments are particularly pronounced for the ability to handle an increasing working memory load in spatial tasks such as the water radial-arm maze (WRAM). However, the extent of age-related cognitive changes may be impacted by the memory domains required to solve the task. Using the WRAM, in young, middle-aged, and aged rats, our laboratory has noted that as working memory load increases, not only do errors in working memory arms increase, but errors into reference memory arms increase as well. This suggests that working and reference memory are linked and that demanding use of both memory types simultaneously can impact performance outcomes. Here, we tested whether the addition of a reference memory component impacted working memory performance in young (6 mos) vs aged (21 mos) female rats. Four groups were tested. One young and one aged group were tested on an 8-arm WRAM task requiring working memory only, with 7/8 arms containing platform escape. Another young and another aged group were tested on a 12-arm WRAM task that also had 7/12 arms containing platform escape, plus 5 reference memory arms with no platform. Performance comparison of the mazes enables evaluation of age-related changes in the ability to handle a working memory load with or without distinct reference memory requirements. Because there are critical links between the cholinergic system, aging, and performance, choline acetyltransferase (ChAT) activity was assayed in several brain regions after testing. Results showed all rats performed worse in the 12-arm vs the 8-arm maze, and there was a larger age effect in the 8-arm, working memory only, version. Trajectories of learning to handle a working memory load differed by age, and this was impacted by whether the distinct reference memory component was present. Moreover, there was an age-related increase in ventral hippocampus and

frontal cortex ChAT activity. Analyses to parse out relations between the cholinergic system and memory-specific abilities in young versus aged animals are currently being pursued. Understanding region-specific relationships between the cholinergic system and prowess for different memory types may unveil distinct neurocircuitries underlying age-related changes in memory.

Title: The effects of the botanical estrogen isoliquiritigenin on cognition in young adult female rats

Authors: ***P. KUNDU**[1], T. TUNUR[2], D. KOROL[2], S. BANDARA[1], S. MONAIKUL[1], W. G. HELFERICH[1], S. SCHANTZ[1];
[1]Univ. of Illinois Urbana-Champaign, Urbana, IL; [2]Syracuse Univ., Syracuse, NY

Abstract: It is well established that estrogens modulate cognition in a task-dependent manner. Estrogen replacement generally improves hippocampus-sensitive learning although this effect can vary with age, stress status, and hormone regimen. Many dietary supplements contain estrogenic compounds, the efficacy and safety of which are poorly understood. This study investigated the efficacy of the commercially available botanical estrogenic compound isoliquiritigenin (ISL) to alter performance on a hippocampus-sensitive metric change in object location (MCOL) task. ISL is a compound found in licorice root that is currently used in over-the-counter dietary supplements. Because the Western diet is high in saturated fat, and high fat diets (HFD) have been shown to negatively impact cognition in rodent models, we also explored whether a HFD would impair performance on this hippocampus-sensitive task and whether ISL could mitigate the negative effects of the HFD. Thus, we included HFD as well as low fat (LFD) groups. Young adult (3-month old) Long-Evans female rats were ovariectomized and exposed to either a HFD (44.8% kcal from fat) or a LFD (17.2% kcal from fat) for five weeks prior to testing. A subset of rats on each diet was exposed to ISL at a concentration of 0.05% of the diet

for three weeks prior to testing. Since estradiol improves performance on the MCOL task, we used an estradiol group as a positive control. Rats in the estradiol group were injected subcutaneously 48 and 24 hours prior to testing with 45 µg/kg of estradiol. In the MCOL task, rats were allowed to explore two objects in a black Plexiglas® chamber measuring 28x28x21 inches. Exploration time was recorded for three 5-min trials with a 3-min inter-trial interval in the rat's home cage. For the fourth 5-min trial, the objects were moved closer together and exploration time was again recorded. An increase in object exploration time in the final trial suggests that the rat detected the change in object locations. ISL led to a significant increase in exploration time in the final trial relative to the third trial. To a lesser degree, estradiol also increased object exploration time on the final trial. Diet had no effect on its own and did not interact with ISL exposure. In this study we showed that ISL improved performance on a hippocampus-sensitive task that depends on the natural tendency to explore novel objects but avoids food restriction or aversive stimuli. We are currently using Western blot analysis to assess the levels of estrogen-sensitive synaptic proteins in the hippocampus, which could provide clues as to the mechanism of action for the improved performance in ISL exposed animals. Title: Excreted but not forgotten: Estriol effects on spatial working and reference memory task performance in middle-aged ovariectomized rats

Authors: *G. A. STONEBARGER[1,2], S. V. KOEBELE[1,2], H. A. BIMONTE-NELSON[1,2]; [1]Psychology, Arizona State Univ., Tempe, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: Many common forms of hormone therapy (HT) for menopausal and post-menopausal women contain estrogens that are not native to women. Recently, there has been a focus on HT options during menopause that contain bioidentical (naturally and endogenously circulating) hormones. The three primary bioidentical, endogenously circulating estrogens in women and rats are 17β-estradiol, estrone, and estriol. Of these, estriol is the only estrogen that is not currently used as a primary estrogenic component in commonly prescribed hormone therapy treatments in the United States. Presumably due to its status as a "weak estrogen," meaning that it has a low estrogen receptor binding affinity compared to 17β-estradiol, it has not been cognitively characterized. Due to estriol's previously observed neuroprotective effects on the hippocampus *in vitro*, we propose estriol as a promising candidate for HT that may exhibit a positive cognitive profile. In order to begin to characterize estriol's cognitive effects, female middle-aged Fischer-344 rats were given a tonic low- or high- dose of estriol or a vehicle, then tested on a 15 day water radial-arm maze and 5 day Morris water maze. Water radial-arm maze results indicate that both the low- and high- dose estriol groups were impaired on working memory performance compared to vehicle animals, but there were no differences among groups on the Morris water maze. However, uterine weight - an indicator of estrogenic stimulation - and body weight analyses indicated that both doses were likely high enough to induce supraphysiological estriol levels. Cognitive performance and health data will be presented and discussed in the context of additional findings testing other bioidentical estrogens, along with contemplations of evaluating lower doses, varied routes of administration, and behavior testing parameters.

Title: Examination of mechanisms through which estrogen receptor-dependent transcription persists in brains of female ERE-Luc mice lacking ovarian estrogens

Authors: *K. J. POLLARD[1], E. GRISSOM[2], J. DANIEL[2];
[1]Neurosci., [2]Psychology and Neurosci., Tulane Univ., New Orleans, LA

Abstract: We examined the role of ovarian estrogens, neuroestrogens, the extracellular signaling related kinase (ERK) cascade, and the phosphoinositide-3-kinase (PI3K) cascade in the maintenance of estrogen response element (ERE)-dependent transcription across several brain regions using female estrogen receptor (ER) reporter mice, ERE-Luc, which express the luciferase reporter gene under the transcriptional control of the ERE DNA sequence. In an initial experiment, we compared the effect of ovariectomy (OVX) on ERE-dependent transcriptional activity in the uterus to tissue taken from cerebral cortex, hippocampus, and hypothalamus. Levels of ERE-dependent transcription were reduced to negligible levels in uteri of OVX mice as compared to gonadally intact females. Interestingly, levels of luciferase activity across brain regions were not reduced in OVX mice when compared to intact mice, regardless of estrous cycle stage. To investigate mechanisms by which ER-dependent transcription persists in the brain following OVX, a second experiment was conducted. For three days, the ER antagonist ICI (182.780), the aromatase inhibitor letrozole, or vehicle solution was delivered continuously ICV via cannulae connected to osmotic minipumps. ICI significantly reduced ERE activity in all brain regions examined, confirming that transcription was ER-dependent. The extent of attenuation of ERE activity observed after letrozole treatment varied by brain region, suggesting that neuroestrogens differentially contribute to ER-dependent transcription in each of these brain regions. Collectively these data show that (1) ERE-dependent transcriptional activity in the brain is not reduced following removal of ovarian estrogens and (2) the influence of brain-derived estrogens varies across brain regions. In the final experiment experiment, mice were given ICV infusions of ERK or PI3K inhibitors to determine the contribution of these kinase cascades to ERE-dependent transcriptional activity across brain regions. Results of this experiment are pending.

Title: An orderly interaction? Maze order impacts the outcome of estrogen effects on memory

Authors: *S. V. KOEBELE[1,2], A. M. QUIHUIS[1,2], C. N. LAVERY[1,2], Z. M. T. PLUMLEY[1,2], H. A. BIMONTE-NELSON[1,2];

Abstract: Aging and the loss of ovarian hormones are each associated with memory decline for spatial navigation. In females, there is evidence that estrogen administration during a critical window of opportunity during middle-age may attenuate age-related memory decline. This beneficial effect of estrogens is thought to be dependent upon a variety of factors, including dose, timing, and route of administration. Additionally, the order in which animals experience a battery of maze tasks may impact performance and flexibility to shift from one task to another. Indeed, our laboratory has shown that female rats with prior maze experience transfer the benefits of practice to a novel spatial memory task. Here, we evaluated the effect of 17β-estradiol treatment and maze task learning order on spatial memory performance during middle-age. Eleven-month-old Fischer-344-CDF female rats were ovariectomized and received a tonic dose of Vehicle, low 17β-estradiol, or high 17β-estradiol via a subcutaneous mini-osmotic Alzet pump. Animals were trained on the delayed-matching-to-sample water maze (DMS), a low-cognitive demand spatial working and recent memory task, and the water radial-arm maze, a spatial working and reference memory task that involves increasing working memory load capacity as trials progress and is considered to be a more taxing memory task (i.e. high-cognitive demand). Half of the animals were trained on DMS first, and the other half was trained on WRAM first, before each group learned the second task. Results indicate that 17β-estradiol-treated animals that experienced WRAM first learned DMS better than animals without prior maze experience, such that animals with prior maze experience treated with tonic 17β-estradiol made fewer errors on DMS compared to 17β-estradiol-treated animals without prior experience. Divergent memory effects were revealed with respect to WRAM performance. Previous maze experience on DMS did not impart the same beneficial effects of enhanced performance on WRAM compared to animals that had no prior maze experience. Overall, these data indicate that the order in which maze batteries are administered matters, and that 17β-estradiol treatment while learning a complex cognitive task confers an enhanced capacity for learning a novel spatial memory task; however, previous experience on a less cognitively demanding memory task does not enhance learning and memory performance on a novel task to the same extent. Results suggest that 17β-estradiol exposure and high-memory demand performance are important factors for cognitive flexibility to transfer learning skills to novel tasks and attenuating age-related memory impairments.

Title: Role of acetylcholine in the rapid estrogenic facilitation of social learning

Authors: *K. S. ERVIN[1], W. QIU[2], M. SAWULA[2], E. CHOLERIS[2];
[2]Dept. of Psychology and Neurosci. Program, [1]Univ. of Guelph, Guelph, ON, Canada

Abstract: Social learning is a common, adaptive learning strategy in which animals acquire information from conspecifics, avoiding costly trial-and-error individual learning. The social transmission of food preferences (STFP) is a form of social learning in rodents in which an observer prefers a novel food it smelled on the breath of a conspecific demonstrator over other novel foods. Estrogens modulate social learning on this task, both on a long-term/genomic (Clipperton et al,2008,Neuropsychopharmacology,33:2372) and a rapid/non-genomic time scale, specifically through the G protein-coupled estrogen receptor (GPER) (Ervin et al,2015,Psychoneuroendocrinology:doi:10.1016/j.psyneuen.2015.04.002). Consistent with previous literature showing that the STFP is dependent on muscarinic acetylcholine receptor signaling (Boix-Trelis et al,2007,Neurobiol Learn Mem,87:659; Carballo-Márquez et al,2009,Hippocampus,19:446; Carballo-Márquez et al,2009,Neurobiol Learn Mem,91:98), we found that female mice treated IP with the muscarinic antagonist scopolamine were impaired in the STFP. Estrogens increase acetylcholine release in the brain (Mitsushima et al,2009,J Neuroendocrinol,21:400) and GPER is present on cholinergic neurons (Hammond et al,2011,Psychoneuroendocrinology,36:182). Thus estrogens may rapidly facilitate social learning by enhancing acetylcholine release in brain regions important for the STFP. We treated female ovariectomized CD1 mice with 17β-estradiol, the GPER agonist G1, or sesame oil vehicle SC 15min prior to a brief interaction with a previously fed demonstrator, using a protocol with which we previously observed rapid enhancing effects of estrogens on the STFP. 30min prior to estrogen treatment, mice were pretreated IP with either saline vehicle or scopolamine at a subeffective that does not impair social learning on the STFP. If estrogens improve social learning by enhancing muscarinic acetylcholine signaling, scopolamine pretreatment will block the rapid enhancing effect of 17β-estradiol and G1. Little is known about the neural mechanisms underlying social learning, thus our investigations of estrogens' interactions with neurotransmitter systems will greatly contribute to our understanding of this important and ubiquitous learning strategy. Supported by NSERC.

Title: A comparison of the effects of hormone therapy estrogens, 17β-estradiol and conjugated equine estrogens, on the midbrain serotonin system: Associations between dorsal raphe nucleus tryptophan hydroxylase-2 mRNA levels and cognitive, anxiety-like, and depressive-like behaviors

Authors: *R. HIROI[1,2], G. WEYRICH[1,2], J. S. TALBOOM[3,2], A. JORDAN[1,2], S. V. KOEBELE[1,2], S. MENNENGA[1,2], L. T. HEWITT[1,2], P. MENDOZA[1,2], C. N. LAVERY[1,2], H. A. BIMONTE-NELSON[1,2];
[1]Psychology, Arizona State Univ., Tempe, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ; [3]Banner Sun Hlth. Res. Inst., Sun City, AZ

Abstract: Evidence indicates that decreased serotonin (5-HT) function is associated with a wide range of cognitive and affective disorders. Women, particularly during menopause, are more vulnerable to these disorders than men, and postmenopausal women exhibit decreased serotonergic activity. The serotonergic neurons in the dorsal raphe nucleus (DRN) are a major source of 5-HT in the forebrain. In particular, polymorphisms of tryptophan hydroxylase-2 (TpH2, the brain-specific, rate-limiting enzyme for 5-HT biosynthesis) are implicated in cognitive and affective disorders. Benefits of 17β-estradiol (E2), the most potent naturally circulating estrogen in women and rats, on cognitive, anxiety-like, and depressive-like behaviors have been shown. Moreover, E2 also has been shown to increase TpH2 mRNA in the specific subdivisions of the DRN, and this increase plays a critical role in the regulation of anxiety-like and depressive-like behaviors. Although conjugated equine estrogen (CEE) is a commonly prescribed estrogen component of hormone therapy (HT) in menopausal women, there is a

marked gap in knowledge regarding how CEE affects these behaviors and the brain 5-HT system. Therefore, we evaluated and compared the effects of CEE and E2 treatments on TpH2 mRNA in the midbrain and on behavior. Female rats were ovariectomized, administered either vehicle, E2, or CEE, and tested on a battery of cognitive, anxiety-like, and depressive-like behaviors. The brains of these animals were subsequently analyzed for TpH2 mRNA. The results showed that E2 increased TpH2 mRNA in the caudal and mid subdivisions of the DRN, corroborating previous findings. In contrast, CEE increased TpH2 mRNA in the caudal and rostral, but not the mid DRN, suggesting that distinct estrogens can have subregion-specific effects on TpH2 gene expression. We also found differential correlations between the level TpH2 mRNA in specific DRN subregions and behavior, depending on the type of behavior. These distinct associations imply that regulation of cognition vs anxiety-like vs depressive-like behaviors are modulated by unique serotonergic neurociruitry, opening the possibility of novel avenues of targeted treatment for different types of cognitive and affective disorders.

Title: The G-protein-coupled estrogen receptor (GPER/GPR30) modulates cell-signaling proteins that regulate actin polymerization in the dorsal hippocampus of female mice

Authors: *J. KIM, A. M. FORTRESS, K. M. FRICK;
Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: The G-protein coupled estrogen receptor (GPER/GPR30) is a novel membrane estrogen receptor expressed in areas of the brain including the hippocampus. Previously, we demonstrated that a dorsal hippocampal infusion of the GPER agonist G-1 mimicked the effects of 17β-estradiol (E2) on object recognition and spatial memory consolidation in young

ovariectomized female mice. Although our data also suggested that the molecular mechanisms involved in the memory-enhancing effects of GPER differed from those of ERα and ERβ activation, the mechanisms through which GPER regulates memory remain poorly understood. Among several physiological changes underlying memory formation, hippocampal spine remodeling depends on the reorganization of the actin cytoskeleton. Therefore, the present study examined the effects of a dorsal hippocampal infusion of E2 or G-1 on cell-signaling molecules that regulate actin reorganization. Ten week-old ovariectomized C57BL/6 female mice received a bilateral dorsal hippocampal infusion of vehicle, G-1 (4 ng/hemisphere), or E2 (5 µg/ hemisphere), and the dorsal hippocampus was dissected bilaterally 5, 15, or 30 minutes later. Western blot analyses were conducted for proteins including the actin-binding protein cofilin, which depolymerizes actin filaments. G-1 significantly increased phosphorylation of cofilin 5 and 15 minutes after infusion. Because phosphorylation inactivates cofilin, thereby increasing actin polymerization, these data suggest that activation of GPER may increase dendritic spine morphogenesis through actin polymerization. The G-1-induced increase in cofilin phosphorylation was blocked by co-infusion of the selective GPER antagonist G-15, suggesting that GPER activation is necessary for G-1 to regulate cofilin phosphorylation. In contrast, E2 had no effect on cofilin phosphorylation at any of the time points measured. Other cell-signaling molecules involved in actin polymerization are currently being investigated. Collectively, these data provide further support for the conclusion that the molecular mechanisms through which GPER regulates hippocampal function may differ from those of ERα and ERβ.

Title: A G-protein coupled estrogen receptor agonist in the hippocampus rapidly improves object and social recognition in female mice

Authors: ***J. LYMER**, A. ROBINSON, E. CHOLERIS;
Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Estrogens have been shown to rapidly affect learning and memory in female mice. Specifically, systemic administration of 17β-estradiol, the estrogen receptor (ER) α agonist, PPT, or the G-protein coupled estrogen receptor (GPER) agonist, G-1 rapidly improved social recognition, object recognition, and object placement, while the ER β agonist, DPN improved only social recognition. These paradigms were completed within 40 minutes of drug administration and therefore focus on the rapid, likely non-genomic effects of estrogens. The brain regions involved in mediating these effects are still little understood. The dorsal hippocampus is known to be involved in a number of learning and memory processes and is therefore a good candidate. The research focuses on the role of the GPER specifically in the dorsal hippocampus. G-1 (50, 100, 200nM) was infused (0.5μL/side, 0.2μL/min) directly into the dorsal hippocampus of female mice 15 min prior to testing in social recognition, object recognition, and object placement paradigm. Each mouse was tested in one of the three paradigms, each consisting of two 5min habituations where two stimuli were presented, and one 5 min test phase where one of the stimuli presented was novel and the other was familiar. The social and object recognition paradigms were performed in either the home cage or a Y-apparatus, which has minimal spatial and contextual cues, to help dissociate between the estrogenic facilitation of recognition learning itself, or the facilitation of the use of spatial and contextual cues inherent in the tasks. Dorsal hippocampal activation of the GPER improved social recognition (50nM G-1) and object recognition (200nM G-1) but not object placement in the home cage. Additionally, social recognition (100, 200nM G-1) and object recognition (200nM) were enhanced in the Y-apparatus, where minimal spatial and contextual cues were present. Therefore, the GPER in the dorsal hippocampus appears to be involved in the rapid estrogenic facilitation of social and object recognition, and not necessarily involved in the processing of spatial and contextual information. Title: A sex difference in levels of myelin basic protein in the orbitofrontal cortex of adult rats is not impacted by gonadectomy

Authors: *J. DARLING[1], J. M. DANIEL[1,2];
[1]Neurosci. Program, [2]Psychology, Tulane Univ., New Orleans, LA

Abstract: Previous work from our lab revealed that adult female rats have increased levels of myelin basic protein (MBP), a marker of myelination, in the orbitofrontal cortex (OFC) as compared to adult males. However, in prepubertal rats no sex difference in levels of MBP in the OFC is apparent. Therefore, we hypothesized that adult levels of circulating hormones mediate the observed sex difference in MBP levels in adult animals. To test this hypothesis we compared levels of MBP in gonadally intact and gonadectomized adult rats. Male and female adult rats (90d of age) underwent gonadectomies or sham surgeries. Two weeks following surgeries, animals were killed and OFC were dissected and processed for western blotting. Consistent with our previous results, female rats had increased levels of MBP in the OFC than did males. However, there was no impact of gonadal hormone status on levels of MBP. These results indicate that sex differences in levels of MBP in the OFC of adult rats are not due to activational effects of gonadal hormones. Future work will examine the ability of gonadal hormones to act during the perinatal and/or pubertal periods to result in sex differences in adult levels of MBP in the OFC.

Title: Estradiol-mediated spine changes in the dorsal hippocampus and medial prefrontal cortex depend on ERK and mTOR activation in the dorsal hippocampus of ovariectomized female mice

Authors: *J. J. TUSCHER[1], V. LUINE[2], M. FRANKFURT[3], K. M. FRICK[1];

Abstract: Dendritic spine plasticity is thought to underlie the formation and consolidation of memories. Both natural fluctuations and systemic administration of the sex-steroid hormone 17β-estradiol (E_2) can regulate spine density in the dorsal hippocampus (DH) of rodents. In a previous study, we found that infusion of E_2 directly into the DH also increases dendritic spine density in the DH and medial prefrontal cortex (mPFC). Specifically, E_2 significantly increased basal and apical spine density on CA1 pyramidal neurons 30 minutes after infusion, an effect that persisted for 2 hours. DH E_2 infusion also significantly increased basal spine density on pyramidal neurons in the mPFC by 2 hours after infusion, suggesting that E_2-mediated activity in the DH drives spinogenesis in the mPFC. Previous research has shown DH E_2 infusion enhances hippocampal-dependent object recognition and spatial memory consolidation by rapidly activating ERK-dependent signaling of mammalian target of rapamycin (mTOR), a key protein synthesis pathway involved in spine remodeling. To determine if the E_2-induced spine changes we observed in CA1 and mPFC also depend upon rapid activation of the ERK and mTOR cell-signaling cascades, female mice were infused bilaterally into the DH with vehicle, the ERK inhibitor U0126, or the mTOR inhibitor rapamycin, followed immediately by an intracerebroventricular (ICV) infusion of vehicle or E_2. We found that the increased spine density in CA1 and mPFC observed 2 hours after ICV infusion of E_2 was blocked by DH infusion of the ERK inhibitor U0126 or mTOR inhibitor rapamycin. Collectively, these data suggest that E_2 treatment elicits ERK- and mTOR-dependent spinogenesis on CA1 and mPFC pyramidal neurons, effects which likely support the memory-enhancing effects of E_2 in hippocampus-dependent tasks.

Title: Rapid Effects of gonadal hormones on spatial memory and hippocampal spines in male rats

Authors: *V. N. LUINE[1], L. F. JACOME[2], F. LEMA[2], K. BARATELI[2], D. BUITRAGO[2], M. FRANKFURT[3];

[1]Hunter Col., New York, NY; [2]Psychology, Hunter Col. of CUNY, New York, NY; [3]Sci. Educ., Hofstra North Shore-LIJ Sch. of Med., Hempstead, NY

Abstract: Estrogens rapidly enhance hippocampal dependent recognition memory in ovariectomized (OVX) rats by activating cell-signaling cascades, epigenetic processes and dendritic spine density in the hippocampus within 5-30 min of treatment. Whether gonadal hormones elicit similar changes in castrate (CAS) male rats is unknown. Thus, we assessed effects of testosterone (T) and estradiol (E2) on object placement memory and dendritic spine density in the hippocampus. When 750 µg/kg of T was injected immediately after the T1 training trial and retention was tested 2 h later, CAS receiving vehicle spent the same amount of time exploring objects at the old and new locations (3.21 + 0.78 vs 2.72 + 0. 55 sec) whereas T-treated males spent significantly more time exploring at the new location (2.54 + 0.43 vs 5.95 + 1.50 sec, $p < 0.05$). Effects of estrogen were assessed by injecting 20 µg/kg of E2 immediately following the T1 training trial. CAS, vehicle treated males spent the same amount of time exploring objects at the old and new locations (3.91 + 0.15 vs 2.93 + 0.21 sec) whereas E2 treated CAS spent more time exploring at the new location (2.3 + 0.2 vs 5 + 0.05 sec, $p < 0.05$). In a separate experiment, the effects of the hormonal treatments on spine density in the hippocampus were assessed. CAS received vehicle, T or E2 and were sacrificed 30 min or 2 h later, and brains processed for Golgi impregnation using the FD Rapid GolgiStain Kit (Neurotechnologies, Inc). Spines from tertiary apical and secondary basal dendrites in CA1 pyramidal cells and primary dendrites of granule cells in the dentate gyrus (DG) were counted as previously described by the laboratory. After 30 min, a significant increase in CA1 apical spines (ANOVA = $p< 0.003$) was seen with T (40%) and E2 (28%). There were no differences between T and E2, and no effects were present on spines in basal CA1 or DG. Results at two hours post treatment were similar to 30 min, a significant group effect in apical ($p < 0.003$) but not basal CA1 spines with T increasing spine density by 21% and E2 by 31%. No effects were found in the DG. These results show that T and E2 rapidly enhance memory consolidation in the object placement task and cause specific changes in dendritic spine density within the hippocampus, increases in the apical tree of CA1 dendrites in CAS male rats. Effects of E2 are similar to those in OVX rats. In both sexes, E2 did not increase DG spine density. However, in females, basal, but not apical, spines are increased by E2 indicating an anatomical sex difference in CA1. Overall, results show novel gonadal hormonal effects in males and indicate that both sexes respond to gonadal hormones with rapid enhancements in memory and hippocampal spine density.

Title: Rapid and lateralized effects of estrogen manipulation on cognitive auditory processing in a seasonal songbird

Authors: *G. DE GROOF[1], J. BALTHAZART[2], M.-A. CEULEERS[2], C. A. CORNIL[2], A. VAN DER LINDEN[1];
[1]Univ. of Antwerp, Wilrijk, Belgium; [2]Res. Group in Behavioral Neuroendocrinology, Univ. of Liège, Liège, Belgium

Abstract: It has been recently demonstrated that the synthesis or concentration of brain estradiol (E2) is regulated within minutes by neuronal activity in birds [e.g. 1,2]. Recent studies demonstrate the existence of rapid behavioral effects of E2 that are additionally modulated by the photoperiod in mice [3] and by seasons in songbirds [4]. Here, we examined using functional Magnetic Resonance Imaging (fMRI) whether manipulation of E2 rapidly alters auditory processing in the highly social European starling (Sturnus vulgaris) in a season-dependent manner. Adult testosterone-treated male starlings (N=9) were exposed to synthetic pure tones and to two types of male starling song conveying species-specific and individual-specific information [5]. They were imaged twice by fMRI in December (8L:16D; photosensitive), March (11L:13D; late photosensitive) and May/June (16L:8D; photostimulated), a control session immediately followed by a session in which the aromatase inhibitor Vorozole was injected (30mg/kg i.p., 10 min before fMRI). In May/June an extra session was added where E2 (0.5mg/kg i.p.) was injected. Aromatase inhibition differentially affected neural activation elicited by the songs in different seasons. A clear statistically significant effect of Vorozole was detected in the left (but not right) caudal NCM in March but not in December nor May/June. Adding E2 increased neural activation elicited by the stimuli in both left and right NCM. E2 also affected song selectivity (individual-specific vs. species-specific songs), in that they selectively inhibited the neural activation elicited by species-specific songs. The differential response to E2 synthesis inhibition between the different seasons could indicate either a differential aromatase

expression/activity [6] or a change in sensitivity to E2 that would be associated with the increasing photoperiod. T was clamped to stable concentrations during the entire experiment so that the observed changes cannot be attributed to variation in activation by T. Lateralization of the effects of Vorozole on auditory responses in starlings is fascinating and very similar to behavioral findings in zebra finches [7]. Aromatase activity measured *in vitro* in these brains collected one year after the first imaging session (January - photosensitive) was however not different between left and right NCM. The lateralized effect of aromatase inhibition must therefore relate to other steps in estrogen action. 1. Remage-Healey L, et al., (2011). 2. Cornil CA, et al. (2012). 3. Trainor BC, et al. Title: Estrogen withdrawal induces depression-like behavior, cognitive dysfunction and temperature dysregulation in a rodent model of perimenopausal symptoms

Authors: *M. GULINELLO[1], C. SANCHEZ[2], Y. LI[2];
[1]Neurosci., Albert Einstein Coll of Med., Bronx, NY; [2]Lundbeck Res. USA, Paramus, NJ

Abstract: Background: The perimenopausal period in human is associated with a range of symptoms including hot flashes, depression and cognitive dysfunction due to the rapid fluctuation of estrogens. Although depression-like behavior has been demonstrated in several rodent models of perimenopause, few of these models have characterized functional changes in more than one relevant behavioral domain. In our current study, we assessed depression-like behavior, cognition and temperature regulation in a rodent model of perimenopausal syndrome that is easy to implement. **Methods**: Female, gonadally intact Sprague Dawley rats were group housed and had ad libitum access to tap water (control) or to water containing 20ug/ml beta-estradiol for 3 weeks (2mg/kg per day) followed by abrupt cessation of estradiol (estrogen withdrawal - EWD). A behavioral test battery was conducted 24-28 hours after EWD and

included the forced swim test and tail temperature measurements (before and after forced swim test) and social memory tests of cognition. Student t-tests were used to analyze the results with $p<0.05$ considered significant. **Results:** Estrogen withdrawal induced depression-like behavior (increased immobility in the forced swim test). During EWD, rats had increased basal tail temperature and slower temperature recovery after the forced swim test, indicating a failure of temperature regulation. Rats undergoing EWD also exhibited impaired social memory. **Conclusion:** Similar to perimenopausal women, estrogen withdrawal in intact rats induced depression-like behavior, temperature dysregulation and memory deficits. This model is feasible to widely implement and would be useful for study the pathophysiology and therapeutic treatments perimenopausal symptoms.

Title: Physiological arousal enhances memory for negative material in post-menopausal women not on hormone replacement therapy

Authors: *S. E. NIELSEN, M. MATHER;
USC, Los Angeles, CA

Abstract: Few studies have investigated the effect of physiological arousal on memory for emotional material in post-menopausal women, particularly those not on a hormone replacement therapy (HRT) regimen. Our recent work suggests that the effects of arousal on memory are modulated by levels of 17β-estradiol and progesterone in young women (Nielsen, Barber, Chai, and Mather, under review); under arousal, women with lower levels of these sex steroid hormones recalled significantly more negative than positive images. Thus, we tested whether physiological arousal at encoding differentially modulates memory for negative and positive emotional images in post-menopausal women not taking HRT; these older women should have very low levels of sex steroid hormones. Based on our previous work showing the relationship between hormone levels and arousal effects among younger women (Nielsen et al., under review), we predicted that arousal at encoding would enhance short-term emotional memory for

negative images (i.e., high priority images) and suppress memory for positive images (i.e., low priority images). To induce arousal at encoding, some women were administered an isometric handgrip protocol, which has reliably increased endogenous norepinephrine levels in previous studies (see Nielsen et al., under review; Nielsen and Mather, 2015). For the control condition, the handgrip task was replaced with a relaxed water bottle hold. Immediately after, all participants saw a slideshow containing negative, positive, and neutral pictures. Later, all women completed a free recall test for the images. We used eye-tracking technology to assess pupil diameter changes (index of arousal) in response to the handgrip or control task, and we collected salivary samples to assess changes in salivary alpha-amylase (a biomarker for norepinephrine) and levels of 17β-estradiol and progesterone. We tested whether increases in arousal enhanced the tendency to preferentially recall the negative rather than the positive images. A preliminary mixed-model ANOVA revealed a significant two-way interaction between condition (handgrip v. control) and picture valence (negative v. positive) in post-menopausal women ($p < .05$). Follow-up analyses suggest that under arousal, post-menopausal women exhibited an enhanced negativity bias compared to women who completed the control condition ($p < .05$). These preliminary results suggest that physiological arousal at encoding enhances memory for negative, but not positive images, in women as they age and their sex steroid hormone levels substantially decrease.

Title: Anastrozole treatment to ovariectomized rats induces compensatory plastic changes in prefrontal third-layer pyramidal neurons concomitant to working memory impairment

Authors: *D. A. VELÁZQUEZ-ZAMORA[1], N. I. MARTÍNEZ-TORRES[2], M. CERVANTES[3], I. GONZÁLEZ-BURGOS[2];
[1]Univ. Politécnica De La Zona Metropolitana D, Tlajomulco DE Zuniga, Mexico; [2]Inst. Mexicano del seguro Social, Guadalajara, Mexico; [3]Univ. Michoacana de San Nicolás de Hidalgo, Morelia, Mexico

Abstract: Local synthesis of neuroesteroids such as estradiol depends on aromatase activity. Aromatase is expressed in glial cells and neurons in some brain structures such as prefrontal cortex. The prefrontal cortex has a key role in processing the afferent information related with working memory. This executive function is showed to be altered under the absence of estrogenic activity during loss of ovarian function, although the local activity of cerebral-derived estradiol persists. Particularly, both working memory performance and dendritic spines of pyramidal neurons of the layer III of prefrontal cortex are sensitive to the gonadal-proceeding estradiol effects. However, the possible plastic changes in prefrontal dendritic spines underlying working memory performance may be associated with the effects of brain-derived estradiol have not been reported. In the present study, 58 female rats were assigned to four groups: Rats from a control group were ovariectomized bilaterally (Ovx; n=12). Rats from other control were ovariectomized bilaterally, and 1mL of saline solution was administered to each of them (Ovx+Veh; n=12). Another control group of rats were studied in the proestrus stage of their estrous cycle (Proestrus; n=12). An experimental group of rats were ovariectomized bilaterally and treated with 1 mg/kg of Anastrozole in saline solution (Ovx+Ans; n=12). The corresponding pharmacological treatment to Ovx, Ovx+Veh and Ovx+Ans groups was applied at day 6 after ovariectomy. Six animals per group were used for behavioral testing of allocentric working memory in a Y maze. The brains of the remaining six animals per group were used for a morphological study of dendritic spines of layer III pyramidal neurons from prelimbic/infralimbic prefrontal cortex, using a modified version of the Golgi technique. Ovx+Ans group showed less correct responses than all the other groups studied. On the other hand, Ovx+Ans group had less spines than those seen in Proestrus group, but more spines than both Ovx and Ovx+Veh. In addition, only Ovx+Ans group showed filopodial structures. These findings suggest that inhibition of local synthesis of estradiol could be associated with the decreased number of dendritic spines and a compensatory surge of filopodia, as a response to the deficient performance of the working memory task.

Title: Sex differences in neonatal hippocampal neurogenesis impact early life forgetting

Authors: *S. L. STOCKMAN, J. M. BOWERS, M. M. MCCARTHY;
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Exposure to early life adversity is a major driver of adult health (Felitti et al., Am J Prev Med, 1998). Females are more sensitive to these exposures evident in an increased likelihood to manifest disease, particularly affective-related disorders (Sildberg et al., Arch Gen Psychiatry, 1999). Elevated neurogenesis has been implicated in disruption of established hippocampus-dependent memories causing forgetting (Akers et al. Science, 2014). The magnitude of change in neurogenesis required to shift from learning to forgetting is on par with elevated hippocampal neurogenesis we observe in neonatal males compared to females during the critical neonatal period (Bowers et al., Biol Sex Diff, 2010). Thus we propose elevated neurogenesis in neonatal male hippocampus promotes forgetting of the trauma associated with adverse early life events and diminishes the long-term consequences of such exposure. In order to explore sex differences in early forgetting, we have first demonstrated the ability of neonates to learn utilizing established and novel paradigms. The first paradigm used is an odor-aversion learning assay. In our test, pups are conditioned with odor-footshock pairing on PN6 consisting of a novel vanilla odor with a 1.5mA constant current shock. Testing on PN8 consists of a Y-maze that requires pups to choose between two arms, one containing the vanilla odor and the other with a familiar odor. Learning is evident in aversion to the vanilla odor paired with the aversive stimulus. The second paradigm is a novel learning test we have developed called the Neonatal Learned Aversion (NeoLA) box that employs principles of conditioned place aversion through utilization of pup aversion for cold and bright lights and preference for darkness and warmth. This test utilizes an apparatus divided into a cold and dark side and a warm and bright side. At the start of a trial animals are placed in a hutch on the cold/dark side and given 5 minutes to cross to the warm/bright side. Animals are assisted if they do not cross in 5 min. They are then left on the bright/warm side for 2 min. There are 4 training trials per day from PN4 to PN7. Pups find both the cold and the light aversive but learn to escape the cold with a decreasing latency of 300 seconds down to 89 seconds. Following establishment of learning, assessment of retention at a later time point (PN12) allows for evaluation of forgetting. Investigation of sex differences in neonatal forgetting will provide a basis to understand the contributions of neurogenesis in mediating forgetting of trauma associated with early life adverse event exposure and subsequently understand sex differences in the consequences of such exposure.

Title: Estradiol and luteinizing hormone affect spatial memory by influencing cell proliferation and expression of brain-derived neurotrophic factor

Authors: N. BOHM-LEVINE, A. GOLDBERG, E. VARRONE, *J. E. THORNTON; Neurosci. Dept, Oberlin Col., Oberlin, OH

Abstract: In humans, both ovariectomy and menopause are associated with memory loss. Concomitant with this, there is a substantial drop in estradiol (E) and a large increase in luteinizing hormone (LH) due to decreased negative feedback by E. Ovariectomized (ovx) female rats also exhibit deficits in various forms of spatial memory and either raising E or lowering LH levels reverses these memory deficits (e.g. Berry et al., 2008; Ziegler and Thornton, 2010). Estradiol has been shown to increase neurogenesis and expression of neurotrophic factors in the hippocampus, which may account for estradiol's mnemonic benefits (Barker and Galea, 2008; Solum and Handa, 2002). The present studies investigated whether LH decreases hippocampal cell proliferation and/or brain-derived neurotrophic factor (BDNF) levels. Female Sprague-Dawley rats were ovx and implanted with either an E or blank (blk) capsule. Animals were injected with the LH homologue hCG (human chorionic gonadotropin), Antide (a gonadotropin releasing hormone receptor antagonist that decreases LH levels) or vehicle (0.9% saline), and brains were collected 4-6 hours later. Tissue was processed using immunohistochemistry and examined for cells expressing Ki67, a nuclear protein present during mitosis, and for BDNF. E treatment significantly increased the number of Ki67-immunoreactive cells in the dentate gyrus compared to controls (ovx + E vs. ovx + blk); however, decreasing LH with Antide treatment had no clear effect on cell proliferation (ovx + Antide vs. ovx + blk). In contrast, both E and Antide treatment significantly increased BDNF levels in the dorsal hippocampus of ovx rats (ovx + E and ovx + Antide vs. ovx + blk). To further investigate whether the hormone-mediated mnemonic improvements are dependent on BDNF, ovx + E animals were injected with the BDNF TrkB receptor antagonist ANA-12 (0.5mg/kg, Sigma) or vehicle, 4-6 hours prior to behavioral testing on the Object Location Test (OLT). Consistent with previous results, ovx + E animals displayed improved spatial memory compared to ovx + blk. Conversely, ANA-12 treatment led to a loss of spatial memory in ovx + E animals, indicating an important role for BDNF in E-induced memory recovery. Future studies will determine whether ANA-12 treatment similarly attenuates Antide's effects on spatial memory in ovx rats.

Title: Hippocampal aromatization modulates spatial memory in the zebra finch via the action of estradiol on membrane receptors

Authors: *D. J. BAILEY[1], E. R. PAITEL[2], J. A. GUNDERSON[1], Y. V. MAKEYEVA[1], C. J. SALDANHA[3];
[1]Biol., [2]Psychology, St. Norbert Col., De Pere, WI; [3]Biol., American Univ., Washington, DC

Abstract: Synaptic aromatization has recently emerged as an intensely studied aspect of neuroendocrine function. Aromatase expression in the adult zebra finch hippocampus (HP) is among the highest compared to other neural loci and is localized primarily pre- and postsynaptically. Previously we established that application of an aromatase inhibitor to the male zebra finch HP increased the number of learning trials in a spatial memory task and the mistakes made during/time to complete the probe trials. Notably, these birds performed indiscernibly from those with HP lesions. While these data suggest that synaptic estradiol (E2) may be important in HP-dependent memory function, studies involving (1) concurrent replacement of this steroid in birds treated with an aromatase inhibitor and (2) the role of estrogen receptors, particularly the G protein-coupled estrogen receptor (GPER) implicated in rapid E2 signaling, are necessary to test this hypothesis. Adult male zebra finches were anesthetized and received a bilateral craniotomy above the HP. Birds were given one of the following manipulations: silicone pellets (SIL) or identical pellets soaked with the aromatase inhibitor ATD (1,4,6-androstatriene-3,17-dione), ATD+E2, the GPER agonist G-1 or the antagonist G-15. Three days later, birds were food-deprived and tested for acquisition and retention of a food location. ATD-treated birds took significantly more trials to reach criterion relative to SIL birds, but the performance of ATD+E2 birds was statistically indistinguishable from both SIL and ATD birds. While application of G-1 to the HP did not significantly affect acquisition relative to SIL birds, all G-15 birds were unable to reach the predetermined criterion level. During probe trials 1 hr following acquisition, ATD birds took the longest to reach the baited cup and made more mistakes relative to the other groups. Interestingly, ATD+E2 animals displayed the lowest overall retention latencies and made significantly fewer mistakes than birds treated with ATD. Thus, spatial memory acquisition and performance appear aromatase dependent, while its E2 dependence is more reliably revealed

following consolidation and/or during recall. This study provides evidence that (1) the decrease in spatial memory performance of ATD-treated birds likely reflects a specific effect on synaptic E2 synthesis and (2) this effect is at least in part mediated by GPERs. Additional studies on tissue collected from these birds will begin to determine the signal transduction systems mediated by synaptic E2 provision and necessary for HP-dependent memory function.

Title: Luteinizing hormone receptor activation in the CNS increases neurite outgrowth and spatial memory

Authors: *J. A. BLAIR[1], H. MCGEE[2], X. WANG[3], G. CASADESUS SMITH[2,1];
[1]Biomed. Sci., [2]Biol. Sci., Kent State Univ., Kent, OH; [3]Pathology, Case Western Reserve Univ., Cleveland, OH

Abstract: Elevated peripheral levels of luteinizing hormone (LH) have been linked to deficits in spatial memory and reductions in dendritic spine density *in vivo*. An inverse relationship exists such that pharmacologically reducing levels of LH in the periphery results in its increase in the CNS, thus improving cognitive performance. Therefore, we hypothesized that increases in LH receptor (LHR) signaling in CNS ameliorates learning and memory as well as improves neuronal morphology. To test our hypothesis, we delivered an LH analogue (hCG) into the lateral ventricles of young female mice with an ovariectomy-induced decrease in CNS LH levels. Our preliminary data suggest that LH rescues ovariectomy associated deficits in spatial memory in Morris water maze. To elucidate LHR action *in vitro* we treated primary hippocampal neurons with hCG, which resulted in an increased number of secondary neurites and branch points. In conclusion, our work shows that central delivery of LH improves learning and memory as well as dendritic arborization, suggesting that increased LHR signaling in the CNS will ameliorate cognitive function in aging females.

Title: Does maternal genistein impair non-spatial, hippocampal-dependent memory in adulthood?

Authors: *C. C. WRENN, C. T. LANGRECK, S. A. LOTHSPEICH;
Coll Pharm. & Hlth. Sci., Drake Univ., Des Moines, IA

Abstract: The soy-derived phytoestrogen genistein has received interest as an endocrine disruptor due to its ability to bind estradiol receptors. Among the functions that may be impacted by endocrine disruptors are learning and memory. Previous work from our laboratory has shown that exposure of male rats to genistein through the maternal diet results in impaired learning in the water maze, a hippocampal-dependent spatial task. In the current study we tested the hypothesis that maternal exposure to genistein also impairs learning in a hippocampal-dependent non-spatial task, the social transmission of food preference (STFP). STFP is an olfactory task in which rats use their memory for a socially presented scent cue to guide food choice. We exposed male rats to genistein by allowing pregnant dams to consume food containing the phytoestrogen (5 mg/kg) throughout gestation and lactation. After weaning, we placed male rats on a phytoestrogen-free diet and tested them in STFP at approximately 2-3 months of age. Control and genistein-exposed rats did not differ in their ability to use memory for a scent to guide food choice. These data suggest that genistein-exposure during development does not cause an impairment in a non-spatial hippocampal task. Future work will assess the effect of maternal genistein exposure on other hippocampal tasks such as trace fear conditioning.

Title: Estrogen sensitive G-protein coupled receptor (GPER1) rapidly regulates dendritic spine turnover and PSD-95 dynamics

Authors: *K. SELLERS[1], P. RAVAL[1], I. A. WATSON[1], T. Z. DEEB[2], J. MUKHERJEE[2], F. ERLI[3], D. GADD[1], N. J. BRANDON[4,2], D. P. SRIVASTAVA[1];

Abstract: In the mammalian forebrain, the majority of excitatory synapses form on dendritic spines. Changes in the number of dendritic spines are important for brain development, plasticity and the refinement of neural circuits. In addition, alterations in dendritic spine number occur during the acquisition of learned behaviours, suggesting an intimate relationship between the regulation of these post-synaptic structures and cognitive function. Multiple studies have demonstrated that the 17β-estradiol (E2), the major biologically active form can modulate cognition within a rapid time frame. In addition to this there is increasing body of evidence to suggest that E2 is capable of rapidly activating a number of signalling cascades resulting in alteration of dendritic spines, consistent with its effects on cognition. While these effects have been attributed in the main to signalling via the estrogen receptors (ER) ERα and ERβ, recent studies have suggested that the recently identified E2 sensitive receptor, G-protein coupled estrogen receptor 1 (GPER1), may also mediate E2-dependent modulation of cognition. However, whether signalling via GPER1 can also mediate spine-morphogenic responses are not clear. Here we report using superresolution microscopy that GPER1 is present at a subset of synapses in excitatory cortical neurons where it forms nanodomains with PSD-95. We demonstrate that signalling through GPER1 results in the activation of distinct signalling cascades in primary cortical neurons. Time-lapse imaging demonstrates that pharmacological

activation of GPER1 results in an increase in dendritic spine turnover and motility, and an increase in spine linear density. Moreover, GPER1-medaited spinogenesis is dependent on its C-terminal, a domain essential for its synaptic localisation and interaction with synaptic proteins including PSD-95. In addition, we observe an increase in PSD-95 trafficking, resulting in its localisation in newly formed spines. Activation of GPER1 also resulted in altered synaptic expression of AMPA-receptors and AMPA-receptor mediated transmission. These findings suggest that in cortical neurons, E2 signalling via GPER1, is capable of remodelling neuronal circuits by increasing the number of excitatory synapses.

Title: Local activation of Ras-like small GTPase Rap1 is required for estrogen-induced spine formation

Authors: *D. P. SRIVASTAVA[1], A. SHUM[2];
[1]Inst. of Psychiatry, Psychology and Neuroscien, London, United Kingdom; [2]Northwestern Univ., Chicago, IL

Abstract: There is a growing appreciation that estrogens, in particular, 17β-estradiol (estradiol) exert a positive effect on cognitive function within a rapid time frame (minutes to hours). These cognitive enhancing effects have been shown to be dependent on the activation of specific signalling pathways and are accompanied by increases in spine density in several areas of the brain. Recent studies have now begun to link the activation of specific signalling pathways with estradiol-induced spine plasticity. Interestingly, the initial formation of dendritic spines by estradiol is independent of protein synthesis and gene transcription, and thus, wholly reliant on

the activation of cytosolic signalling pathways. However, the direct observation of estradiol-induced signalling in dendrites or in dendritic spines has not been shown. The Ras-family of small GTPases, which includes Rap1, play important roles in the morphogenesis of dendritic spines. We have previously shown that a Rap1-dependent pathway is critical for estradiol-induced spine formation in cortical neurons. Using a unimolecular FRET-sensor for Rap1, we have monitored the spatiotemporal dynamics of Rap1 activation in live cortical neurons following treatment with estradiol. In distal dendrites and dendritic spines, we observe a highly compartmentalized activation of Rap1 following estradiol treatment. This is maximal within 30 minutes, consistent with estradiol's effects on dendritic spine density. Remarkably, we find that active Rap1 accumulates within dendrites directly below and preceding the formation of a nascent dendritic spine. Subsequently, activate Rap1 diffuses into the newly formed spine, suggesting that Rap1 is play a role in co-ordinating the formation of a nascent spine. Importantly, overexpression of a dominant-negative Rap1 mutant (Rap1 N17) blocks estradiol-induced spine formation. These data demonstrate that estradiol specifically activates a Rap-dependent pathway locally within dendrites and dendritic spines, which co-ordinate the formation of nascent dendritic spines.

Title: The effect of sex and social status on gene expression in Syrian hamster brain

Authors: *K. E. MCCANN, D. M. SINKIEWICZ, A. NORVELLE, K. L. HUHMAN; Neurosci. Institute, Ctr. for Behavioral Neurosci., Georgia State Univ., Atlanta, GA

Abstract: Male and female Syrian hamsters are highly territorial and are readily aggressive towards an intruding conspecific. After losing one agonistic encounter, however, hamsters abandon all territorial aggression and, instead, become highly submissive. This change in behavior has been termed conditioned defeat. While both males and females exhibit conditioned defeat, the behavioral expression varies and is overall more pronounced in males. To investigate potential molecular mechanisms leading to sexually dimorphic expression of conditioned defeat,

we used transcriptomic analysis. First, we sequenced the entire brain transcriptome of male and female hamsters and compared baseline expression levels. Using a false discovery rate of <0.001 and a log2 fold change of >1 or <-1, we found 306 differentially expressed genes, 232 of which were up regulated in females compared with males. Next, we sequenced transcriptomes of basolateral amygdalae taken from dominant and subordinate animals and compared these with amygdalae from home cage controls. The basolateral amygdala is necessary for both acquisition and expression of conditioned defeat, and thus we sought to investigate differential gene expression in this nucleus of males and females of different social status. In males, expression of 37 genes decreased and 10 genes increased in both subordinate and dominant animals compared with socially isolated controls. Interestingly, 14 genes showed directional opposition (i.e., 8 increased in dominants while decreasing in subordinates; 6 increased in subordinates that decreased in dominants). Ultimately, 10 unique genes were specifically up-regulated in subordinate, and 12 unique genes were specifically up-regulated in dominant males. A similar pattern emerged in females. Expression decreased in 26 genes and increased in 16 genes in dominant and subordinate animals compared with controls. Only 6 genes showed directional opposition in females (2 genes increased in dominants that decreased in subordinates, and 4 genes increased in subordinates that decreased in dominants). Overall, 11 unique genes were specifically up-regulated in subordinate females and 10 were specifically up-regulated in dominant females. We are currently analyzing these data to determine if the genes that are differentially expressed are similar between males and females and to establish what role, if any, these genes play in the behavioral changes observed following agonistic experience. Title: Brain derived neurotrophic factor in the medial prefrontal cortex reduces the acquisition of conditioned defeat

Authors: *A. M. ROSENHAUER, B. M. THOMPSON, T. E. LARKIN, K. L. HUHMAN; Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Syrian hamsters readily display aggressive behaviors to defend their territories under laboratory conditions and thus are ideal for the ethologically relevant study of the effects of social stress on brain and behavior. Hamsters also show a striking failure to exhibit their normal territorial aggression after a single pairing with a larger, more aggressive conspecific that results in social defeat. This behavioral change has been termed conditioned defeat (CD) and is exhibited by animals even when they are subsequently paired with a smaller, non-aggressive intruder (NAI) in the defenders' home cages. Our lab has worked to delineate the neural circuit and the neurochemical signals that mediate CD. We have shown that, similar to classical fear conditioning, CD is dependent on neural activity in the basolateral amygdala (BLA) and the medial prefrontal cortex (mPFC). Surprisingly, we have also shown that peripherally administered brain-derived neurotrophic factor (BDNF) TrkB receptor agonists, which are known to promote learning and memory, unexpectedly reduce the acquisition and consolidation of CD. As it is known that the mPFC can inhibit fear learning by its downstream effects on the BLA, a critical node in the neural circuit mediating CD, it is possible that the peripherally administered BDNF-active drugs inhibited CD via their action in the mPFC. The purpose of this experiment was to test this possibility. Thus, BDNF (0.4 ng in 200 nl saline) was administered into the medial pre-frontal cortex prior to a 15-minute defeat training session. Hamsters were then tested 24 hr later with a NAI. Hamsters microinjected with BDNF displayed significantly less submissive behavior than did vehicle controls during testing indicating that BDNF in the mPFC decreases the acquisition of CD. We are now beginning to explore whether BDNF has different effects on CD acquisition depending on what subregion (i.e., prelimbic versus infralimbic) of the mPFC is targeted. Title: Brain derived neurotrophic factor impairs consolidation of conditioned defeat learning but does not impair learning of social cues

Authors: *K. A. PARTRICK, B. M. THOMPSON, T. E. LARKIN, Z. SONG, K. L. HUHMAN;
Neurosci. Inst., Atlanta, GA

Abstract: Syrian hamsters are territorial animals that attack intruders. After a brief social defeat, however, hamsters no longer display territorial aggression, even when paired with a smaller, non-aggressive intruder (NAI). Instead, defeated hamsters display submissive behavior, and this response has been termed conditioned defeat (CD). Brain derived neurotrophic factor (BDNF) and its receptor TrkB are known to mediate fear learning and are prevalent in brain regions known to be important for CD. Surprisingly, our lab has previously shown that TrKB receptor agonists administered centrally or peripherally decrease the consolidation of CD, while a TrkB receptor antagonist administered peripherally enhances CD. Therefore, it appears that BDNF may impair fear leaning following social defeat. Alternatively, it is possible that BDNF improves learning of cues associated with the original defeat so that hamsters display a reduced generalization when paired with an NAI. The purpose of this experiment was to test whether the TrkB receptor agonist 7,8-dihydroxyflavone (7,8-DHF; 10 mg/kg ip) alters learning of social cues. Hamsters were exposed to the flank gland secretion of a conspecific on a glass slide (3min) on Day 1. Immediately after the scent exposure, hamsters were injected with 7,8-DHF or vehicle. On Day 2, hamsters were re-exposed to a slide with scent from the familiar opponent as well as a second slide with flank secretions from a novel conspecific. Time (s) spent sniffing each scent during a 3min trial was recorded. In general, hamsters spend more time during the second test sniffing the novel scent, demonstrating that they are capable of social recognition 24 after scent exposure. Hamsters given 7,8-DHF exhibited neither enhancement nor impairment of social learning. Equal numbers of animals (i.e., 8 of 10) in each group preferred the unfamiliar scent during testing, demonstrating similar social recognition between groups. These data suggest that our previous finding that 7,8-DHF reduces conditioned defeat is not due to a non-specific effect of 7,8-DHF on learning of social cues. Instead, it appears that BDNF may promote resilience to social defeat in hamsters. Supported by NIMH award R01MH062044 to KLH. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.

Title: Effects of environmental enrichment and social isolation and the reversion of those conditions on anxiety and fear conditioning

Authors: *A. MORA-GALLEGOS, S. SALAS, J. FORNAGUERA;
Univ. of Costa Rica, San Jose, Costa Rica

Abstract: Environmental enrichment (EE) and social isolation (SI) have lasting effects on brain and behavioral parameters including emotions such as fear and anxiety. We focused on differences between EE and SI rats and on the possible effects produced by the reversion of those conditions on fear and anxiety. We measured anxiety (Open Field Test-OFT and Plus Maze-PM), fear (Fear Conditioning-FC) and levels of DOPAC (DA) and dopamine (DA) on prefrontal cortex (PFC), and amygdala (AMY) using HPLC-EC. In experiment 1, anxiety tests were carried out before, one and two months after starting housing conditions. FC procedure was conducted after two months of housing. After behavioral tests, animals were sacrificed for neurochemical analysis. In experiment 2, housing conditions were reverted (EE to SI and SI to EE), and maintained also for two months, keeping their respective control groups. Anxiety tests were done as in experiment 1 and fear to the context (FCC) was conducted at the end of housing. Sacrifices were conducted as in experiment 1. In experiment 1 EE rats were less reactive on anxiety tests and FC. Anxiety effects are reflected mainly in OFT locomotion and exploration but also in PM behaviors. In FC procedure, EE rats showed higher levels of freezing. EE rats showed higher DA turnover in PFC and in AMY than SI rats (not significant). In experiment 2, in OFT and PM, EE showed less anxiety behaviors than SI similar to experiment 1. For reversion conditions we found that SI-EE behaviors are more alike to EE and that EE-SI behaviors are more alike to SI, after two months of the reversion. Reverted conditions didn´t show differences in FCC. For neurochemistry, although there were no significance, EE rats showed higher DA turnover on PFC and AMY than SI rats, and reverted conditions seem to decrease when compared to their original housing conditions. Taken together, our results confirm that EE rats have better strategies to cope with anxiety and fear, and these effects at behavioral and neurochemical levels are maintained at two and four months of housing. Additionally, reversion of housing conditions can modify animals' behaviors and DA turnover in the PFC and AMY.

Title: Effects of differential housing on emotional behaviors and expression of BDNF and CRF in hippocampus and amygdala

Authors: *S. SALAS, A. SEQUEIRA, J. FORNAGUERA, A. MORA-GALLEGOS;
Univ. of Costa Rica, San José, Costa Rica

Abstract: Fear and anxiety are central for the understanding of many psychological disorders and neurodegenerative diseases.These emotions seem to be modulated by the environment in which the subject develops. To study the effect of rearing environments on fear and anxiety,we used differential housing conditions during 2 months (social isolation, standard control and environmental enrichment) on male Sprague-Dawley rats and tested different behavioral parameters in the open field test, plus maze test and fear conditioning paradigm. One week after the last testing session, animals were sacrificed in order to analyze the expression of BDNF and CRF in the hippocampus and amygdala, by means of RT-qPCR. Social isolated rats showed anxious behavioral patterns in the open field test, while enriched rats seem to be less reactive to the new environment. In the plus maze test, analysis of time spent in open and close arms did not show housing effects, but other behaviors like stretched-attended posture, head dipping, rearing and grooming did, showing consistence with the open field test results. There were also performance differences on fear conditioning task; enriched animals showed higher levels of freezing than the other two groups. This behavior has been classically associated with more efficient emotional memory. In regard to the expression analysis, enriched animals showed higher levels of BDNF in the hippocampus than the other two groups, while control animals had higher levels of BDNF in the amygdala, as well as CRF in both regions. Our results suggest that environmental enrichment has an effect primarily on hippocampal BDNF, region related to memory and spatial information processing. In the amygdala, the similarities showed between enriched and isolated animals, could be explained by a more generalized coping mechanism for emotional challenges.Even though the enriched group showed better performance in the behavioral tests, there seem to be some coincidence in regulatory mechanisms of gene expression in both hippocampus and amygdala.

Title: Cellular mechanisms by which social status alters behavioral responses to stress

Authors: S. SEDDIGHI, A. K. BARNES, C. T. CLINARD, *M. A. COOPER;
Dept. of Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Understanding the cellular mechanisms that control resistance and vulnerability to stress is an important step toward identifying novel targets for the prevention and treatment of stress-related mental illness. Dominant and subordinate animals have been shown to exhibit different behavioral and physiological responses to stress, with dominants often showing stress resistance and subordinates showing stress vulnerability. We have previously found that dominant hamsters exhibit reduced social avoidance following social defeat stress compared to subordinate hamsters, although the extent to which stress resistance in dominants generalizes to non-social stressors is unknown. In this study dominant, subordinate, and control male Syrian hamsters were exposed to acute restraint stress for 30 minutes. In one cohort of animals, brains were collected for c-Fos immunohistochemistry following restraint stress. In a second cohort, blood samples were collected immediately following restraint and animals were tested for anxiety-like behavior in an open field arena 24 hours later. Preliminary data indicate that restrained animals exhibited increased plasma cortisol compared to non-restrained controls. Also, restraint stress increased the number of c-Fos-positive cells in several brain regions including the infralimbic cortex, prelimbic cortex, medial amygdala, and paraventricular nucleus of the hypothalamus. Analysis of c-Fos immunoreactivity, plasma cortisol, and anxiety-like behavior in dominant and subordinate animals is ongoing. This project will address whether resistance to social defeat stress in dominant hamsters generalizes to restraint stress and extend existing literature on the domain-general vs. domain-specific nature of stress resilience.

Title: Metabolomics of Resilience to Social Stress

Authors: *B. N. DULKA[1], A. K. BOURDON[2], C. T. CLINARD[1], M. B. MUVVALA[3], S. R. CAMPAGNA[2], M. A. COOPER[1];
[1]Psychology, [2]Chem., [3]Univ. of Tennessee, Knoxville, TN

Abstract: Social defeat represents a naturalistic form of conditioned fear and is an excellent model in which to investigate the biological basis of stress resilience. While there is growing interest in identifying biomarkers of resilience, until recently it has not been feasible to associate levels of multiple neurochemicals in several brain regions to stress-related phenotypes. Metabolomics is a quantitative analysis of small molecules present in biological systems and has been increasingly used for the discovery of biomarkers. The objective of the present study was to identify neurochemicals in select brain regions that distinguish susceptible and resilient individuals in two rodent models of acute social defeat: one with mice and another with Syrian hamsters. We expect that this comparative approach will add strength to the generalizability of these findings. In the first experiment, male mice were subjected to acute social defeat stress using a resident-intruder model and tested for social avoidance 24 hours later in an open field arena to phenotype individuals as resilient or susceptible. One week later, mice were subjected to a second acute social defeat episode, and tissue was immediately collected from the medial prefrontal cortex (mPFC), amygdala (AMY), nucleus accumbens (NAC), and hippocampus (HPC). Liquid chromatography coupled with both tandem and high resolution mass spectrometry (LC-MS) was then used for neurochemical and metabolite detection. In the second experiment, we paired male Syrian hamsters in daily agonistic encounters for 2 weeks, during which they formed stable dominant-subordinate relationships. Then, 24 hours after the last pairing animals were exposed to acute social defeat stress. Immediately after social defeat tissue was collected from the mPFC, AMY, NAC, and HPC, and each sample was analyzed using LS-MS. Preliminary analyses indicate several small molecules that significantly differ between defeated and non-defeated animals. For example, defeated hamsters exhibited higher levels of DOPAC in the HPC and AMY and lower levels of NAD+/NADH in the AMY, HPC, and mPFC compared to home cage controls, suggesting increased metabolism of dopamine and impaired energy

metabolism, respectively. Analyses to identify metabolites that distinguish susceptible and resilient animals are ongoing. We believe that taking a metabolomics approach is an essential first step toward developing novel biomarkers for stress-related mental illness.

Title: The role of androgen receptor signaling in the maintenance of dominance status and resistance to conditioned defeat

Authors: *C. T. CLINARD, S. G. ADLER, M. A. COOPER;
Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Winning aggressive disputes is one of several experiences that can alter responses to future stressful events. We have previously tested dominant and subordinate male Syrian hamsters (Mesocricetus auratus) in a conditioned defeat model and found that dominant individuals show reduced defeat-induced changes in behavior compared to subordinates. Also, resistance to the effects of social defeat in dominants is experience-dependent and requires 14 days of dominance encounters to develop. Testosterone is a potential neuroendocrine signal regulating differences in how dominants and subordinates respond to stress because winning aggressive encounters can increase plasma testosterone and androgen receptor expression in select brain regions. Our objective was to determine whether a surge in testosterone after winning aggressive interactions modulates the experience-dependent neural plasticity supporting stress resiliency. In the first experiment, male hamsters were paired in 10-min aggressive encounters and blood samples were collected immediately before and 15-min after agonistic interactions. Dominants showed a significant rise in plasma testosterone compared to their baseline hormone measurement, whereas subordinates and control animals showed no change in testosterone. The second experiment investigated whether changes in androgen receptor immunoreactivity occur during the maintenance of dominance relationships. We paired male hamsters in daily agonistic encounters for 14 days to establish and maintain

dominant/subordinate relationships, and then collected brain tissue for androgen receptor immunohistochemistry. Dominant animals showed significantly more cells expressing androgen receptor immunoreactivity, compared to subordinates and controls. In the third experiment, we are currently investigating if this androgen receptor-dependent signaling is necessary during the maintenance of dominance status for resistance to conditioned defeat. These results suggest that daily surges in plasma testosterone during the maintenance of dominance status coincide with the development of conditioned defeat resistance, and that testosterone is a potential neuroendocrine signal modulating experience-dependent neural plasticity controlling resistance to conditioned defeat in dominant hamsters.

Abstract: Stress is a precipitating factor for neuropsychiatric disorders, such as anxiety and depression. Preclinical and clinical evidence suggest that stress effects on the brain and the ensuing behavioral responses differ between the sexes. Gene expression and epigenetic studies are helping to unravel the molecular underpinnings of such sex differences. Brain-derived neurotrophic factor (BDNF) has been postulated to lay at the core of the stress-response in the hippocampus, a brain region implicated in mood disorders, and a common single-nucleotide polymorphism in the human BDNF gene (Val66Met) has been associated with increased vulnerability to depression. Here we hypothesized that mice heterozygous for the Met allele

would exhibit gene expression changes similar to stressed mice even without applied stressors. We used double transgenic mice bearing both a heterozygous variant $BDNF_{Met}$ knock-in and a Bacterial Artificial Chromosome (Bac) in which the EGFP-L10a is selectively expressed in the vulnerable CA3 region. Genetically-targeted translating ribosome affinity purification (TRAP) and RNA-Seq analysis revealed that about 76% of the total entities analyzed were affected similarly in acutely stressed (FST, forced-swim test) $BDNF^{+/+}$ females and in unstressed $BDNF^{+/Met}$ females. Interestingly, $BDNF^{+/Met}$ males did not exhibit the same profile when compared to FST $BDNF^{+/+}$ males and both differed with respect to sex. One marker of acute stress, c-Fos, was only increased in FST $BDNF^{+/+}$ males and females, indicating that $BDNF^{+/Met}$ mice had not activated the immediate early gene transcription cascade. Yet, we found that genes that were simultaneously upregulated in FST $BDNF^{+/+}$ and $BDNF^{+/Met}$ females belonged to stress sensitive pathways, such as methylation, histone modification, circadian regulation, PI3K-Akt-mTOR, and TNF-NF-kB pathways. Moreover, the analysis of single candidate genes within these pathways highlighted considerable sex differences. These results suggest that the heterozygous variant BDNF Val66Met polymorphism mimics some effects of acute stress in a sex dependent manner and that the CA3 is likely to be a crucial hippocampal region for the establishment of sex differences in animal models of stress-related disorders.

Title: Sex-dependent programming of opioid receptor expression within the juvenile nucleus accumbens by early life stress

Authors: *L. CHANG[1], S. L. KIGAR[2], A. CUARENTA[2], H. C. GUNDERSON[2], B. A. BALDO[2], V. P. BAKSHI[2], A. P. AUGER[2];

Abstract: Early life stress (ELS) has been found to modify typical brain development and potentially leading to increased risk for neuropsychiatric disorders, such as depression and

anxiety. Importantly, sex differences are often observed in the prevalence, age of onset, and manifestation of some of these conditions. This suggests that variations in the underlying circuitry between males and females may set up mental health risk or resilience to early life perturbation. Furthermore, many of these disorders present with atypical social reward, often in the form of social anhedonia. As endogenous opioids play an important role in reward-related behaviors, we wanted to investigate if ELS alters typical development of the opioid reward system within the nucleus accumbens, a major site of reward. We modeled ELS by exposing male and female Sprague-Dawley pups to predator odor on postnatal days 1 through 3 for 5 minutes each day. We observed a significant decrease in mu- and kappa-opioid receptor mRNA levels in stressed females compared to control females 30 minutes after the last predator odor exposure. This confirms our hypothesis that ELS does indeed disrupt typical development of the opioid system within the nucleus accumbens. However, there seems to be some specificity in the impact of ELS as it did not alter delta-opioid receptor mRNA levels within this region. Interestingly, ELS had no significant effect on opioid receptor mRNA expression in the male nucleus accumbens, indicating that the impact of ELS on brain development is dictated by biological sex. This suggest that ELS disrupts opioid reward system during neonatal developmental, possibly re-shaping the connections within this system at a crucial time point in a sex-dependent manner. The sex-specific impact of ELS within the developing nucleus accumbens may set up risk or resilience differently for males and females to certain mental disorders with abnormal sociability, such as schizophrenia and depression, or perhaps later addiction. We are currently in the process of determining whether the influence of ELS on the alterations in gene expression is acting through epigenetic mechanisms, and whether these modifications are stable until the juvenile period or transient in the neonatal period.

Title: Adolescent psychosocial stress induces immediate and sustained increases in anxiety-like behavior and deficits in social behavior in male rats

Authors: *V. GHISAYS[1], J. STREICHER[2], J. CALDWELL[2], S. BERMAN[2], A. BIRKENHAUER[2], C. ESTRADA[1], M. B. SOLOMON[2];

Abstract: Social defeat stress is a common problem among adolescents. Several data suggest that social stress increases the susceptibility for psychopathology including anxiety and depression later in adulthood. Here, we examined the immediate and sustained effects of social defeat on anxiety-like, depression-like and social behavior in adolescent male rats. In Experiment 1 male rats were exposed to a battery of behavioral tests including open field, social preference/avoidance test in either neutral, familiar (home cage) or threatening (resident aggressor) environments and social interaction test in their home cage. Testing animals in multiple contexts allows us to extract a more thorough behavioral phenotype in defeated males. This is particularly important, given that many laboratories assess the behavioral consequences of social stress in primarily anxiety-provoking conditions (i.e., open field, forced swim test). Adolescent males exposed to chronic social defeat stress exhibited immediate and sustained (lasting through adulthood) increases in anxiety-like behavior and deficits in social behavior, depending upon the testing environment. For example, deficits in social behavior were more prominent in uncontrollable and threatening environments versus controllable and neutral environments. Notably, defeated adolescents and adult males were more likely to display active coping strategies (defensive burying/digging behaviors towards constrained conspecifics) only in controllable, familiar environments (home cage), but not in a neutral or threatening (aggressor home cage) environments. In Experiment 2 we examined the impact of social defeat on behaviors commonly associated with a depression-like phenotype using the forced swim and olfaction hidden cookie tests. Social defeat did not alter 'helplessness' behavior in the FST nor did it impact the latency to find (appetitive) or consume a cookie. These data confirm the findings of many laboratories indicating that social defeat is a potent stressor in males, but underscore the importance of considering the context in which animals are tested. Given the sustained increases in anxiety-like behaviors in previously defeated adolescent males, these findings may further our understanding of how social stress during the formative years increases susceptibility to psychological disorders in adulthood.

Title: The role of estradiol signaling in the medial amygdala on emotionality, cognition and metabolic function in female rats

Authors: *C. ESTRADA[1,1], V. GHISAYS[1], J. CALDWELL[2], J. STREICHER[2], S. BERMAN[2], A. BIRKENHAUER[2], M. B. SOLOMON[2];
[1]Psychology, [2]Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Anxiety and depression are the two most common mental illnesses in the United States. Notably, women are twice as likely as men to suffer from these psychopathologies. Estradiol (E2) exerts potent effects on emotionality in women and female rodents across the reproductive lifespan. Previous data from our laboratory and others indicate that systemic administration of physiologically relevant doses of E2 decreases endocrine stress responses, depression-like and anxiety-like behaviors. The medial amygdala (MeA) mediates fear and endocrine stress responses, arousal, and affiliative behaviors in male and female rodents. Of note, reduced estrogen receptor (ER) α expression in the MeA is temporally associated with anxiogenic and depressive-like behavior in postpartum rats, suggesting that decreased ER signaling in the MeA contributes to anxiety-like and depression-like behaviors in females. The goal of the present study was to do an in-depth behavioral assessment of the impact of estradiol signaling specifically in the MeA on emotionality and cognition in both nonsocial and social behavioral assays. We accomplished this goal using adult ovariectomized females with bilateral E2 or cholesterol micropellets aimed at the MeA. Following adequate recovery from surgery, females were exposed to a battery of behavioral tasks designed to gauge different aspects of anxiety-like, cognitive and depression-like behaviors including the open field, novel object recognition, social preference/recognition, social interaction and forced swim tests. Contrary to our hypothesis, E2 signaling in the MeA had marginal effects on behavioral indices of emotionality and cognitive function. However, E2 signaling in the MeA significantly decreased body weight gain, food intake and visceral adiposity in ovariectomized females relative to those receiving bilateral MeA implants of cholesterol. Notably, previous work highlights a critical role for the MeA in body weight regulation in rodents. Given the prominent role of systemic E2 for being metabolically beneficial in rodent models of obesity, these data highlight the MeA as a critical node for the E2 mediated effects on metabolic function. In an effort to understand how E2 signaling in the MeA regulates energy homeostasis in ovariectomized females, we are

currently examining neuronal activity in hypothalamic and brainstem regions known to regulate feeding and/or body weight regulation.

Title: Neuroendocrine and behavioral effects of CORT 118335, a novel glucocorticoid and mineralocorticoid receptor antagonist in male rats

Authors: ***E. T. NGUYEN**, S. BERMAN, J. STREICHER, A. C. WULSIN, J. CALDWELL, J. P. HERMAN, M. B. SOLOMON;
Dept. of Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis due to aberrant glucocorticoid secretion is associated with psychopathology. Consistent with this fact, compounds targeting both Type I (mineralocorticoid MR) and Type II (glucocorticoid GR) corticosteroid receptors are being advanced as putative antidepressants or anxiolytics. Previous findings from our laboratory indicate that compounds selectively targeting GR decrease both neuroendocrine and behavioral (depression-like) responses to stress in male rats. The goal of the present study was to determine the impact of GR/MR antagonism on neuroendocrine and behavioral responses to stress in male rats. This was accomplished by using CORT 118335, a dual GR/MR antagonist. In two separate experiments, adult male rats were treated for 5 days with vehicle, CORT 118335 (10mg/kg or 30mg/kg), or imipramine (10mg/kg) (tricyclic antidepressant) and exposed to either restraint stress or the forced swim test (FST). Relative to vehicle, both doses of CORT 118335 potently suppressed neuroendocrine responses to restraint and FST stress exposure. The decreased neuroendocrine output in animals treated with CORT

118335 was not accompanied by an antidepressant-like effect of the compound in the FST, as there was no difference in immobility between animals treated with this compound versus vehicle. Consistent with our previous findings, imipramine (positive control) modestly decreased neuroendocrine responses to both restraint stress and FST relative to animals treated with vehicle and decreased immobility in the FST, consistent with antidepressant effects. Notably, inactivation of the infralimbic cortex (IL) decreases depression-like behavior in rats and in alignment with the behavioral observations, imipramine decreased c-Fos immunolabeling in the IL. Taken together, the data suggest dissociation between corticosterone responses and immobility in the FST. The data further suggest that compounds targeting both MR/GR may be useful for mitigating glucocorticoid hyper-secretion to stress, but their ability to modulate mood-like responses to stress (at least under the context of the present study) may be limited.

Title: Learning in the company of individuals with similar phenotypes can facilitate fear extinction in rats selectively bred for their locomotor response to novelty

Authors: *K. E. PRATER[1,2], E. L. AURBACH[1,2], H. LARCINESE[2], P. BLANDINO, Jr.[2], S. J. WATSON[2], S. MAREN[3], H. AKIL[2];

Abstract: As we search for new treatments for anxiety disorders, it is important to understand why certain individuals are more vulnerable to developing PTSD after a traumatic event and how we can help vulnerable individuals improve their prognosis. We believe that our rat model of individual differences in locomotor response to a novel environment provides insight into vulnerability and resilience to anxiety disorders. In experiment one, rats selectively bred for high (bHR) or low (bLR) locomotor response to a novel environment and rats from the F1 generation of a bHR-bLR cross (bIRs), which display an intermediate locomotor phenotype, received a standard fear conditioning and extinction paradigm. bLRs demonstrated decreased extinction learning and extinction retention compared to bIRs and bHRs, while bHRs exhibited faster extinction and greater retention than bIRs. This indicates that bLRs, like PTSD patients, may be vulnerable to maladaptive fear behaviors, while bHRs may be more resilient. In a second study, it was found that although bLR extinction learning remains deficient compared to bHRs, grouping animals solely with their in-group phenotype during fear conditioning and extinction results in increased extinction learning compared with animals trained in isolated pairs or mixed phenotypes. We are replicating these findings, and studying the neural correlates underlying these differences in extinction learning. These results may have significant implications for the study of fear behavior in animals and humans, as individual differences in temperament may significantly impact fear extinction learning.

Title: GPR55 receptor activation in the ventral hippocampus modulates mesolimbic dopaminergic activity and causes schizophrenia-related emotional and social cognition disturbances

Authors: *S. R. LAVIOLETTE[1], M. LOUREIRO[2], J. RENARD[2];
[2]Anat. & Cell Biol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: Disturbances in the brains endocannabinoid signaling system are linked to schizophrenia-related symptomology. Cannabinoids produce their central actions primarily via the CB1 receptor (CB1R). However, emerging evidence points to the existence of novel cannabinoid-sensitive targets, such as the G protein-coupled receptor-55 (GPR55R). Interestingly, it has been proposed that deleterious emotional/cognitive side effects associated with cannabinoid-based pharmacotherapies such as rimonabant, may be related to effects on the GPR55 receptor. Nevertheless, the potential role of GPR55 in modulating mesolimbic dopamine (DA) activity and associated emotional processing and social cognition behaviours is unknown. GPR55R is expressed in the hippocampus, in humans and rodents. Pre-synpatic GPR55R's are also known to regulate glutamate (GLUT) release within the mammalian hippocampus (Sylantyev et al., 2013). The ventral hippocampus (vHIPP) plays an integral role in the formation of emotional associative memories through interactions with the mesolimbic dopamine (DA) system. We have previously shown that intra-vHIPP stimulation of cannabinoid CB1 receptor transmission strongly modulates the activity of dopaminergic (DA) neurons in the ventral tegmental area (VTA) and nucleus accumbens (NAc). In the present study, we tested whether activation of the GPR55R directly within the vHIPP was able to 1) modulate VTA DAergic neuronal activity and/or 2) influence the formation of emotional associative memories and social behaviours/cognition. Using *in vivo* electrophysiological recordings in rats, we found that intra-vHIPP microinfusions of palmitoylethanolamide (PEA), an endogenous lipid that acts as a selective GPR55 agonist, potently increased VTA DA neuron firing and bursting activity. Furthermore, GPR55 activation profoundly disrupted natural sociability and social recognition memory. In addition, intra-vHIPP GPR55 activation altered the formation of context-dependent fear memory. While co-infusion of the selective GPR55 antagonist (CID16020046) blocked the behavioral effects induced by intra-vHipp PEA, co-infusion of a selective CB1R antagonist failed to modulate GPR55-mediated effects. Furthermore, co-infusion with a selective NMDA receptor antagonist, completely blocked the behavioural deficits induced by intra-vHIPP GPR55 activation, demonstrating a functional role for GLUTergic transmission in the effects of GPR55 within the vHIPP. Our data add critical new insights into the role of the GPR55 receptor in DA-related behaviors and emotional regulation known to be disturbed in neuropsychiatric disorders.

Title: Corticotropin-releasing factor activates different circuits in male and female rats

Authors: *K. WIERSIELIS, S. COHEN, G. VAN BUSKIRK, D. LOSEN, H. KEITA, J. BERGMANN, N. BAKSH, B. WICKS, D. BANGASSER;
Temple Univ., Philadelphia, PA

Abstract: Stress-related psychiatric disorders, such as anxiety and depression, occur twice as frequently in women than in men. Corticotropin-releasing factor (CRF) orchestrates the stress response and is dysregulated in these disorders. Thus, sex differences in responses to CRF could contribute to the sex bias in disease prevalence. We previously identified sex differences in CRF1 receptor signaling and trafficking in the locus coeruleus (LC) that rendered the electrophysiological responses of female LC neurons more sensitive to CRF than those of male rodents. However, the extent of sex differences in CRF sensitivity has not been systematically explored. Here we begin to address this question by examining how the central administration of ovine CRF differentially activates stress-related brain regions in adult male and female rats using the immediate early gene, cFOS. Because many sex differences are mediated by circulating ovarian hormones, central CRF or vehicle was administered to females in the proestrus phase of the estrous cycle (higher estrogen and progesterone levels), females in the diestrus phase (lower estrogen and progesterone levels), and gonadally intact males. Our results revealed that although for some brain regions, such as the paraventricular nucleus of the hypothalamus, CRF increased cFOS expression relative to vehicle treatment in all groups, most brain regions showed sex and cycle stage-specific effects of CRF on neuronal activation. For example, CRF increased cFOS in diestrus females, but not proestrus females or males, in several brain regions, including the periaquductal gray, ventromedial dorsal raphe, and the laterodorsal tegmental nuclei. Conversely, the basal nucleus and the nucleus accumbens of proestrus females and males had more cFOS profiles than did diestrus females following central CRF administration. In the LC there was no effect of cycle, but rather females had more CRF-induced cFOS profiles than males, a result consistent with our predictions based on previous studies. Collectively, these findings indicate that central CRF administration activates different circuits in males and females, and that differences are further revealed across the female estrous cycle. Surprisingly, although cFOS has been widely used, previous studies were almost exclusively conducted with male rats. Thus, sex differences in the activation of brain circuits by stressors, neuropeptides, and other stimuli, may be an important, but underexplored, determinant of sex differences in behavior and pathology.

Title: Sexual dimorphism in the pattern of c-Fos activation evoked by acute and chronic stress

Authors: ***A. SOOD**, K. CHAUDHARI, N. KACHEWAR, V. VAIDYA;
Tata Inst. of Fundamental Res., Mumbai, India

Abstract: Stressful events have profound effects on the physiology and behavior of an organism. The nature (physical or psychological), severity (severe or mild) and duration (acute or chronic) of the stressor determine to a large extent, if the response elicited will be adaptive or maladaptive. The brain apart from perceiving and orchestrating the stress response is also a target of stress. While acute stress enhances immune function and facilitates formation of memories pertaining to emotional events, chronic stressors lead to memory impairment and atrophy of the apical dendrites of the pyramidal neurons of the CA3 region of the hippocampus. Though sexual dimorphism in the physiological and behavioral responses to stress has been characterized in rodents and monkeys, sex based differences in the pattern of neuronal circuit activation evoked by stress remain poorly understood. In the present study we have used c-Fos as a marker of neuronal activity to examine the activation pattern of different brain regions in male and female rats exposed to either an acute or chronic stress regime. We used immobilization for 2 hours [Acute Immobilization Stress (AIS)] or forced swim (FS) as acute stressors or immobilization for 2 hours each day for 10 consecutive days [Chronic Immobilization Stress (CIS)] as a chronic stressor. While the pattern of CIS evoked changes in c-Fos expression was similar among males and females in brain regions like the Paraventricular nucleus of the hypothalamus (PVN) and Habenula, we noted sexual dimorphism in the medial prefrontal cortex (mPFC) and specific hippocampal subfields. We observed that CIS led to a significant decrease in the number of c-Fos positive cells in the medial prefrontal cortex (mPFC) of females but not in males. CIS also caused a decline in the number of c-Fos positive cells in the DG of both males and females but in the CA3 region of only females. In addition, we observed that the baseline

activity is lower in the dentate gyrus (DG), but higher in the CA3 region of females compared to males. Since different neuronal circuits involved in the stress response are organized into functional networks, we are in the process of performing cross correlation analysis to look at functional connectivity between different brain regions that may vary in a sexually dimorphic manner. We are also using retrograde neuronal tracing techniques to understand the contribution of different afferent inputs in the activation of the mPFC- a brain region known to be activated by acute stress.

Title: TIA-1 is a prion-related RNA binding protein that regulates alternative splicing of the glucocorticoid receptor in a sex-specific manner

Authors: ***J. B. RAYMAN**, E. R. KANDEL;
Neurosci., Columbia University/HHMI, New York, NY

Abstract: Post-traumatic stress disorder (PTSD) arises from an interplay of genetic and environmental factors. To explore the molecular neurobiology of gene × environment interaction in the context of PTSD, we developed a mouse model for stress vulnerability based on deletion of TIA-1, a prion-related RNA binding protein that is involved in cellular stress. Among its many roles in RNA metabolism, TIA-1 facilitates the preferential translation of mRNAs required to contend with environmental challenge. Previous observations that cellular stress can be induced by prolonged exposure to high levels of glucocorticoids led us to hypothesize that TIA-1 operates at the nexus of systemic and cellular stress. By dismantling the cellular stress response through deletion of TIA-1, we reasoned that a key homeostatic feedback mechanism would be lost, leading to the development of maladaptive behavioral changes. Here, we find that naive TIA-1 KO mice are indistinguishable from wild-type controls in all behavioral measures evaluated thus far. However, several weeks after exposure to contextual fear conditioning, TIA-1

KO mice demonstrate increased anxiety and avoidance behavior compared to wild-type littermates. Electrophysiological studies reveal aberrant synaptic plasticity in the ventral hippocampus of TIA-1 KO animals in response to corticosterone treatment, consistent with a role for TIA-1 in normal emotional memory formation during stress. In addition, molecular data suggest that TIA-1 regulates alternative splicing of the glucocorticoid receptor, which is known to be important for hippocampal synaptic plasticity during stress. Interestingly, the latter effects are all female-specific. Finally, preliminary data indicate that prion-like aggregation of TIA-1 is critical for dynamic splicing of the glucocorticoid receptor during stress. In summary, TIA-1 actively modulates glucocorticoid-dependent signaling in the female brain in response to glucocorticoid exposure. Our results may provide new insights into a second functional prion in brain that has a role in the biology of stress-related psychiatric illness.

Title: Sex-specific molecular plasticity in the rodent hippocampus following chronic variable stress

Authors: *D. R. HOMIACK[1], M. STANLEY[1], B. BARRILEAUX[2], N. LIM[1], L. SCHRADER[1,2];
[1]Neurosci., [2]Cell and Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: In animal models, chronic stress or glucocorticoid treatment can induce depressive-like behavior in male rodents. In addition to anhedonic behaviors, chronic stress causes impairments in spatial memory and structural plasticity in the male hippocampal formation. In spite of the gender disparities observed in major depressive disorder in the human population, previous rodent studies largely find that female rodents are less affected by chronic stress than male rodents. The molecular alterations caused by chronic stress in the hippocampal formation are poorly characterized, particularly in female rodents. Here we report that chronic variable

stress (CVS) causes sex-specific alterations in the extracellular-signal-regulated kinase (ERK/MAPK) and adenosine-monophosphate-activated protein kinase (AMPK) pathways following chronic variable stress (CVS) in the hippocampus of intact rats. CVS exposure reduced phosphorylation of ERK/MAPK and its downstream target, cyclic-AMP-response element binding protein (CREB), throughout the male, but not female hippocampus. Reductions in phosphorylated CREB were not due to decreased protein kinase A (PKA) activity, as phosphorylated PKA substrate was either unchanged or increased throughout the male and female hippocampus of CVS-exposed animals. Sirtuin1 is a protein deacetylase involved in energy metabolism, which has increased activity, but not expression following CVS in the male DG (Ferland et al., 2013). Consistent with our previous findings, acetylation of the SIRT1 substrate, p53, was reduced in the male but not female DG. Concordantly, CVS increased AMPK substrate phosphorylation in the male DG. Interestingly, neither acetylated p53 nor AMPK substrate were affected by CVS in the female DG. Our findings implicate DG-localized AMPK as an upstream activator of SIRT1 and a potential molecular regulator of depressive-like behavior in male animals. Additionally, these results provide molecular evidence of stress resilience in the female hippocampus.

Abstract: Opioid system dynamics in the rat hippocampus are highly sex dependent, as the hormonal milieu modulates opioid peptide levels, mu-opioid and delta-opioid receptor (DOR) trafficking in select populations of neurons and opioid-dependent long-term potentiation. Further, our recent studies have shown that sex differentially affects the response of the hippocampal opioid system to chronic stress (Pierce et al., 2014; Milner et al., 2013). Previous studies have established that DOR trafficking and density have baseline sex differences in hippocampal CA1 pyramidal cell dendrites (Williams et al., 2011). The current study aimed to investigate whether sex and/or chronic stress affected DOR distributions in CA3 region, as this region is important in context learning and therefore the establishment of addiction behaviors. Male and diestrus female rats were subjected to 10 days of chronic immobilization stress (CIS), followed by brain perfusion and fixation with acrolein and paraformaldehyde. Hippocampal sections were labeled for DOR (with silver intensified immunogold particles; SIG) using dual labeling immunohistochemistry and the subcellular distribution of DOR in CA3 pyramidal cell dendrites in stratum radiatum was analyzed using electron microscopy. In control (unstressed) rats, males exhibited significantly larger pyramidal cell dendrites, increased number of plasmalemmal DOR SIGs, but significantly decreased density of cytoplasmic and total DOR SIGs in pyramidal cell dendrites. This latter finding suggests that at baseline levels, males have fewer reserve pools of DORs. Following CIS, males displayed no significant changes in the morphology of CA3 pyramidal cell dendrites, while females showed increases in pyramidal cell diameter. Males had a decreased proportion of plasmalemmal DOR SIGs while females displayed no change in plasmalemma DOR SIGs on pyramidal cell dendrites. Moreover, CIS in females decreased DOR SIG cytoplasmic and total density to the levels seen in control and CIS males. These findings suggest that after CIS, fewer DORs are available for binding on pyramidal cell dendrites in males and that the reserve pools of DORs in pyramidal cell dendrites in females have been trafficked to other locations. These changes may contribute to sex differences in learning mechanisms leading to the acquisition and/or relapse of drug addiction.

Title: Social isolation during adolescence alters dendritic branching and spine density of pyramidal neurons in the hippocampal CA1 of adolescent female rats

Authors: *R. ADEROGBA[1,2], A. AKAD[2], F. SHAEFFER[2], W. HUANG[2], A. RAO[2], L. KLINGENSMITH[2], Y.-W. CHEN[2], T. CHOWDHURY[2], C. AOKI[2];
[1]CUNY Hunter Col., New York, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Social isolation during the vulnerable period of adolescence produces behavioral, physical, and biochemical alterations. The hippocampus is a component in the limbic system that plays a role in spatial learning, memory, anxiety and regulation of stress. Interestingly, previous studies indicate that stress causes differential response in hippocampal sub-regions. The effects of stress have been shown to be gender specific. For example, females are more susceptible to stress-increased anxiety-related behaviors. Here, we tested the effects of social isolation during adolescence (postnatal days 36-44) upon 8 Sprague-Dawley female rats, compared to 8 age-matched pair-housed female rats. In particular, we conducted 3-D Sholl analysis of pyramidal neurons after the Golgi procedure, to quantify dendritic branching and followed this by spine density analysis, using the Neurolucida system. In the caudal-ventral hippocampus, which preferentially regulates anxiety, social isolation evoked an increase in dendritic branching in stratum radiatum (SR) but lowered spine density, compared to the paired controls. No change was detected in stratum lacunosum-moleculare (SLM). In the rostral-dorsal hippocampus, which preferentially mediates spatial learning and contextual memory, social isolation reduced both dendritic branches and spine density in SR, indicating a net loss in the spine number. Again, no change was detected in the SLM. Comparisons of the anatomical subdivisions of the hippocampus revealed that pyramidal neurons of the rostral-dorsal hippocampus of control rats exhibit greater dendritic branching in SR than pyramidal neurons of the caudal-ventral hippocampus. This regional difference was absent within the SR of singly housed rats, due to decreased branching in the rostral-dorsal subdivision and increased branching of the caudal-ventral region. Conversely, SLM of the dorsal-rostral region of socially isolated rats showed more branching than SLM of the caudal-ventral region. Together, our data indicate that social isolation of adolescent females elicits pathway-specific changes in the hippocampus that affect

both the rostral-dorsal and caudal-ventral hippocampus. This morphological change may contribute towards altered spatial and contextual memory performance as well as anxiety regulation.

Title: Neonatal maternal separation alters, in a gender specific manner, the expression of regulatory elements of the TRH system and the response of the thyroid axis to energy deficiency

Authors: *E. L. JAIMES, M. GUTIÉRREZ-MARISCAL, P. JOSEPH-BRAVO;
Inst. De Biotecnología, UNAM, Cuernavaca, Morelos, Mexico

Abstract: Neonatal maternal separation (MS) induces a functional adaptation of the hypothalamic-pituitary-adrenal axis (HPA), leading to epigenetic changes that alter the stress response in adult life. As the activity of the HP-thyroid (HPT) axis is susceptible to various forms of stress, we studied if MS during the lactation period altered HPT axis function and its response to a situation of negative energy balance such as fasting in the female adult rat. Wistar dams were divided into a naïve (N) or a MS group. From PD 2 -21, pups in the MS group were separated from their mothers 3h/day. At PD60, rats were housed 2/cage, and half of the N and MS rats were fasted for 48 h. Trh mRNA levels were quantified in coronal brain sections of the rostrocaudal extent of the paraventricular nucleus (PVN) by *in situ* hybridization. Adenohypophyseal TRH-R1, pyroglutamyl peptidase II (PPII) and TSH-β mRNA were semi-quantified by RT-PCR and, serum hormones by radioimmunoassays or ELISA. Gender differences were observed in the fasting response of N rats; the decrease in body weight, Trh expression, and T3 or the increase in corticosterone serum concentrations, were higher in females than in males. MS increased white adipose tissue mass and leptin levels only in females. Altered basal expression of key elements involved in HPT function was produced by MS:

increased Trh mRNA expression compared to the N group in the medial (m)PVN; diminished TRH-R1 and TSH-β mRNA in the adenohypophysis, and in serum T3 levels albeit the latter, only slightly. In response to fasting, MS rats lost significantly less body weight than the N group, without reducing body fat. Fasting induced changes were of smaller magnitude in MS rats compared to N, whether female or males; these include the decrease in mid-PVN Trh expression, increased that of TRHR1 in adenohypophysis; and expected reduction in D1 liver activity was blunted. These changes were also stronger in MS female than in male rats; the former showed increased white adipose tissue mass and leptin levels. In conclusion, maternal separation can alter the expression of genes that control TRH levels in the neuroendocrine axis, and may interfere with peripheral aspects of thyroid hormones turnover. The activity of the HPT axis is altered at adult stage in response to a 48 h fasting in the MS group which may contribute to a metabolic adaptation that leads to low body weight loss.

Title: Behavioral and hormonal role of the individual components of the task elevated T maze (ETM) in female rats

Authors: ***N. L. GARCIA SALDIVAR**, M. R. A. GONZÁLEZ LÓPEZ, S. E. CRUZ MORALES;
UNAM FES-Iztacala, Tlalnepantla, Mexico

Abstract: Exposure to different tasks to evaluate behavior (learning, memory, anxiety) may induce stress, probably related to the presence of aversive components of the procedure. The elevated T-maze (ETM) allows to measure anxiety, learning and memory through a combination of escape (E) and avoidance (AV) trials in two brief sessions. The ETM consist of one enclosed and two open arms, the open arms are the main aversive component. In male rats the exposure to avoidance trials increases corticosterone concentration in plasma, but no in escape. In female rats, the response to stress of the HPA axis is dependent of the estrous cycle. The objective of this study was to evaluate the anxiety and corticosterone levels in female rats during diestrous

(D2) and proestrus (P), by the exposure of different arrays in the ETM. Wistar female rats in D2 and P were exposed to the ETM in different conditions: groups exposed to conventional training (T) consisting of three avoidance and one escape trials (D2-T, P-T); groups exposed only to the avoidance trials (D2-AV, P-AV); groups exposed only to the escape (D2-E, P-E); additionally, intact groups were used as control (D2C, PC). After behavioral procedures, the subjects were sacrificed and blood samples were obtained to measure corticosterone (ELISA). As expected no significant differences in avoidance latencies were detected in the groups exposed to training (D2-T, P-T) and those exposed only to avoidance trials (D2-AV, P-AV). For escape latencies significant differences were detected, the P group showed higher latencies compared with all other groups. Corticosterone levels increased significantly in D2-AV and P-AV groups compared with their respective controls (D2-C, P-C) and trained groups D2-T and P-T. For escape the concentration of corticosterone were higher for D2-E compared with D2-C. The changes observed in escape latencies and costicosterone levels were dependent of the presence or not of avoidance trials. The P-E showed less anxiety than the D2-E; this could be explained by the difference in levels of gonadal hormones in these two phases. It is concluded that exposure to the ETM induce anxiety that is dependent upon the estrous cycle and arrangement of escape trials regarding avoidances.

Title: Locus coeruleus (LC) neuronal activity and sniffing behavior in female rats during social interaction (SI): impact of adolescent social isolation

Authors: *A. L. CURTIS;
Dept Anesthesiol., Children's Hosp. Philadelphia, Philadelphia, PA

Abstract: Social interactions are core aspects of human interpersonal skills. Dysfunctional social interactions are typically associated with a range of anxiety disorders which, in turn, are salient elements of certain psychiatric and personality disorders. A critical window for disruption of brain development through which events can have an enduring impact that affect behaviors and cognition in adulthood is adolescence. Social isolation during adolescence has sex specific effects such that for female rats, it increases stress responsiveness and predisposes to anxiety-like behaviors in adulthood. The present study investigated the long term effects of adolescent social isolation of female rats on social interactions in adulthood. Because our previous studies suggested that social stress during adolescence had long term effects on activity of LC-NE neurons, LC activity before and during social interactions were compared between females exposed to adolescent social isolation and group housed controls. Female adolescent rats were housed in isolation (PND30-50) and then group housed. Controls remained group housed throughout adolescence and adulthood. Starting at 70 days of age, all rats were implanted with a microwire bundle to record LC neuronal activity. Rats were placed in an open field alone and LC activity and behavior were recorded for 10 min (baseline values). At this time a weight-matched stimulus female rat was placed in the field and social interactions were quantified while recording LC activity for another 10 min (interaction values). In stressed rats, LC discharge rate robustly increased over the LC rate in controls by a factor of two, while basal LC spontaneous rates were similar. In general, interactive behavior of both groups of test rats were not different in type nor total time with sniffing representing 80% of total interactive behavior. However, total time of face sniffing was greater and the duration of the individual face sniffing events were longer for stressed vs. control rats. Linkage between LC activity and sniffing behavior was suggested by further peaks of LC activity superimposed on the already robust LC activity occurring immediatedly before and after, not during, a sniffing event in the stressed females, but not in controls. In conclusion, the robust elevation in LC activity coincident with increased sniffing behavior for stressed females suggests that isolation stress may increase interactive urgency and the saliency of social stimuli. For isolation-stressed females, appropriate interactive behavior and social rank recognition may be disrupted by an urgency for face sniffing.

Title: Estrogen as a neuroprotector against negative effects of morphine in fear extinction

Authors: *F. RODRIGUEZ-ORTIZ[1], A. TORRES-REVERÓN[2], E. SANTINI[3], D. L. RAMOS-ORTOLAZA[1];
[1]Biol., Pontifical Catholic Univ. of Puerto Rico, Ponce, PR; [2]Ponce Hlth. Sci. Univ., Ponce, PR; [3]Palm Beach Atlantic Univ., West Palm Beach, FL

Abstract: Morphine is an opiate primarily used to treat pain. High and frequent doses of morphine can lead to dependence and, eventually might lead to mood and anxiety disorders as well. Previous animal studies using a model of post traumatic stress disorder have suggested that morphine dependence could negatively affect recovery from this disorder in males but not females. Specifically, it was shown that morphine dependent male rats, but not females, continue to show fear upon presentation of a tone associated with a foot shock. Based on the notion that estrogen may be a neuroprotector, this study was aimed at determining whether lower levels of estrogen receptors on male brains, particularly in the nucleus accumbens (NAc), would be related to the persistent fear observed in these morphine-dependent animals. To achieve this, brains from morphine-dependent and saline control male and female Sprague Dawley rats were dissected after cued fear conditioning and extinction. Proteins were extracted and separated by SDS-PAGE and transferred to nitrocellulose membranes. Western Blots were performed to measure levels of estrogen receptors (ER) subtypes α and β. Our results showed high levels of ERα in the NAc of morphine-dependent female rats compared to morphine-dependent males and controls. Preliminary results do not show changes in ERβ levels. Given the neuroprotective role of estrogen, our results suggest that higher levels of ERα in the NAc of morphine-dependent females protect them so that they are able to recover from a previous traumatic experience. Males' persistent fear, on the other hand, could be due to the significantly lower levels of these receptors in the brain. These results suggest an important role of sex hormones in behavioral responses to morphine dependence, particularly with regards to the persistence of fear and anxiety disorders. It seems like activation of estrogen receptors might help reduce the fear and manage some of the adverse effects of chronic morphine in the brain.

Title: Combined vicarious stress and social buffering in the prairie vole

Authors: *J. J. WARDWELL[1], N. MCNEAL[2], M.-A. L. SCOTTI[2], W. COLBURN[2], A. DOTSON[2], E. IHM[2], M. WOODBURY[2], A. J. GRIPPO[2];
[1]Psychology PM 328, Northern Illinois Univ., Dekalb, IL; [2]Northern Illinois Univ., DeKalb, IL

Abstract: Stress is highly pervasive within modern society, and has been associated with many adverse psychological and physiological health effects. In social species, research has shown that the stress level of one individual can affect another, with lower-stress animals attenuating the stress of higher-stress animals (social buffering), and higher-stress animals amplifying the stress of lower-stress animals (vicarious stress). The underlying mechanisms of these phenomena however, are less understood. The current study examined the behavioral and physiological effects of two animals simultaneously experiencing a stressor from two different perspectives (one directly and one indirectly) in a highly gregarious rodent species, the prairie vole (Microtus ochrogaster). This species is unique amongst rodents because it shares many behavioral and physiological properties with humans, including monogamy, bi-parental care of offspring, as well as autonomic cardiac and hormonal regulation. It was hypothesized that animals directly experiencing a species-relevant stressor with a comparatively less-stressed sibling observing would exhibit an attenuated stress response when compared to animals directly experiencing the stressor alone. It was also hypothesized that observer animals that were indirectly exposed to a sibling experiencing a stressor would exhibit an elevated stress response when compared to animals that did not. To test this, adult male sibling prairie voles were placed in a testing apparatus where one animal directly experienced a stressor (the tail suspension test), while the other could freely observe within the confines of an open field. Control animals experienced the tail suspension test or open field, but did so in isolation. Physiological and behavioral results indicate that the direct experience of a stressor without the benefit of a comparatively less-stressed sibling present was the most distressing condition, while exposure to the open field without observing a sibling experience a tail suspension test was the least distressing. Physiological stress response measures were found to be significantly ($p<0.05$) elevated in animals that observed a sibling experience a stressor when compared to those that did not. The current study suggests that social buffering and vicarious stress effects can occur at the same

time, in response to the same stressor. With further research utilizing this animal model, it is possible that a greater understanding of the mechanisms behind these stress effects can be reached.

Title: Effects of extended developmental and adult social isolation on neurochemistry and cortisol levels in response to a social stimulus in zebrafish (Danio rerio)

Authors: *S. SHAMS[1], D. CHATTERJEE[2], R. GERLAI[2,3];
[1]Cell & Systems Biol., [2]Psychology Dept., Univ. of Toronto Mississauga, Mississauga, ON, Canada; [3]Cell & Systems Biol., Univ. of Toronto Mississauga, Mississuaga, ON, Canada

Abstract: Social isolation models exist in rodents, birds, and non-human primates, where social deprivation leads to deficits in development and/or maintenance of behavioural, physiological, and neural indices. The zebrafish is a highly social species. A wide range of sophisticated genetic techniques are available for the zebrafish, and thus this species may be an excellent translational tool for the exploration of the mechanisms of social behaviour of vertebrates. Similar to other model animals, changes in the social environment of zebrafish can significantly affect subsequent development and expression of behaviour and brain function. To investigate how social isolation affects zebrafish, we studied the effects of extended social isolation (6 months) in both adult and developing zebrafish and compared them with group-housed control. Developmental social isolation started immediately after fertilization, where embryos were separated and kept deprived of all visual and tactile contact with conspecifics. Adult isolation groups were raised in social groups until reaching sexual maturity and then isolated for 6 months, while social control fish remained in groups of five fish throughout their development and adulthood. We exposed these groups of isolated and control fish to a social stimulus, animated moving images of five zebrafish presented on computer screens placed on either side of the test tank. Immediately after the stimulus presentation, we dissected the subjects' brains and analyzed

their neurochemical profiles from whole brain extracts using high precision liquid chromatography (HPLC). We quantified the levels of dopamine, DOPAC (dopamine's metabolite), serotonin, and 5-HIAA (serotonin's metabolite) of socially isolated and control zebrafish. We also measured cortisol levels using salivary Cortisol Enzyme Immunoassays kits. We found that developmental social isolation altered dopamine neurotransmission, while social isolation in adulthood changed serotonin levels in the brain, findings that may represent an important distinction between development and maintenance of social behaviour. Additionally, social isolation also influenced the cortisol response to social stimulus presentation. We found adult isolation to reduce cortisol levels, a result that questions the optimal nature of high density group housing widely employed in zebrafish facilities. Title: Reciprocal crosstalk between the sensory and sympathetic innervation of brown and white adipose tissue

Authors: *V. RYU[1,2], T. J. BARTNESS[1,2];
[1]Biol., Georgia State Univ., Atlanta, GA; [2]Obesity Reversal Ctr., Atlanta, GA

Abstract: Utilizing the sensory system (SS)-specific anterograde transneuronal tract tracer, the H129 strain of herpes simplex virus-1 and the fat pad sympathetic nervous system (SNS)-specific retrograde transneuronal tract tracer pseudorabies virus (PRV152), we previously demonstrated the neuroanatomical reality of the interscapular brown (IBAT) and inguinal white (IWAT) adipose tissue SS-SNS short and long feedback circuits. Functionally, we and others have shown that activation of IBAT and IWAT SNS innervation is the primary initiator of thermogenesis and lipolysis, respectively, with SS nerves responding to increases in IBAT and IWAT SNS drives. Therefore, we injected H129 intra-IBAT and PRV152 intra-IWAT as well as vice versa to define the extent of IBAT-SS/SNS and IWAT-SNS/SS communication centrally and peripherally. Surprisingly, we found H129+PRV152 colocalized neurons in the SNS ganglia

and DRG innervating IBAT/IWAT coupled with significant co-infections mostly related to IBAT-SS and IWAT-SNS feedback loops in multiple brain sites. These doubly-infected neurons imply short and long SS-SNS crosstalk between IBAT and IWAT. Demonstrative brain regions with the greatest representation of doubly-infected neurons were the nucleus of the solitary tract, intermediate and pontine reticular nuclei, periaqueductal gray, paraventricular hypothalamic nucleus, lateral hypothalamus and medial preoptic area. Collectively, our results strongly support the neuroanatomical fact of IBAT-SS/SNS and IWAT-SNS/SS short and long neural feedback circuits. In addition, prominent crosstalk between IBAT-SS and IWAT-SNS perhaps provides the neuroanatomical underpinnings for the interaction of IBAT-SS for the control of IWAT lipolysis as occur specifically with conditions of cold exposure, food restriction/deprivation, exercise and more generally with changes in adiposity.

Title: Central glucoprivation rapidly stimulates lipolysis in some but not all white adipose tissue depots via the sympathetic nervous system

Authors: *L. A. SZYMANSKI[1], T. J. BARTNESS[2];
[1]Biol., [2]Biology, Ctr. for Obesity Reversal, Georgia State Univ., Atlanta, GA

Abstract: Tract tracing studies in our lab have identified neural pathways from the paraventricular hypothalamus to white and brown adipose tissue via hindbrain areas that have been implicated in the control of glucoprivic feeding and hyperglycemia in other rodents. It is likely that in Siberian hamsters these hindbrain neurons modulate the increases in sympathetic drive to white adipose tissue (WAT) after peripheral glucoprivic treatment. Hamsters treated with the glucoprivic agent 5-thio-D-glucose (5TG) show significantly greater rates of norepinephrine turnover (NETO) in epididymal (EWAT), retroperitoneal (RWAT), and mesenteric (MWAT) white adipose tissue compared to saline-treated hamsters. The current experiments test the hypothesis that central glucoprivation is sufficient to stimulate lipolysis in peripheral fat pads and confirm that increases in NETO to specific fat pads after 5TG treatment

correspond to increases in intracellular markers of increased lipolytic activity, specifically hormone-sensitive lipase (HSL) and phosphorylated HSL (pHSL). Adult hamsters received an injection of 50 nmoles of 5TG into the 4th ventricle (4V) and were sacrificed 15, 30, 60, and 210 minutes later. Inguinal white adipose tissue (IWAT), EWAT, RWAT, and MWAT were collected for measurement of HSL and pHSL using Western blot. Plasma concentrations of glucose, free fatty acids, and glycerol were measured at the time of sacrifice as further physiological measures of increased lipolysis. At 210 minutes after 5TG treatment there were no significant differences in the relative expression of pHSL/HSL in white adipose tissue, nor were there significant differences in plasma glucose, glycerol, and free fatty acids compared with saline treated animals, suggesting that the effects of central glucoprivation are acute and the animals had recovered after 3.5 h. At 30 min after 5TG treatment, when plasma glucose is significantly higher than saline-treated animals, preliminary results show an increase in the relative expression of pHSL/HSL in EWAT, supporting the idea that the increased sympathetic drive to EWAT seen in the previous experiment results in increased lipolytic activity. Preliminary results did not show increased relative expression of pHSL/HSL in IWAT 30 min after 5TG treatment, which also supports the previous results which showed no increases in NETO in IWAT after 5TG treatment. It is likely that glucose-sensing hindbrain neurons that have been identified as part of the pathway modulating sympathetic output to adipose tissue rapidly stimulate lipolysis in response to glucoprivation.

Title: Brain activation and inhibition in food intake and meal structures by abdominal surgery in mice

Authors: L. WANG[1], *Y. TACHE[2];
[1]UCLA, Los Angeles, CA; [2]UCLA Dep Med. Div. Digestive Dis, Los Angeles, CA

Abstract: There is still a lack of therapy to shorten recovery from postoperative ileus. Abdominal surgery inhibits food intake and gastric emptying (Stengel et al., AJP 2011), and induces c-Fos expression in the hypothalamic and medullary nuclei in rats (Bonas and Taché, Brain Res 1994; Wang et al., Brain Res 2011) indicative of activation of brain circuitries that may impact also on feeding behavior. In this study we mapped c-Fos in the brain, and assessed food intake and meal structures altered by abdominal surgery in mice. Male mice (C57BL/6) without access to food for 6-7 h received laparotomy and cecal palpation under isoflurane anesthesia 1-2 h before the dark phase. Controls remained in home cages. Brain sections were processed for c-Fos immunoreactivity (ir) 2 h post-surgery. For food intake monitoring and meal pattern analysis, mice were maintained in an automated episodic feeding monitoring system (BioDAQ, Research Diet Inc.). In control mice, there was moderate c-Fos-ir in the paraventricular nucleus (PVN), arcuate nucleus (Arc), and preoptic, lateral and dorsomedial areas of the hypothalamus, medial bed nucleus of stria terminalis (BST) and Edinger-westphal nucleus (E-W). Abdominal surgery increased Fos-ir in the prelimbic (119.1 ± 5.6 vs. 25.8 ± 5.0), insular (65.6 ± 7.6 vs. 10.2 ± 1.7) and cingulate (99.9 ± 6.5 vs. 29.4 ± 9.5) cortexes, nucleus of accumbens (82.2 ± 6.8 vs. 14.8 ± 4.7), lateral septum (133.5 ± 17.7 vs. 54.4 ± 4.4), BST (in ventral lateral subnucleus 69.9 ± 4.0 vs. 3.9 ± 1.6), supraoptic nuclei (100.3 ± 6.0 vs. 1.9 ± 0.8), PVN (214.8 ± vs. 101.1 ± 6.9), Arc (88.8 ± 7.9 vs. 30.1 ± 7.8), E-W (53.7 ± 2.7 vs. 22.7 ± 1.1), periaqueductal area (PAG) lateral area (49.5 ± 2.1 vs. 20.9 ± 2.1), external subnucleus of lateral parabrachial nucleus (95.0 ± 7.0 vs. 4.7 ± 1.2), locus ceruleus (75.0 ± 7.4 vs. 3.9 ± 0.4), Barrington's nucleus (36.7 ± 3.4 vs. 5.4 ± 0.7), A5 (data not shown), ventrolateral medulla (24.4 ± 2.7 vs. 1.1 ± 0.4), nucleus tractus solitarius (96.1 ± 8.0 vs. 5.6 ± 1.5) and area postrema (39.0 ± 4.1 vs. 7.0 ± 1.9). Abdominal surgery significantly reduced food intake assessed at 2, 4, 6, 12 and 24 h by 97-86% compared to controls. The meal structure analysis showed a significant reduction of feeding bouts, time spent on meals, and meal frequency and duration and size, prolonged intermeal interval and higher satiety ratio. Brain circuits of mice responsive to abdominal surgery include visceral regulatory centers, areas involved in pain and integrative nuclei related to stress, which may underlie visceral and behavioral alterations induced by abdominal surgery including inhibition of gastric emptying and food intake linked with increased satiation and satiety.

Title: The blood-brain barrier regions in diet-induced obesity - dietary fats induce changes only in the medium eminence

Authors: A. F. S. RAMALHO[1], M. FIORAVANTE[1], J. MORARI[1], C. SOLON[1], N. R. V. DRAGANO[1], *A. L. OLIVEIRA[2], L. A. VELLOSO[1], E. P. ARAUJO[1];

Abstract: Hypothalamic inflammation and dysfunction are induced by dietary fats and play an important pathophysiological role in experimental obesity. Histological and molecular studies have failed to demonstrate an inflammatory action of dietary fats in regions other than the hypothalamus. This raises the possibility that dietary fats may disturb the blood-brain barrier (BBB) specifically in the hypothalamus. To investigate this hypothesis we used microdissection to prepare RNA from samples collected from the main BBB regions; medium eminence (ME), vascular organ of the terminal lamina (OVLT), subcommissural organ (SCO) and subfornical organ (SFO). Hippocampus was used as a control region. Real-time PCR revealed that after seven days on a high-fat diet, only ME presented increased expression of the inflammatory cytokine TNFa. The tanycyte marker GLAST underwent significant increase only in ME and OVLT. Confocal imaging staining for the tanycyte markers IGFBP2 and caveolin-1 showed an early disorganization of the alignment of cells in the limit of the ME which was confirmed by transmission electron microscopy. There were no changes in the distribution and organization of IGFBP2 and caveolin-1 positive cells in the other regions of the BBB. On time-course experiments we observed that the expression of at least two markers of tanycytes, caveolin-1 and GLUT1 are reduced after two weeks feeding on a high-fat diet, which is accompanied by a reduction of the hypothalamic expression of inflammatory cytokines. After four weeks on high-fat diet the tanycytes are detected irregularly distributed within the arcuate nucleus. We hypothesized that changes in the local expression of neurotrophic factors could be involved in the abnormalities of the tanycyte distribution and marker expression. In fact, BDNF expression was increased after one week on high-fat diet but reduced after two weeks. Confocal microscopy showed that in lean mice BDNF was predominantly present outside the cells in the transition between the ME and the arcuate nucleus, whereas in mice fed on the high-fat diet for two weeks it was present within the tanycytes. The immunoneutralization of BDNF resulted in reduced hypothalamic expression of the anti-inflammatory cytokines IL10 and IL6. In conclusion, dietary fats act specifically in the ME to promote tanycyte disorganization and induction of inflammatory markers. BDNF emerges as a neutrophic factor potentially involved in this regulation.

Title: Developmental exposure to PBDE flame retardants induces hypothyroidism and impacts hedonic tone in adult rats

Authors: ***L. L. DRISCOLL**[1], J. WATTS[2], R. KASEMODEL[2], T. TUMMINO[2], W. HARRIS[2], R. LACH[2];
[1]Colorado Col., Colorado Spgs, CO; [2]Colorado Col., Colorado Springs, CO

Abstract: Although they are no longer used in the manufacture of new products, polybrominated diphenyl ethers (PBDEs) are ubiquitous in the environment, and they bioaccumulate in wildlife and humans, especially in the United States. In humans, the highest levels are found in breastfed infants and small children, which has implications for brain development. Previously, we have found that when rat pups are exposed to the US-produced PBDE commercial mixture DE-71, thyroid hormone (especially thyroxine or T4) levels are dramatically suppressed. Behaviorally, exposed animals demonstrate mild learning deficits, and female rats demonstrate motivational impairments later in life. Exposed female rats also voluntarily consume more sucrose water than do non-exposed rats of both sexes. In the current study, male and female rats exposed to 30 or 60 mg/kg/day DE-71 on postnatal days 6-12 had suppressed serum T4 levels as pups. As adults, the higher dose female rats voluntarily consumed more ethanol than did exposed males or controls. In contrast, there were no treatment differences in anxiety levels or responses to a pentobarbital challenge in the open field. These results, paired with the finding that this same treatment group demonstrates increased sucrose consumption and decreased motivation to complete cognitive tasks, suggests that particularly in females, early exposure to DE-71 can influence hedonic tone in adulthood. It is important to recognize that these types of motivational disruptions can inaccurately manifest themselves as cognitive deficits in appetitively motivated tasks.

Title: Potential glutamatergic and endocannabinergic interaction regulates food intake

Authors: ***A. SANCHEZ-FUENTES**, A. L. BECERRIL MELÉNDEZ, A. ROMANO LÓPEZ, O. AMANCIO BELMONT, M. MÉNDEZ DÍAZ, A. E. RUIZ CONTRERAS, O. PROSPÉRO GARCÍA;

Abstract: The endocannabinoid and glutamatergic systems have been involved in the regulation of food intake (FI) and energy balance (EB). The hypothalamus regulates both processes FI and EB integrating information from peripheral tissues. Glutamate release in the lateral hypothalamus (LH) seems to be a main signal to induce food intake via mGlu5R. mGlu5R mechanism to enhance food intake is not completely understood. In this context, we decided to examine pharmacologically the potential modifications of mGlu5R stimulation on food intake when DGL activity was hampered or the CB1 was blockaded. Wistar albino male rats received LH injections into the LH, by using a within-subjects Latin-square design with vehicle, (RS)-2-Chloro-5-hidroxyphenylglycine (CHPG, 5.6 μg; selective agonist of mGlu5r), Tetrahydrolipstatin (THL, 1.2 μg; DGL inhibitor), AM251 (CB1 antagonist) and a combination of them. We found that the activation of mGlu5rs significantly increased ($P<0.05$) the total food intake during the first four hours after injection, but markedly during the first hour. AM251 or THL blocked this effect. Taken together, these results suggest a potential interaction of the endocannabinoid and glutamatergic systems to regulate food intake. It seems like 2-AG is the endocannabinoid resulting from the activation of mGlu5rs in the LH. In conclusion we believe glutamate via mGlu5R promotes 2-AG synthesis and release in the LH thereby inducing food intake.

Title: Neuroanatomical evidence for neurohumoral transmission by melanin-concentrating hormone neurons in the rat

Authors: V. R. KONANUR, T. M. HSU, *S. E. KANOSKI, J. D. HAHN;
USC, Los Angeles, CA

Abstract: Melanin-concentrating hormone (MCH) is a cyclic 19 amino acid peptide with diverse biological functions. The role of neuronal MCH ranges from the regulation of energy homeostasis to the control of sleep and fundamental behaviors. The majority of MCH-expressing somata are restricted to five regions of the lateral hypothalamic area (LHA), and the zona incerta (ZI) (Hahn, J. D. 2010). However, MCH neuron axons are distributed widely, and reach multiple brain regions. Here we investigated a novel non-synaptic route whereby MCH of hypothalamic or ZI origin could reach distant neural targets, by volume transmission via the ventricular system. The neural tracer cholera toxin B subunit (CTB) was injected unilaterally into the lateral ventricle of male rats. Dual immunofluorescent detection of CTB and MCH was then performed to visualize CTB-containing and MCH-expressing somata. Initial observations revealed abundant retrograde labeling within the hypothalamus and ZI, and numerous instances of colabeled neurons. Subsequent analysis of an experimental dataset (restricted to the side of the brain contralateral to the injection side) found that out of 660 MCH somata (in the ZI and hypothalamus), approximately a third (216 = 32.7%) colocalized CTB; this represented 43.8 % of CTB-containing somata counted within the lateral hypothalamic zone and ZI. Somata colocalizing MCH and CTB were present in the ZI and in 13 regions of the lateral hypothalamic zone; however, about two-thirds (69%) of colabeling was restricted to just three regions: The ZI (37.5%), the LHA dorsal region (LHAd; 17.6%), and LHA juxtadorsomedial region (LHAjd; 13.8%). It is also noteworthy that colabeling was comparatively low in the LHA ventral region medial zone (LHAvm; 6.4 %) and the LHA magnocellular nucleus (LHAm; 2.8 %)_two regions

found here (and shown previously) to contain abundant MCH somata. Additional immunofluorescent analysis at confocal microscopic resolution revealed close appositions of synaptophysin- and MCH-expressing axon terminals with laterally-extending branches of vimentin-expressing ependymal cells at the level of the third ventricle (presumptive tanycytes). Furthermore, high-sensitivity enzyme-linked immunosorbent assay indicated the presence of MCH in the cerebrospinal fluid of rats under physiological (untreated) conditions. Collectively, these data suggest MCH-expressing neurons within the ZI and/or LHA release MCH into the ventricular system to activate MCH-responsive neurons via a neurohumoral route, and the extent to which this occurs varies between MCH neuron subpopulations.

Title: Hypothalamic chemoarchitecture in the adult male rat: Creating canonical atlas maps for co-visualized immunoreactive peptidergic neuronal populations (α-MSH, nNOS, MCH) and their fiber systems in multiple brains

Authors: *C. E. WELLS[1], A. ACOSTA[2], D. ALDRETE[2], A. CARRION[2], L. CASTRO[2], A. C. ESCAPITA[2], E. ESPINOZA[2], K. DE LA FUENTE[2], A. GARRETT[2], A. GOMEZ[2], N. GOMEZ[2], C. Abstract: While the hypothalamus is a major homeostatic control center and its functions have been extensively studied, the precise circuitry underlying many of these functions remains undescribed. We have begun to remedy this situation by contributing to a chemoarchitectural

atlas of the rat hypothalamus, based upon the Swanson reference atlas of the rat brain. Here we expand our previous reporting of the distribution of and interactions among α-melanocyte stimulating hormone (α-MSH), melanin-concentrating hormone (MCH), and neuronal nitric oxide synthase (nNOS) in the adult male rat, to include data from multiple brains. To do so, we have recruited a cohort of freshmen undergraduates and taught them formal atlas-mapping techniques within an HHMI-funded laboratory based course: Brain Mapping & Connectomics. Working in groups, they have completed comprehensive sets of maps based upon five additional brains. This has allowed expression patterns for α-MSH, MCH, and nNOS to be compared across brains, and individual variability to be assessed. While there is some variation in the density of fibers in many regions, the overall patterns are markedly consistent between brains, although there are some exceptions for individual animals (for example, case K10-053 has drastically increased MCH expression surrounding the 3rd ventricle versus other brains studied). This work marks the first time that the anatomical distributions of α-MSH, MCH, and nNOS have been mapped together in the hypothalamus with such detail and, to our knowledge, the first time that freshmen have contributed to chemoarchitectural brain atlas development as part of a teaching lab. The chemoarchitectural atlas will aid in experimental design and data interpretation for investigators studying the functionality of the rat hypothalamus.

Title: Distribution and chemical identification of neurons projecting to the ventral tegmental area: a combined retrograde tracing and immunohistochemical study in the adult male rat, with special reference to the lateral hypothalamic area

Authors: *E. M. WALKER[1], B. DE HARO[2], R. H. THOMPSON[3], A. M. KHAN[2];
[1]Biol. Sci., [2]Biol. Sci. and UTEP Systems Neurosci. Lab., Univ. of Texas El Paso, El Paso, TX;
[3]Biol. Sci., USC, Los Angeles, CA

Abstract: The lateral hypothalamic (LHA) and ventral tegmental (VTA) areas help orchestrate motor behaviors related to feeding. Diencephalic-derived hypocretin 1/orexin A (H/O) and melanin-concentrating hormone (MCH) are implicated in the control of ingestive behaviors and arousal and send their projections to the VTA. However, it is unclear how these peptidergic neurons contribute to the precise connectivity between the LHA and VTA. We performed bilateral injections into the VTA of 43 male rats; each injection delivered either the retrograde tracers FluoroGold (2%; FG) or cholera toxin subunit b (CTb). We characterized the injection sites in two representative cases (one FG and one CTb) and mapped the back-filled cell bodies to the Swanson rat brain atlas (Brain Maps, 3rd edition, 2004). We also used immunohistochemistry to double-label the traced neurons using antibodies targeting CTb and either H/O (FG case) or MCH (CTb case), in order to examine the spatial arrangement of H/O+ and MCH+ cell bodies projecting to the VTA. We found that the injection sites mapped to Swanson atlas levels 36 (FG) and 38 (CTb), within the middle portion of the VTA. Tracer-filled neurons were found in several forebrain and hindbrain locations, including the prefrontal cortex, nucleus accumbens, lateral septum, discrete LHA subdivisions, the lateral habenula and the lateral part of the parabrachial nucleus. In all regions, most of the labeled neurons were located primarily ipsilateral to the injection site. For both injection cases, the nucleus accumbens and lateral septum contained the greatest number of back-filled cells, and the parabrachial nucleus and lateral habenula the least. Some CTb+ neurons were immunostained for calbindin, particularly around the anterior commissure. FG+ cells were found in the deep layers of the medial prefrontal cortex, but similar labeling was not seen for CTb labeled cells. A few of the traced neurons found in the suprafornical LHA (LHAs) expressed H/O, whereas a few of the traced cells found in the dorsal LHA expressed MCH. Our data confirm previous findings that some LHA neurons projecting to the VTA express H/O and MCH, and extend them by providing information about the precise subdivisions within the LHA that harbor these neurons. They also build on previous work by demonstrating that efferent projections to the VTA from specific LHA subdivisions are peptidergic. From the initial characterization of the injection cases we have made thus far, it is apparent that discrete parts of the VTA receive an integrated series of inputs from neuronal populations widely distributed in the brain, and that the LHA provides an important contribution to this afferent information.

Title: Connections of the rostral portion of the hypothalamic arcuate nucleus: A combined anterograde and retrograde study in the adult male rat

Authors: *A. MARTINEZ[1], B. E. PINALES[2], A. M. KHAN[2];
[1]Biol. Sci., [2]Biol. Sci. and UTEP Systems Neurosci. Lab., Univ. of Texas At El Paso, El Paso, TX

Abstract: The arcuate nucleus (ARH) is an important periventricular neuroendocrine structure and also serves as an active sentinel of metabolic state, contributing critically to the regulation of energy balance. While ARH function has been intensively investigated, a complete understanding of ARH neuronal connections to and from larger network targets remains poorly understood. To address this knowledge gap, we performed neuroanatomical tract tracing using a cocktail injection of anterograde and retrograde tracers. Specifically, cholera toxin subunit b (CTb) and Phaseolus vulgaris leucoagglutinin (PHA-L) were co-administered into the rostral ARH of adult male Sprague Dawley rats. To visualize tracer staining, immunohistochemical techniques were applied and the sections imaged at high resolution using wide-field microscopy. Using an adjacent Nissl-stained tissue series as a guide, both cell bodies sending projections to the ARH, and axons projecting from ARH neurons were mapped to the Swanson rat brain atlas (Brain Maps, 3rd edition, 2004). ARH-projecting regions (Swanson nomenclature), marked by CTb-filled cell bodies, included the ORBv, TTd layer 4, ILA layer 6a, LSi, LSd, LSv, CLA, ACB, BST(ad, dm, pr,v), ZI, LPO, MEPO, MPO, MPN(m, c, l), ADP, PS, AHA, SCH, RCH, PVHap, pv, LHA, MEAad, MEApd, CEAm, VMH, and PMv. Regions receiving ARH innervation as determined through PHA-L fiber staining included (again, Swanson nomenclature): the LSv, LS, ACB, BST(ad, dm, pr, v), ZI, LPO, MEPO, MPO, MPN, AVPV, AV, PS, AHA, AHN, PSCH, PT, SI, SON, PVT, DMH, VMH, ME, PH, PVp, and PMv. Initial mapping results have confirmed ARH connectivity previously described. They have also identified new patterns not previously documented elsewhere, including general trends of reciprocal connectivity for nuclei sending or receiving ARH innervation. Rostral ARH afferents and efferents appear to travel ipsilaterally to and from the nucleus, respectively, since we observed minimal CTb and PHA-L immunoreactivity contralateral to the injection site. With our rostral ARH injection site, we also observed sparse cell body and fiber staining in midbrain regions. In combination with other data, these data may be indicative of possible rostrocaudal differences for arcuate neuron projections and afferents. In summary, this study closely examines

rostral ARH forebrain afferents and efferents through high resolution mapping of CTb-ir perikarya and PHA-L axons to the Swanson rat brain atlas. The data provide detailed information about how the ARH is connected to the rest of the forebrain to form the networks relevant for the regulation of energy homeostasis.

Title: Behavior-associated and post-consumption glucose entry into the nucleus accumbens extracellular space during glucose free-drinking in trained rats

Authors: *K. T. WAKABAYASHI, E. A. KIYATKIN;
Behavioral Neurosci. Br., NIH/NIDA, Baltimore, MD

Abstract: Glucose is the primary energetic substrate for the metabolic activity of brain cells and its proper delivery from the arterial blood is essential for neural activity and normal brain functions. Glucose is also a unique natural reinforcer, supporting glucose-drinking behavior without food or water deprivation. While it is known that glucose enters brain tissue via gradient-dependent facilitated diffusion, it remains unclear how glucose levels are changed during natural behavior and whether the direct central action of ingested glucose can be involved in regulating glucose-drinking behavior. Here, we used glucose biosensors with high-speed amperometry to examine the pattern of phasic and tonic changes in extracellular glucose in the nucleus accumbens (NAc) during unrestricted glucose-drinking in well-trained rats. We found that the drinking behavior is highly cyclic and is associated with relatively large and prolonged increases in extracellular glucose levels. These increases had two distinct components: a highly phasic but relatively small behavior-related rise and a larger tonic elevation that results from the arrival of consumed glucose into the brain's extracellular space. The large post-ingestion increases in NAc glucose began minutes after the cessation of drinking and were consistently associated with periods of non-drinking, suggesting that the central action of ingested glucose could inhibit drinking behavior by inducing a pause in activity between repeated drinking bouts. Finally, the difference in NAc glucose responses found between active, behavior-mediated and passive

glucose delivery via an intra-gastric catheter confirms that motivated behavior is also associated with metabolic glucose use by brain cells. Supported by NIDA-IRP.

Title: Leptin suppresses development of GLP-1 innervation to the paraventricular nucleus of the hypothalamus

Authors: *J. E. BIDDINGER[1,3], R. B. SIMERLY[3,2];
[1]Developmental Neurosci., [2]Children's Hosp. Los Angeles, Los Angeles, CA; [3]USC, Los Angeles, CA

Abstract: The nucleus of the solitary tract (NTS) receives and integrates visceral nutritional status, and primarily sends this information to the hypothalamus to coordinate energy balance and neuroendocrine responses. Leptin acts directly on NTS neurons to regulate food intake and energy expenditure. In addition to leptin's role in satiety signaling, it also functions as a neurotrophic factor during development, as leptin is required for normal axon outgrowth from the arcuate nucleus of the hypothalamus to the paraventricular nucleus of the hypothalamus (PVH). Given the importance of leptin signaling in the regulation of ingestive behavior, and leptin's previously identified role in specifying patterns of innervation within the hypothalamus, we tested if leptin is required for development of neuronal projections from the NTS to the hypothalamus. The projections of NTS neurons that express leptin receptors (LepRb) were visualized by injecting an AAV virus into the NTS of LepRb-cre mice that resulted in cre-dependent GFP axonal labeling. The PVH contained a dense plexus of labeled axons in these mice, indicating that the PVH is a primary target of NTS LepRb-expressing neurons. Using immunohistochemistry, we identified GLP-1 as the predominant neurochemical phenotype of LepRb-expressing neurons in the NTS: 70% of GLP-1 neurons co-express leptin receptors at postnatal (P) day 16, and 100% of these neurons are responsive to leptin at this time as determined by leptin-induced pSTAT3 immunoreactivity. In neonatal mice, GLP-1 axons reach the PVH between P6 and P10, which is coincident with an early postnatal surge in leptin levels.

Compared with wild-type mice, GLP-1 fiber density is significantly greater in the PVH of leptin-deficient *Lep*$^{ob/ob}$ mice at P16, a difference that persists into adulthood, with no change in GLP-1 neuron number in the NTS. These results suggest that leptin acts directly at the level of the NTS to inhibit development of neural projections conveying leptin-sensitive, visceral sensory information to the PVH, which may contribute to sustained dysregulation of food intake and energy expenditure.

Title: Central inhibition of c-jun n-terminal kinase suppresses feeding and reduces body weight

Authors: *P. LOGRASSO, S. GAO;
Scripps Res. Inst., Jupiter, FL

Abstract: The role for c-Jun N-terminal Kinase (JNK) in the regulation of energy homeostasis is not well understood especially as it relates to the role for individual JNK isoforms and mechanism of action. To investigate this we explored the role for JNK in the control of food intake and body weight by utilizing of a series of highly selective JNK inhibitors. SR-3306 is a potent JNK1/2/3 (pan JNK) inhibitor with good brain penetration. SR-4073 is a potent JNK1/2/3 (pan JNK) inhibitor with poor brain penetration. Our preliminary data utilizing SR-3306, and its structurally similar non-brain penetrant counterpart SR-4073, suggests feeding behavior was controlled centrally by JNK and not peripherally. Use of SR-3306 in *Jnk1* and *Jnk2* knockout mice support the notion that neither JNK1 nor JNK2 was crucial for feeding control. The reduction of food intake was accompanied by decreases in body weight. A pair-feeding study further showed that the weight loss effect was entirely accounted for by reduced food intake. Importantly, the conditioned taste aversion test showed that the anorectic action following SR-3306 treatment was not due to compound toxicity. The potential central actions of JNK were also assessed. Similar to the findings by systemic treatment, a bolus intracerebroventricular (i.c.v.) injection of the compound reduced food intake and body weight. Thus, the activity of JNK in the CNS appeared to mediate the anorectic actions of JNK inhibition. We also assessed the effects of

SR-3306 on mice fed with 60% kcal fat diet (high-fat diet). Daily i.p. injection of the compound (30mg/kg) for 8 days decreased high-fat diet intake, and markedly reduced body weight gain and fat mass. In addition, JNK inhibition improved leptin sensitivity in DIO mice suggesting that JNK may exert its anorectic effects through the leptin pathway. Collectively, the data demonstrate that central inhibition of JNK activity exerts an anorectic effect and reduces body weight and implicates JNK in the regulation of body weight homeostasis.

Title: Initial chemoarchitectural and connectional characterization of polymodal association cortical structures with the diencephalon: Immunohistochemical and tract tracing studies

Authors: ***K. NEGISHI**[1], J. HAMDAN[2], A. M. KHAN[2];
[2]Biol. Sci. and UTEP Systems Neurosci. Lab., [1]UNIVERSITY OF TEXAS AT EL PASO, El Paso, TX

Abstract: Polymodal association cortical structures (CTSpm) located in the medial prefrontal region of the brain, including the anterior cingulate area (ACA) and prelimbic areas (PL), have been associated with a multitude of functions. CTSpm structures are well known for their roles in attention, working memory, and goal-directed behaviors. Recent efforts have emphasized a role for various CTSpm, in conjunction with visceral sensory-motor areas such as the infralimbic area (ILA), in reward-risk appraisal, the extinction of learned behaviors and induced feeding under sated states. These diverse functions are ostensibly constrained by the underlying anatomy and connectivity of various CTSpm structures, which have known connections to a variety of thalamic and hypothalamic cell populations. It is therefore worthwhile to establish clear ACA and PL connectional relations across their rostrocaudal extent using combined anterograde and retrograde tracer injections targeting these regions. Although CTSpm connections have been

previously reported, their precise distributions throughout diencephalic structures have not been completely elaborated. Here, we examine CTSpm networks using the cytoarchitectonic criteria and nomenclature of the Swanson atlas of the rat brain (2004). Initial tracer injections of the anterograde and retrograde tracers, PHA-L and CTb, respectively, were centered primarily within the dorsal part of the anterior cingulate cortex (ACAd) or the rostral PL. For these cases, both PHA-L fibers and CTb-filled cell bodies were mainly focused in the lateral part of the mediodorsal nucleus, paratenial nucleus, zona incerta, basolateral amygdala, claustrum, and the primary motor cortex. These results are consistent with previous reports (Coolen et al., 2006; Sesack et al., 1989). Lighter distributions of PHA-L fibers were also observed in midline thalamic structures including the paraventricular, central medial and to a lesser extent, the nucleus reuniens. ACAd projections were notably sparse within the hypothalamus. In addition to cytoarchitectonic boundaries, diencephalic structures were further distinguishable by chemically defined cell populations. Our approach allows us to navigate these diverse and often overlapping cell groups using immunocytochemistry. These findings will inform functional investigations using cell type-specific methods such as optogenetics or DREADD technology.

Title: Contribution of D1 and D2 type neurons to nucleus accumbens efferent pathways and their influence on feeding

Authors: ***C. W. BOND**[1], K. E. FURMAN[1], B. B. LAND[2], D. OTTENHEIMER[1], R. J. DILEONE[1];
[1]Yale Univ., New Haven, CT; [2]Univ. of Washington, Seattle, WA

Abstract: The nucleus accumbens (NAc) is a basal ganglia structure critically important for reward learning and food seeking. The NAc is primarily composed of two distinct populations of medium spiny neurons (MSNs), expressing either D1 or D2-type dopamine receptors, with differential roles in reward learning and feeding behavior. The lateral hypothalamus (LH) and ventral pallidum (VP) are two prominent target sites of the NAc MSNs. We sought to describe the composition of these projections in more detail in the mouse and to assess their activity and influence during feeding behavior. Using retrograde tracing of LH-projecting D1 and D2

neurons, we find that the LH pathway is predominantly composed of D1 expressing neurons. Anterograde viral labeling of D1 and D2 specific efferents shows results consistent with this finding. To assess the activity of LH-projecting D1 and D2 neurons, food-restricted animals injected with a retrograde tracer, Fluorogold were re-fed for 90 minutes. Neural activity during re-feeding was determined by cFos expression. We find that few LH-projecting MSNs are cFos+ during re-feeding, with only 12% of Fluorogold labeled cells activated. Moreover, 89% of active Fluorogold labeled cells express the D1 receptor, consistent with the predominant anatomical composition. These anatomical and activity assessment studies, together with functional manipulation of D1 and D2 pathways, better describe how the NAc controls feeding.

Title: Leptin promotes the development of oxytocin projections from the paraventricular hypothalamic nucleus to the dorsal vagal complex

Authors: *A. ELSON[1], R. SIMERLY[2];
[1]Anat. and Neurobio., [2]Developmental Neurosci., Children's Hosp. Los Angeles, Los Angeles, CA

Abstract: The paraventricular nucleus of the hypothalamus (PVH) contains multiple cell types that respond to varied internal and external signals and integrates this information to coordinate autonomic responses. Descending projections from the PVH to the dorsal vagal complex (DVC) represent a key pathway for autonomic regulation and Oxytocin (Oxy) neurons have an established role in the DVC as a modulator of autonomic processes. During development, leptin functions to direct targeting of axons from the arcuate nucleus of the hypothalamus (ARH) to the PVH and here we confirmed that inputs onto Oxy neurons in the PVH from AgRP neurons in the ARH are reduced in leptin-deficient *Lep*$^{ob/ob}$ mice. However, it is unknown if leptin is required

for the development of downstream projections to the DVC. We used Oxy Receptor-Venus mice to confirm expression of the Oxy receptor in the nucleus of the solitary tract (NTS) and dorsal motor nucleus of the vagus nerve (DMX), the sensory and motor components of the DVC, respectively. To determine if leptin is required for the development of Oxy projections from the PVH to the DVC, we used a genetically targeted axonal marker to visualize projections of Oxy neurons in leptin-deficient $Lep^{ob/ob}$ mice. The density of projections from PVH Oxy neurons to the NTS were markedly reduced in $Lep^{ob/ob}$ mice on postnatal day 16, prior to the onset of obesity, yet there was no change in the number of Oxy neurons in the PVH. Because they lack leptin receptors, the developmental actions of leptin on Oxy neurons are likely due to indirect influences that are dependent on innervation by leptin-sensitive neurons such as those in the ARH, or possibly through target-derived mechanisms that result from developmental actions of leptin on NTS neurons. By exerting lasting effects on the architecture of descending hypothalamic pathways, perturbations in leptin signaling during development may contribute to autonomic dysfunction.

Title: Electric remodeling of AgRP and POMC neurons is driven by diet composition and precedes weight gain and leptin insensitivity

Authors: ***J. GAMMONS**, W. WEI, D. SUTHERLAND, A. SMITH, C. KACZOROWSKI, K. O'CONNELL;
Physiol. and Biophysics, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Obesity leads to chronic metabolic disruption and continues to be a rising epidemic. Centrally projecting neurons from the arcuate nucleus of the hypothalamus (ARH) regulate feeding behavior and demonstrate altered biophysical properties in response to long term consumption of a high-fat diet (HFD). Hypothalamic leptin insensitivity develops as a result of chronic HFD, however this is preceded by persistent, unregulated firing of AgRP/NPY neurons that regulate appetite, thus leading to increased food intake. To investigate the impact of short-

term HFD consumption on neuronal excitability, mice were fed HFD ad libitum for up to 6 days and spontaneous firing from AgRP/NPY neurons in acute brain slices measured. This brief HFD consumption resulted in a significant increase in AgRP neuronal spiking to a rate nearly identical to long-term HFD-fed mice. Remarkably, we found that 100 nM leptin still robustly inhibited AgRP/NPY firing in short-term HFD-fed mice, thus the increased excitability of AgRP neurons is not a consequence of leptin-insensitivity. To determine the role of diet composition versus calorie consumption, mice were pair-fed high-fat diet (HFD-CR) yoked to an age-matched control group fed a low-fat diet (LFD). HFD-CR mice gained significant weight compared to the LFD group and AgRP neurons from HFD-CR mice exhibited increased spiking nearly identical to mice fed ad libitum, suggesting that diet composition may be more important than calorie intake for modulating the intrinsic excitability of arcuate AgRP/NPY neurons. POMC/CART neurons reduce feeding behavior when activated by endogenous hormones such as leptin and are regulated by AgRP/NPY neurons, but the intrinsic and synaptic excitability, as well as effects of leptin resistance, have yet to be determined. In order to discriminate between the roles of POMC and AgRP neurons on energy homeostasis and the impact on neuronal excitability through circulating hormones, POMC-GFP mice fed HFD will be used for acute brain slice recording of both intrinsic and synaptic excitability. Remodeling of the feeding circuitry within the hypothalamus will also be investigated using immunohistochemical techniques. As the effect of caloric intake appears to be outweighed by the content of diet on AgRP firing, we postulate the same will apply to POMC neurons. We will also determine whether HFD directly alters POMC neuronal excitability or if changes in POMC neuronal activity occur secondary to the response of AgRP neurons to HFD.

Title: Neuroanatomical characterization of bombesin receptor subtype 3 (brs-3) neurons using brs3-t2a-cre-er^{t2} mice

Authors: *S. H. ZAHLER, C. XIAO, R. A. PINOL, M. L. REITMAN;
DEOB, NIDDK, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Introduction: Bombesin receptor subtype 3 (BRS-3) is an orphan G-coupled-protein receptor. BRS3 is expressed largely in the central nervous system and is involved in the regulation of body temperature, food intake, and heart rate. We now report a mouse line that produces tamoxifen-regulated Cre in cells expressing Brs3. Methods: Brs3-T2A-CreER^{T2}mice were produced by homologous recombination into the native genomic Brs3 locus. Brs3-T2A-CreER^{T2} and Ai9 mice (carrying a Cre-activated tdTomato reporter) were bred, and the progeny were treated with tamoxifen to express the fluorescent reporter. Results: Dense tdTomato fluorescence in neurons was observed in the following hypothalamic regions: preoptic area (POA), paraventricular nucleus of the hypothalamic (PVH), dorsomedial hypothalamus (DMH), and bed nucleus of the stria terminalis (BNST). High expression was also present in the medial amygdala (MeA) and parabrachial nucleus (PBN). Dense fibers were observed in the dorsal raphe nucleus (DR), nucleus of the solitary tract (NTS), ventral tegmental area (VTA), and periaqueductal gray (PAG). The Cre expression pattern is consistent with that previously reported for Brs3 using mRNA *in situ* hybridization and ligand binding. Conclusions: The BRS3-T2A-CreER^{T2} mice faithfully express Cre in Brs3 neurons, including multiple hypothalamic nuclei. The availability of this mouse will facilitate neuroanatomical and physiological studies of Brs3.

Title: Structural changes induced for acute hyperglycemia in median eminence tanycytes and vasculature

Authors: *F. A. MARTINEZ ACUÑA[1], M. CIFUENTES[2], K. SALAZAR[1], N. JARA[1], F. NUALART[1];

Abstract: The median eminence (ME) is located in the basal region of the third ventricle of the brain. The ME contains blood vessels lacking a blood-brain barrier, thus allowing the diffusion of glucose from the blood into brain tissue. The transfer of glucose is also limited by a second barrier (EM-CSF) formed by specialized glial cells, the beta-2 tanycytes. Structural modifications of these cells could regulate the passage of glucose to the CSF in order to stimulate glucosensing. We evaluated the effect of hyperglycemia on the cell architecture and vascularization of the ME. We used intraperitoneal injections of glucose to generate hyperglycemia in Wistar rats; these were sacrificed 30 min after injection. The brain tissue was dissected for confocal spectral microscopy (multilabeling and 3D reconstruction) and electron microscopy analysis (TEM). Using 1µm and 40µm brain sections, we evaluated vimentin and GFAP expression in glial cells as well as changes in the blood vessel structure. 3D-imaging was performed by Z-stack microscopy and analyses were rendered using Imaris software. Furthermore, ultrastructural studies were performed using TEM. We confirmed the presence of blood vessels unrestricted by a barrier in the ME. Hyperglycemia produced a significant increase in the arborization of glial cells in this region. Electron microscopy showed beta-2 tanycytes hyperplasia, increased peri-capillary spaces, and more vesicles in the endothelial cells. Acute changes in glycemia induced structural changes in the ME which would maximize the transfer of glucose to regions of the hypothalamus involved in glucosensing.

Title: Identification and provisional mapping of a novel population of hypothalamic calbindin-immunoreactive neurons that project to the hypothalamic paraventricular nucleus: A combined immunohistochemical and tract tracing study in the adult male rat

Authors: *B. DE HARO[1], A. M. KHAN[2];
[2]Biol. Sci. and UTEP Systems Neurosci. Lab., [1]Univ. of Texas at El Paso, El Paso, TX

Abstract: Calbindin (CaBn), the calcium-binding protein that is widely expressed in the mammalian central nervous system, is an important neuronal macromolecule. In the hypothalamus, the expression of CaBn has been causally linked to changes in the firing patterns of peptidergic neurons. We have shown that CaBn is widely expressed in many hypothalamic regions, and is often co-expressed with neurons expressing hypocretin/orexin (H/O), and to a lesser extent, melanin-concentrating hormone (MCH). However, the connections CaBn+ neurons make with other neurons has not, to our knowledge, ever been investigated in the hypothalamus. Here, we undertook a tract tracing study where we targeted either the retrograde tracers Fluorogold (FG), or cholera toxin subunit B (CTb) into the paraventricular hypothalamus (PVH), and analyzed the ensuing patterns of retrograde labeling of neurons within the hypothalamus. In particular, we performed multi-fluorescence immunohistochemistry and confocal/wide-field imaging to identify whether tracer-filled cell bodies expressed CaBn, H/O, or MCH; or a combination of these markers. We then mapped the distribution of these neuronal populations to the Swanson rat brain atlas (Brain Maps: Structure of the Rat Brain, 3rd edition, 2004). We found retrogradely filled neurons throughout the hypothalamus, primarily on the side ipsilateral to the injection site. Our initial mapping of these neurons (Levels 28-31 of the Swanson atlas) indicates that the hypothalamic regions containing retrogradely labeled neurons included the dorsomedial, ventromedial, and arcuate nuclei; the LHA, and the posterior hypothalamus. In the LHA, the majority of these cells were in the suprafornical, juxtadorsomedial, and the juxtaventromedial (dorsal and ventral zones) sub-regions. Whereas only some (1-10) of the retrogradely filled cells were H/O+ or MCH+, many more (30-50 neurons per case) co-expressed CaBn; of these, a small percentage (8-10 neurons) were also H/O+. Our data identify and provisionally localize a novel CaBn+ population of neurons projecting to the PVH that is widely distributed within various regions of the tuberal and posterior hypothalamus. Projections from these areas might be involved in the modulation of ingestive, neuroendocrine, and pre-autonomic functions. Based on previous work demonstrating a role for CaBn in modulating peptidergic neuronal firing rates, our data suggest the possibility that these CaBn-expressing neurons exhibit unique firing patterns as compared to their surrounding non-CaBn+ neighbors, and that CaBn may confer unique functional properties to these neurons to help influence PVH function.

Title: Pharmacological inhibition of ventral hippocampal NMDA receptors accelerates meal onset and increases meal frequency

Authors: *R. C. HANNAPEL, M. B. PARENT;
Neurosci. Inst., Atlanta, GA

Abstract: Decades of research suggest that different mechanisms regulate meal initiation versus termination. There is extremely limited evidence regarding the mechanisms that regulate meal onset and the interval between two meals (i.e., the postprandial intermeal interval; ppIMI). We previously demonstrated that temporary inactivation of ventral hippocampal neurons at the end of a sucrose meal (i.e., during the ppIMI) accelerates the onset of the next sucrose meal, and increases meal frequency and total intake. Additionally, sucrose consumption elevates ventral hippocampal expression of the immediate-early gene activity regulated cytoskeletal-associated protein (Arc), a marker of synaptic plasticity. Collectively, these findings led us to hypothesize that ventral hippocampal neurons inhibit meal onset, and that they do so through plasticity-dependent mechanisms. As an initial test, we determined the effects of pharmacologically inhibiting ventral hippocampal N-methyl-D-aspartate receptors (NMDARs) on sucrose intake. Adult male Sprague-Dawley rats (n = 8) were implanted with a unilateral cannula aimed at either the left or right ventral hippocampus (hemisphere counterbalanced) and then trained to consume a 32% sucrose solution at a scheduled time daily. On experimental days, the rats were given the competitive NMDAR antagonist 2-Amino-5-phosphonovalerianacid (APV; 30 mM, 1 μl in phosphate-buffered saline) or vehicle (within subject design) and then given the sucrose solution. Sucrose consumption, the time between sucrose meals, and the number of sucrose meals were measured for 4 hr following the infusion. The results demonstrated that ventral hippocampal infusions of APV significantly decreased the interval between the first two sucrose meals ($p < 0.05$), increased the total number of meals consumed ($p < 0.05$), and tended to increase total intake ($p = 0.07$). These findings are consistent with the hypothesis that ventral hippocampal neurons inhibit meal onset and energy intake, and that this effect requires NMDAR-dependent synaptic plasticity.

Title: Effects of intranasal insulin on prefrontal-hypothalamic brain circuits in lean, fasted subjects

Authors: *L. TIEDEMANN, J. HETTEL, K. GIESEN, S. BRASSEN;
Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Introduction: The homeostatic feeding-system predominantly comprises the hypothalamus and the brainstem, in which hormonal regulators of hunger and satiety trigger food intake. While animal research identified various hypothalamic sub-nuclei involved in eating behavior (Gao and Horvath, 2007), only few imaging studies in humans were able to specifically track hypothalamus engagement (Kullmann 2014). We use intranasal insulin administration combined with high resolution functional imaging to investigate how central insulin modulates homeostatic but also hedonic neural responses to food stimuli. Method: In our ongoing study, so far 10 young, healthy participants (6 women, 26.4 +/- 3.7 years) underwent a double-blind, placebo-controlled cross-over design. On two scanning days, separated by one week, after an overnight fast, participants received either intranasal insulin (160IU) or placebo (NaCl) and then performed a rating task on high and low palatable food stimuli inside the scanner (3 T, EPI multiband, 1.5mm³). Results: Imaging data analysis of the placebo session reveals that our paradigm robustly activates brain regions of the homeostatic and reward related system including the hypothalamus, ventral striatum and the ventromedial prefrontal cortex (vmPFC). Comparing insulin with placebo, activation in the medial hypothalamus and the vmPFC was significantly ($p < 0.05$ FWE) reduced in the insulin condition. Discussion: Even in this rather small sample from our ongoing study we could demonstrate that central insulin modulates intrinsic brain activation in rewarding and homeostatic brain circuits. In the context of existing findings on neural correlates of ingestive behavior, our results therefore support the assumption that effects of central insulin on the hedonic brain system together with its impact on hypothalamic and metabolic mechanisms cause reduced food intake. Functional connectivity analyses in the final sample will help us to further elucidate direct interactions between both systems as a function of central insulin activity.

Title: Ventral striatopallidal control of macronutrient intake

Authors: *D. WIRTSHAFTER, I. R. COVELO, N. HORODENSKA, J. A. LUVIANO, Z. I. PATEL, T. R. STRATFORD;
Psychology, Univ. Illinois At Chicago, Chicago, IL

Abstract: Injections of the GABA antagonist bicuculline (BIC) into the ventral pallidum (VP) induce massive increases in food intake which, in animals adapted to a diet containing separate sources of macronutrients, are preferentially directed towards fats. We attempt here to clarify the behavioral nature of this effect and its anatomical and pharmacological substrates. We conducted several experiments to characterize the factors responsible for the preferential fat intake: (1) Intra-VP BIC produces massive and selective increases in lard intake even in animals not preexposed to the individual macronutrient components. In contrast, food deprivation (DEP) in these conditions preferentially increases carbohydrate (CARB) intake. These finding suggest that the BIC effect does not depend on learning about the postingestive consequences of fat intake. (2) BIC in the VP selectively increases corn oil intake in animals adapted to a diet consisting of oil, CARB and protein. In contrast, DEP has less of an effect on oil than on CARB or fat intake. This result demonstrates the BIC preferences extend to liquid plant, as well as solid animal, fats, even though a different response is required to ingest them. (3) Intra-VP BIC selectively increases lard intake in animals given a choice between lard and a 5% sucrose solution. In contrast, DEP has a larger effect on sucrose. This result indicates that the preferential fat intake seen in the earlier experiments cannot result from difficulties in consuming the powdered CARB or protein dietary components. (4) In animals adapted to a diet consisting of powdered protein and of equicaloric gelatins containing high concentrations of either lard or CARBs, BIC in the VP increased the intake of both gelatins with no effect on protein intake. This result suggests that animals are not detecting fat per se, but rather prefer the “mouth feel” typical of fats. In contrast, DEP increased intake of protein and of CARB-gelatin more than lard-gelatin, again emphasizing that BIC and DEP induce different patterns of intake. In order to determine whether all orexigenic treatments of the VP induce fat selective feeding, we studied the effects of the opioid agonist DAMGO injected in the central VP. These injections significantly increased food intake, but the fat selectivity seen with BIC was not present. We also conducted similar experiments

with DAMGO in the nucleus accumbens core; we found that these injections increased feeding but, in contrast to the results of previous workers, this effect was not fat selective. The reasons for these discrepancies are not clear, but the results serve to highlight the unique effects produced by blocking GABA in the VP.

Title: Aromatase levels in amygdala, obesity and self control: PET and personality studies

Authors: *A. BIEGON[1], N. ALIA-KLEIN[2], T. HILDEBRANDT[2], D. PARETO[3], S. KIM[4], J. LOGAN[5], J. FOWLER[6], G.-J. WANG[4];
[1]Neurol., Stony Brook Univ., Stony Brook, NY; [2]Mount Sinai Sch. of Med., New York, NY; [3]Hosp. Val d'Hebron, Barcelona, Spain; [4]NIAAA, Bethesda, MD; [5]NYU Med. Sch., New York, NY; [6]Brookhaven Natl. Lab., Upton, NY

Abstract: Aromatase is the last and obligatory enzyme catalyzing the biosynthesis of estrogens throughout the body. We hypothesized that aromatase levels in amygdala, measured by positron emission tomography (PET) and the tracer [11C]vorozole would predict body mass index (BMI), because of the amygdala's specific role in feeding related memory, food preference, ability to override hypothalamic signaled satiety, and sensitivity to estrogens. Forty three healthy men (n = 19) and women (n = 24) were recruited from the community and underwent a brain PET scan with [11C]vorozole. A subgroup of 29 subjects (17 women, 12 men) were also administered the Multidimensional Personality Questionnaire (MPQ). Another small group (N=8, men only) had body fat measurement performed in addition to BMI and PET. The total volume of distribution VTg , was derived from a graphical analysis (Logan plot) of the time activity data. Subjects were divided into 3 BMI groups, normal weight (BMI<25) Overweight(25<BMI <30) and obese (BMI>30); matched for age and sex composition. Two way ANOVA by weight class and sex revealed a highly significant effect of BMI (p=0.0008), no main effect of sex and no sex X BMI interaction, with the highest values of VTg in the normal weight group and lowest values in the

obese group. A significant negative correlation between body fat and VTg was seen in the men who had this measurement performed. Aromatase availability in the subgroup administered the MPQ exhibited a significant positive correlation with the personality trait, Constraint ($R=0.49$, $p<0.01$, Pearson correlation). These results support a role for estrogen locally produced in the amygdala in the well know effects of estrogen on appetite suppression.

Abstract: Objective Neuroimaging studies suggest that modifying connectivity of brain circuits involved in eating behavior could provide therapeutic benefits in obesity. Transcranial direct current stimulation (tDCS) is an emerging tool for brain modulation for various diseases. We aimed to assess whether tDCS, modifies brain connectivity and behavioral response in obese subjects. Methods Fifteen overweight subjects were treated with real tDCS or sham tDCS in a cross-over design. Functional MRI (fMRI) was performed with visual food cues with high or low calorie food pictures immediately after tDCS. Questionnaires were performed to assess appetite, desire for food, mood and food addictive patterns (Yale Food Addiction Scale). Body composition and blood tests were performed. Brain connectivity was analyzed using SPM software. Results Active tDCS treatment significantly increased baseline adjusted fullness score compared with sham tDCS treatment (1.18 ± 0.98 vs. -0.18 ± 1.66, $p<0.05$) and competent mood (4.80 ± 1.14 vs. 5.60 ± 1.08, plow calorie), right precentral gyrus (high calorie<low calorie) were differently activated by visual food cues ($p<0.0001$, $k=21.3$). Active tDCS treatment significantly decreased brain activation of hippocampus, insula, pallidum, precuneus, and

orbitofrontal cortex regions (p<0.0001, k=16.1). Effect of tDCS on behavior scores were correlated with body composition and food addictive patterns (p<0.05). Effect of tDCS on fullness score was positively correlated with effect of tDCS on connectivity between right dorsolateral prefrontal cortex and right thalamus (p=0.045, r=0.648) Conclusion Brain stimulation with tDCS modulated eating behavior and subcortical brain activities. Our study implies that the brain stimulation with tDCS represents a promising option for treating obesity in humans by modulation of neural connectivity associated with reward and motivation in response to food cues.

Abstract: Tissue metabolism is often studied using the radiolabeled glucose analog, 2-deoxy-D-glucose (3H-2-DG), which is taken up by high-glucose-using cells in brain, kidney, and tumors. After glucose is absorbed into a cell, phosphorylation prevents it from being released; therefore metabolic activity in different brain regions can be quantified *ex vivo* through the use of autoradiography. Phencyclidine (PCP) is a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist that is commonly used to induce schizophrenic-like symptoms in preclinical studies. In schizophrenic patients and PCP treated rodents hypometabolism is seen in prefrontal cortex, thalamus and temporal lobes. Currently Clozapine is used in the treatment of schizophrenia. It is an atypical antipsychotic medication and it prevents impaired NMDA receptor expression caused by corresponding antagonists. The objective of the current study was to quantify metabolic changes in prefrontal cortex, thalamus and temporal lobes after PCP treatment and to determine whether pre-dosing with clozapine blocks the effect of PCP treatment. G protein–coupled receptors (GPCRs) are involved in a wide variety of physiological processes, like sight, taste, smell, behavioral and mood regulation. They activate intercellular signal transduction pathways and, ultimately, cellular responses. Ligand binding to GPCRs induces an interaction of the receptor with G protein stimulating the release of GDP simultaneously with the exchange of GTP. The use of 35S-GTPγS with autoradiography has been applied to study intracellular activation after ligand binding to GPCRs. It is possible to study activation of several different receptors at once using single radiolabeled compound since receptor activation is quantified. ARG provides universal tool to study metabolic changes and GPCR activation of novel compounds in brain. These methodologies are easily applicable to various disease models. Combining these assays with behavioral readouts provides for a rich evaluation of the pathophysiology of CNS disorders and of the mechanisms of action of novel treatments designed to treat those disorders. The current data demonstrate how the combination of assays can be utilized to advance our understanding of disease states and treatment options.

Title: Pharmacological blockade of inhibitory neuronal activation reduces the evoked fMRI response to LOT stimulation in the rat olfactory bulb

Authors: *A. J. POPLAWSKY[1], H. FUKUDA[1], S.-G. KIM[2];
[1]Radiology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Biomed. Engineering, Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci. (IBS), SKKU, Suwon, Korea, Republic of

Abstract: Introduction: Functional magnetic resonance imaging (fMRI) measures the hemodynamic response to neuronal activity; but more evidence is needed to understand whether the evoked activity of inhibitory neurons is involved in neurovascular coupling. The olfactory bulb is an ideal model system to study this issue because inhibitory neurons are almost exclusively targeted by stimulation of the lateral olfactory tract (LOT) at synapses localized to the external plexiform layer (EPL). During stimulation, antidromic action potentials cause pre-synaptic glutamate release from dendro-dendritic synapses of excitatory mitral cells that then activate inhibitory granule cells via post-synaptic glutamate receptors. We previously showed that the fMRI signal increases due to LOT stimulation are highly localized to the evoked synapses in EPL; but it is unknown whether this vascular response is initiated by the pre-synaptic glutamate release or by post-synaptic events originating from the inhibitory neurons. Methods: In isoflurane-anesthetized rats, LOT was continuously stimulated in a block design experiment (-200 μA, 200 μs pulse duration, 40 Hz, 1 min stimulus duration, 4 min interstimulus interval); and high-resolution (110 x 110 x 500 μm3) cerebral blood volume-weighted fMRI responses were measured at 9.4 T. This contrast-enhanced fMRI technique was shown to increase sensitivity in capillaries near the site of neuronal activity. Next, to decrease the evoked activity of inhibitory neurons without affecting glutamate release, 25 mM APV (NMDA receptor antagonist) was applied to the dorsal surface of the bulb in the following paradigm: 60 min pre-drug vehicle infusion (baseline), 90 min APV infusion (drug), and 180 min vehicle washout (recovery) periods. Results: Percent fMRI signal change maps were calculated for each single LOT stimulation trial, and then trials across time were correlated to the drug delivery paradigm. Significant drug effects ($p < 0.01$ in single rats) were confined to the dorsal bulb and penetrated ~1 mm below the surface. Here, the average evoked signal change was 7.0 ± 1.8% (mean ± SEM, n = 2 rats) for the baseline, 3.2 ± 0.7% for the drug, and 5.3 ± 1.0% for the recovery periods. In control regions ventral to the drug penetration limits, the percent changes for the same three periods were 5.2 ± 1.3%, 4.8 ± 1.0%, and 4.7 ± 0.7%, respectively. Thus, the fMRI signal decreased by 53.9 ± 1.6% ($p = 0.02$, one-sample T-test) at the drug penetration site when only a 6.5 ± 3.8% ($p = 0.34$) decrease was observed in control regions. Conclusions: Our

preliminary results indicate that post-synaptic activities of inhibitory granule cells contribute to the evoked fMRI response.

Title: Resting state fmri of the ferret: sensory, default mode, and higher-order networks

Authors: ***Z. C. ZHOU**[1], A. P. SALZWEDEL[2,3], S. RADTKE-SCHULLER[1], Y. LI[1], K. K. SELLERS[1,4], Y.-Y. I. SHIH[5,3,6], F. FRÖHLICH[1,4,7,8], W. GAO[2,3];

Abstract: Translational research benefits from a diverse set of animal model species for the study of physiological and pathological brain networks. In particular, resting state functional connectivity has emerged as a powerful tool for the assessment of large-scale brain connectivity. However, no such examination of functional connectivity has been performed in ferrets, an intermediate model species that has recently gained traction for the study of higher-order brain function. Here, we present evidence for distinct networks in the ferret brain that exhibit similar topology and connectivity patterns to those observed in humans. We performed independent component analysis (ICA) and seed-based connectivity analysis on resting state function magnetic resonance imaging (fMRI) data collected from anesthetized female ferrets (*Mustela*

putoris furo). A 10 minute resting state echo-planar imaging scan was performed for each animal using a Bruker 9.4T scanner. Animals were anesthetized with 0.5-1% isoflurane and xylazine and paralyzed with vecuronium bromide. Group analysis from four animals reveal three distinct functionally connected sensory networks (visual, auditory, and somatosensory), and three "higher-order" networks ($p < 0.05$, 20 voxel minimum). Among these higher-order networks, we identified a putative default mode network (DMN) composed of the medial frontal cortex, anterior and posterior cingulate cortex, lateral temporal (auditory) cortex, lateral posterior parietal cortex, prelimbic cortex, and premotor cortex. This network shows similar topology to the DMN in humans and macaques (1). The second network was composed of the orbitofrontal cortex, dorsal lateral frontal cortex, posterior cingulate cortex, insula cortex, and premotor cortex. The third higher-order visual network consisted of extrastriate cortex and posterior parietal cortex. Seed-based connectivity maps showed connectivity patterns consistent with the results from the ICA approach ($p < 0.05$, 20 voxel minimum). These results suggest the presence of distributed, functionally connected networks in the ferret brain. The similarity in the organization of these functional networks to those in the human brain further supports an expanded role of the ferret in basic and translational neuroscience. Gaps in the characterization of the ferret brain limit our ability to draw conclusive similarities between ferret and human brain networks; however, this study highlights the importance of further delineating subdivisions of the ferret brain using both structural and functional methods. Title: Neurovascular coupling in motor cortex: Inversion of the hemodynamic response as a property of baseline cortical state

Authors: *R. E. SLACK, P. PATEL, L. BOORMAN, M. JONES, J. BERWICK; Psychology, Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Alterations in cortical state as shown by electrophysiological recordings of neural activity are thought to be heavily involved in priming for sensory discrimination (Zagha et al.,

2013). A corollary of these cognitive benefits is that state changes have also been shown to have critical effects on global cerebral perfusion (Braun et al., 1997). However at a detailed level, we still know little about how changes in state may impact the interpretation of well used imaging techniques such as Blood Oxygen Level Dependent (BOLD) functional magnetic resonance imaging (fMRI) which measure a cerebral vascular response, rather than actual changes in neural activity. We used an anesthetised rodent model to record neural signals from two 16 channel electrodes inserted in the whisker somatosensory and motor cortex respectively. At the same time, we recorded the vascular response using 2D Optical Imaging Spectroscopy (2D-OIS) to investigate the impact of cortical state changes on the concomitant hemodynamics. Our investigation indicates that the cortical state is key for the interpretation of spontaneous and evoked hemodynamic responses. The hemodynamic response to a 16s 5Hz electrical stimulation of the whisker pad showed a significant difference in somatosensory cortex dependent upon the pre-stimulus neural baseline state. Additionally during these same state changes, we found that the hemodynamic response in motor cortex switched from an increase to a decrease in total haemoglobin concentration (Hbt), and that the inversion of the response was dependent upon the pre-stimulus neural baseline state. These state dependent hemodynamic changes have important implications for vascular based brain imaging tools such as BOLD fMRI, especially when used in isolation. If brain state can cause the same stimulus in the same region, in this case motor cortex, to respond with an inverted hemodynamic response, this could cause a serious confound in the interpretation of fMRI signals and strongly suggests the assessment and categorisation of baseline brain state is necessary for greater information gain, particularly in the analysis of single trial datasets. An understanding of the neural signals controlling the hemodynamic response in whisker motor cortex may be generalizable to other brain regions and may be important for the understanding of fMRI signals, specifically the negative BOLD signal.

Title: The effects of endothelial dysfunction on neural activity, hemodynamics and neurovascular coupling

Authors: *M. A. SHAIK[1], S. H. KIM[2], Y. MA[2], T. H. ZHAO[2], E. M. C. HILLMAN[2]; [2]Biomed. Engin., [1]Columbia Univ., New York, NY

Abstract: Accumulating evidence suggests that the vascular endothelium plays an integral role in driving functional hyperemia in response to neural activity in the brain. In a recent study, we demonstrated that specific and localized disruption of endothelial signaling in the vasculature via ROS-mediated damage abruptly interrupts the propagation of vasodilation in the pial arterioles, altering the overall hemodynamic response to stimulus. We have also previously observed apparent high-speed propagation of vasodilation along pial arterioles suggesting the involvement of established fast endothelial signaling mechanisms, which are known to be altered during endothelial dysfunction. Recognizing that there are many systemic physiological conditions that directly affect endothelial health, including cardiovascular disease, hypertension and diabetes, we therefore hypothesize that these diseases states could lead to altered neurovascular coupling in the brain. Furthermore, in conditions where functional hyperemia is not fully responsive to neural activity, such impaired neurovascular coupling could lead to acute neural deficits and long-term neurodegeneration. To study the interplay between endothelial health and neurovascular coupling, we have developed a wide-field optical imaging system capable of recording neural activity (via Thy1-GCaMP), oxygenation dynamics and speckle-based blood flow in awake, behaving mice. We use a newly developed mathematical model to predict hemodynamic activity from neuronal recordings. The optimally fitted hemodynamic response function (HRF) is compared between mice with healthy and disrupted endothelial signaling. Endothelial dysfunction is introduced via BBB impermeable pharmacological manipulation or with mouse models of systemic vascular disease. Changes in both neuronal activity and the HRF are compared under stimulus and resting state paradigms across a large area of the cerebral cortex. These results should provide new insights into the role of systemic vascular dysfunction in neuronal dysfunction with the overall goal of identifying therapeutic opportunities for conditions with a neurovascular component.

Title: Blood oxygenation level dependent (BOLD) contrast based pharmacological MRI in naïve rats and mice

Authors: *K. LEHTIMÄKI[1], A. NURMI[1], O. KONTKANEN[1], P. J. SWEENEY[1], L. PARK[2]; [1]Charles River Discovery Res. Services Finland, Kuopio, Finland; [2]CHDI Management/CHDI Fndn., Los Angeles, CA

Abstract: Pharmacological MRI (phMRI) is an innovative technique that allows researchers to non-invasively map brain function in response to the hemodynamic changes induced by the introduction of pharmacological stimuli. Blood oxygenation level dependent (BOLD) contrast is one of three main approaches that can be employed in order to obtain a spatial and temporal distribution as well as strength of the activation upon pharmacological stimulus in the brain (the others being: relative cerebral blood volume (rCBV) using iron oxide based contrast agents for gauging cerebral blood volume and arterial spin labeling for cerebral blood perfusion (ASL)). BOLD functional MRI represents the most promising translational tool between pre-clinical and clinical research because it is a widely accepted method in clinical functional brain studies. In this pre-clinical proof-of-concept framework, we have established BOLD phMRI measurements in 7T and 11.7T MR field strengths in anesthetized naïve rats and mice. Validation work has been carried out on the use of several different anesthetic agents both with, and without, mechanical ventilation. It is shown here that paralyzed and ventilated animals under urethane anesthesia maintain the most optimal physiological status under testing conditions and give the most reliable detection of brain responses upon introduction of pharmacological stimuli. Time series data for the BOLD phMRI were acquired using a single-shot spin-echo EPI sequence both in rats and mice and at both field strengths (7T and 11.7T). Time-resolution of functional images was 2 seconds and the functional paradigm consisted of a 20 minute scanning period pre-dosing followed by the bolus injection of the pharmacological agent to be studied (here shown as nicotine and amphetamine responses) and a 40 minute follow-up period. Physiological parameters (temperature, ECG) and pre and post scan arterial blood gases were recorded in order to confirm a consistent physiological status of the animals during the scans. Data were pre-processed with slice-timing and motion correction and spatial smoothing before registration to a reference brain for group-analysis. Results are shown as group-level independent component analysis maps and region of interests (ROI) based time- and dose-response curves. The results and the technical framework established within this study, provide a means to approach drug testing in various pre-clinical rat and mouse models in order to obtain a temporal and spatial profile of the studied compounds at different concentrations and routes of administration.

Title: Dissociable spatial properties of functional connectivity in gray and white matter

Authors: ***M. J. TOBIA**, D. GALLAGHER, R. DEWAL, P. KARUNANAYAKA, Q. YANG; Dept. of Radiology, Hershey Med. Ctr., Hershey, PA

Abstract: Resting state fMRI (R-fMRI) has uncovered the large-scale network organization of the human brain via functional connectivity analyses, which has greatly enriched systems neuroscience. R-fMRI functional connectivity is based on correlations of low frequency fluctuations (LFFs) between neighboring and/or long distance voxels. In general, functional connectivity in gray matter (GM) is attributed to the blood oxygenation level dependent (BOLD) effect, and voxels in white matter (WM) are uncorrelated to GM due to lack of BOLD. However, WM voxels also display LFFs and significant correlations among themselves, suggesting a non-BOLD mechanism of functional connectivity in WM. In addition, the WM contains electric current propagating along fiber tracts. We, thus, hypothesize that the correlation of LFFs in WM is caused by its electric current, and WM functional connectivity would be anisotropic and oriented along its fiber tracts. To test our hypothesis, we analyzed R-fMRI data using a local functional connectivity (LFC) tensor to quantify the anisotropy of correlated LFFs in WM. Computation of the LFC tensor involves two steps: 1) compute the Pearson correlation between a home voxel and each voxel in its 3D neighborhood defined as a radius of 2 voxels, and 2) fit the tensor model to the local correlation matrix using linear least squares. This process is repeated to generate a tensor for every voxel, from which metrics for the average spatial correlation (ASC) and anisotropy can be derived. R-fMRI data were collected from 12 healthy young adults with eyes closed (TR = 2 sec; 150 volumes). After standard preprocessing, nuisance regression and bandpass filtering (.008-.1 Hz), the LFC tensor was computed for each voxel. We expected the ASC to be greater in GM than WM due to the BOLD effect in GM only, and we expected the anisotropy to be greater in WM due to electric currents along anisotropic fiber tracts. The group average ASC was greater in GM (.45, +/- .05) than WM (.33, +/- .03). A two-sample t-test revealed a highly significant difference between GM and WM, $t(22) = 8.56$, $p = 1.8e-08$. The

group average anisotropy was greater in WM (.26, +/- .07) than in GM (.24, +/- .07), t(22) = -2.28, p = .03. These different spatial properties of functional connectivity show that the mechanism of correlation among voxels is different between GM and WM, and suggests that WM R-fMRI is influenced by oscillating electric signals that propagate along anisotropic fibers in the brain.

Title: Novel BOLD model for hemodynamic response with brief stimulation in the human brain

Authors: *J. KIM, D. RESS;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Most attempts to explain the BOLD response have assumed non-linear venous dilation, thus yielding “balloon” models. However, recent brief stimulation experiments showed prompt arterial dilation without venous volume changes. Accordingly, we assume that arterial dilation creates an underdamped flow (CBF) response to yield a new “arterial impulse” model. The CBF and oxygen demand (CMRO2) responses are combined to predict longitudinal oxygen saturation (SO2) in capillary and venous compartments, which are then linked to the BOLD signal. Our model is validated against measurements of the BOLD hemodynamic response function (HRF) evoked by brief stimulation in human visual cortex. Methods: The BOLD signal depends on SO2 changes in capillaries and veins. We assume a uniform cylindrical geometry for the vessels and finely grid their lengths. Model includes flow, oxygen dissociation, and diffusion into extravascular tissue, to obtain continuous SO2 spatial profiles. CBF response is modeled by a linear network, which describes the impulse response produced by prompt arterial dilation. CMRO2 response is modeled by a gamma function. The HRF was measured using a 2-s stimulus of 4-Hz flickering dots followed by a 26-s blank period. High-resolution fMRI data (0.9-mm voxels) was obtained in 7 subjects (spiral acquisition, 1.5-s/volume). Each session produced ~85 HRF responses that were averaged across visual areas V1-3. The model was fit to the HRFs by

adjusting CBF and CMRO2 parameters. Results: The model predicts substantial SO2 variations along the length of capillaries and veins (Fig A). HRF measurements are in good agreement with model fits (Fig B), which are based on estimates of the corresponding CBF and CMRO2 responses (Fig C). The model predicts an offset linear correlation with near unity slope between CBF and CMRO2 peak amplitudes (Fig D). Conclusion: We establish a new arterial impulse model based on the hypothesis that prompt arterial dilation is a key physiological mechanism for the HRF, and demonstrate its efficacy in predicting the BOLD HRF.

Title: Clinical and prognostic significance of brain SPECT changes in the default mode network areas

Authors: *D. G. PAVEL[1], S. R. BEST[2];
[1]PathFinder Brain SPECT, [2]The Neurosci. Ctr., Deerfield, IL

Abstract: Introduction: Resting Brain SPECT (Single Photon Emission Computed Tomography) evaluates the functional status of the gray matter. Based on the fact that it is specifically able to identify the area of the two main components of the Default Mode Network (DMN) : anterior cingulate / adjacent mesial frontal pole and, posterior cingulate / precuneus , we looked at the possible improvement of image interpretation when abnormalities in these areas were detected. Methods: In this pilot study we selected cases where marked hypo or hyperperfusions in one or both components of DMN were present and correlated them with clinical history and outcome after variable periods of followup. The brain SPECT was done with a triple head gamma camera using 99mTc_HMPAO . The display uses a discrete color code, orthogonal slices, multiple thresholded volume displays and automatic generation of 8 Talairach normalized surface views. Results 16 patients , ages 17- 69 who had a followup of 18 months or more. 6 had DMN

underperfusions (4 in the posterior and 2 in the anterior component area) and 10 had DMN hyperperfusions (3 in both components, 4 in the posterior and 3 in the anterior component). Underperfusions. The 4 patients with posterior DMN underperfusion were ultimately confirmed as Alzheimer's or mixed dementia. The 2 with anterior DMN underperfusion were in patients with significant comorbidity, one of them confirmed as early fronto-temporal lobar degeneration. Hyperperfusions. The 3 patients with hyperperfusion in both components of DMN required prolonged treatment including medication, rTMS (repetitive Transcranial Magnetic Stimulation) and/ or ketamine perfusion without or with augmentation with TMS). One 22 y.o. patient required intensive treatment over 2 ½ year involving all these protocols before transitioning from unemployable to a fully employed person with further professional goals. The remaining 8 patients with only partial DMN hyperactivity, required prolonged treatment but overall were easier to treat. Discussion We interpret these results in light of the known functional anti-correlation, normally exhibited by the DMN in the presence of conscious activity : the more extensive the abnormality, the more severe the interference is with the anti-correlation during conscious activity . This can result in prolonged system perturbations leading to the dysfunctions of comorbid mental disorders. Conclusions: The location type and amount of abnormality detected in the DMN areas can suggest the level of dysfunction present in each case, lead to better clinical understanding and also provide additional prognostic information.

Title: Capturing the dynamics of neuronal activity, brain oxygenation and brain blood flow during acute cortical stroke

Authors: *H. ZHAO[1], D. CHOW[2], M. G. KOZBERG[3], M. A. SHAIK[3], S. H. KIM[3], E. M. C. HILLMAN[3];
[2]Radiology, [3]Biomed. Engin., [1]Columbia Univ., New York, NY

Abstract: Determining the risks and benefits of thrombolytic therapy in stroke patients poses a major challenge. Current methods using stroke core and salvageable penumbra mismatch, a metric thought to correlate with hemorrhagic risk, have proven unreliable in clinical trials. Seeking improved metrics, we have developed a mouse model in which we can characterize the minute-by minute progression of acute stroke, with a particular focus on stroke onset. To achieve this, we use high-speed optical imaging of the bilaterally-exposed cortex of Thy1-GCaMP mice during localized, optically-induced unilateral acute stroke to simultaneously capture optical intrinsic signal, GCaMP fluorescence and laser speckle reflection data representing oxy- and deoxy-hemoglobin concentrations, neuronal activity and blood flow, respectively. We record the spatiotemporal changes of these parameters over 1-3 hours following acute stroke both with and without somatosensory stimulation. Prior to stroke, our analysis reveals bilateral spontaneous neuronal activity appearing as symmetric waves traversing the cortex. These waves become disrupted by the progression of the ischemic region during the early minutes of stroke. Prolonged ischemia attenuates these neuronal events with evidence of a gradual temporal decoupling of neuronal activity in the affected region. Our simultaneous acquisition of hemodynamic and blood flow measurements permit analysis of the order in which the neuronal and vascular deterioration occurs and can distinguish degradation of neurovascular coupling from alterations in neural network ‘functional connectivity’. Our technique provides a new approach to finding and understanding biomarkers of early stroke and therapeutic response.

Title: Human MRI tensor-based corroboration of transport indices of gliovascular glymphatic fluidic system of brain for clearing Alzheimer's Amyloid

Authors: *P. K. ROY;
Natl. Brain Res. Ctr., Manesar (NCR Delhi), India

Abstract: INTRODUCTION:The clearance of amyloid and solutes from brain, via its interstitial CSF-originated Gliovascular lymphatic (Glymphatic) system has been experimentally formulated in rodent models [1]. A substantiation of this system quantitatively in the clinical human is desirable. . METHODS: . We use the Curie-Neumann principle to elucidate that the transport tensors in a fluidized phase of brain interstice share eigenvectors. We infer that in each brain voxel, there would be common eigenvectors of diffusion mobility tensor D and that of other mobility tensor (say convection tensor or fluid permeation tensor). Using 3 tesla Philips MRI scanner on human subjects, we delineate how one can construct the general transport tensor from MRI diffusion tensor for each voxel by choosing a set of basis functions in which both the tensor ellipsoids become in parallel format. Cross-property relationships are delineated by a statistical correlation expansion of the tissue's microstructure consisting of a parenchymal matrix space embedding an amorphous convoluted glymphatic space. . RESULTS: . We show the linearity between eigenvalues of tensors as that of permeation and perfusion processes, using experimental findings, from diffusion tensor imaging and fluidic mobility measurement. We find that different transport processes, when analyzed using our generalized tensor imaging approach [2], are actually interrelated due to boundary condition of tissue geometry, where the thermodynamic transport tensors related are fluidic permeation tensor, molecular diffusion tensor or haemodynamic perfusion tensor. Using the aforesaid generalized tensor MRI approach developed, we noninvasively estimate the energy flux index, diffusion index and conduction index for the interstitial fluid phase to be respectively 0.49 W/m/K, 5.62 um^2/ms and 4.85 siemens/m. These values are respectively within 94%, 85% and 94% of surgically measured values of those indices in the fluidic phase of the lymphatic system using invasive electrodes, whence the mean predictive accuracy of our mathematical model is 91%. Using thermodynamic transport principles [3], we obtain a quantitative approach to solute/amyloid clearance from brain. . CONCLUSION: . A ready MRI-based substantiation of the glymphatic fluidic system in brain is explored in human scenario, along with indicating a thermodynamic transport approach to amyloid clearance from brain. . Title: Ultra-fast MREG detection of glymphatic pulsations

Authors: *V. KIVINIEMI[1], X. WANG[2], V. KORHONEN[1], P. LEVAN[3], S. KEILHOLZ[4], M. NEDERGAARD[5];

Abstract: Background: Glymphatic convection of CSF through the extra-cellular matrix is partially mediated by cardiac pulsations . We investigated if we could identify more sources for glymphatic pulsations in the human brain with ultra-fast MREG sequence. Methods: Nine subjects were scanned in rest after informed consent using 3T MREG sequence. MRI-compatible ECG was used to identify cardiac T-peak (ECG 0.8-1.2 Hz) and bellows for respiratory (0.15 - 0.35 Hz) frequencies. Low frequency (LF 0.027-0.073 Hz) and very low frequency (VLF 0.01-0.027 Hz) waves were identified from MREG data with FSL groupPICA dual-reg. QPP algorithm to separate pulsations from MREG data . Results: Three different physiological mechanisms of brain pulsations were identified; periodic cardiac and respiratory pulsations and quasiperiodic VLF/LF waves. The cardiac pulsations originated from basal peri-arterial regions extending centrifugally. Respiratory pulsations extended centripetally in cortical peri-venous areas. The VLF/LF waves had a unique quasiperiodic spatiotemporal patterns related to separate vasomotor control mechanisms. Conclusion: Critically ultra-fast MREG data opens a new view into human brain physiology by enabling comprehensive 3D imaging of glymphatic pulsations mechanisms. Basically this opens a new way to image abnormal brain pulsations early in the course of glymphatic system failures. References: 1Nedergaard, Maiken. Science 340(6140) 1529-30. 2 Majeed, et al. Title: Genetic influences on resting-state networks: a twin study

Authors: ***Z. MA**[1], Y. FU[2], C. HAMILTON[1], Z. LIANG[1], X. HOU[4], X. MA[2], X. HU[2], Q. HE[3], W. DENG[5], Y. WANG[5], L. ZHAO[5], H. MENG[2], T. LI[5], N. ZHANG[1];

Abstract: Abnormalities of resting-state networks (RSNs) are often associated with neuropsychiatric diseases. Given this critical correlation, it has been hypothesized that RSNs can be used as an endophenotype (Khadka, et al., 2013). A foremost step for testing this hypothesis is to examine the heritability of RSNs. However, the investigation of the genetic basis of RSNs has

been limited in the default mode network at the region-of-interest level (Korgaonkar, et al., 2014), while the genetic control on other RSNs has not been determined yet. In the present study, we examined the genetic influences on eight well-characterized RSNs using a twin design. Using the resting-state functional magnetic resonance imaging data collected from 32 monozygotic and 24 dizygotic twin pairs, RSNs were extracted using group independent component analysis (Calhoun, et al., 2001). The genetic effects on each RSN were quantified by fitting the functional connectivity covariance of each voxel in the RSN to the classic ACE twin model (Neale and Cardon, 1992). The data showed that although environmental effects accounted for the majority of variance in wide-spread areas, there were specific brain regions that showed significant genetic control for individual RSNs. In addition, there was large variability in genetic influences across different RSNs. Sensory networks tend to be under stronger genetic control relative to cognitive networks. These results suggest that part of the human brain functional connectome is shaped by genetic constraints. Importantly, this information can be useful for bridging genetic analysis and network-level assessment of neuropsychiatric diseases.

Title: Cognitive factors associated with spatial navigation

Authors: ***M. FRAHMAND**[1], L. KORTHAUER[2], N. T. NOWAK[2], I. DRISCOLL[2];
[1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Univ. of Wisconsin- Milwaukee, Milwaukee, WI

Abstract: Although effective spatial navigation requires memory for objects and locations, other cognitive factors may also impact performance. The virtual Morris Water Task (vMWT) is a translational version of the classic paradigm used to investigate place learning and memory in rodents. The vMWT requires participants to acquire, consolidate, and retrieve distal environmental cues to navigate a large pool and find a hidden escape platform. Previous research has explored associations between vMWT performance and neuropsychological tests of visuospatial abilities or memory, but effective navigation may also require considerable

executive resources to select search strategies and monitor performance. Executive functions refer to higher-level control of cognitive processes, including cognitive flexibility, planning, and logical reasoning. The objective of this study was to assess associations between spatial navigation and cognitive abilities in three areas: 1) executive functioning (measured using Delis-Kaplan Executive Function System [D-KEFS] Towers, Category Switching, and Color-Word Interference subtests); 2) verbal skills (category and lexical fluency tasks); and 3) visuospatial ability (Mental Rotations Task). We hypothesized that higher executive functioning and visuospatial abilities, but not verbal skills, would be associated with lower latency and distance to complete vMWT learning trials. Furthermore, we predicted that associations between executive functioning and navigation performance would be strongest during the first trial of the vMWT, which requires selection and employment of effective search strategies. Participants included 55 adults (8 males, 47 females; ages 18-52). As predicted, higher total latency to complete vMWT learning trials was associated with lower set switching ($r = -.33$, $p = .03$) and longer time to complete the Color-Word Interference task ($r = .3$, $p < .05$), which measures ability to inhibit irrelevant information . Longer vMWT total distance was also associated with more errors on a visuospatial task requiring mental rotation of objects ($r = .41$, $p < .01$). Regarding performance on the first trial of the vMWT, the association between lower latency to find the hidden platform and higher set switching accuracy trended toward significance ($r = -.27$, $p = .06$). Our findings indicate that the ability to inhibit irrelevant information, use logical reasoning, and switch between mental sets are important considerations in one's ability to spatially navigate, in addition to memory and visuospatial ability. This may inform our knowledge of factors that may contribute to age-related differences in navigation performance.

Title: Virtual water maze performance in middle-aged adults

Authors: *N. T. NOWAK[1], J. DOSHI[2], L. KORTHAUER[1], E. AWE[1], C. DAVATZIKOS[2], I. DRISCOLL[1];
[1]Psychology, UW - Milwaukee, Milwaukee, WI; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Spatial navigation performance declines with age and often shows a male advantage. Computerized versions of traditional rodent learning and memory tasks, such as the virtual Morris water maze (vMWM), provide a means to test human navigation in a controlled setting. Navigation outcomes have been related to the BOLD response, identifying a number of brain regions associated with performance, including the hippocampus, caudate nucleus, parahippocampal gyrus, prefrontal, parietal, and posterior cingulate cortices. Brain structural integrity declines with age and has also been related to navigation. For example, the volumes of some of these same areas identified with fMRI were related to age differences in navigation performance (e.g., Moffat et al., 2007). The purpose of this study was to assess the relationships between age, sex, vMWM performance and volumes of brain regions implicated in navigation. Imaging was performed on a 3T GE scanner at the Medical College of Wisconsin. A multi-atlas label fusion method was applied for ROI segmentation (Doshi et al., 2013). Multiple atlases were warped individually to the target image (Ou et al., 2011). An image intensity based term was used for modulating the segmentations in the boundaries of the ROIs according to the intensity profile of the subject image. Volumetric measurements were calculated in each ROI. Our sample (N = 103; 59 women) of non-demented individuals (Dementia Rating Scale: M=140; MMSE = 29) ranged between 40 and 61 years of age (M = 51). Older age was associated with more time and longer distance to find the hidden platform, and greater heading direction error across the hidden platform and probe trials (p's ≤ 0.05). We rated each participant's strategy as either "place" (i.e., taking a relatively direct path from start to platform) or "random" (i.e., relatively circuitous path) from maps of their search paths. Those categorized as using a place strategy outperformed those categorized as using a random strategy on most measures of navigation performance (p's ≤ 0.05). In contrast to many studies of younger adults, we did not observe a male advantage in vMWM performance. We did not observe significant relationships between navigation and gray matter volumes (e.g., hippocampus, caudate nucleus) that have been reported in samples that include younger and older adults, albeit significant brain atrophy is not expected within our narrow age group of middle-aged adults. However, our results are congruent with the age-related deficit in navigation performance reported in other studies, and provide further evidence that wayfinding may begin to decline in middle age before the detection of overt cognitive impairment.

Title: Associations between pattern separation and structural brain integrity in middle age

Authors: *L. E. KORTHAUER, N. T. NOWAK, E. AWE, I. DRISCOLL;
Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Pattern separation is a process that segregates overlapping information, reduces interference, and allows the establishment of unique representations between memories that share similar elements. Transverse patterning discrimination task (TPDT) requires pattern separation for successful performance and is dependent on the hippocampus, a structure critical for normal learning and memory and often implicated in age-related cognitive decline (Driscoll & Sutherland, 2005). The aim of the present study was to characterize TPDT performance in midlife and to identify associations with structural brain integrity, as subtle differences in brain-behavior relationships may emerge years before the onset of overt impairment. Healthy adults (n = 71) aged 40 to 60 completed the TPDT and underwent multimodal MR imaging. The TPDT begins with a set of three phases of elemental discriminations (A+B-, C+D-, E+F-; non hippocampus-dependent). Phases 4-6 are transverse patterning discriminations (phase 4: G+H-; phase 5: G+H- and H+I-; phase 6: G+H-, H+I-, I+G-). To assess structural brain integrity, cortical reconstruction and volumetric segmentation of T1-weighted SPGR data was performed with Freesurfer Version 5.3.0 (http://surfer.nmr.mgh.harvard.edu). Within this middle-aged sample, older age was associated with more trials to complete the transverse patterning phases ($p < .01$), while there was no association between age and the number of trials to acquire elemental discriminations. The associations between hippocampal volume and number of trials to acquire elemental or transverse patterning discriminations after controlling for age and intracranial volume were not significant. However, a higher number of trials to complete transverse patterning was associated with lower cortical thickness across a range of frontal brain regions, including the left frontomarginal gyrus ($p = .01$), left transverse frontopolar cortex ($p = .02$), bilateral inferior frontal cortex ($p's < .05$), bilateral middle frontal sulcus ($p = .04$), and right superior frontal sulcus ($p = .02$). Significant correlations were also found in the anterior ($p < .01$) and mid-anterior ($p = .04$) cingulate cortex and bilaterally in the pre- and post-central gyri ($p < .05$); more trials to complete transverse patterning were associated with thinner cortex in these regions. These correlations remained significant after controlling for age. Collectively, these findings suggest that age-related deficits in pattern separation may begin in middle age and that

TDPT performance is associated with the structural integrity of underlying brain regions, particularly in the frontal cortex.

Title: Which way and how far? Tracking of translation and rotation information for human path integration

Authors: ***E. R. CHRASTIL**[1,2], K. R. SHERRILL[1,2], M. E. HASSELMO[1], C. E. STERN[1,2]; [1]Dept. of Psychological & Brain Sci., Boston Univ., Boston, MA; [2]Athinoula A. Martinos Ctr. for Biomed. Imaging, Charlestown, MA

Abstract: Path integration, the constant updating of a navigator's knowledge of position and orientation during movement, requires both visuospatial knowledge and memory. This study aimed to resolve current questions regarding distance coding in the human brain and to additionally investigate coding of rotation signals that are also important for navigation. To achieve these goals, this study examined the brain mechanisms that support the tracking and memory of translational and rotational components of human path integration. We used functional imaging to investigate two fundamental elements of path integration: 1. Distance tracking: translation in a straight line, and 2. Angle tracking: rotation in place. Critically, movement had no defined end-point or goal, in contrast to previous studies. Rather, navigators accumulated translational and rotational information during passive virtual self-motion. Univariate parametric results show that activity in hippocampus, retrosplenial cortex (RSC), and parahippocampal cortex (PHC) increased with movement during both distance and angle encoding, suggesting these regions track translation and rotation during path integration. By implementing a modified delayed match to sample (DMS) paradigm, we also examined the encoding and maintenance of path integration signals. Results of the DMS paradigm showed that hippocampus, RSC, and PHC were recruited during successful encoding and maintenance of path integration information, with RSC selective for tasks that required processing heading angle changes. Preliminary functional connectivity analysis of this navigational network, as well as

motion processing areas hMT+ and V6 and frontal executive function regions mPFC and dlPFC, showed functional connections between these areas during both encoding and delay. These results suggest that processing in this navigational hub (hippocampus, PHC, and RSC) relies on communication with regions sensitive to optic flow (hMT+ and V6) and executive function areas (mPFC and dlPFC). Furthermore, these functional connections were stronger for participants who were more accurate at the two tasks, suggesting that coordinated processing by brain regions in multiple networks could underlie individual abilities in human path integration. Together, the results provide evidence that hippocampus, PHC, and RSC flexibly track task-relevant translation and rotation signals for path integration and could form the hub of a more distributed network supporting spatial navigation.

Title: High confidence false memory for spatial context is mediated by the parahippocampal cortex

Authors: *J. M. KARANIAN, S. D. SLOTNICK;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Prior research suggests that the primary role of the parahippocampal cortex is processing of spatial layouts and sensory details (e.g., Epstein & Kanwisher, 1998; Epstein & Ward, 2010), while other work suggests that the parahippocampal cortex mediates spatial and non-spatial contextual processing (e.g., Diana et al., 2011; Eichenbaum et al., 2007). The large majority of studies have reported that parahippocampal cortex activity is greater during true memory than false memory, which seems to support the sensory processing hypothesis as true memories have greater sensory detail than false memories. However, contextual details were also greater for true memory than false memory in these studies such that sensory processing and contextual processing were confounded. To better assess the role of the parahippocampal cortex, in a previous fMRI study, we dissociated sensory and contextual processing for true memory and false memory so that false memories required relatively more contextual processing than true memories (Karanian & Slotnick, 2014). In that study, we found greater parahippocampal cortex

activity for false memory than true memory, which supports the contextual processing hypothesis. In the present fMRI study, we further investigated the role of the parahippocampal cortex by assessing activity in this region as a function of context memory confidence. We hypothesized that high versus low confidence false memories for spatial context would be associated with greater activity in the parahippocampal cortex, under the assumptions that high confidence false memories are associated with relatively greater spatial context processing and that both high and low confidence false memories lack sensory detail. Data from 16 participants were acquired at 3T with a 32-channel head coil and a random-effect general linear model analysis was conducted. During encoding, participants viewed abstract shapes to the left or right of fixation. During retrieval, old items were presented at fixation and participants identified the context of each item as either previously in the "left" or "right" visual field followed by an"unsure"-"sure"-"very sure" confidence rating. Preliminary analyses revealed greater parahippocampal cortex activity for high confidence false memories (context incorrect-"very sure") as compared to low confidence false memories (context incorrect-"unsure"). To our knowledge, this is the first time that the parahippocampal cortex has been found to be modulated as a function of context memory confidence. These findings provide additional support for the hypothesis that the parahippocampal cortex mediates contextual processing.

Title: Visual field position biases in the human medial temporal lobe

Authors: *K. F. LAROCQUE, N. WITTHOFT, K. GRILL-SPECTOR, A. D. WAGNER; Dept. of Psychology, Stanford Univ., Stanford, CA

Abstract: The medial temporal lobe (MTL) is known to play a critical role in episodic memory. Functional neuroimaging and lesion data suggest that MTL subregions play differential roles in processing distinct types of event content, with perirhinal cortex (PRc) and parahippocampal cortex (PHc) playing differential roles in processing complex visual stimuli (e.g., faces, objects) and visuospatial information (e.g., scenes), respectively. Here, we examined whether MTL subregions play differential roles in processing content that is encountered in distinct positions in the visual field. Specifically, we examined whether eccentricity biases present in visual cortical regions that differentially project to MTL subregions are propagated forward to these MTL subregions, and whether biases for stimuli presented in the contralateral visual field are also propagated forward to the MTL. In two studies (n = 6, n = 5), participants underwent fMRI at 3T. Participants maintained fixation while viewing visual stimuli presented in different locations across the visual field. MTL subregions were anatomically defined in native space for each participant. Within each subregion, we examined the degree of activation for stimuli presented in the center relative to the periphery of the visual field (eccentricity bias), and within each hemisphere of each subregion, we examined the degree of activation for stimuli presented in the contralateral relative to ipsilateral visual hemifield (hemifield bias). In both studies, PRc and PHc showed differential eccentricity biases: PRc showed a stronger bias for stimuli presented in the center of the visual field relative to PHc. Additionally, MTL subregions showed biases for stimuli presented in the contralateral visual hemifield. These findings suggest that visual field biases are present in MTL subregions, with distinct MTL subregions demonstrating distinct visual field biases, and provide insights into the roles that these subregions play in declarative memory for distinct types of event content.

Title: Incongruent visual animations make unrelated narratives more memorable by driving stronger brain responses

Authors: *S. S. COHEN[1,3], L. C. PARRA[2];
[2]Biomed. Engin., [1]City Col., New York, NY; [3]Psychology, The Grad. Ctr. at the City Univ. of New York, New York, NY

Abstract: Our ability to remember a story is dependent on reliable encoding of the initial experience. We wondered if the initial encoding can be facilitated by exposing subjects to incongruent sensory stimuli via a separate sensory channel. We hypothesized that visual context, even if unrelated, will more effectively drive brain responses to an auditory narrative and therefore result in improved retrieval. To test this we presented autobiographical narratives both with and without accompanying animations while recording electroencephalographic responses and assessed memory three weeks later. We found that audiovisual narratives were recalled more effectively than the identical story presented as audio alone for all 10 stories tested. Notably, this benefit was almost as strong when the animations were incongruent with the semantics of the audio, and despite the fact that the visual information in isolation did not result in any meaningful recall. As predicted, the memory benefits coincided with an increase in the reliability of brain responses evoked by each story across individuals . Moreover, subjects with more reliable brain responses also recognized story elements better even after controlling for stimulus modality. Finally, information was retained more accurately if evoked responses were more reliable during the presentation of the relevant information. Our interpretation of these results, supported by a corresponding modulation of alpha activity, is that these audiovisual stimuli effectively engage attention, driving the brain more reliably, and making the story more memorable, even when the visuals do not contribute any factual information.

Title: The impact of visual interference on representational content in the medial temporal lobe and ventral visual stream regions during a delayed match-to-sample task

Authors: *E. B. O'NEIL, A. C. H. LEE;
Psychology, Univ. of Toronto, Scarborough, Scarborough, ON, Canada

Abstract: Recent findings (see Graham et al. Neuropsychologia, 2010 for review) suggest that the perirhinal cortex (PRC), a medial temporal lobe (MTL) region that receives a majority of its inputs from the ventral visual pathway, supports perceptual discrimination of complex objects. This finding has led some to view PRC as the apex of the ventral visual pathway (Murray & Bussey, TICS, 1999). This role in perception is in addition to the well-known role of the MTL in declarative memory, as well as recent work pointing to a role of this region in supporting working memory for faces and objects. Despite a growing acceptance of the broader contributions of the MTL beyond declarative memory, little is known about the specialized role ventral visual stream (VSS)- and PRC-based representations serve as visual information is perceived, maintained and encoded. This is in part due to the fact that perceptual discrimination tasks typically used to probe non-mnemonic contributions of MTL structures require discriminating between several concurrently presented stimuli. Here, we used functional magnetic resonance imaging to examine MTL and VSS responses to individual stimuli in the context of a delayed match-to-sample task designed to address these issues. A study item was presented, and following a delay, participants were presented with a test item, indicating with a button press if this item differed from the study item. Critically, interfering items from a different stimulus category than the target were presented to participants while the target item was being maintained in working memory, creating conflict between the contents of working memory and ongoing perception. This design, in conjunction with representational similarity analysis and multivoxel pattern analysis approaches, allowed category evidence to be tracked and compared at each phase across the brain. Our preliminary findings revealed differential contributions of MTL and VSS structures across perception, maintenance, and interference phases. Together, our findings help shed light on the specialized nature of representations in the VSS and MTL, and how these representations support perception as well as working and long-term memory.

Title: Neural spatial memory ROCs indicate the hippocampus operates in a threshold manner

Authors: *B. JEYE[1], J. M. KARANIAN[1], P. P. THAKRAL[2], S. D. SLOTNICK[1];
[1]Psychology, Boston Col., Chestnut Hill, MA; [2]Ctr. for Vital Longevity, Univ. of Texas, Dallas, TX

Abstract: There is a long-standing debate as to whether recollection is a threshold/all-or-none process or a continuous/graded process. To differentiate between these two models of recollection, the shape of the receiver operating characteristics (ROC) - a plot of hit rate versus false alarm rate - can be evaluated. Specifically, a threshold model predicts a linear ROC, whereas a continuous model predicts a curved ROC. In the current functional magnetic resonance imaging (fMRI) study, we evaluated the shape of the ROC generated from activity in the hippocampus, a region known to be involved in recollection. During encoding, participants viewed abstract shapes in the left or right visual field. During retrieval, the same shapes were presented at fixation and participants classified each shape as previously in the "left" visual field or previously in the "right" visual field, followed by a three point confidence rating ("unsure", "sure", or "very sure"). To isolate neural activity associated with recollection of spatial information for the left visual field, we contrasted accurate memory for items in the left visual field (old-left-hits) versus inaccurate memory for items in the left visual field (old-left-misses). This contrast produced two activations in the hippocampus. To isolate neural activity associated with recollection of spatial information for items in the right visual field, we contrasted accurate memory for items in the right visual field (old-right-hits) versus inaccurate spatial memory for items in the right visual field (old-right-misses). This contrast did not produce any activations in the hippocampus. We also collapsed across visual field and contrasted all old-hits versus old-misses, which produced two additional activations in the hippocampus. Five-point ROCs were generated by plotting the hit rate versus false alarm rate based on the magnitude of hippocampal activity associated with each confidence rating for old-left shapes and old-right shapes ("very sure right", "sure right", "unsure right", "unsure left", "sure left", "very sure left"). The two hippocampal ROCs that differed from chance were linear and better fit by a threshold model than a continuous model. These hippocampal ROCs are distinct from behavioral ROCs, which are always curved and better fit by a continuous model than a threshold model. The present results indicate that the hippocampus operates in a threshold manner during recollection.

Title: Spontaneous use of spatial memory strategies are associated with greater cortical plasticity following a virtual spatial memory intervention program in healthy older adults

Authors: *V. D. BOHBOT[1], D. SODUMS[1], K. KONISHI[1], L. DAHMANI[1], L. BHERER[2];
[1]Douglas Mental Hlth. Univ. Institute, Dept. of Psychiatry, McGill Uni, Verdun, QC, Canada;
[2]CRIUGM, Dept. of Psychology, Univ. of Montreal, Montreal, QC, Canada

Abstract: Aim: People spontaneously use different strategies dependent on the hippocampus (HPC) and caudate nucleus (CN) when navigating in virtual environments. In previous studies, we found the use of spatial memory strategies to be associated with increased activity and grey matter in the HPC while the use of stimulus-response strategies is associated with increased activity and grey matter in the CN. While healthy aging affects grey matter in both the HPC and CN, the HPC shows an accelerated atrophy relative to other brain areas. As such, we developed a computerized spatial memory intervention program (SMIP) to specifically stimulate the HPC. This program was designed to promote the use of spatial memory strategies, taking particular attention to avoid use of stimulus-response strategies. The goal of this study was to investigate whether initial spontaneous navigation strategies affect grey matter as a result of the SMIP intervention. Methods: Healthy older adult participants (n=21) underwent the SMIP or control condition (n=33). The SMIP is comprised of 16 one-hour spatial memory training sessions administered twice a week over 8 weeks. Each participant underwent assessment of spontaneous navigational strategies with the 4 on 8 virtual maze, as well as a Magnetic Resonance Imaging scan before and after the SMIP. Results: After the SMIP, there was an increase in grey matter throughout cortex, including the frontal, parietal, temporal cortices, and bilateral HPC. Participants were categorized as responders (n=11) or non-responders (n=10) depending on whether they showed a significant increase in grey matter. As predicted, spontaneous navigation strategy significantly predicted hippocampus and cortical plasticity: 88% of spatial learners showed cortical plasticity as a result of the SMIP, as opposed to only 25% of response learners. In other words, in the responder group there were significantly more spatial learners (7/11) than in the non-responder (1/10), as determined by a chi square test ($p<0.05$). Conclusion: These results indicate the potential efficacy of a spatial memory training program at increasing HPC grey matter, and sheds further light on the relationship between navigational strategy, the HPC and its associated cortical circuits. Specifically, we showed that spontaneous spatial navigational strategies are associated with greater grey matter plasticity as opposed to the response strategy which is associated with cortical rigidity. Such evidence has substantial implications in regards

to the potential of spatial memory training programs at reducing the chances of developing memory deficits through the beneficial effect on HPC grey matter.

Title: High total cholesterol and LDL-cholesterol levels are associated with decrease use of hippocampal-dependent spatial strategies

Authors: *K. KONISHI[1], R. JOOBER[2], K. MACDONALD[2], J. BREITNER[3], V. D. BOHBOT[2];
[1]Psychiatry, Douglas Mental Hlth. Univ. Institute, McGill Univ., Verdun, QC, Canada; [2]Douglas Mental Hlth. Res. Inst., Montreal, QC, Canada; [3]Psychiatry, Ctr. for Studies on Prevention of Alzheimer's Dis. (StoP-AD), Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: People can navigate in a new environment using multiple strategies, which are dependent on different memory systems. The spatial strategy is associated with increased fMRI activity and grey matter in the hippocampus while the response strategy is associated with increased fMRI activity and grey matter in the caudate nucleus. High cholesterol levels are associated with atrophy in the hippocampus and cognitive impairment in older adults. As such, in the current study we investigated the functional relationship between plasma cholesterol levels and the function of the hippocampus in humans. Specifically, we investigated the association between total cholesterol, high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C) levels, and navigation strategies. Methods: 139 healthy older adult participants (mean age = 65.8 ± 4.4 years) were tested in this study. Medical history pertaining to the use of cholesterol-lowering medication was obtained using a questionnaire. Participants were tested on the 4on8 virtual maze (4/8VM). The 4/8VM consists of an 8-arm

radial maze, in which 4 arms are accessible and 4 are blocked. Participants have to retrieve objects located at the end of the 4 accessible arms. Then, all 8 arms become accessible and participants have to retrieve objects now located in the 4 arms that were previously blocked. After participants have learned the task, a probe trial is given in which all landmarks are removed. On the probe trial, those that used a spatial strategy make more errors compared to those that used a response strategy because they relied on the landmarks to remember the object locations. A verbal report is administered at the end of the task to assess navigation strategy use. A subset of participants (n = 63) fasted for 12 hours and gave blood samples for lipid profiling. Total cholesterol, HDL-C, and LDL-C levels were measured from the blood samples. Results: We found that people using response strategies have significantly higher levels of total cholesterol and LDL-C levels compared to those using spatial strategies. Furthermore, cholesterol-lowering medication had a modulatory effect on navigation strategy, whereby there was a significantly higher proportion of spatial strategy users among those who take cholesterol-lowering medication. Conclusion: In the current study, we show high total cholesterol and LDL-C levels may decrease the use of strategies that are associated with increased grey matter and function in the hippocampus. These results help explain the relationship between cholesterol and cognition and may have implications for healthy aging.

Title: Common neural correlates of spatial memory and olfaction

Authors: *L. DAHMANI[1], R. PATEL[2], M. CHAKRAVARTY[2], V. D. BOHBOT[2];
[1]McGill Univ., Verdun, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Aim: In a previous study, we found that spatial memory was associated with increased fMRI BOLD activity and grey matter density in the hippocampus and medial orbitofrontal cortex, among other areas. In fact, the orbitofrontal cortex was previously shown to be involved in olfactory identification and we previously found spatial memory and olfactory identification to

be positively related. The aim of the current study was to determine whether olfactory identification and spatial memory have common structural neural correlates. Methods: We tested 58 healthy young adults on a test of olfactory identification, the Monell Extended Sniffin' Sticks Identification Test (MONEX). On this test, participants have to smell 40 sticks and have to identify the odour among four presented choices. Participants also underwent structural MRI scanning and were administered two virtual navigation tasks, namely the 4-on-8 virtual maze and the virtual town wayfinding task. In the 4-on-8 virtual maze, participants have to learn the location of 4 objects among 8 arms. In the wayfinding task, they have to learn the location of 8 landmarks in a virtual town. We used MAGeT-Brain (Multiple Automatically Generated Templates) to automatically segment and measure the volume of hippocampal subfields and extra-hippocampal white matter using multiple atlases and investigated the relationship between these volumes and navigation and olfactory performance. Results: MONEX scores positively correlated with white matter volume of the right fimbria and the left fornix. In the 4-on-8 virtual maze, faster learning was positively correlated with white matter volume in the same areas. In the wayfinding task, there was a positive correlation between the percentage of landmarks that participants were able to locate and white matter volume in the right fimbria. Conclusion: We had previously found that spatial memory performance was positively associated with olfactory identification. In the current study, we additionally show that both spatial memory and olfactory identification are related to the volume of extra-hippocampal white matter. Our results indicate that spatial memory and olfaction are related functions and that this relationship may be mediated by their common neural correlates.

Title: Dopamine and verbal memory: the effect of an acute phenylalanine/tyrosine depletion on the word frequency mirror effect task

Authors: ***Z. K. CHAUDHARY**[1], J. THERRIAULT[2], A. DAGHER[3], M. LEYTON[4], V. D. BOHBOT[2];

[1]Neurosci., [2]McGill Univ., Verdun, QC, Canada; [3]Neurol. & Neurosurg., [4]Dept. of Pschiatry, McGill Univ., Montreal, QC, Canada

Abstract: Aim: In recognition memory, familiarity and recollection involve distinct memory processes that rely on different neural correlates. Both deficits are seen in at least some patients with Parkinson's disease (PD), but familiarity deficits develop earlier than recollection problems. It remains unclear whether either deficit reflects loss of dopamine neurons. To investigate the role of dopamine in recognition memory more directly, we tested whether decreasing dopamine synthesis in healthy volunteers would produce the pattern of performance deficits that is seen in patients with PD. Methods: Twenty healthy young adults (mean age = 24 y.o.) were tested in a within-subject, double-blind, counter-balanced, placebo-controlled experiment to lower dopamine synthesis using the acute phenylalanine/tyrosine depletion (APTD) method. Participants took part in two testing days one month apart where they ingested an amino acid mixture that was i) nutritionally-balanced (BAL), or ii) devoid of the dopamine precursors, phenylalanine and tyrosine (APTD). Performance on the word frequency mirror effect task was assessed on both days following presentation of 48 words to memorize (half high frequency (HF), half low frequency (LF)). After a delay participants classified 96 words (half old, half new) as "Remember" (conscious recollection), "Know" (familiar: no specific contextual recollection) or "New" Results: An analysis of variance revealed that there was no significant 3-way interaction between the 3 variables; test day (APTD vs. balance), word frequency (high or low) and scores (hits or false positives) previously reported in Parkinson's patients, who had elevated false alarm rates for high frequency words. A 2-way ANOVA comparing hits and false positives separately across test day irrespective of subjective Remember/Know judgments showed no main effect of test day and similar number of hits and false positives. On both days the word frequency mirror effect was replicated; there was a main of effect of word frequency (more hits to LF compared to HF words and more false positives to HF than to LF words, $F(1, 15)= 28.62$, $p<0.001$). Conclusions: We replicated the word frequency mirror effect, but this was not modulated by decreased dopamine synthesis. It is possible that an analogous performance pattern between Parkinson's and the APTD condition was not seen since the extent to which the latter lowered dopamine was less than that seen in patients ($\geq$ 80% vs. 30 to 50%). Alternatively, dopamine might not directly influence recognition memory. For example, familiarity recognition memory deficits are usually apparent only in those with additional non-dopamine related symptoms.

Title: Strategy changes across the menstrual cycle and with maternal experience in a human virtual navigation task

Authors: *D. HUSSAIN[1], S. HANAFI[2], K. KONISHI[2], W. BRAKE[1], V. D. BOHBOT[2]; [1]Psychology, Concordia Univ., Montreal, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: A spatial or response strategy can be used to learn to navigate an environment, and these strategies depend on the hippocampus and the caudate nucleus, respectively. In rodents, high estradiol (E2) has been shown to bias females to use a spatial strategy while low E2 is associated with response strategy use (Korol et al., 2004; Quinlan et al., 2008). However, this effect disappears with reproductive experience (Hussain et al., 2013). In women, steroid hormones vary over the course of the menstrual cycle such that E2 peaks during the second half of the cycle (i.e. the luteal phase). Furthermore, the high E2 phase of the menstrual cycle is associated with an increase in hippocampal grey matter (Protopescu et al., 2008). We therefore hypothesized that women tested during the luteal phase would be more likely to use a spatial strategy on a virtual navigation task, and that this difference would no longer be observed in mothers. **Methods:** Fifty-four young women with (n = 28) and without (n = 26) maternal experience (ages 23-36 years) were tested either during the follicular (n = 23) or luteal (n = 31) phase of the menstrual cycle on the 4-on-8 virtual maze (4/8VM). The 4/8VM consists of an 8-arm radial maze, in which 4 arms are open and 4 are blocked. Participants have to retrieve objects located at the end of the 4 open arms. Then, all 8 arms are open and participants have to retrieve objects now located in the 4 previously blocked arms. Strategy use is assessed with a verbal report and a probe trial in which all landmarks are removed, leading to impaired performance in spatial learners. **Results:** Consistent with our hypothesis, it was found that women tested in the luteal phase predominantly used a spatial strategy (64.5%), whereas the opposite pattern was observed in the follicular group (spatial = 30.4%; X^2 = 6.14, p = .013). Contrary to our hypothesis, this pattern was also observed in women with maternal experience (X^2 = 5.04, p = .025). In addition, non-mothers needed more trials to reach criterion in the luteal than in the follicular phase, whereas the opposite pattern was observed in mothers ($F_{(1,50)}$ = 6.38, p = .015, η^2 = .113). **Conclusion**: These findings suggest that women tend to use a spatial strategy when tested during the luteal phase whereas they tend to use response during the follicular phase, and this occurs with and without maternal experience. This indicates that multiple memory system bias changes with fluctuating E2 levels across the menstrual cycle; however, unlike in rodents, this does not change with reproductive experience.

Abstract: In the present study, we examined the role of the medial temporal lobe (MTL) in prospective time estimation at short and long timescales using a novel behavioral paradigm adapted from rodent work. Amnesic patients with MTL damage and healthy control participants estimated the duration of nature-based video clips that were either short (less than or equal to 90 seconds) or long (more than four minutes). Consistent with previous work in rodents, we found that amnesic patients were impaired at making estimations for long, but not for short durations. Critically, these effects were observed in patients who had lesions circumscribed to the hippocampus, suggesting that the pattern observed was not attributable to the involvement of extra-hippocampal structures. That the MTL, and more specifically the hippocampus, is critical for prospective temporal estimation only at long intervals suggests that multiple neurobiological mechanisms support prospective time estimation.

Title: Damage to the medial temporal lobes impairs spatial precision and spatiotemporal binding while sparing allocentric memory

Authors: *B. KOLARIK[1,2], K. SHAHLAIE[3], A. HASSAN[2], A. BORDERS[1], K. KAUFMAN[1], G. GURKOFF[3], A. YONELINAS[1], A. EKSTROM[2];

Abstract: Separate lines of research suggest roles for the human hippocampus in both spatial navigation and the binding of item and context information in episodic memory. Reconciling these two accounts has proven difficult. Here, we tested a novel model of hippocampal function termed the precision and binding model (PBM) (Yonelinas, 2013), which postulates roles for the hippocampus in complex, high-resolution binding as part of a larger role in both spatial navigation and episodic memory. Using a virtual analogue of the Morris Water Maze (vMWM), we tested a patient with damage to the medial temporal lobes (MTL) on multiple target locations. We analyzed search patterns on probe trials using a sliding window centered on the target rather than employing spatial quadrants, as done in past work, to better test for deficits in spatial precision. Analysis of patient search patterns during probe trials revealed a tendency to search in the vicinity of the hidden platform although with less spatial precision than controls. These data suggest some sparing of allocentric spatial memory in patients with MTL damage but that the precision of this memory is reduced relative to controls. To further characterize the precision deficit we used a curve fitting analysis to model the accuracy of the search trajectories for the patient and the lowest performing half of our control sample. This analysis revealed that control performance was best fit with a second-order function indicating precise memories for the target location even at the smallest analysis window. In contrast, patient performance required a third parameter to capture the steep drop in precision as the analysis window decreased in size. These results highlight the severe precision deficit the patient displayed relative even to the worst

performing controls. Additionally, we show that memory and precision impairments become more severe when the patient was required to remember more than one target location, suggesting deficits in spatiotemporal binding. Together, our findings suggest a role for the hippocampus in spatial precision and spatiotemporal binding, consistent with the PBM model.

Title: High-resolution hippocampal activation patterns predict memory precision

Authors: *A. A. BORDERS[1], J. D. STOKES[1,2], C. T. KYLE[2], A. D. EKSTROM[1,2], A. P. YONELINAS[1];
[1]Psychology Dept., [2]Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: The human hippocampus is widely known to support human episodic memory, however, recent evidence suggests that the hippocampus may serve a more specific role in insuring the encoding and retrieval of precise details and associations of memories during both episodic and working memory tasks (Yonelinas, 2013). In contrast, surrounding regions in the medial temporal lobe (MTL), e.g. parahippocampal cortex, are thought to support comparable memory processes using coarse, less precise representations. However, given the complex connectivity profile within the MTL, it seems likely that dynamic interactions between subregions within the MTL act together to support a range of memory precision, ultimately predicted by task demands. To explore these network dynamics, we collected high-resolution functional images of the MTL during an associative recall task. Participants were presented with a location on a circle followed by a unique word and asked to memorize the pair. At retrieval, a studied word was presented and the participant used a mouse to indicate the precise recalled location paired with the word. This allowed for assessment of precision-evoked activation during encoding and retrieval. Participants were also asked to rate their confidence regarding their accuracy on each trial. Results showed that cortical areas in the medial temporal lobe were involved during the retrieval of the word-location pairs, but activity in these regions did not

differentiate between precise and coarse retrieval responses. In contrast, patterns of activation within the hippocampal subregions predicted increased memory precision and memory confidence.

Title: Dynamic spatiotemporal organization of individual episodic memory retrieval networks

Authors: ***A. SCHEDLBAUER**[1], A. WATROUS[2], C. KADIPASAOGLU[3], N. TANDON[3], A. EKSTROM[1];
[1]Univ. of California, Davis, Davis, CA; [2]Univ. of Bonn, Bonn, Germany; [3]Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Past work has suggested that increases in functional connectivity characterize successful episodic memory retrieval, as measured through phase consistency between distal electrodes in electrocorticography (ECoG) patients and beta time-series correlations in healthy participants undergoing functional magnetic resonance imaging (fMRI). However, multilobular ECoG recordings, in addition to offering excellent regional coverage, also offer superior temporal resolution. Capitalizing on both the superior spatial and temporal resolution of ECoG, we investigated whether the evolution of specific network configurations might also be predictive of correct episodic memory retrieval. We hypothesized that the single-trial evolution of networks underlying correct memory retrieval would involve lower variability in node connectivity compared to incorrect retrieval. Patients performed an episodic memory task in which they freely navigated a virtual environment and encoded spatiotemporal contextual details.

Those who performed above chance were able to remember information regarding spatial and temporal distances between landmarks visited during navigation. Adapting pairwise phase consistency (PPC: Vinck et al. 2010) for single trial estimates, we replicated our earlier findings of greater connectivity for correct versus incorrect retrieval but at the single trial level. We then employed the global variability coefficient (GVC: Cole et al. 2013) to assay variability in connectivity across nodes while simultaneously controlling for differences in connectivity between the two networks. We found overall lower GVC in the correct compared to the incorrect network, indicating a more stable pattern of connectivity over time within the correct retrieval network. Our findings suggest that changes in the configurations of networks of interacting brain regions can provide novel insight into whether memory retrieval will succeed or fail, even on a single trial.

Title: Integration of familiar and novel spatial templates in episodic memory

Authors: *J. STOKES[1], C. KYLE[2], A. EKSTROM[3];
[1]Ctr. for Neurosci., UC Davis, Davis, CA; [2]Ctr. for Neurosci., [3]Univ. of California, Davis, Davis, CA

Abstract: Theoretical models of hippocampal function suggest its involvement in both the encoding and retrieval of familiar representations (e.g., spatial context information) as well as the rapid encoding and retrieval of novel episodic events. Yet an important and unsolved question regards how exactly the hippocampus integrates new episodic information with existing cortical

representations, for example, encoding a new event in a familiar geometry (e.g., visiting a new town that has a square-like spatial layout). In a previous study, we demonstrated that CA3/DG showed reductions in pattern similarity in response to changes in spatial context. In contrast, the CA1 subfield, historically considered a major output junction of the hippocampal formation, showed prominent increases in pattern similarity during the processing of salient shaped configurations (i.e. circle or square-shaped) compared to less distinctive configurations (i.e. morphed shapes) (Stokes, Kyle and Ekstrom, 2015). Due to the high familiarity of both shapes in the paradigm (circle and square), the extent to which integration of spatial context depends upon existing vs. novel shape templates, remains an open question To address this, prior to scanning, participants underwent extensive pre-training on irregular, novel shapes. While undergoing high-resolution fMRI targeting the hippocampus, participants processed videos of spatial environments involving the trained shape, a completely novel untrained shape, and an intermediate morph shape. Similar to our past work, participants indicated whether the environment represented in the video they had just seen was the same or different from the previous video. We predicted that CA3/DG would show pattern similarity effects that differ as a function of environmental similarity, despite the fact that these shapes were completely novel to participants. Our preliminary findings support this prediction, showing that CA3/DG serves a role in discriminating changes in spatial context during the formation of novel spatial representations, specifically during periods involving overlapping sensory information. Our second prediction involved CA1, in which we anticipated higher pattern similarity for the trained compared to untrained shape, consistent with its hypothesized role in integrating new information within the hippocampal circuit. Preliminary results suggest that CA1 shows higher sensitivity to trained templates when compared to untrained templates. Overall, these findings suggest that the interplay between novel sensory inputs and prior experience are supported by unique contributions in hippocampal subregions.

Title: A tale of two temporal retrieval strategies: dynamic expression of temporal sequence retrieval

Authors: *J. S. LIEBERMAN, C. T. KYLE, J. D. STOKES, A. D. EKSTROM;
Ctr. for Neurosci., Univ. of California Davis, Davis, CA

Abstract: Episodic memories depend on accurate retrieval of temporal details underlying specific events. Past research suggests that participants can use two fundamentally different retrieval mechanisms for retrieving the order of temporal events, one involving a recency strategy ("which object came before another object?") and the other involving an associative strategy ("were the two objects the same distance from a third object?"). Yet the neural basis for retrieving temporal information using these two strategies remains unclear. To address this, participants learned two unique sequences of objects, then performed two versions of a temporal order judgment task during whole-brain fMRI. In both versions, on each 6-s trial, participants were visually presented with 3 objects (1 target and 2 probes) and asked to make judgments about the relative positions of the objects within the list order via a button press. However, the type of judgment made was unique to each version and required participants to use a distinct retrieval strategy. In version 1 (the "chaining" task), participants used an associative recall mechanism ("are the two probes the same distance from the target?"). In version 2 (the "distance" task), participants used a temporal distance/recency judgment as the recall mechanism ("which of the two probes is closer to the target?"). We predicted that, despite the similarities in visual input and encoding, we would see differences in the brain networks involved in retrieval using the two strategies. We used univariate analyses to examine brain regions that were unique to one strategy or common to both strategies. Preliminary results showed that both mechanisms recruited the bilateral hippocampus and bilateral visual cortex, consistent with prior research. Associative retrieval, however, showed significantly greater activation than the distance task in the parietal lobe, including the right superior parietal lobule and bilateral supramarginal gyrus. In contrast, recency-based retrieval showed greater activation in the frontal and temporal lobes compared to associative retrieval, including the bilateral parahippocampal gyrus, bilateral superior temporal gyrus, and left and midline medial prefrontal cortex. In contrast to past results, which have generally conceived of retrieval involving a unitary network of brain areas ("retrieval network"), our findings show that how information is accessed during retrieval can involve fundamentally different networks of brain areas. They further argue that while temporal retrieval involves some common brain areas, recruitment of unique brain networks may be critical to how we access temporal information.

Title: Low frequency hippocampal oscillations differentiate between successful retrieval of related versus unrelated spatiotemporal context

Authors: *M. COPARA[1], K. KIM[3], M. ROLLO[3], C. KADIPASAOGLU[3], N. TANDON[3], A. EKSTROM[2];

Abstract: Current evidence strongly supports the central involvement of the hippocampus (HPC) in storing and retrieving memories for recent events. However, a critical question regards exactly how the HPC represents the 'when and where' of an event memory. Recently, we showed that HPC represents unrelated spatiotemporal information by decreasing pattern similarity across contexts, which we determined using multivoxel pattern similarity (MPS) and high-resolution functional magnetic resonance imaging (fMRI). Another candidate mechanism for storing and retrieving different vs. similar events involves frequency multiplexing, which may relate to the recruitment of distinct vs. overlapping ensembles depending on the frequency of interactions (e.g., Watrous and Ekstrom,, 2014). To address how this occurs on the fast time scale characterizing neural events, we employed intracranial electroencephalography in patients undergoing seizure monitoring while they retrieved either related or unrelated spatial and temporal contexts from a virtual reality spatial navigation task. Our preliminary findings show that there are significantly more electrodes showing greater spectral power in spatial retrieval than temporal retrieval for unrelated spatiotemporal context whereas related spatiotemporal context showed less of a difference between spatial and temporal conditions. This suggests that when patients retrieve unrelated spatial and temporal contexts, there is more neural

differentiation in the hippocampus compared to when patients retrieved related contexts and this may be an important mechanism that the hippocampus utilizes to differentiate spatiotemporal contexts.

Title: Hippocampal low-frequency oscillations elicited during virtual navigation persist in the absence of visual and self-motion cues

Authors: *L. K. VASS[1], M. S. COPARA[1], M. SEYAL[2], K. SHAHLAIE[3], S. TOMASZEWSKI FARIAS[2], P. Y. SHEN[4], A. D. EKSTROM[5];

Abstract: Low-frequency (delta/theta band) oscillations have been observed during spatial navigation in both rodents and humans, but the conditions required to elicit these oscillations in humans remain controversial. Whereas some theories propose that hippocampal low-frequency oscillations are primarily generated in response to sensorimotor input, others propose that these oscillations can be driven by internally-generated memory processes. To adjudicate between these possibilities, we recorded intracranial hippocampal EEG activity in patients undergoing seizure monitoring while they explored a virtual environment. Critically, this environment contained teleporters, which allow the patient to experience movement through space in the absence of visual (i.e., optic flow) and self-motion (e.g., vestibular, proprioceptive) cues. If low-frequency oscillations are driven solely by visual or motoric exploration of an environment, then

these oscillations should attenuate once the patient enters the teleporter. To test for this possibility, we used the oscillatory detection method P_episode to quantify the proportion of time low-frequency oscillations were present during the task. We then compared the percent time in an oscillatory state immediately prior to teleportation when patients virtually navigated in the presence of visual information to the percent time in an oscillatory state during the teleportation period. Preliminary results indicate that hippocampal low-frequency oscillations are sustained during teleportation and do not differ significantly in prevalence between visual-motor movement and teleportation periods. In contrast, higher-frequency oscillations in the beta and gamma bands were modulated by these teleportation events. These results suggest that low-frequency hippocampal oscillations can be driven by internal mechanisms and do not require visual or self-motion cues to persist.

Title: Temporal encoding strategies produce comparable boosts in free recall performance to spatial encoding strategies

Authors: ***N. R. BOUFFARD**, J. STOKES, C. KYLE, J. LIEBERMAN, A. EKSTROM; Univ. of California, Davis, Davis, CA

Abstract: The method of loci is a highly effective mnemonic technique that recruits existing salient memory for spatial locations and uses this information as a scaffold for remembering a list of items (Yates, 1966). By mentally pairing each spatial locus with a list item, the list is more likely to be recalled, and in the same order as it was presented (Bower et al., 1970; Roediger et

al., 1980). One possible account for the effectiveness of the spatial method of loci comes from the perspective that it utilizes evolutionarily preserved mechanisms for spatial navigation within the hippocampus (Macguire et al., 2003). Recently, though, neurons coding temporal features have also been described in the hippocampus (Mauk et al., 2004; Meck et al., 2013), challenging the primacy of spatial-based functions to hippocampal processing. Given the presence of both spatial and temporal coding mechanisms within the hippocampus, we predicted that temporal coding strategies might also enhance memory. In the current study, we had participants learn lists of unrelated nouns using a spatial method of loci (using the layout of their home as the scaffold) or a temporal method of loci (using autobiographical life events as the scaffold). We then tested their memory for the lists with a free recall task. As predicted, participants learned the lists the fastest when implementing the spatial method of loci compared to other strategies that participants spontaneously used prior to instruction at the beginning of the study. The temporal method also improved participants list learning speed compared to the uninstructed strategies, but not to the extent of the spatial method, which we attributed to the initial difficulty in using autobiographic events to remember list items. Participants also completed a delayed recall task at the end of the study where they were asked to recall all of the lists they had learned. We found that words learned using temporal and spatial methods were more likely to be recalled than words learned using other strategies. Importantly, we found no significant difference in delayed recall performance between the spatial and temporal methods. These results suggest that although the temporal method of encoding we employed may require more trials to master than a spatial one, temporal representations can produce comparable boosts in memory performance to spatial methods during free recall.

Title: Prospective representation of navigational events in the human hippocampus

Authors: *T. I. BROWN[1], K. F. LAROCQUE[1], S. E. FAVILA[1,2], V. A. CARR[1], A. M. GORDON[1], B. BOWLES[1,3], A. D. WAGNER[1];

Abstract: The mental representation of future states is a critical component of goal-directed behavior. The hippocampus and neighboring medial temporal lobe (MTL) cortices are believed to play a critical role in spatial navigation through representation of goal locations (McKenzie et al., 2013) and prospective location coding (Johnson and Redish, 2007), and by supporting goal-directed route planning (Brown et al., 2014; Hartley et al., 2003). Using whole-brain high-resolution functional magnetic resonance imaging (hr-fMRI), we examined whether the human MTL supports goal-directed navigation by representing future goal states during initial navigational planning. On day 1, thirteen healthy, right-handed young adults learned to navigate to hidden goal locations in a virtual circular track environment. Each location was uniquely associated with a distinct pair of fractal images. On day 2, participants repeatedly navigated to the goals during hr-fMRI scanning. Participants began each trial at a familiar location, after which the environment was hidden from view and participants were cued by of one of the fractals to plan navigation to its location. Participants subsequently navigated to this goal. Using multivoxel pattern analyses (MVPA), results demonstrate that hippocampal patterns of activity contain information during initial planning that codes the goal location to which participants will subsequently navigate. Moreover, when navigating to a distal location, classifier evidence for intervening locations along the route is greater than evidence for other non-goal locations. Hippocampal evidence for the future goal is correlated with that of an interconnected neocortical network, including MTL cortex and retrosplenial cortex. Collectively, these results suggest that the human hippocampus and related cortical structures prospectively represent future goal states, and support mental route simulation facilitating flexible planning of navigation behavior.

Title: Temporal features of narrative construction are different for healthy older adults and patients with hippocampal damage

Authors: *A. DEDE[1,4], R. O. HOPKINS[5,6], L. R. SQUIRE[4,1,2,3];
[1]Psychology, [2]Neurosciences, [3]Pyschiatry, Univ. of California San Diego, San Diego, CA; [4]Veterans Affairs San Diego Healthcare Syst., San Diego, CA; [5]Psychology and Neurosci., Brigham Young Univ., Provo, UT; [6]Pulmonary and Critical Care Division, Dept. of Med., Intermountain Med. Ctr., Murray, UT

Abstract: Patients with damage to the hippocampus have sometimes been reported to be impaired at both remembering the episodic past and imagining the episodic future. Studies in this literature have counted the number of episodic and semantic details given when participants constructed narratives about remembered and imagined events. However, analyses based on detail counts alone do not allow for inference into what aspects of narrative construction may change as a result of hippocampal damage. Our study followed a procedure developed by Race et al. (2011) in which a time limit was imposed on narratives and minimal probe questions were used. We tested patients with hippocampal lesions (n=7) and found that their narratives from the near past contained fewer details than did those of controls (but this was not the case for narratives about the remote past). Total detail counts were also similar to controls in both the near and distant future. However, analysis of the temporal dynamics of narrative construction revealed differences between the patients and controls in all time periods (even when the number of details was similar for the two groups). Controls produced narratives that were longer and more variable in duration than the narratives produced by patients. Controls produced details slowly at the beginning of their narratives but increased their speed of detail production later in their narratives. Patients exhibited the opposite pattern. In addition, controls produced more semantic information at the beginning of their narratives and more episodic information later in their narratives. Again, patients exhibited the opposite pattern. These results suggest that patients with hippocampal damage are capable of remembering richly detailed episodic past events and imagining richly detailed future events. Despite their ability to produce narratives that are richly detailed, patients with hippocampal damage still exhibited changes in their narrative structure in comparison to controls, suggesting that some aspects of narrative construction were affected by hippocampal damage. We suggest that the changes in the narrative structure of the patients may reflect the consequences of their deficit in anterograde memory.

Abstract: "Global-first" topological properties pattern recognition in Rodent Xue-Mei LIU[1], Zheng ZHOU[1], Nan LIU,Yong-qiang TANG, Li-Ping WANG[1]* *[1]Shenzhen Key Lab of Neuropsychiatric Modulation, Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences, Shenzhen 518055, China* *Correspondence: Li-Ping WANG, PhD & MD, lp.wang@siat.ac.cn **Abstract:** "Global-first" topological approach, is one of the crucial theories in primitive visual perception. Previous systematic evidence has showed that human and several animal models possess topological perception, yet the detail mechanism of this perception is poorly understood. To dissect neural circuits of topological recognition, we need simpler and more accessible animal models. Here, we designed two experimental models, trained by foot shock or food rewarding, to detected whether rodent possess topological perception. The results showed that the mice could discriminate the topological different patterns, with random choice to topological equivalent patterns. And we also demonstrated that the rats were sensitive to topological difference, but were insensitive to topologically equivalent patterns. We concluded that mice and rat both possess the ability of topological pattern recognition, thus, the models provided us a model to study the neural substrates of topological perception. **Keywords:** Topological perception; rodent;

Title: Decomposing the bilingual language control network into preparatory processes and execution

Authors: *R. SEO[1,2], A. STOCCO[1,2], C. S. PRAT[1,2];
[1]Psychology, Univ. of Washington, Seattle, WA; [2]Inst. of Learning and Brain Sci., Seattle, WA

Abstract: Bilingual language control is complex because bilinguals must select contextually appropriate words and rules to communicate in a dynamically changing target language (TL). In a recent meta-analysis, Luk et al. (2012) described 7 regions involved in bilingual language control. The majority of the paradigms investigated conflate preparatory processes (i.e., the cue indicating TL) with the execution of a task. To better understand the functions of these 7 regions, we created a paradigm where participants were instructed to use a TL by using a non-linguistic cue (# or *) before the presentation of any word on which to execute the desired operation on. To compare the processes involved in preparing to use a TL to those involved in preparing to execute a grammatical rule, a second preparation phase presented one of four grammatical rules. Afterward, participants received word stimuli in the TL of interest and were asked to mentally manipulate them according to the rule indicated. The task was subject-paced with jittered spacing between phases, allowing for the separate estimation of each phase. fMRI data were acquired from 23 early Spanish-English bilinguals. 7 spherical ROIs were defined based on the meta-analysis reported, and mean beta weights were extracted for each ROI. 3 (task phase) x 2 (TL) ANOVAs were run on each of the 7 ROIs independently, and a main effect of task phase was found for all regions. Based on the patterns of results found in the follow-up analysis, three functional sub-networks were identified. The first, a “Preparatory Network” involved the right prefrontal cortex only. This region was primarily active during the Prepare TL phase, and may be involved in inhibition. The second sub-network was identified as the “Language Tracking” network and consisted of the right caudate nucleus, left inferior frontal gyrus (BA47), and left middle temporal gyrus. This network was equally active during the Prepare TL and Execute phases, but was more active in these phases than during the Prepare Grammar phase. The fact that this network did not activate as strongly when preparing to execute grammatical rules suggests that this circuit is recruited to control TL rather than language processing in general. The final “Execution Network” consisted of regions that were more active during rule execution than in any preparatory process, and included the left middle frontal and superior frontal gyri, and Broca’s area, which is central to grammatical processes. The identification of these three circuits further reveals how each of the previously defined bilingual language control regions are involved in the preparation and execution of TL specific processes in the bilingual brain.

Title: Analysis of hemispheric differences in gene expression in primates

Authors: *A. VERENDEEV[1], G. MUNTANÉ[3], T. M. MAYNARD[2], C. C. SHERWOOD[1]; [1]Dept. of Anthrop., [2]Dept. of Pharmacol. and Physiol., George Washington Univ., Washington, DC; [3]Inst. de Biologia Evolutiva, Univ. Pompeu Fabra - CSIC, Barcelona, Spain

Abstract: Language and handedness are two examples of asymmetrical brain function in humans. Although these behaviors have been well characterized in their neurobiology and neuroanatomy, their genetic underpinnings have not been explored in much detail. Using qPCR, we assessed hemispheric differences in gene expression in rhesus macaque (*M. mulatta*, n=5) and humans (n=5) in genes previously associated with language and handedness (*pcsk6*, *mns1*, *gli3*, *mgrn1*, *foxp2*, *kiaa0319*, *lefty1*, *nodal*, *drd4*, and *ccdc78*). Overall, we found no evidence of differential expression between the two hemispheres among the genes examined. However, *kiaa0319*, a gene implicated in dyslexia in humans, showed a very pronounced lateralization in its expression with a strong leftward bias. *Foxp2*, on the other hand, did not differ in its expression between the two hemispheres in either species.

Title: Developmental changes in the functional and structural connectivity within brain networks involved in phonological processing

Authors: *B. L. SUSSMAN[1], Y. LIU[2], F. CAO[1];
[1]Communicative Sci. and Disorders, Michigan State Univ., East Lansing, MI; [2]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: We investigated concomitant developmental changes in structural and functional connectivity in the neural language networks of Chinese children and adults with DTI and PPI analyses. We investigated functional connectivity in the language network during an auditory rhyming task using PPI between four left hemisphere regions: inferior frontal gyrus (IFG), superior temporal gyrus (STG), inferior parietal lobule (IPL), and middle occipital gyrus (MOG). We examined structural connectivity by using DTI tractography to reconstruct three left-hemisphere tracts associated with language (arcuate fasciculus, inferior longitudinal fasciculus, and inferior fronto-occipital fasciculus). Tractography analysis revealed that the investigated fascicles had differential developmental trajectories that correlated with PPI values. In particular, the arcuate fasciculus showed a steady increase in fractional anisotropy (FA) across age with higher FA in fifth-graders than third-graders and higher FA in adults than in fifth-graders. In contrast, the inferior longitudinal fasciculus and inferior fronto-occipital fasciculus showed relatively late FA increases with higher FA in adults than in children but no difference between third-graders and fifth-graders. PPI analysis revealed only one significant developmental change; which is the increased connectivity from MOG to STG, suggesting greater integration of orthographic information in phonological processing in adults. Correlation analysis between PPI and DTI found that, within children, PPI connectivity from STG to both IPL and IFG were positively correlated with FA in arcuate fasciculus. This suggests that functional connectivity in the anterior language network relies on the development of the underlying arcuate fasciculus in elementary school years. We also found that, within adults, PPI from STG to MOG was positively correlated with FA in inferior longitudinal fasciculus and inferior fronto-occipital fasciculus, and that PPI from MOG to STG was positively correlated with FA in inferior longitudinal fasciculus. It suggests that the late matured long-range fiber tracts play an important role in supporting the posterior language network involving orthographic representations in adults. Finally, we found that FA in inferior longitudinal fasciculus was negatively correlated with PPI from STG to IFG in adults, suggesting that there may be a developmental shift from anterior to posterior language network in phonological processing in Chinese adults; which may be driven by literacy acquisition.

Title: Impaired articulation but unimpaired auditory processing in KE family members with mutation of FOXP2

Authors: K. SCHULZE[1], L. HALLIDAY[2], S. AMITAY[3], F. VARGHA-KHADEM[1], *M. MISHKIN[4];
[1]Section on Cognitive Neurosci. and Neuropsychiatry, Univ. Col. London Inst. of Child Hlth., London, United Kingdom; [2]Psychology and Language Sci., Univ. Col. London, London, United Kingdom; [3]MRC Inst. of Hearing Res., Nottingham, United Kingdom; [4]NIMH, Bethesda, MD

Abstract: Background Half the members of the KE family (affected family members, aKE) suffer from an inherited neurodevelopmental speech impairment caused by the mutation of the FOXP2 gene. The core problem underlying this impairment has been identified as an orofacial and verbal dyspraxia, a higher order oromotor deficit that manifests most prominently as an articulatory disorder (Vargha-Khadem et al, 2005). Aim The primary objective of the present study was to determine whether there might be an additional core deficit, viz., an impairment in auditory processing associated with aKE's speech difficulties. Methods To compare auditory processing in aKE (n = 7), unaffected KE family members (uKE, n = 3), and controls (n = 13), we employed complex listening tasks that measure the ability to process the temporal and spectral aspects of auditory information (Tone detection in quiet, Amplitude modulation, Backward masking, Simultaneous masking, Frequency modulation detection, Frequency discrimination, Tone detection in noise). Results There was a significant effect of group for Frequency discrimination ($p = 0.007$, corrected α-level = 0.005), but this was due to a significantly lower, thus better, frequency discrimination threshold in the aKE compared to controls ($p = 0.001$, corrected α-level = 0.017). No other psychoacoustic tests yielded a significant group effect. Conclusions Our results suggest that the aKE's FOXP2 mutation does not interfere with auditory processing and, conversely, that auditory processing difficulties do not contribute to the aKE's articulation impairment. Title: Deciphering the role of CNTNAP2 in cognitive disorders; from molecule to patient

Authors: ***P. RODENAS CUADRADO**[1], N. PIETRAFUSA[2], T. FRANCAVILLA[2], A. LA NEVE[2], P. STRIANO[3], S. C. VERNES[1];
[1]Max Planck Inst. For Psycholinguistics, Nijmegen, Netherlands; [2]Dept. of Basic Med. Sci., Univ. of Bari, Bari, Italy; [3]Dept. of Neurosciences, Rehabilitation, Ophthalmology, Genetics, Maternal and Child Hlth. Univ., "G. Gaslini" Inst., Genova, Italy

Abstract: Investigations into CNTNAP2 are of high interest as disruptions in this gene are involved in a range of cognitive disorders including autism. CNTNAP2 is expressed across a number of brain regions including the cortex, striatum and thalamus, recapitulating the circuitry known to modulate higher order cognitive processes, suggesting an important role of CNTNAP2 in brain development. Furthermore, molecular links with FOXP2 suggest that CNTNAP2 may be involved in language related pathways. Given the range of phenotypes produced by CNTNAP2 disruption and the early and widespread expression pattern of its protein product CASPR2, it is likely that this gene has multiple roles in the brain, however these remain poorly understood. We are investigating CNTNAP2 at a phenotypic and molecular level to understand its function in the developing and adult brain, and why mutations in CNTNAP2 lead to specific neurological phenotypes. Patient studies reveal a complex relationship between genotype and phenotype. CNTNAP2 is located on 7q35 and spans 2.3 Mb, making it a large physical target for disruptive mutations. Accordingly a large number of mutations have been identified at the CNTNAP2 locus in patients with a range of cognitive phenotypes that often include intellectual disability (ID) and epilepsy. We compared novel patients with previously reported individuals harboring CNTNAP2 mutations and found complex phenotypic profiles of varying severity in patients with heterozygous mutations. Furthermore heterozygous changes were also found in unaffected individuals, suggesting that mutation of a single copy of CNTNAP2 is not fully penetrant. By contrast, detailed phenotypic analysis of patients with homozygous CNTNAP2 loss revealed a syndromic disorder characterised by severe intellectual disability, early-onset drug-resistant

epilepsy, reduced or absent language, communicative impairments and autism. Further phenotypic and molecular investigations into these patients will be essential for identifying the core effects of CNTNAP2 in cognitive disorder. We are currently investigating the properties of normal and mutant CNTNAP2 to understand the molecular function of CASPR2 and how these variants give rise to cognitive phenotypes. These molecular screens will not only shed light into the contribution of CNTNAP2 variants to complex neurodevelopmental disorders such as epilepsy, autism and language impairment, but also further our understanding of the role of CNTNAP2 in normal brain development.

Title: Rapid learning and consolidation of novel morphosyntax in human neocortex: neuromagnetic evidence

Authors: *A. LEMINEN[1], L. KIMPPA[3], M. LEMINEN[2], M. LEHTONEN[4], J. P. MÄKELÄ[5], Y. SHTYROV[2];
[1]Aarhus Univ., Aarhus C, Denmark; [2]Ctr. of Functionally Integrative Neurosci., Aarhus Univ., Aarhus, Denmark; [3]Cognitive Brain Res. Unit, Univ. of Helsinki, Helsinki, Finland; [4]Åbo Akademi Univ., Turku, Finland; [5]BioMag Lab., Helsinki, Finland

Abstract: Research into neurobiological mechanisms of morphosyntactic processing of language has suggested specialized systems for decomposition and storage, which are used flexibly during the processing of both inflections (e.g., boy+s, boy + plural marker) and derivations (boy+ish, boy plus attenuator), the main morphological tools humans use to change and create words.

However, the neural underpinnings of acquisition of novel morphology are still obscure. We investigated the role of semantic information in morphosyntactic affix learning and the role of overnight consolidation in the formation of neural memory traces for new affixes. First, participants were implicitly trained on a subset of novel affixes combined with real word stems (not included in the actual experiment) by listening to and reading these novel combinations presented with respective pictures (e.g. cup-ku = small cup). After the training session, the participants had to report the meaning of the novel suffixes, following which their neuromagnetic brain responses were acquired using MEG. The participants passively listened to the newly trained suffixes presented with either real word or pseudoword stems, or similar items that included previously untrained affixes (counterbalanced across participants). The MEG recording (but not training) was repeated again after a one-night sleep using the same stimuli, to test the effects of overnight consolidation. Analysis of event-related fields showed that on Day 1, as early as 50 ms after the suffix onset, novel suffix combined with real stems, elicited significantly larger responses than pseudostem+novel suffix combinations, regardless of whether the suffixes were trained or untrained, implying a robust activation of a memory trace for the known stem but not yet the new affix. On Day 2, these differences disappeared, suggesting the consolidation-related enhancement of the memory traces for the newly learned suffixes and/or complex words. At the later processing stages (~120ms), there was an increase in the magnitude of the responses on Day 2, also indicating an overnight consolidation of memory traces for novel complex combinations. The neural source reconstruction showed the increase of activation in bilateral fronto-temporal cortical generators, particularly for trained suffixes, suggesting that these areas underpin the formation of novel neural memory trace the novel derivational endings. Overall, the results demonstrate the rapid and dynamic processes of build-up and consolidation of neocortical memory traces, taking place as a result of a short period of exposure to novel morphology.

Title: Automatic processing of morphosyntax by second language learners

Authors: *L. A. HEDLUND[1], A. LEMINEN[2], S. HUT[1], L. KIMPPA[1], M. LEMINEN[2], Y. SHTYROV[3];
[1]Cognitive Behavior Res. Unit, Helsinki, Finland; [2]Dept. of Clin. Med., Ctr. of Functionally Integrative Neuroscience, Arhus Univ., Arhus, Denmark; [3]Ctr. for Cognition and Decision Making, Higher Sch. of Econ., Moscow, Russian Federation

Abstract: In our surroundings, we often encounter complex things, comprised of multiple subparts. A striking example of such a complexity is offered by language. Many words are complex, i.e. they have more than one meaningful element (=morpheme), e.g., boy-s, boy+plural marker (inflection); boy-ish, boy+attenuator (derivation). Recent MMN findings (Leminen et al., 2013, Cortex) have shown that the brain automatically processes native language (L1) inflections by decomposing them into morphemes, while derivations are likely to form unitary representations. However, little is still known about the brain mechanisms responsible for the processing of complex words in a second language (L2). To investigate this issue, we presented beginning and advanced L2 learners and L1 speakers of Finnish with a balanced set of inflected and derived words and complex pseudowords (real stem+pseudosuffix), while recording EEG in a passive multifeature paradigm. L1 speakers replicated the morphological MMN pattern that showed stronger responses for derived than for inflectional words, indicating the existence of full-form memory traces for derivations and decompositional parsing for inflected forms. Crucially, neither beginning nor advanced L2 learners showed such an effect, suggesting weaker memory circuits for L2 derived words and thus likely automatically decompose them into stem and suffix, similar to inflections. All groups showed a syntactic ERP pattern - a stronger response to pseudowords than to real words. We show that morphological parsing takes place already early on in L2 grammar learning, and even advanced L2 learners seem to continue using the parsing route for all types of morphological complexities.

Title: What was that word? Selective interference during memory consolidation of novel words in adults

Authors: *L. KACZER[1], E. HOCHMAN[2], L. BAVASSI[2], M. PEDREIRA[2];
[1]Lab. de Neurobiologia de la Memoria, IFIBYNE CONICET, Argentina; [2]Lab. de Neurobiologia de la Memoria, IFIBYNE CONICET, Buenos Aires, Argentina

Abstract: We analyzed the role of memory consolidation in the acquisition of novel words using an interference procedure. We separately studied the effects of interference in the aspects of word form (phonology and orthography) and the semantic content. Participants learned 9 nonwords, visually presented, associated with a picture and a definition. A short term memory test was performed 5 min after learning, and a long term memory test took place 48 h after. During testing participants were asked to recall the words when given the corresponding pictures (word form test), and recall the definitions when given the corresponding word name (semantics test). The interference consisted of a similar learning task and was presented at different times respect to the end of the first session (5m, 30m, 4h, 24h). Results show that only the word form memory was affected by the interference, while the semantic memory was immune to the treatment. The interference was found to be time limited, supporting the proposal that memory consolidation is the process being affected. Our results suggest a dissociation between the memory systems involved in novel word learning. Semantic aspect would be rapidly incorporated by fast mapping, while the word form memory would form gradually and imply a systems consolidation process.

Title: Impaired sensorimotor integration in auditory feedback control of vocal pitch in Alzheimer's disease

Authors: *K. RANASINGHE[1], N. S. KORT[1], A. J. BEAGLE[1], H. KOTHARE[1], J. S. GILL[1], D. MIZUIRI[1], S. M. HONMA[1], B. L. MILLER[1], K. A. VOSSEL[1,2], J. F. HOUDE[1], S. S. NAGARAJAN[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Gladstone Inst. of Neurolog. Dis., San Francisco, CA

Abstract: Speech and language networks are affected early in the disease course of Alzheimer's disease (AD). Identifying the neural defects underlying these behavioral deficits will enable us to uncover the earliest manifestations of network dysfunction in AD, and hence useful biomarkers of the disease. A compelling example of speech-motor integration is the pitch perturbation reflex in which speakers respond rapidly to shifts of the pitch of their auditory feedback. In response to brief perturbations of pitch in their auditory feedback subjects alter their vocalization to oppose the direction of the applied pitch shift. Previous neurophysiological studies have linked these specific adjustments in vocal output to integration between sensory feedback error-detection and motor error-correction circuits of speech motor control system. These network integrations are indeed highly vulnerable targets in AD, which is characterized by neuronal loss and functional dysconnectivity of temporal and parietal cortices of the brain. In this study we tested the hypothesis that AD patients will demonstrate altered speech execution ability, specifically the pitch-perturbation reflex, resulting from lack of modulation of distinct network components. We examined the neural and behavioral responses of pitch-perturbation reflex in AD patients (n=12) compared to an age-matched control group (n=11). Subjects phonated the vowel /a/ while a real-time signal processor briefly perturbed (±100 Cent for 400 ms) pitch of their auditory feedback. We used magnetoencephalography and examined the high-gamma (65 - 150 Hz) evoked response during the pitch altered feedback response. We documented the degree of compensation demonstrated behaviorally by each subject by changing their pitch in response to the pitch altered feedback. Behaviorally, AD patients demonstrated an elevated compensatory response compared to age-matched controls (33.4% and 23.0% in patients and controls respectively, $p < 0.0001$, unpaired t test). Neural analysis revealed that, AD patients show a significantly enhanced high-gamma evoked activity compared to age-matched control subjects. Specifically, patients demonstrated an enhanced activity over the left premotor and posterior temporal regions.

Interestingly, this was also accompanied with a significant reduction of prefrontal activity during the early phase of the response. These results implicate the lack of sensory-motor network modulation of speech-motor-control network in AD during auditory feedback control of pitch.

Title: Graphical features of the structural connectome of the human brain in speech skills

Authors: ***K. JUNG**[1,2], Y. CHANG[2], M. LEE[1,2], J.-G. LEE[2], J.-H. LEE[3], S. J. KIM[1], N. KIM[1,2], M. KWON[3];

Abstract: The purpose of this study was to find relations between speech skills and structural connectome features. Fifty-four healthy right-handed participants (27 males, 27 females; mean age, 44.02±17.98 year; range, 23-77 year) underwent tests for speech skills that consists of speech fluencies (verbal, semantic, phonemic test), the number of words per minute, the number of correct information units (CIU) per minute, CIU-words ratio, Boston naming test, and Montreal cognitive assessment. And diffusion-weighted images for diffusion tensor imaging (DTI) and T1-weighted image were obtained. Preprocessing was conducted by FSL for DTI fibre tracking and Freesurfer for cortical parcellation and deep grey matter segmentation. To measure edges of a structural connectome, fibre tracking was performed by DSI studio. The parcelled and segmented regions were analysed as nodes. Undirected weighted connectivity between nodes were computed by counting the number of tracked fibres for each node. Connectome features were acquired by using brain network toolbox in Matlab. To find relations between speech skills and connectome features, multiple linear regressions were performed. In addition, significant

regions were sorted and selected by descending order of adjust r-square values of the multiple regression analyses. There were different descending orders for verbal, semantic, and phonemic fluencies. The number of words and CIUs per minute had similar descending order. They contained right precentral gyrus, right entorhinal cortex, left isthmus of cingulate gyrus and left hippocampus. On the other hand, there were also different regions such as left postcentral gyrus and left accumbens for the number of words per minute and left middle temporal gyrus and left frontal pole for the number of CIUs per minute. In summary, structural human connectome can show differences between different speech skills by using graphical features of the connectome. In addition, the connectome features can provide information to reveal characteristics of nodes that are related with speech language.

Title: Left inferior parietal lobe engagement during rule learning from speech involves temporal orienting of attention

Authors: *R. DE DIEGO-BALAGUER[1,2,3], J. L. AMENGUAL[2,4,5], M. RUZZOLI[6], A. CALLEJAS[2,5], A. MARTINEZ-ALVAREZ[2,3,5], S. SOTO-FARACO[6];

Group, Ctr. for Brain and Cognition, Univ. Pompeu Fabra, Barcelona, Spain

Abstract: Predicting the order of elements in time is an essential capacity that the cognitive system is able to apply to multiple perceptual modalities. In the auditory domain, learning rules from a new language requires keeping track of systematic dependencies while ignoring variable information (e.g. he plays, he sleeps, he speaks). This process may benefit from the use of temporal orienting of attention to the dependent elements as well as executive control in order to ignore irrelevant information. In order to test the involvement of temporal orienting of attention in rule learning we performed a two session experiment (fMRI + rTMS). In the first fMRI session participants were exposed to an artificial language with non-adjacent dependencies in order to localize the peak activation for the task within the left inferior parietal lobe (L IPL). In the second session participants underwent a 1Hz off-line TMS protocol (15 minutes) where the individual peak of activation in the L IPL was stimulated. As a control condition, participants were stimulated in a region of no interest (ROnI: i.e. POz location). Immediately after rTMS application participants performed a temporal orienting task and a language-learning task with a different artificial language compared to that used in the fMRI session. Results showed that stimulation of the L IPL coordinate interfered with temporal orienting of attention, compared to the control coordinate. In contrast, rule learning was enhanced by L IPL stimulation compared to the ROnI. These results indicate that interfering with L IPL activation suppresses orienting of

attention while producing benefits on rule learning. We conclude that, although attention seems to be involved in rule learning, it is not essential and therefore distinct mechanisms may be applied for rule extraction from language under different circumstances.

Title: Superior verbal skills in the congenitally blind

Authors: *V. OCCELLI, S. LACEY, C. STEPHENS, K. SATHIAN;
Emory Univ., Atlanta, GA

Abstract: Previous research on the consequences of blindness has provided evidence that congenital absence of sight results in superior verbal memory abilities, possibly as a compensatory mechanism for visual deprivation (e.g., Amedi et al., 2003; Raz et al., 2007). The present study sought to establish whether the superiority of the blind is limited to verbal memory, or whether it generalizes to other verbal tasks or across different kinds of memory abilities. Eight congenitally blind and eight age-matched sighted participants were administered a battery of tests assessing linguistic functions: verbal memory (recall of word lists at different time points after presentation); phonemic and semantic fluency (time-limited generation of items either starting with a specified letter or belonging to a specified category); verbal working memory (backward repetition of number sequences of varying length); and comprehension of sentences varying in syntactic complexity. They were also tested on spatial skills: spatial memory (recall of haptically learned configurations) and spatial imagery (mental construction and comparison of patterns cued verbally by number sequences within a matrix). The congenitally blind group significantly outperformed the sighted controls on most linguistic tests: verbal memory, phonemic and semantic fluency, and verbal working memory. In contrast to the differences on verbal tasks, the two groups were comparable on spatial tasks. Taken together, these results show that congenital blindness is associated with superior verbal skills, including verbal memory and working memory, but that this superiority does not generalize to spatial skills.

Title: Which language should I use?: Bilingual speakers show distinct patterns of parasympathetic regulation when code-switching in an emotional context

Authors: ***L. E. QUIÑONES-CAMACHO**[1], S. SAVAGE[2], C. LAMAR-PRIETO[3], E. L. DAVIS[1];
[1]Dept. of Psychology, [2]Dept. of Sociology, [3]Dept. of Hispanic Studies, Univ. of California Riverside, Riverside, CA

Abstract: For many years, researchers have attempted to understand bilinguals' physiological responses to emotional stimuli. Most studies ask participants to listen to, read, or repeat a few words at a time. Although physiological differences are often found, we do not know how physiology might change when emotional events are discussed in detail. Respiratory Sinus Arrhythmia (RSA) is a cardiac measure of parasympathetic function used to index peripheral nervous system (PNS) activation. The aim of this study was to assess whether bilinguals' RSA reactivity during an interview about emotional films would differ depending on the language spoken. 98 Spanish-English bilinguals (M = 20.8 years; SD = 2.11; 73 women) took part in this study, which employed a 2 (emotion: sadness, fear; within-person) X 2 (language frame: Spanish, English; within-person) X 2 (video type: mild emotional intensity, moderate intensity; between-person) mixed experimental design. Each person saw four films and was interviewed (in Spanish or English) about them afterward. Order of language was counterbalanced across participants, but emotion film order was consistent across the Spanish and English blocks (e.g., Sad-Fear-Sad-Fear). Electrocardiograph data was collected for the entire session to derive RSA. We conducted a MANOVA to examine the effects of the first language spoken, the first emotion elicited, and the emotional intensity of the films on RSA reactivity during the four interview phases. There was a significant multivariate effect for RSA reactivity based on the first language used, $F(4, 75) = 5.776$, $p < .001$, and a 2-way interaction of language and intensity $F(4, 75) = 2.655$, $p = .039$. There were marginal univariate effects of language on RSA reactivity to the Spanish interview about sadness, $F(1, 78) = 2.233$, $p = .066$, and to the Spanish interview about

fear, F(1, 78) = 1.769, p =. 075, such that speaking English first resulted in more RSA augmentation. The interaction of language and intensity predicted RSA reactivity for the English interview about sadness, F(1, 78) = 2.282, p = .033, such that starting in Spanish resulted in more augmentation for people who saw mildly intense films, whereas starting in English resulted in more augmentation for people who saw moderately intense films. Our results suggest that when bilinguals code-switch when discussing emotional events, the language they speak first influences PNS activity. Greater RSA augmentation is not necessarily adaptive when interacting with someone else, suggesting that starting a conversation about an emotional event in English hindered participants' ability to effectively regulate arousal.

Title: Stimulus expectancy and response entropy in adult cochlear implant users

Authors: *N. M. AMICHETTI[1], E. ATAGI[2], A. WINGFIELD[2], Y.-Y. KONG[3];
[1]Neurosci., [2]Brandeis Univ., Waltham, MA; [3]Northeastern Univ., Boston, MA

Abstract: Cochlear implants (CI) have recently gained traction for older adults whose hearing loss is too severe to receive significant benefit from hearing aid use. Indeed, post-lingually deafened older adults are receiving implants well into their 80s. Despite the increase in CI use by older adults, there is a lack of research into the issues facing this emerging population at the level of natural discourse. Almost the entirety of research on CI users has been on intelligibility with single word or simple sentences. Faced with perceptual challenges (e.g., speech is often under-articulated and is rapid, often exceeding 180 wpm) and declines in working memory that accompany aging, one might expect older CI users to require more phonetic information from a word to identify it in the absence of a constraining context than younger CI users. Moreover, this difference could be reduced or eliminated in the presence of a constraining context. In addition, one might expect that response entropy, calculated as the number of potential competitors and the uniformity of their probability distributions, may affect the onset duration needed to correctly identify a target word. We report the results of an experiment in which younger and older adult CI users listened to sentences with progressive increases in contextual constraints from a no

context condition to a high context condition. Sentence final words were presented using a word-onset gating paradigm, in which words were heard with increasing amounts of word-onset information until they were correctly identified. Results will be discussed in terms of the effects of linguistic context (target expectancy) and response entropy (competition from the distribution of lexical alternatives that may also fit the context) on word recognition.

Title: The development of parsing routes for complex words in second language learners

Authors: ***S. HUT**[1], A. LEMINEN[2,1], L. HEDLUND[1], L. KIMPPA[1], M. LEMINEN[2,1], Y. SHTYROV[2,3];
[1]Cognitive Brain Res. Unit, Inst. of Behavioural Sci., Univ. of Helsinki, Helsinki, Finland; [2]Dept. of Clin. Medicine, Ctr. of Functionally Integrative Neurosci., Aarhus Univ., Aarhus, Denmark; [3]Ctr. for Cognition and Decision Making, Higher Sch. of Econ., Moscow, Russian Federation

Abstract: While learning a second language, proficiency and abilities in that language continuously develop. Active knowledge of semantics and grammar increases, along with automatised skills needed for grammatical processing. These skills are particularly necessary as many words in everyday language are complex, i.e. they consist of more than one meaningful element (=morpheme), e.g., cat-s, cat+plural marker (inflection). Previous studies show the ability of native (L1) speakers to parse novel complex words (derivations, e.g., chicken+ish) online even if they have never encountered them previously. How do second language (L2) learners process complex and novel derivations in their L2? To address this issue, a passive multifeature MMN paradigm was used while recording EEG. During the experiment, L1

speakers as well as beginning and advanced learners of Finnish were presented with spoken 1) real derived words, 2) novel derivations (novel combinations of a real stem+real suffix), and 3) pseudowords (real stem+pseudosuffix). In L1 speakers, real derivations elicited a larger MMN than novel derivations, demonstrating early automatic access of full-form memory traces for real derivations. In contrast, pseudowords showed larger responses than both novel and existing derivations, demonstrating a syntactic ERP pattern. Compared to L1 speakers, advanced L2 learners also showed a syntactic ERP pattern for pseudowords but only when compared to real derivations. In advanced L2 learners, no differences were found between real and novel derivations, pointing towards weaker memory traces for real derivations as compared to L1 speakers. Finally, no significant differences were found between the stimuli types in beginning learners. We conclude that L1 speakers have stronger memory traces for derived words and parse and integrate novel meaningful derivations more flexibly than L2 learners. Advanced L2 learners, however, have developed sensitivity to lexicality as well as to the morphosyntactic structure of complex words, while beginning learners have not, as suggested by the syntactic ERP pattern. Instead, beginners do not distinguish between these different morphology types yet and therefore possibly use the parsing route to decompose all complex items into their constituents.

Title: Non-verbal communication during the speaking and listening phases of a dyadic conversation in children with high functioning autism and children with williams syndrome

Authors: ***M. B. KIM**[1], P. LAI[2], D. TRAUNER[3], J. REILLY[4], U. BELLUGI[2];
[1]Lab. for Cognitive Neurosci., Salk Inst. For Biol. Studies, La Jolla, CA; [2]Salk Inst. for Biol. Studies, La Jolla, CA; [3]UCSD, La Jolla, CA; [4]San Diego State Univ., San Diego, CA

Abstract: How do children with different neurodevelopmental disorders use non-verbal communication when communicating with an adult compared to typically developing children?

In this study, school age children (ages 7-14) were examined during a dyadic social interaction with an adult. Typically developing (TD) children (n = 26), children with High Functioning Autism (HFA; n = 23) and children with Williams Syndrome (WS; n = 14) were observed in their non-verbal communicative behaviors, focusing on eye gaze, facial expression, and their co-occurrences. We examined these behaviors during both the speaking and listening portions of the interview. According to the results, there was no significant difference between the duration of speaking segments ($p = 0.258$) and listening segments ($p = 0.132$) for all three groups. Next, the percentage of eye contact was examined during speaking portions and all groups behaved comparably ($p = 0.800$). However, during the listening phase, the percentage of eye contact was significantly different between the HFA and WS groups, and between the HFA and TD groups. In both cases, the HFA group produced a smaller percentage of eye contact compared to their peers. For the production of facial expression during the speaking phase, a significant difference was observed ($p = 0.032$). Post-hoc testing using Tukey-HSD found a difference between the HFA and WS groups; HFA group was less expressive as the WS group. A trend was found for the HFA and TD comparison ($p = 0.072$), once again the HFA group were producing less facial expression during the speaking phase than the TD group. The percentage of facial expression during the listening phase was significantly different ($p < 0.001$) among the three groups. The HFA group did not use facial expressions as frequently as the WS and TD groups. Finally, co-occurrences of eye contact and facial expression during the speaking phase was not significantly different ($p = 0.114$) in our groups. Importantly, co-occurrences of eye contact and facial expression during the listening phase did result in group differences ($p < 0.001$) as the HFA group had a significantly lower percentage of co-occurrences than both the WS and TD groups. Our results suggest that the HFA group behave similarly during both the listening and speaking portions, a pattern not observed in the TD and WS groups. For the TD and WS groups, our results suggest nonverbal behaviors are more expressive during the listening phase than the speaking phase, especially eye contact. To answer our initial question, the HFA group showed a pattern of hypo-social communicative behaviors compared to the WS group, which displayed non-verbal behaviors similar to the TD group during this task.

Title: Characterizing multiple channels of social behaviors and expressivity in adults with Williams Syndrome during narratives

Authors: *T. V. DANG[1], P. LAI[1,2,3], J. REILLY[3], U. BELLUGI[1];
[1]Salk Inst. For Biol. Studies, La Jolla, CA; [2]Univ. of California San Diego, La Jolla, CA; [3]San Diego State Univ., San Diego, CA

Abstract: Williams Syndrome (WS) is a genetic disorder, characterized by hyper-sociability and gregariousness. Previous studies using a wordless picture book, Frog, Where Are You? (Mayer, 1969) found school aged children (5-10 years) with WS had high levels of affect and sociability in their narratives (Losh et al., 2000). How are affect and sociability expressed in adults with WS? The goal of this study is to better define the social phenotype of adults with WS by analyzing multiple channels of communication in social and expressive behaviors. In this study, participants (WS n=22, TD n=16) were asked to produce narratives as we examined: 1) evaluative devices, 2) eye gaze behaviors, 3) hand gestures. Using the Reilly Evaluation Coding System (Reilly et al.,1998; 2004), there were no differences in total evaluations, which included cognitive and social elements. When we examined social categories (i.e., sound effects, attributing emotions, intensifiers, etc.), a significant difference was found (p= 0.007); the WS group used 62% of social evaluations, while the TD group used only 47%. For example, 18 of the 22 WS individuals had at least one sound effect in their narratives, while only 3 of the 16 TD individuals produced a sound effect in their narratives. When investigating eye gaze behaviors, there were significant differences in average frequency (p=0.011) and average duration (p=0.003); the WS group produced more eye contact. The last expressive channel analyzed was the use of gestures. Interestingly, only 38% of the TD group produced one gesture during the narrative task, while over 72% of the WS group produced gestures. A Chi-Square test found a dependent relationship between group and gesture use χ;2(1,37)=4.259, p=0.039. Our results suggest that in these three channels, social behavior and expressivity in the WS group were more evident compared to their TD peers. In line with the results from children with WS (Losh et al., 2000; Reilly et al., 2004), adults with WS are producing more social evaluative devices, which are used to attract and maintain the listener's attention through the narrator's perspective and attitude. The eye gaze results are noteworthy since this task does not require explicit eye contact with the experimenter, yet the WS group still uphold eye contact suggesting their predisposition to engage with others. The gestures observed highlight the expressivity of the WS group, as the majority of the gestures were used to emphasize their stories, a pattern not observed in the TD group. Taken together, these results can better help define the adult WS social profile, and future research can begin linking social behaviors to potential neural mechanisms.

Title: Task-based connectivity between the inferior frontal lobes increases following left hemisphere stroke and is associated with worse naming performance

Authors: *L. SKIPPER-KALLAL[1], E. H. LACEY[1,2], S. XING[1], K. SPIEGEL[1], M. E. FAMA[1], P. E. TURKELTAUB[1,2];
[1]Neurol., Georgetown Univ., Washington, DC; [2]MedStar Natl. Rehabil. Hosp., Washington, DC

Abstract: The role of the right hemisphere in aphasia recovery has been debated for over a century. Some argue that the right hemisphere plays a compensatory role, aiding recovery (e.g., Basso et al., 1989), while others posit that right hemisphere activity interferes with recovery (e.g., Barwood et al., 2011). In this experiment, we examined the functional networks that synchronize during covert object naming, and how the communication within this network relates to naming performance outside of the scanner, controlling for differences in stroke distribution that also relate to performance. Twenty participants with chronic left hemisphere stoke, as well as 25 age-matched controls, participated in this study. The participants underwent a T2* weighted MRI scan while they performed a delayed-response object naming task. Only correct trials were analyzed. Participants also underwent a battery of language and other cognitive tests, which were reduced to four oblique factors (Naming, Motor speech, Executive function and Comprehension) using factor analysis. VLSM analyses were carried out for the Naming factor. Lesions in the left pars triangularis and pars orbitalis were associated with worse performance on Naming. To account for relationships between lesion location and naming ability, we calculated the proportion of the VLSM results damaged in each individual (Percentage of Critical Area Damaged, PCAD). The functional data was then analyzed using a psychophysiological interaction (PPI) analysis, which identified regions that synchronized with right BA 44 specifically during word retrieval. Participants in the stroke group showed greater connectivity than controls between the seed region and left pars triangularis and insula during word retrieval. A regression was then carried out examining how activation in this left hemisphere region related to Naming performance, while controlling for age, gender, education,

handedness, chronicity, lesion size and PCAD, in the stroke group. The level of activation in the area identified by the PPI analysis significantly predicted participant performance on the Naming factor, such that high levels of activation related to worse performance. Activation of this region during word retrieval also had a significant negative relationship with performance on the Philadelphia Naming Test. These results show that the right frontal lobe synchronizes with left frontal language areas to a greater degree for stroke participants than for healthy people, and activation of this region in the left hemisphere during a language task is related to poor naming performance, even when controlling for the impact of the stroke itself.

Title: Predicting behavioral preferences in language use from electrophysiological activity

Authors: P. M. ALDAY[1], D. ROEHM[2], M. SCHLESEWSKY[1], *I. BORNKESSEL-SCHLESEWSKY[1];
[1]Univ. of South Australia, Adelaide, Australia; [2]Univ. of Salzburg, Salzburg, Austria

Abstract: Traditional event-related potential (ERP) research has often divided components into "stimulus-locked" and "response-locked". Yet, when we consider that ERP components index evoked electrical activity within the perception-action loop, it becomes clear that a component is not "response-locked" but rather "response-locking". Response-related ERPs have been observed in a range of response settings (e.g. the readiness potential and the P300 for positive or neutral settings, the ERN for negative or incorrect responses). In studies on language, this has been extensively studied with a late positivity for dispreferred sentences, which seems to be strongly dependent on the task (Haupt et al 2008). Additionally, neural correlates for behavioral preferences without a canonical intersubject answer have been observed in other domains (e.g. beverage: McClure et al 2004, car manufacturer: Schaefer et al 2006), suggesting that it may be possible to measure preferences in language. (An example of such preferences is the pronunciation of "route" in American English -- it can rhyme with either "root" or "gout" depending on the individual speaker.) Here, we demonstrate the feasibility of using the electrophysiological response to predict binary judgments in language, thus deriving action from

brain activity. Moreover, we show that this works in both judgments with and without a canonical answer. Data were reanalyzed from Roehm et al (2013). Sentences were presented phrase-wise using RSVP to 32 monolingually raised native speakers of German (17 women, mean age 24) after they had given informed consent. After each sentence, subjects performed a binary acceptability judgment as well as a probe task. In 3 conditions, the acceptability judgment had a canonical answer, while the fourth lacked one and was subject to individual preference. Using generalized linear mixed-effects models with the single-trial acceptability judgment as the dependent variable, we found that the mean single-trial EEG amplitude from centro-parietal sites in the 600-800ms post-stimulus time window was a significant predictor of response across all conditions. Restricting the analysis to the condition without a canonical judgment reduced the size of the effect but did not remove it. These results demonstrate the feasibility of using electrophysiological activity to predict behavior, thus situating action in its correct place in the perception-action loop. Moreover, they suggest that the difference between "preferred" and "required" response is a quantitative and not a qualitative one.

Title: Cognitive demands in speech comprehension task modulates the effective connectivity: An optical tomography study

Authors: *M. S. HASSANPOUR[1], A. T. EGGEBRECHT[2], J. E. PEELLE[3], J. P. CULVER[4]; [1]Dept. of Radiology, Washington Univ. In St. Louis, Saint Louis, MO; [2]Dept. of Radiology,, [3]Dept. of Otolaryngology, [4]Dept. of Radiology, Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Speech perception is processed in a hierarchical and distributed fashion. Although neuroanatomy of speech perception is thoroughly investigated, little is known about how these distributed regions interact during the course of speech comprehension. In these study we use a semi-exploratory approach and investigate interregional interactions within speech network. Using event-related high-density diffuse optical tomography (HD-DOT) recordings of the brain hemodynamic activity during processing of auditory sentences that vary in their intelligibility and linguistic complexity, we assessed the modulatory effect of task demands on interregional interactions. Quiet imaging setting of HD-DOT system enables presenting the auditory stimulus in an acoustically well controlled environment and therefore isolating the complexity to linguistic aspects of speech. We presented listeners with spoken sentences that contained either a subject-relative (syntactically easy) or object-relative (syntactically complex) center embedded clauses, along with a control noise condition. In order to identify which networks have connectivity values that are modulated by task demands, we employed generalized psycho-physiological interaction (gPPI) analysis method. We modeled and characterized the activity in a brain region in terms of the interactions of both a task and functional connectivity to another region. Results show that intelligibility significantly increases the effective connectivity (EC) between left frontal lobe and several cortical areas also modulates the connections between left angular gyrus and left middle frontal gyrus in several regions. Processing complex sentences increases bilateral connections between ventral parts of prefrontal cortex and has strong modulatory effect on the connections between left temporal cortex and right ventral inferior frontal gyrus as well as connections between left parietal lobe and left prefrontal cortex. Overall, results highlight the presence of a hierarchical EC within distributed speech processing network.

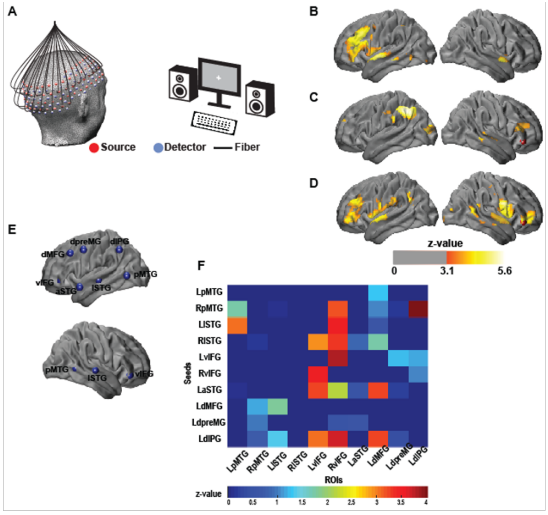

Figure 1: (A) Schematic view of HD-DOT experimental set up, subject position and imaging cap structure (a subset of optical fibers is shown for clarity). (B) Mani effect of sentences (Complex sentences > Noise), (C) Resting state functional connectivity for seed at right ventral inferior frontal gyrus (RvIFG). (D) Effective connectivity between RvIFG seed and rest of brain increases during complex sentences compared to noise. (E) Canonical/group seeds. Seeds at 10 ROIs located at posterior middle temporal gyrus (pMTG), lateral superior temporal gyrus (lSTG), ventral inferior frontal gyrus (vIFG), anterior superior temporal gyrus (aSTG), dorsal middle frontal gyrus (dMFG), dorsal premotor gyrus (dpreMG) and dorsal inferior parietal gyrus (dIPG) were selected for effective connectivity analysis. (C) Effective connectivity shows effective between several seeds with and right and left vIFG connectivity increases significantly during complex sentence processing.

Title: Using cochlear implant simulations to examine the effects of signal degradation and linguistic complexity on sentence comprehension and listening effort

Authors: *E. ATAGI[1], N. M. AMICHETTI[1], W. ALFORD[1], Y.-Y. KONG[2], A. WINGFIELD[1]; [1]Volen Natl. Ctr. for Complex Systems, Brandeis Univ., Waltham, MA; [2]Communication Sci. and Disorders, Northeastern Univ., Boston, MA

Abstract: Use of cochlear implants among older adults is increasing. Currently, users' degree of success with their cochlear implants is nearly always measured by their ability to understand speech consisting of single words or simple sentences. Spoken communication, however, generally consists of a series of more complex sentences that require greater processing demands. Such processing demands cause older adults with hearing loss to show poor

comprehension of spoken sentences with complex syntax, even when they are able to identify the words (Tun et al., 2010). This challenge arises due to the extra effort required in the early perceptual stages of speech processing, which in turn negatively affects the later stages of comprehension and encoding (e.g., Rabbitt, 1991). Thus, when combined with age-typical slowing of processing speed and limits to attentional capacity, linguistic complexity can compound the effects of even a mild hearing loss in older adults (Wingfield et al., 2006). The extra effort required for successful identification of a degraded signal has been recently demonstrated with young adults listening to cochlear implant simulations (i.e., spectrally degraded, vocoded speech). These studies observed gradient levels of listening effort with increasing spectral resolution even beyond the point at which speech intelligibility plateaued at a high level (Pals et al., 2013; Winn et al., 2015). The present study used vocoded speech at three levels of spectral resolution to simulate cochlear implant listening in older and young adults to examine the effort necessary to process speech with multiple degrees of both signal degradation and linguistic complexity. Listeners were presented with syntactically complex sentences at two levels of difficulty: an easier, subject relative construction (e.g., The boy that kicked the girl left the room) and a harder, object relative construction (e.g., The boy that the girl kicked left the room). Comprehension was measured by the accuracy of listeners' responses to a comprehension question following each sentence (e.g., Who did the kicking? Who was kicked?). Additionally, listening effort was measured by recording listeners' pupil sizes before, during, and after each sentence presentation. Results were analyzed for response accuracy to the comprehension questions and the listening effort differentially incurred by the different levels of signal degradation and linguistic complexity.

Title: The impact of stress on precise and rough speech processing in early infancy

Authors: *C. TEICKNER[1], A. BECKER[2], U. SCHILD[1], C. K. FRIEDRICH[1];
[1]Psychology, Eberhard Karls Univ. Tuebingen, Tuebingen, Germany; [2]Univ. of Hamburg, Hamburg, Germany

Abstract: We formerly showed that when it comes to speech processing infants seem to process phonemes and prosody separately (Becker et al., 2014). In the current study we investigated how detailed phonetic processing (place of articulation) is when stress in the prime-target pairs either matches or mismatches. We presented 3-month-old infants with primes (single syllables) and targets (complete early learned initially stressed German words) while recording their event-related potentials (ERPs). Three types of phoneme overlap were presented in prime-target pairs: complete overlap (e.g., ma-Mama), partial overlap (e.g., na-Mama) or non-overlap (vo-Mama). These three conditions were presented two times, once with stressed primes and once with unstressed primes. In accordance with the results of a previous study solely on phoneme processing (Teickner et al., 2014), we found that at three months after birth speech processing is precise enough to even track variation of the place of articulation of only one phoneme. Our results show that even when primes are unstressed, infants still perceive slightest phoneme mismatches (e.g., na - Mama). Previous studies found that two-day-old newborns prefer their native language over a foreign language (e.g., Moon et al., 1993). This means that, already *in utero*, they process prosody that can be applied in speech perception after birth. However, since most of the fine-grained segmental information does not get through the womb, the processing of phonemes can only begin after birth. In the current study, we found that phonemes and prosody are processed separately. It seems that when 3-month-old infants perceive speech, processing of segmental information is given top priority. Thus, seemingly the mechanism responsible for processing suprasegmentals can be suppressed when focusing on phoneme processing becomes more important.

Title: The bilateral inferior parietal lobules in support of Chinese multi-character word recognition

Authors: *N. LIN;
Inst. of Psychology of the Chinese Acad. of, Beijing, China

Abstract: The majority of Chinese words are multi-character words. In Chinese text, single and multi-character words are embedded in long strings and there is no perceptual cue to mark word boundaries. Therefore, a Chinese sentence can be segmented into words as well as nonwords. The lack of perceptual word boundaries does not harm Chinese reading, indicating that Chinese readers can differentiate multi-character words from nonwords highly efficiently. How Chinese readers differentiate multi-character words from nonwords is an important and special question in psychological and computational linguistic sciences and has been investigated for over two decades. However, until now, only one neuroimaging study (Zhan, Yu, & Zhou, 2013) has investigated the neural mechanisms underlying that processing. Using functional MRI, we investigated Chinese multi-character word recognition by comparing brain activations evoked by two-character words (e.g. “奔跑”), transposable nonwords (e.g. “跑奔”), and nontransposable nonwords (e.g. “跑吻”) during lexical decision. We included the transposable nonword condition because a direct comparison between the word and nonword conditions might be confounded by factors associated with response-type and stimulus familiarity. It has been found that a transposable nonword, which is produced by transforming the positions of the characters of a real word, can automatically activate the corresponding word representation. Therefore, the comparison between transposable and nontransposable nonwords should to some extent reveal the neural mechanisms underlying multi-character word recognition. We found that the transposable nonwords evoked stronger activations in the bilateral inferior parietal lobules (bIPLs) than nontransposable nonwords. No other brain activation difference between transposable and nontransposable nonwords was observed. The involvement of the bIPLs in Chinese multi-character word recognition was further confirmed by a conjunction analysis of the contrasts “word > nontransposable nonword” and “transposable nonword > nontransposable nonword”. In addition, we found that the bIPLs showed stronger activation to high-frequency words than to low-frequency words. Our results are in accordance with a recent finding that the activation level of the bIPLs during Chinese reading is a significant biomarker for one’s knowledge of written Chinese. In terms of the existing evidence about the functions of the bIPLs in language processing, our findings indicate that Chinese multi-character word recognition might rely on the access of the mapping between orthographical and phonological/semantic representations.

Title: The effect of degree of automaticity in processing hierarchical structure in arithmetic and language

Authors: *H.-A. JEON, A. D. FRIEDERICI;
Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: It has recently been suggested that a degree of automaticity in cognitive processing is a crucial factor in modulating the functional organization of the prefrontal cortex (PFC): the posterior-to-anterior gradient system for more controlled processes with a low degree of automaticity and the posterior-confined system for automatic processes with a high degree of automaticity. The neural mechanism involved in processing arithmetic has been investigated along with mathematical proficiency. It has been suggested that people with high proficiency retrieve mathematical facts stored in memory quickly and effortlessly, whereas people with low proficiency derive answers from procedural knowledge that is slow and prone to error. Taking these observations together, we investigated the neural networks for hierarchical processing in language and arithmetic depending on individual levels of proficiency. We recruited two groups of participants: mathematicians with a high level of mathematical proficiency and non-mathematicians with a low level of mathematical proficiency. Participants went through hierarchical processing with center-embedded sentences in language and center-embedded calculations in arithmetic. Using functional magnetic resonance imaging, we observed a significant difference between groups when processing arithmetic. While a broad fronto-parietal network was being activated in non-mathematicians, focal activation in the left precentral gyrus and left superior parietal lobule were found in mathematicians. However, no group difference was found in language. To elucidate the effect of degree of automaticity on the functional segregation within the PFC, a correlation analysis was conducted between individual degree of automaticity and the percent BOLD signal change from peak activations within the PFC. As a result, significant activation in its posterior area (precentral gyrus) was observed for arithmetic in mathematicians, being positively correlated with the degree of automaticity. However, non-mathematicians recruited a wide posterior-to-anterior network, with peak activation in the anterior region (pars triangularis, BA45) showing a negative correlation with the degree of automaticity. For language, no group difference was found in the activation pattern within the

PFC and the posterior region of the PFC (BA44) was positively correlated with the degree of automaticity in both groups. From the current data we discovered that the organizational principle of the degree of automaticity in the PFC can also be applied to the arithmetic domain, making a possible broad generalization of this organizational rule.

Title: Phonological verbal fluency task demands more attentional resources than Semantic verbal fluency task in patients with Parkinson's disease

Authors: *M. E. PIEMONTE, M. R. PIKEL;
Univ. Sao Paulo, Sao Paulo, Brazil

Abstract: The reduction in dopamine levels in striate cortical circuits caused by Parkinson 's disease compromises the gait automatic control by progressively limiting the ability to manage multi-tasks. However, it remains unclear what the more efficient way to test gait performance in dual-task avoiding the influence of the learning and educational level.Aim: To compare the efficacy of two different forms of the verbal fluency task used as a secondary task in order to promote the division of attention during the gait in PD patients.Methods: Gait performance of the 30 idiopathic PD patients, mean age of 64.5 years, mean years of schooling 4-12 , at stages 1-3 of according to the Hoehn&Yahr Classification, asymptomatic for depression and dementia, were tested 4 times in 2 weeks. The first two tests were performed on the same day, with 2 hours of rest between them. The other two tests were performed 7 and 14 days after the first day. The participants were asked to walk for 30 seconds in a comfortable speed in three different conditions: Single Task (ST), i.e., without a secondary task; Dual-Task condition with phonological form of verbal fluency task (DTP), in which the subjects are required to produce words, as many as possible, beginning with a given letter (F-A-S); and Dual-Task condition with semantic form of verbal fluency task (DTS), in which subjects are asked to articulate words, as

many as possible, belonging to a given category as fruits, vegetables and animals.Results: One 3X4 RM-ANOVA using as factor Condition (ST, DTP, DTS) and test time points (T1,T2,T3,T4) as repeated measures for gait speed showed a significant effect only for conditions (p=.00001,ES=.99). Tukey pos hoc test showed significant differences in speed between ST and DTP conditions (p=.0001,ES=.99), and ST and DTS (p=.0001,ES=.99). One 2X4 RM-ANOVA using as factor Conditions (DTP and DTS) and test time points (T1,T2,T3,T4) for gait speed and number of words evoked showed only a significant effect of conditions (p=.01,ES=.71 and p=.00002,ES=.99 respectively). Tukey pos hoc test showed a significant lower speed in the DTP and significant higher number of words in the DTS condition. There was no significant correlation between gait speed and number of words evoked and years of schooling. Conclusion(s): Both forms of verbal fluency task were efficient to promote a decrease in gait performance, which is expected under dual-task conditions, and, more importantly, neither one suffered learning or educational level effect. The DTP test demanded more division of attention. It can be observed by more reduction in gait speed and less number of words evoked in comparison with DTS.

Title: A functional anatomical map of human speech production

Authors: ***K. KATLOWITZ**[1], M. A. LONG[2], M. SVIRSKY[3], T. MCALLISTER BYUN[4], R. C. CLARY[2], H. OYA[5], M. A. HOWARD, III[5], J. D. W. GREENLEE[5];
[2]Dept. of Neurosci. and Physiol., [3]Dept. of Otolaryngology, [4]Dept. of Communicative Sci. and Disorders, [1]New York Univ. Sch. of Med., New York, NY; [5]Human Brain Res. Lab, Dept. of Neurosurg., Univ. of Iowa, Iowa City, IA

Abstract: Spoken language is one of the fundamental ways that we interact as a society. Two important neocortical centers that have been most commonly studied with respect to speech production are a subregion of the inferior frontal gyrus (commonly referred to as Broca's area) and the ventral primary motor cortex. Activity within both of these areas is correlated with a number of speaking tasks, as measured by fMRI (Price, 2012) or electrocorticography (Bouchard et al., 2013; Sahin et al. 2009; Cogan et al. 2014). Focal perturbations to these circuits such as electrical stimulation (Penfield and Roberts 1959; Ojemann 2002) and transcranial magnetic stimulation (Pascual-Leone et al. 1991) can result in speech arrest, suggesting that these regions are likely to be involved in speech production. However, the relative roles undertaken by Broca's area and the precentral gyrus in the production of speech are still poorly understood. To address this issue, we used a device to rapidly and reversibly lower the temperature of focal motor and premotor cortical areas in neurosurgical patients, controlling the speed of neural dynamics within those regions in an analog manner (Bakken et al., 2003; Long and Fee, 2008; Tang et al., 2010). By analyzing the changes to the fine structure of speech resulting from this manipulation, we could establish a causal relationship between those local circuits and speech production. We cooled 42 total areas in 16 awake individuals undergoing a craniotomy (1-7 regions per patient) while they recited two alternating word lists ('Monday', 'Tuesday', 'Wednesday', 'Thursday', 'Friday' or '21', '22', '23', '24', '25'). Speech timing was measured by manually demarcating reproducible spectrotemporal landmarks that often corresponded to identified phonemes. Changes in speech 'quality' were measured on a visual analog scale using a crowdsourcing approach. Mapping the effect to the cooling location revealed that cooling the left hemisphere resulted in significant speech changes in 14 of 30 cases while the same manipulation performed on the right hemisphere was only effective in 1 out of 12 instances. Strikingly, the timing and quality of human speech can be manipulated preferentially in specific brain regions following left-sided cooling. Cooling in the inferior frontal gyrus resulted in significant changes in speech timing, while cooling in the motor strip resulted in the degradation of speech quality. These results support a segregated, hierarchical model of speech production.

Title: A novel implicit associative learning framework: validation, role of attention and relation to Bayesian decision making

Authors: *A. ALAMIA[1], A. CLEEREMANS[2], E. OLIVIER[1], A. ZENON[1];
[1]Univ. Catholique De Louvain, Bruxelles, Belgium; [2]Univ. Libre de Bruxelles, Bruxelles, Belgium

Abstract: Implicit learning provides a rare opportunity to investigate how the brain operates in the absence of conscious intent. It has been investigated in many different domains, from sequence to statistical learning and from artificial grammar learning to contextual cueing in visual search. The current study is composed of three parts: first we propose a new experimental design to investigate how simple stimulus-response associations can be learned implicitly; second, we study the relationship between implicit learning and visual attention, and third we aim to determine how implicit and explicit information is combined together when making a perceptual discrimination task. All experiments followed the same procedure and design. In each trial, the participants had to report the motion direction of a patch of dots, which could be of three different colors. Unbeknownst to the participants, two of these colors were always associated with the same direction/response, while the third color was uninformative. In the first part, across a series of four experiments, we showed that the participants learned systematically the association between color and direction, while remaining strikingly unaware of it. In addition, we showed that performance feedback was crucial to the occurrence of implicit learning in this task, and that both the stimulus-response and stimulus-stimulus associations could be implicitly learned. In the second part we tested whether the allocation of visual attention to the informative feature (i.e. color) is required to learn the association and whether regularities, even though learnt implicitly, attract attention. Preliminary results show that attention is indeed required for implicit learning to occur, and that regularities attract attention consistently. Finally, we investigated in a last series of experiment how implicit information is combined with explicit information to make a perceptual decision. Interestingly, preliminary results suggest that, in contrast to our predictions, implicit information has a constant weight in the decision, irrespective of the reliability of explicit information, in violation of Bayesian optimal weighting of information sources. In conclusion, we provide a novel robust implicit learning framework, which allows us to investigate the interaction between implicit learning and other higher cognitive functions, such as visual attention and perceptual decision making.

Title: A review of transcranial direct current sensation monitoring

Authors: *M. P. WEISEND[1], M. S. SHERWOOD[1], M. K. HOWES[2], K. M. GRUNDY[2]; [1]Wright State Res. Inst., Beavercreek Township, OH; [2]Antioch Col., Yellow Springs, OH

Abstract: Transcranial direct current stimulation (tDCS) is widely touted as a method to enhance cognition in healthy participants and treat symptoms of conditions such as attention deficit hyperactivity disorder, stroke, depression, tinnitus, and others. tDCS causes sensations at the skin's surface, therefore, proper blinding procedures are critical to determining tDCS effectiveness. At present, the results of blinding procedures are reported infrequently and incompletely. We examined blinding techniques and there quantification in 200 primary research papers from 2011-2015. Nearly all reports claimed single (63%), double (32.5%), or other (6.5%) blinding techniques. However, only 32.5% of papers reported gathered participant input for tDCS elicited sensations and still fewer 10.5% presented the results of sensation questionnaires. Only 3.5% of the papers reported the findings of sensation questionnaires, performed an appropriate statistical analysis, and found effective blinding. One paper reported ineffective blinding with similar rigor. In spite of the common knowledge that tDCS elicited sensations can reveal information about stimulation conditions to subjects and researchers, quantification, reporting, and analysis of tDCS induced sensations to support claims about blinding are rare in the extant literature. The lack of rigorous support for blinding claims in tDCS studies invites well founded skepticism about the validity of tDCS as a technology to enhance cognition in healthy participants and treat neurological disorders. The tDCS community would benefit from an agreed upon standard for reporting results. The standard should include reporting differences in sensations between tDCS conditions to better understand the empirical support for the claims of blinding participants.

Title: Contribution of attentional selection to learning during probabilistic inference

Authors: *C. GUO, S. G. HOFFMAN, P. KHORSAND, A. SOLTANI;
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Naturalistic decision making is challenging as it often entails simultaneously learning about and combining partial evidence from various sources of information. Learning is especially challenging when processing multiple sources of information (i.e. cues), because the brain must solve the nontrivial task of assigning the correct weight to each cue using binary feedback (e.g. reward/no reward, success/failure), which is probabilistic in nature. The simultaneous aspect of learning and cue combination, as well as the large number of available cues, point to a role for attentional selection in naturalistic decision making and probabilistic inference. Existing information can influence what cues are attended/processed and can subsequently impact decision making. Moreover, it is possible that only evidence associated with the attended/processed cues is subsequently updated following reward feedback. In order to directly test the influence of attentional selection on probabilistic inference, we manipulated the saliency of 1 of 4 cues used to make decisions. More specifically, on each trial subjects were presented with 4 cues (simple geometric shapes) and asked to choose between two alternative options (red and blue targets) in order to receive reward points. Each cue carried a unique weight of evidence (WOE, log likelihood ratio that the cue is presented given either red or blue target is assigned with reward). The combined WOE from all cues presented on a given trial determined the reward probabilities on the two targets. After completing a few blocks of decision making and receiving feedback (choice session), the subjects estimated how much each cue or a combination of cues predicted reward on one of the two targets (posterior probabilities). We examined how biases in subjects' estimates of posteriors changed when we increased the saliency of one shape (via increasing brightness of the particular shape). We found that attentional manipulation during the choice session did not increase the subjects' tendency to select the choice alternative supported by the highlighted shape. However, this manipulation selectively increased the subjects' estimates of the predictive power of the highlighted shape. In other words, although reward feedback may stop subjects from developing an overall erroneous bias due to increased saliency, its interaction with attentional selection altered what was learned about individual shapes. Overall, these results demonstrate that the interaction between attentional selection and reward processes has a strong influence on probabilistic inference.

Title: Disentangling the involvement of primary motor cortex in value-based reinforcement learning and value-based decision making

Authors: ***G. DEROSIERE**, P. VASSILIADIS, S. DEMARET, A. ZENON, J. DUQUE; Inst. of Neurosci., Brussels, Belgium

Abstract: When one makes the decision to act in the physical world, the neural activity in primary motor cortex (M1) encodes the competition between potential action choices. Traditional approaches have viewed this activity as reflecting the unfolding of the outcome of a decision process taking place upstream. However, a recently emerging theoretical framework posits that the motor neural structures directly contribute to the decision process. We recently tested this hypothesis by using continuous theta burst stimulation (cTBS) to alter activity in M1 while participants performed a task that required them to select between two fingers in the right hand based on the color of a stimulus (green or red, explicit instruction). Importantly, this finger choice was biased such that, to earn more money, the subjects also had to take into account the shape of the stimulus (circle or square, undisclosed manipulation). So the motor response depended, on the one hand, on a perceptual decision process, interpreting the color of the stimulus according to instructed rules and, on the other hand, on a value-based decision process relying on reinforcement learning. Interestingly, cTBS over M1 modified the extent to which the value-based process influenced the subjects' decisions whereas it had no effect on their ability to make a choice based on perceptual evidence. Importantly, in that study, cTBS was applied at the very beginning of the experiment, before the subjects had learned the task. Hence, we cannot tell from that work whether the effect of M1 cTBS was due to an alteration of value-based reinforcement learning or of value-based decision making, which takes place once learning is complete. Here, we present a study in which we intend to use the same task but with cTBS applied at different times in order to assess the contribution of M1 to the two value-based processes (learning and decision making). More precisely, the experiment will extend over three sessions, each occurring at 24-hours interval. Each experimental session will consist of six

blocks, each lasting about 4 minutes. Pilot data suggest that the value-based process begins to effectively shape the subject decisions in the middle of the second session. Given this, cTBS over M1 will be applied either at the beginning of the first session (before learning) or at the beginning of the third session (after learning). This procedure will allow us to disentangle the involvement of M1 in value-based reinforcement learning and value-based decision making.

Title: Neural functions of memory retrieval and narrative reconstruction during free-viewing of film Memento

Authors: *J. E. KAUTTONEN[1], Y. HLUSHCHUK[1], U. HASSON[2], I. JÄÄSKELÄINEN[1], P. TIKKA[1];
[1]Aalto, Espoo, Finland; [2]Princeton Univ., Princeton, NJ

Abstract: To study memory retrieval as an essential part of human cognition and narrative reconstruction, we collected fMRI data during free-viewing of a non-linear puzzle film 'Memento' (2000, dir. C. Nolan, 106 min). In the film, 22 sequences of the story are presented in an inverse order (from end to the beginning) to simulate the experience of the protagonist who suffers of a memory defect (anterograde amnesia). From those 22 sequences, we selected 15 identically structured scenes which are repeated twice during the film at different timepoints. Our hypothesis was that the second repetition of the scene creates a special "anchor-point" (key-frame) that allows reconstruction of the story based on new information that was not previously available. fMRI data was collected with a 3T MRI scanner with TR=1.56s, resulting in 4107 EPI volumes. Analysis included data from 12 healthy subjects (4 males) with the mean age 27 years. Mental state and comprehension of the story were verified using a post-stimulus questionnaire. Data was analyzed with independent component analysis (ICA), searchlight-based multivoxel pattern analysis (sl-MVPA) and representational similarity analysis (RSA) methods. We used the key-frame segments (6-12s time-windows) and their visually identical counterparts to build two

30x30 dissimilarity matrices for a 'higher-level' (A) and 'lower-level' (B) cognitive models. For model A we assumed greater mutual temporal and spatial BOLD signal similarity during all (visually different) key-frame moments, while for model B greater pairwise similarity was assumed only for the key-frames and their (visually identical) counterparts. Both models were tested with activation patterns and independent component time-courses of each subject. Our searchlights analysis included the whole grey matter and 50 components were used for the ICA analysis. For model A, significant correlation was found with regions located at parietal (angular gyrus and precuneus) and frontal lobes (frontal orbital, middle frontal and superior frontal gyrii) with dominance on the right hemisphere. This is congruous with previous studies related to episodic memory recollection and narrative comprehension. In turn, control model B strongly correlated with low-level visual areas which was expected for the visually identical segments. By exploiting the unique narrative structure of Memento, this study demonstrates the feasibility of using naturalistic stimuli and multivariate methods to study complex neural processes related to narrative comprehension.

Title: The role of the alpha rhythm in regulating neuronal dynamics

Authors: *S. HAEGENS[1], C. B. MIKELL[2], E. H. SMITH[2], J. F. RUSSO[2], T. B. NELP[2], G. P. BANKS[2], S. SINHA[3], S. SHETH[2];

Abstract: The alpha rhythm (8-14 Hz) is thought to reflect a mechanism of functional inhibition, regulating the engagement and disengagement of neuronal populations based on task demands. Broadband activity in the high gamma range (70-150 Hz) is considered a correlate of multi-unit

activity. Taking these two signals, we track activity across a range of cortical areas using electrocorticography recordings in human patients with intractable epilepsy (N=18) performing the Multi-Source Interference Task. This task, a Stroop-like paradigm with Simon and Eriksen flanker distraction elements, allows us to address various cognitive aspects including attention, perception, decision-making and the subsequent motor response. We analyzed recordings both from grid electrodes placed over various cortical areas including frontotemporal and parietal cortex, and depth electrodes in prefrontal regions, including the cingulate cortex. Here we address several outstanding issues regarding the functional role of the alpha rhythm. We find a negative relationship between alpha power and broadband (high gamma) activity. Combined, these activation patterns reflect temporal tracking of task-engaged regions, with alpha decrease and broadband increase locked to specific task aspects. We report different types of responses, distributed over cortex, including sites that only respond to the stimulus presentation, sites that only respond to the decision report and/or the feedback, and interestingly, sites that track the time on task. The latter allows prediction of behavioral performance in terms of reaction times. Furthermore, we find a small subset of sites that show modulation with task difficulty, predominantly in temporal areas, and modulation based on task history (whether there was a condition switch from easy to hard trials or vice versa). Taken together, our results further support the notion that alpha reflects functional inhibition at the local neuronal population level, while broadband high gamma activity reflects neuronal activation. Crucially, the combination of these signals allows us to predict behavioral performance. We provide evidence for the generality of this mechanism across cortical areas, including prefrontal cortex.

Abstract: Categorization is a fundamental cognitive process by which the brain assigns meaning to incoming sensory stimuli. The higher cognitive functions have traditionally been considered the domain of prefrontal areas. However, recent non-human primate studies have increasingly focused on the essential role of the posterior parietal cortex (PPC), especially the lateral intraparietal (LIP) area, in categorization. Previous work showed that PPC played a central role in spatial attention and saccadic eye movement, and more recent work has found categorical signals in LIP. However, whether human PPC is also involved in visual category remains unclear. Here, using multiple voxel pattern analysis (MVPA) on data from functional magnetic resonance imaging (fMRI) visual-spatial category experiments, we show that activity in human IPS1/2-an area shares similar response characteristics to macaque area LIP-can reflect the groups of spot visual stimulus. Moreover, the activity of human IPS1/2 selectivity shifted markedly with retraining. These findings indicate that human IPS1/2 is involved in human visual-spatial categorization.

Title: Deciding where to attend: Increased frontal theta/delta oscillations and their neuronal substrate

Authors: *A. RAJAN[1], Y. LIU[2], H. HUANG[1], J. BENGSON[2], G. MANGUN[2], M. DING[1];

Abstract: We examined the volitional aspects of attentional control by recording simultaneous EEG-fMRI from subjects performing an instructed/willed visual spatial attention paradigm. Each trial started with a cue. Following a random time delay the target in the form of a spatial grating

was presented and the subject discriminated the spatial frequency of the grating. In the instructed attention condition, the cue directed the subject's attention to either left or right hemifield, whereas in the willed attention condition, the cue prompted the subject to choose the side of the visual field to attend. It is hypothesized that willed attention is accompanied by an increased need for conflict resolution and cognitive control. Consistent with the hypothesis we found that: (1) 600 ms following cue onset a significant increase in theta/delta band (2-6Hz) power in the frontal areas was observed for the choice condition as compared to the instruction condition, and (2) increased theta/delta coherence between frontal and parietal areas was found for the choice condition. Moreover, correlating theta/delta power with concurrently recorded BOLD, it was further demonstrated that the frontal theta/delta activity is likely generated and modulated by a neuronal network including the dorsal anterior cingulate region

Title: Human premotor cortex is implicated in the evaluation of the correctness of observed non-motor visual stimulus sequences according to a learned conjunction rule: a magnetoencephalography study

Authors: L. LUNEAU[1], ***J. F. KALASKA**[2];
[1]Univ. de Montreal, Montreal, QC, Canada; [2]Univ. De Montréal, Montréal, QC, Canada

Abstract: Active human sensorimotor behavior evokes widespread changes in oscillatory brain activity, such as beta rhythm (15-30Hz) suppression during the planning and execution of arm movements and post-movement rebound in motor (M1) and premotor (PM) cortex (Kivalik 2011). The intensity of beta desynchronization varies with directional uncertainty during movement planning (Tzagarakis et al., 2010). The discovery of "mirror neurons" also implicated PM in higher cognitive functions such as the interpretation of observed motor actions. Cisek & Kalaska (2004) found that dorsal PM neurons discharged when monkeys observed the visual cues of a learned motor task and that the activity predicted correct outcomes and signaled

incorrect outcomes. Similarly, Koelwijn et al (2008) reported a stronger beta rebound when human subjects observed an actor making mistakes in a motor task than in correctly performed trials. In all of these cases, PM was activated while subjects observed familiar motor actions or stimulus events associated with learned motor tasks. We examined if PM is also active when subjects observe sequences of visual cues not previously associated with any motor actions while a computer performs a 2-choice target selection task guided by a color-location matching (CLM) rule (Cisek & Kalaska 2005) and interpreted whether the observed events respected the rule. We recorded PM beta activity using MEG in 2 subject groups. Group 1 learned the CLM rule by observation: they watched a computer perform the task correctly or incorrectly (condition 1), and then counted correct or incorrect trials in further trial blocks. In a second session, they actively performed the task with a joystick (condition 2). Group 2 learned by action: they learned the CLM rule by trial and error while performing the task actively in the first session, and then did blocks of the active task (condition 2). In a second session they observed the computer perform the task and counted trial outcomes (condition 1). We recorded 3 Group 1 and 3 Group 2 subjects. We observed typical beta suppression/rebound in both Groups when they actively performed the task (condition 2), and also in Group 2 when they subsequently observed the task (condition 1). Critically, we also found beta suppression/rebound in Group 1 subjects when they observed the task (condition 1) before ever performing it actively. In both Groups, the strength of beta rebound differed for observed correct versus incorrect task performance by the computer. These findings support a role for PM in the cognitive act of interpreting the "correctness" of observed arbitrary sensory events even when they have not been associated with any specific motor actions.

Title: Investigating the plasticity of perceptual decision-making in the human brain

Authors: C. DEVINE[1], D. MCGOVERN[1], S. KELLY[2], *R. G. O'CONNELL[1];
[1]Trinity Col. Dublin, Dublin, Ireland; [2]Univ. Col. Dublin, Dublin, Ireland

Abstract: A considerable body of research has established that it is possible to improve perceptual performance through training (Lu et al., 2011) but the precise neural adaptations that give rise to these improvements have yet to be identified. The present study employs a recently developed non-invasive electrophysiological paradigm for isolating neural signals representing each of the three key levels of information processing that are necessary for making simple perceptual decisions (Kelly & O'Connell, 2014). Healthy subjects (N=6 – data collection ongoing) were trained to judge the relative contrast of two superimposed gratings over 5 separate sessions (500 trials/10 blocks per session). The two grating stimuli were flickered at 20Hz and 25Hz respectively, generating distinct steady state visual evoked potentials (SSVEP) whose subtraction indexes the representation of 'sensory evidence'. In addition we tracked the accumulation of this sensory evidence into distinct domain-general and effector-selective decision variable signals. The role of attentional state in learning was also examined by monitoring changes in posterior alpha-band (8-14Hz) activity. Stimulus difficulty was determined individually for each subject prior to training such that baseline performance was approximately 70%. Feedback was given on a trial-by-trial and block-by-block basis and electroencephalography (EEG) was recorded during all training sessions. There was a significant improvement in accuracy across all blocks ($F(49, 196) = 2.65$, $p<.005$) and a reduction in RT that approached statistical significance ($F(49, 196)=1.4$, $p=.056$). Our neural signal analyses will establish whether these behavioural improvements arise from enhanced encoding of sensory 'evidence', changes in the parameters of the neural decision process, changes in motor preparation, changes in attentional engagement or some combination of these factors. zhz

Title: Attention-related brain potentials predict willingness to pay

Authors: ***N. GOTO**, M. MORTAZAVI, M. WATABE, A. SCHAEFER;
Monash Univ. Malaysia, Bandar Sunway, Malaysia

Abstract: It is often assumed that purchasing decisions are influenced by consumers' Willingness To Pay (WTP), that is, that maximum amount of money that a consumer accepts to pay for a given product or service (Ajzen & Driver, 1992). However, little is known about the

neural and cognitive underpinnings of WTP-driven decisions (Plassmann et al., 2007). The main purpose of this study was to examine with brain event-related potentials (ERP) whether such decisions recruit attentional and cognitive control processes, or if they can rely solely on preattentive mechanisms. In a simulated shopping task, 47 participants viewed a series of pictures of 40 desirable products while scalp EEG was recorded. They were offered 10 different prices for each product consecutively, and their task was to accept or decline each offer. If the highest accepted offer exceeded a "true" price undisclosed to the participants, then participants were given a chance to actually buy this product. The highest accepted offer was coded as their WTP. Offers under WTP were coded as underpriced (UP) whereas those above were coded as overpriced (OP). Results showed that response times were longer for WTP offers compared to both OP and UP offers. Next, we observed a larger frontal positive slow wave for WTP offers compared to both UP and OP and a larger late posterior complex for WTP offers compared to OP offers. Overall, both the behavioural data and the spatio-temporal properties of the ERP results suggest that WTP-driven decisions recruit sustained attentional and working memory (WM) processes. Specifically, it is possible that, in a shopping environment, buying decisions driven by WTP require the active maintenance of a set level price in WM and a continuous comparison of this figure with actual prices. In addition, these findings also indicate that attention-related ERPs are potentially useful tools to model price-driven choices. References: Ajzen, I. & Driver, B.L. (1992). Title: Arousal decreases conservativeness in a random dot motion decision making task

Authors: *W. TORGERUD[1], D. MUSSACK[2], T. LEE[4], G. MAFFEI[5], G. COTUGNO[6], P. SCHRATER[3];
[1]Cognitive Sci., [2]Psychology, [3]Univ. of Minnesota, Minneapolis, MN; [4]Univ. of California,

Santa Barbara, CA; [5]Univ. Pompeu Fabra, Barcelona, Spain; [6]King's Col. London, London, United Kingdom

Abstract: Emotional arousal, a key factor often used to characterize and describe emotions, gears up the body to react to stimuli in the environment. Arousal could functionally accomplish this either by increasing attentiveness or by decreasing conservativeness. Increasing attentiveness effectively increases the rate at which the brain processes incoming perceptual information. Alternatively, an individual who is being less conservative in a decision would be comparatively more willing to act on less evidence. In this pilot study we sought to determine the effects of arousal on decision making by using a two alternative forced choice random dot motion coherence task analyzed with a Bayesian hierarchical drift diffusion model (HDDM). Subjects were exposed to trials consisting of one of three different levels of arousal immediately preceding performance on a random dot motion decision making task. The effect of arousal on decision making was modeled as a constant term modulating perceptual evidence accrual rate, decision threshold boundary (conservativeness in response), both, or neither. These four models were compared using hierarchical Bayesian estimation to determine which best fit the data. The hierarchical nature of the model allowed us to compare data both within and across subjects. Biometric data including galvanic skin response (GSR), heart rate (HR), eye tracking, and automatic recognition of facial emotional expression data were collected for each participant during the experiment. This expansive set of biometric data not only enabled us to validate the effectiveness of our arousal stimuli, but importantly, enabled us to derive our emotional dimensions based upon the tasks and measurements themselves, rather than an a priori assignment of dimensions. Rather than assume that arousal is limited to its effects on heart rate we sought to determine a more complete set of emotional measures. We found that the threshold only model most accurately characterizes the data. This implies that arousal influences decision making by decreasing participants' conservativeness in their responses, rather than by altering the accrual of perceptual evidence via attentional allocation. Biometric validation of our arousal manipulations indicates that the biological measures that predict the level of arousal for each stimulus also predict reaction time. In addition, the emotion data could be used to extract a simple signature of arousal which predicts reaction time on a trial-by-trial basis, seconds before the decision is actually executed.

Title: Early target selection signals predict the onset and rate of evidence accumulation during perceptual decision making

Authors: *G. LOUGHNANE[1], D. NEWMAN[2], M. BELLGROVE[2], E. LALOR[1], S. KELLY[3], R. O'CONNELL[1];
[1]Trinity Col., Dublin, Ireland; [2]Monash Univ., Melbourne, Australia; [3]Univ. Col. Dublin, Dublin, Ireland

Abstract: Since it is rarely possible to predict precisely when and where goal-relevant information will present itself, adaptive decision making is heavily reliant on an ability to select motivationally salient sensory events for preferential processing - a phenomenon typically referred to as attentional orienting. To date, research on the critical neural dynamics underpinning orienting and perceptual decision making has proceeded largely in parallel and we still know little about how these two core brain systems interact. Recent work on human EEG has isolated a centro-parietal positivity (CPP) that provides access to the distinct parameters of the neural decision process (e.g. onset time, evidence accumulation rate and decision threshold). In the present study, we probed the impact of early target selection mechanisms on this process. Participants performed elementary perceptual discriminations with and without foreknowledge of the timing and/or location of relevant sensory information. This approach allowed us to identify an early target-selection signal that immediately preceded the onset of the neural decision making process, peaking at approximately 280ms after evidence onset over bilateral visual areas. The selection signal was maximal contralateral to the location of the physical evidence, was exclusively evoked by goal-relevant sensory changes and determined the timing and accuracy of upcoming perceptual reports by modulating both the onset and rate of evidence accumulation during decision formation. These data provide novel insights into the manner in which attention orienting supports decision making in an uncertain environment.

Title: Sensory evoked potentials in human anterior cingulate cortex electrophysiological recordings during a cognitive task

Authors: *A. R. WEISS[1,2], M. J. GILLIES[3], A. L. GREEN[3], J. R. WALTERS[1], T. Z. AZIZ[3]; [1]Neurophysiological Pharmacol. Section, NINDS, Bethesda, MD; [2]Nuffield Dept. of Med., [3]Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Conflict monitoring and error processing are essential executive functions for adaptation to conflicting information. Neuroimaging studies consistently report activity in the medial prefrontal cortex in cognitively demanding conditions, with the anterior cingulate cortex (ACC) believed to be principally active during action-monitoring processes. It is unclear whether ACC activity increases directly with the receipt of error feedback, or simply acts in the detection of response conflict. Ultimately, ACC basic function remains in dispute. This study aimed to investigate ACC function and the role it plays in human cognition. We analyzed local field potentials from electrophysiological recordings from bilateral ACC in chronic pain patients undergoing implantation of deep brain stimulation electrodes. Patients performed a modified Wisconsin card-sorting task, a test sensitive to shifting and flexibility of attention. Utilizing a pre-existing model of response conflict and error likelihood, we revealed a disconnection between sensory evoked potentials from fast response trials featuring low conflict/high error likelihood and slow response trials/low error likelihood (Alexander and Brown, 2012). We observed that the ACC responds differently to correct and incorrect sensory feedback during trials, featuring distinct patterns of 3-8Hz theta and 13-30Hz beta oscillatory activity. Laterality differences are seen between dominant and non-dominant ACC in the initial reaction to the presentation of stimulus and upon receipt of feedback. Additionally, we found that ACC activity at a given site could fluctuate between states of high and low inter-trial coherence with respect to

the requirements of different stages of the cognitive task. Our data offer a valuable electrophysiological comparison of ACC activity, available in awake behaving humans by no other method, in response to sensory feedback during a cognitive task requiring conflict monitoring, error processing, and a selective motor response. This study is believed to be the first demonstration of sensory-evoked potentials in the ACC, and may offer fresh insight into the role of ACC in decision making and learning processes and on the nature of ACC physiology and pathophysiology.

Title: Occurrence pattern of EEG at the on-set of a voluntary movement

Authors: *S. KAWASHIMA[1], A. MORI[2], N. T. MINAKAWA[2], M. TAKAYOSE[2];
[1]Grad. Sch. of Literature and Social Sci., [2]Nihon Univ., Tokyo, Japan

Abstract: It is known in the beta band (13~30 Hz) of electroencephalogram (EEG) studies, the prefrontal area is associated with decision-making. On the other hand, specific frequency (6~7 Hz) in the theta band (3~7 Hz) is called frontal midline theta (Fmθ), and it has been confirmed to be associated with concentration in humans. However, the occurrence pattern of theta and beta bands at the onset of a voluntary movement have not been studied in the 128 channels of electroencephalograph. Therefore, in the present study, we investigated the occurrence patterns of theta and beta bands in at the onset of a voluntary movement. The subjects were eight right-handed healthy male athletes who performed a voluntary movement with a button press of 90 times. The EEGs were recorded on the scalp by 128 channels. The standard electrode during the recording was positioned on the vertex of the head and the grounding electrode was on the Fpz (frontal Midline-Perietal). Recording conditions were defined as follows: 500 Hz as the sampling frequency, 0.1 Hz as a low frequency filter, 200 Hz as a high frequency filter and 100 kΩ or lower as a resistance value between the electrode and the scalp. EEGs are classified into theta, alpha and beta bands, respectively averaged from 5 seconds before the onset of the button press. As a result, the occurrence pattern of the theta band was localized in the midline of the prefrontal and occipital regions from 5 seconds before the button press. On the other hand, the occurrence

pattern of the beta band was especially localized in the prefrontal region from 1 second before. In addition, it was also observed that activity was localized in the occipital region. No activity was found in the prefrontal region of alpha band. The present result suggested that there is a difference between the occurrence pattern of the theta band and the beta band at the onset of a voluntary movement. There is a difference in the projection pathway between the generation source of the theta band and beta band to the prefrontal region and the vassal area in the cerebral cortex.

Title: Functional dissociations between abstract and effector-selective decision signals during delayed perceptual choices

Authors: *D. M. TWOMEY[1], S. P. KELLY[2], R. G. O'CONNELL[1];
[1]Trinity Col. Inst. of Neurosci. & Sch. of Psychology, Trinity Col. Dublin, Dublin, Ireland; [2]Sch. of Electrical, Electronic and Communications Engin., Univ. Col. Dublin, Dublin, Ireland

Abstract: Complementary neurophysiological research in the human and non-human brain has identified neural signals that gradually accumulate evidence for decision making. While studies in rodents and monkeys have focused on effector-selective signals that represent the translation of the evolving decision into a specific motor plan, recent research on the human brain has demonstrated that decisions are also represented in a manner that is abstracted from the specific sensory or motor requirements of a task. These observations raise critical questions about the functional distinctions between abstract and effector-selective decision signals. Monkey neurophysiology has revealed that effector-selective decision signals remain at an elevated level when a delay is imposed between decision commitment and response execution. This observation has directly informed the model assumptions employed in functional neuroimaging

studies seeking to identify domain-general decision making regions. However, it has yet to be determined whether abstract decision signals exhibit the same sustained activity under delayed response conditions. In the present study, participants performed a variant of the prototypical random dot motion task in which they discriminated the direction of coherent motion in a dot kinetogram but did not indicate their decision until a delayed response cue appeared. This approach enabled us to vary the stimulus-response association. In the 'fixed' condition participants knew that the press required at cue onset always corresponded to the direction of the coherent motion. However, in the 'varied' condition they had to wait for the response cue to find out which hand they should use to report on a given motion direction. We traced the dynamics of abstract and effector-selective decision variable signals in the form of the broad-band centro-parietal positivity (CPP) and limb-selective beta-band activity, respectively. Our results reveal that, while effector-selective signals are sustained during the interval between decision and response, the abstract decision signal returns to baseline following commitment. Furthermore, we find that while effector-selective signals only represent the evolving decision when the stimulus-response association is known in advance, the abstract signals were unaffected by this manipulation. Our findings highlight fundamental functional dissociations between effector-selective and abstract decisions signals and will have important implications for functional neuroimaging investigations of decision-making.

Title: Risk-taking decision in motor task can be modulated by transcranial direct current stimulation over dorsolateral prefrontal cortex

Authors: *K. OTA[1,2], Y. MASUGI[1], M. SHINYA[1], K. KUDO[1];
[1]Dept. of Life Sciences, Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan; [2]The Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Recent studies have demonstrated that human motor decision making under risk tends to be suboptimatl as well as economic decision. However, it remains unclear what brain activity

induces this suboptimality. Right dorsolateral prefrontal cortex (DLPFC) plays a role in the inhibitory control of seductive options. It has been shown that activation in the right DLPFC which induces to increase such inhibitory control leads to safer economic decision making. Here, we investigated whether activation in the right DLPFC with transcranial direct current stimulation (tDCS) reduces risk taking behavior in motor decision task. Participants (N = 12) performed a novel motor decision task in two experimental sessions with three different stimulation protocols. Each experimental session consists of a pre-test and a test during stimulation. The participants randomly received either anodal stimulation over the right DLPFC and the cathodal stimulation over the left DLPFC, cathodal stimulation over the right DLPFC and the anodal stimulation over the left DLPFC, and sham stimulation. The order of stimulation protocols was balanced across the participants and it was double-blinded for the participants and the experimenter. The intensity of stimulation was 2 mA and the stimulation lasted for 20 minutes. The task required the participants to make a decision when to press a button to maximize a total gain of 50 trials in each session. They were rewarded with higher gain if they respond closer to a target time (2300ms) but they had no gain if thy responded after the target time (miss trial). In this task, optimal mean response time that maximizes the total gain was calculated depending on each participant's variability in response time. Therefore, the participants were required a decision considering both own variability in motor output and risk of zero gain. We confirmed risk taking behavior in the pre-test of all three protocols. The average observed mean response time across the participants was 2124±75 ms, although the average optimal mean response time was 1995±44 ms. Compared with the pre-test, this discrepancy was significantly decreased only in the test during anodal stimulation over the right DLPFC and the cathodal stimulation over the left DLPFC (pre-test = 129±83 ms, test during stimulation = 87±69 ms, $p < .01$). The numbers of miss trials also decreased in the test during stimulation more than the pre-test (pre-test = 7.0±4.7 trials, test during stimulation = 5.5±3.5 trials, $p = .082$). Other two stimulations did not significantly influence the participant's behavior. These results indicate that the activity in the DLPFC is related to risk-taking behavior in motor decision making.

Title: Modeling of generation of self-organized response in the analog circuit from dynamic memories coded on the neural network using multi-scale biological oscillations

Authors: *M. HIRABAYASHI[1], H. OHASHI[2];
[1]Bio-ICT Lab., Advanced ICT Res. Institute, NICT, Kobe, Hyogo, Japan; [2]Univ. of Tokyo, Tokyo, Japan

Abstract: Objective In biological systems, water, nucleic acid, and protein molecules realize various properties and important functions derived from of hydrogen bonds with natural frequency (ca. 1,000,000,000,000Hz). Although a semiconductor memory presents a memorizing function using flip-flop, which keeps the output state by feedback of the input one, it may be possible that biological systems construct a memory circuit using multi-scale oscillations including this intrinsic frequency band. Here we investigate a neural mechanism of decision making by designing the circuit based on our assumption that a memory is coded in a dynamic state of a network using multi-scale biological oscillations, and a self-organized response is generated by phase modulation in the brain analog circuit. Methods Previous findings indicate that sensory inputs do not induce an action potential but locks the inner state of a spontaneous-firing system by phase modulation [1-2]. According to this idea in order to implement a memory-storing state, we design an oscillating analog circuit that realizes the probabilistic metastable transition state among multiple modes with different phase and frequency, and verify its properties. Results Defining the transition from a probabilistic state to a locked one as a phase transition in this circuit, it can be thought that the metastable transition state is at the critical state toward the locked one. This critical state is stable to small perturbation and low noise. Therefore this strategy is an effective way to control noise in analog systems which are susceptible to it. A series of observed performances show that it is possible to retain memory in a probabilistic transition mode and recall in a locked mode by synchronization triggered by input signals. It is suggested that we will be able to obtain a self-organized response such as the activation of specific circuits by diffusion of locked states in networks, if a circuit is designed to induce further synchronization for significant outputs using amplifier circuits and so on. Conclusions It is expected that the progress of the research on the control mechanism using multi-scale oscillations, including the natural frequency band of hydrogen bonds, will bring the breakthrough of technologies such as information processing or prediction of social behavior based on the decision making algorithm. 1. Title: Temporal dynamics of activity in human anterior cingulate cortex during an event-related color-word Stroop interference task

Authors: *K. L. ANDERSON[1,2], V. PIAI[1,2], J. J. LIN[3], R. T. KNIGHT[1,2];
[1]Helen Wills Neurosci. Inst., [2]Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA;
[3]Comprehensive Epilepsy Program, Univ. of California, Irvine, Irvine, CA

Abstract: It is well established that anterior cingulate cortex (ACC) is an important node in the cognitive control network, though its specific contributions are still under debate. ACC has been found to be active during performance of the Stroop task in many neuroimaging studies, and this region is believed to be involved in cognitive conflict processing. However, to what extent this activity involves conflict detection and resolution, error detection and correction, and more generally, regulation of selection processes is unresolved. We recorded electrical activity (electrocorticography; ECoG) from the anterior cingulate of human patients undergoing pre-surgical monitoring for intractable epilepsy while they performed a classic Stroop task. The task employed an event-related design, with congruent (same color), incongruent (different color), and neutral (non-word) stimulus conditions randomly interspersed. Patients were instructed to respond as quickly and accurately as possible by naming the color of the stimulus. Behaviorally, the fastest response times occurred for neutral stimuli, followed by congruent, and then incongruent trials. Based on the prevailing hypothesis positing the ACC's involvement in conflict detection, we predicted greater high-gamma band (HG, 100-250 Hz; a marker of cortical activation) activity in ACC electrodes following incongruent trials, compared with congruent trials. However, while robust task-related activation in the high gamma band between 200ms and 500ms relative to a pre-stimulus baseline was observed in anterior cingulate electrodes, no consistent differences were found between the neutral, congruent and non-congruent conditions. Our ECoG results provide support for the role of the ACC in continuous top-down regulation of selection processes. However, the lack of condition effects in this event-related design,

controlling for arousal, challenges the notion that the ACC is specifically involved in conflict resolution.

Title: Action selection as a biased competition up to the primary motor cortex

Authors: *C. BUC CALDERON[1], T. VERGUTS[2], W. GEVERS[3];
[1]Univ. Libre De Bruxelles, Brussel, Belgium; [2]Ghent Univ., Ghent, Belgium; [3]Ctr. for Res. in Cognition & Neurosciences, Univ. Libre de Bruxelles, Brussels, Belgium

Abstract: During penalty shootouts, a soccer goalie knows the probabilities associated to each player's shooting side preference. Together with sensory information, this previously cued knowledge is used by the goalie to decide towards which side to dive in order to catch the ball. In this situation, deciding what action (i.e. which side to dive for) to perform has traditionally been explained within the framework of information processing (e.g. Sternberg, 2011). In this view, the soccer goalie would, based on sensory input and probability knowledge, first compute a decision in prefrontal areas, which would subsequently act as input to motor processing yielding the observed action (the dive). Importantly, this view suggests that relevant task factors (e.g. probability of an upcoming action) are integrated in the decision process through a cost/benefit computation implemented at the OFC/vmPFC level (Hare, Camerer, Knoepfle, & Rangel, 2010; Padoa-Schioppa, 2011; Wallis & Miller, 2003). Other authors have emphasized an 'embodied' view on decision-making (Cisek & Kalaska, 2010; Shadlen, Kiani, Hanks, & Churchland, 2008). This evolutionary perspective suggests the involvement of sensorimotor areas in decision-making. Stemming from single-cell recordings in monkey studies and formalized in the affordance competition hypothesis (Cisek, 2007), this competition is suggested to be limited to premotor areas. Recent models of human action selection advocate such a view (e.g. Domenech & Koechlin, 2015). However, in humans, it is not clear up to what level this competition takes place. To formally address this question in humans, we designed a functional Magnetic Resonance Imaging (fMRI) experiment. Participants were shown cues indicating the

probabilities associated with upcoming button presses. If action selection (i.e. pressing the left or right button) is performed through a biased competition in sensorimotor regions, these same regions are expected to integrate relevant task factors (e.g. probability cues). Our results show that the biased competition induced by probability cues is represented up to the primary motor cortex. Specifically, activity in the contralateral primary motor cortex increased with action probability; instead, activity in the ipsilateral motor cortex decreased. This finding strongly suggests that human decision-making derives from a biased competition taking place up to the primary motor cortex.

Title: Dynamics of evidence integration in canonical models of perceptual decision making

Authors: *G. PRAT ORTEGA[1,2], K. WIMMER[2], J. DE LA ROCHA[2], A. ROXIN[1];
[1]Ctr. de Recerca Matemàtica (Computational Neuroscience), Ctr. De Recerca Matemàtica, Bellaterra, Spain; [2]Cortical circuits dynamics, IDIBAPS, Barcelona, Spain

Abstract: The brain is able to interpret streams of high-dimensional ambiguous information and yield coherent percepts. This process of evidence integration has been studied extensively [1] but the underlying neuronal network dynamics remain largely unknown. Several models can explain the behavioral performance in these tasks [1,2], although they rely on different dynamical mechanisms. Here, we characterize the dynamics of evidence integration using three canonical one-dimensional models: (1) the Drift Diffusion Model (DDM), (2) the Perfect Integrator (PI)

and (3) the double-well potential (DW) which captures the dynamics of the attractor networks[3]. We examined the categorization dynamics of these models in response to fluctuating stimuli of different duration seeking contrasting and experimentally testable predictions. Stimuli are drawn from a Gaussian distribution $N(\mu, \sigma)$ and the two stimulus categories are defined by $\mu > 0$ and $\mu < 0$. We find that the models behave differently in response to stimuli with different σ: In the small σ regime, both the DW and the DDM perform transient integration and exhibit a decaying psycophysical kernel (PK) revealing a primacy effect (i.e. only the first part of the stimulus is used for classification). In the large σ regime, the effective integration window in the DDM decreases because the absorbing bound is reached earlier. In contrast, the DW allows for classification reversals whose rate increases with σ producing a change in the PK time course from decreasing to increasing (recency effect). The PI shows constant PK for all σ's (i.e. uniform integration). The discrimination sensitivity(β) in the PI and the DDM decreases monotonically with σ because the two stimulus categories become less separable and because of the reduction in effective integration time in the DDM. Remarkably, the β in the DW as a function of σ shows a local maximum at $\sigma max > 0$. This “stochastic resonance” phenomenon allows some correcting reversals (i.e. transitions to the deeper well) to compensate for the decrease in stimulus separability. Finally, we also find that the models behave differently with σ when the initial condition is offset, what can represent unequal prior probabilities of the two categories: the choice bias caused by the offset decreases with σ in the DW, increases in the DDM and remains constant in the PI. Our analysis makes strong specific predictions to be tested in psychophysical two alternative forced-choice tasks which would pin down the basic principles of sensory integration dynamics. Title: Computational modeling reveals differences in how patients with Parkinson's disease implement bias in perceptual decision-making compared to healthy control subjects

Authors: *M. A. BASSO[1], A. PERUGINI[1], J. DITTERICH[2];
[1]Psychiatry and Biobehavioral Sci. and Neurobio., UCLA, Los Angeles, CA; [2]Ctr. for Neurosci. and Dept. of Neurobiology, Physiol. & Behavior, UC Davis, Davis, CA

Abstract: Patients with Parkinson's disease (PD) as well as a group of age-matched healthy controls (HC) made perceptual judgments about the orientation of dynamic Glass patterns in a two- alternatives forced choice task. Signal strength (coherence) was varied randomly from trial to trial, and choices and response times were recorded. Subjects initially experienced a block of trials with the two possible orientations being presented with equal probability (50:50), followed by a block of trials with unequal priors (80:20) and then a final block with again equal priors (50:50). In this simple task we found that both HC and patients with PD were able to track the priors. Decisions were affected by the prior information, in particular when the sensory evidence was weak. We found interesting differences in how the decision process was affected by the prior information in patients versus HC. We used the drift-diffusion modeling framework to determine how healthy control subjects and patients with PD implemented the decision bias. Within this framework, there are two possible ways decision bias can be generated: 1) a starting point of evidence accumulation that is closer to one decision boundary than to the other or 2) a drift rate offset, meaning that the process drifts towards the boundary associated with the more frequent choice even in the absence of any sensory evidence. The two ways of implementing bias have different consequences for decision times and can therefore be distinguished based on response time data. Modeling the data revealed that HC's starting point closely tracked the priors, whereas their drift rate offset was undergoing only smaller and slower changes. In contrast, PD patients tracked the priors primarily with a drift rate offset, whereas their starting point of evidence accumulation was undergoing only smaller and slower changes. Thus, while both groups were able to track the priors, they apparently used different mechanisms to do so. We propose that the effective adjustment of the starting point of evidence accumulation requires intact basal ganglia.

Title: Faulty use of prior information in patients with Parkinson's disease

Authors: *A. PERUGINI[1], J. DITTERICH[3], M. A. BASSO[2];
[2]Psychiatry and Neurobio., [1]UCLA, Los Angeles, CA; [3]Ctr. for Neurosci. and Dept. of Neurobiology, Physiol. & Behavior, UC Davis, Davis, CA

Abstract: When sensory information is ambiguous, we make perceptual choices based on information that was previously learned about the stimulus. Many studies show that the basal ganglia (BG) are necessary for learning stimulus outcome relationships based on feedback, but little is known about their role in using this learned information to make decisions. In other words, how are memories acquired through experience used to make decisions? Our hypothesis is that the BG makes already established memories available to drive choices of actions that are not value or reward based. To test this idea, we developed a 2-alternative forced choice task in which patients with Parkinson's disease (PD) and healthy subjects (HC) make choices about the orientation of Glass patterns. We manipulated the levels of visual information contained in the stimulus (coherence) and also the statistics of the stimulus by making one orientation more probable then the other (prior). We have shown that patients with PD can learn the unequal priors associated with a stimulus orientation if the prior is strong (yet implicit) and that they can use it to make decisions when sensory information is not available: both HC and patients with PD learned and used the prior (N = 10 control vs bias: $p < .05$); but patients with PD did not use it optimally, rather they perseverated (Perugini et al. Abstract SFN 2014). These preliminary data suggested that the impairment in patients with PD is not in learning the prior, but rather in using it. Here, we conducted new experiments to directly test this hypothesis. First, we modified our task and made the implicit prior less obvious by presenting two randomly interleaved stimuli, one associated with an equal prior (50:50) and the other with an unequal prior (75:25). Subjects computed two different stimulus statistics simultaneously and used them to make choices. We found that whereas HC used the prior correctly when sensory information was uncertain (N = 14 control vs bias: $p < .05$), patients with PD failed to do so (N = 14 control vs bias: $p > .05$). Second, we informed patients about the presence and the type of the prior explicitly before the start of the experiment to exclude the possibility that the deficit in patients was in using the priors and not in learning them. Under these conditions, subjects do not need to learn the priors associated with the stimuli, their only task is to use the information provided to make their choices. We found that patients with PD were impaired in this task when learning was not required (N = 7 control vs bias: $p > .05$). Altogether our data support the hypothesis that patients with PD are impaired in accessing memory information that was previously learned to guide decisions.

Title: Influence of value-dependent endogenous signals on saccadic choice

Authors: *E. CHU[1], L. M. HARRIS[1], V. W. LEE[1], S. FARASHAHI[2], A. SOLTANI[2]; [2]Psychological & Brain Sci., [1]Dartmouth Col., Hanover, NH

Abstract: Saccadic target selection is one of the most frequent decisions made by the nervous system. Every saccade is determined by both external factors, such as the onset time or the physical salience of visual stimuli, as well as internal factors, such as reward expectation. While much is known about how external factors determine target selection, neuroscientists have only recently begun to explore the contribution of internal factors to saccadic choice. Here, we used a modified version of the paired-target task to study the differential effects of value-dependent endogenous signals on saccadic target selection. The two targets (Gabor patches), which could be visually similar or dissimilar, appeared on a computer screen with varying onset asynchrony (TOA). In two sets of experiments, subjects reported what they perceived to be the first of two targets to appear on the screen by making a saccadic eye movement to it. During experiment 1, when the two targets were visually identical, the amounts of reward/gains and punishment/losses associated with correct or incorrect detection on each side of the fixation cross were cued at the beginning of every trial. In experiment 2, when the two targets were different, subjects performed the same type of visual selection but in the absence of any external cues. In this experiment, amounts of gains and losses associated with correct and incorrect responses were based on target identity, and were already learned by the subject. Additionally, we measured subjects' risk and loss aversion by asking them to choose between pairs of gambles with varying amounts of gains/losses and probabilities. Our results were threefold. First, we found a stronger bias (by two-fold) in target selection toward the target that yields a larger gain compared with the one that yields a smaller loss, even when the magnitudes for gains and losses were similar. Nevertheless, the amounts of bias for gain and loss manipulations were correlated within each subject. Moreover, the amounts of bias were equal in both experiments, reflecting that spatial top-down attention was not critical for the observed shifts in behavior. Secondly, we observed an improvement in sensitivity to the TOA for the more rewarding target in both gain and loss manipulations in experiment 2, but not in experiment 1. These results indicate that distinguishable targets associated with different amounts of gains and losses could evoke

differential response onset. Finally, we did not find any correlation between the magnitude of bias in target selection and individual risk/loss aversion, suggesting that the effects of reward on target selection could be independent of reward preference in economic choice.

Title: Reward primes representations in human short-term visual memory

Authors: *C. M. HICKEY, M. V. PEELEN;
Ctr. for Mind / Brain Sci., Univ. of Trento, Rovereto, Italy

Abstract: Reward coding in the midbrain is thought to cause the rapid prioritization of reward-associated visual stimuli, but the neural mechanisms that create such incentive salience are largely unknown. We used human fMRI to study how reward feedback might retroactively influence the perceptual representation of naturalistic visual stimuli. Participants viewed briefly presented images of city- and landscapes that contained examples of trees, cars, and people. For each participant two of these three categories were targets that required manual response. Correct performance garnered reward feedback that could randomly have either high or low magnitude. Using multivoxel pattern analysis we found that high-magnitude reward acted both to reinforce target information encoded in visual cortex and to cause the strong suppression of nontarget information. Critically, this occurred in spite of the fact that the visual stimuli were no longer present when reward feedback was received. Reward thus appears to impact short-term visual memories of the scene. Further analyses identified a network of subcortical and cortical brain areas involved in instantiating this effect. The results identify a mechanism through which reward can act to guide human vision, demonstrating a novel interaction between neural systems responsible for reward processing and visual perception in the human brain.

Title: 3D reconstructions and quantitative analyses of immunocytochemical staining patterns in the human subthalamic nucleus (STN)

Authors: *A. ALKEMADE[1], M. C. KEUKEN[1], G. DE HOLLANDER[1], R. BALESAR[1], M. WEISS[1], A. TRUTTI[1], A. SCHAEFER[2], B. U. FORSTMANN[1];

Abstract: With the development of ultra-high field 7Tesla MRI techniques, we can visualize individual brain structures *in vivo* with unprecedented detail. However, the detail obtained is still well above the cellular level, and fine-grained anatomical resolution using post-mortem anatomical staining methods are still considered a prerequisite to fully understand the biological processes within the brain. The present studies are aimed at the integration of post-mortem analyses and noninvasive imaging techniques. For this purpose, a pipeline that allows 3D reconstruction of immunocytochemical staining patterns within the human subthalamic nucleus (STN) was developed. Tissue blocks obtained from patients suffering from Parkinson's disease (PD) and controls were scanned with 7T MRI, and the STN was manually segmented. Tissues were paraffin embedded and blockface imaging was performed during the cutting procedure. After immunocytochemical staining for markers of GABA-ergic, glutamatergic, dopaminergic, and serotonergic signaling, sections were digitized and 3D staining patterns were reconstructed in MNI-standard space using linear and nonlinear registration. Image analyses were performed in ImageJ using thresholding procedures and staining gradients were quantified. The results indicate that the STN is an inhomogeneous structure, and staining patterns differ between immunocytochemical markers. These studies provide novel quantitative insight in the functional neuroanatomy of the human STN.

Abstract: Working memory declines with age. Previous studies have reported that older adults demonstrated greater and more widespread brain activation than young adults for working memory. The present functional magnetic resonance imaging (fMRI) study investigated whether this pattern of age-related 'over-recruitment' continues into advanced age. During fMRI scanning, two groups of older adults ('young-old'; n=13; 61-70 years and 'old-old'; n=14; 77-82 years) performed an n-back task. Participants were shown with a face or a dot on a screen. In the 0-back task, participants were asked to judge whether the face is female or male for face condition, or whether the dot is located in the center of the screen for location condition. In the 1-back task, participants were asked to judge whether or not the current item was identical to the one immediately preceding it (i.e., the face or the location of the dot presented one trial back). The fMRI data revealed both groups recruited similar networks to support working memory irrespective of material, including the lateral frontal, parietal cortex, and insula. Age-related increase (old-old group > young-old group) in working memory effects for face were found in the right dorsolateral prefrontal cortex (DLPFC) and the bilateral fusiform gyrus, and those for location were shown in the bilateral DLPFC and the left lateral parietal cortex. Among these age-sensitive regions, the bilateral fusiform gyrus and the left lateral parietal cortex also showed material effects (face > location or location > face, respectively). On the other hand, age-related increase in working memory effects in the right DLPFC overlapped across materials. There were no regions where working memory effects was greater in young-old group. Our results demonstrated two main findings. First, age-related over-recruitment of brain activity in working memory continues into advanced age. Second, increased engagement of the right DLPFC, along

with regions involved in the online processing of material information, may serve a compensatory role in mediating working memory function in old-old adults.

Title: The effects of physical exercise with music on prefrontal cortex volume of elderly people: mihama–kiho scan project

Authors: ***K. TABEI**[1], M. SATOH[1], J.-I. OGAWA[2], T. TOKITA[3], N. NAKAGUCHI[4], K. NAKAO[5], H. KIDA[1], H. TOMIMOTO[1];

Abstract: Physical activity is associated with positive effects on the brain of elderly people. In our previous study (Satoh et al., PLoS ONE, 2014), we indicated that physical exercise with musical accompaniment produced more positive effects on cognitive function in elderly people than exercise alone. However, little evidence is available on neuroimaging data of combining physical exercise with music. This study aimed to explore the dynamics of structural brain changes related to physical exercise with musical accompaniment in normal elderly people. We enrolled 199 participants (age 64-84 years old). Eighty participants performed physical exercise (once a week for an hour with professional trainers) with musical accompaniment (ExM group); eighty participants performed the same exercise without music (Ex group); thirty-nine participants were the control group (Cont group). Before and after a year-long intervention, each participant was assessed by neuropsychological batteries. MRIs were performed before and after intervention. After a year-long intervention, ExM and Ex groups had better intellectual function than Cont group. Furthermore, only ExM group had better visuospatial function than Cont group. Voxel-based morphometry (VBM) analyses revealed significantly (FWE corrected, $p \leq 0.05$) higher gray matter (GM) volume in the superior frontal gyrus in ExM group compared to the

Cont group. On the other hand, Ex group showed significantly (FWE corrected, $p \leq 0.05$) higher GM volume in the insula compared to the Cont group, which in line with the previous neuroimaging studies which have implicated the insula in cardiovascular control. This study adds on previous results, showing that physical exercise with music not only induces positive effects on cognitive function, but also fine-grained neuroanatomical changes in the brain of elderly people.

Title: Neuropsychological and neuroanatomical factors associated with speech-in-noise perception in aging

Authors: *K. A. ALTONJI, J. HANSON, M. KASSEL, C. HUMPHRIES, M. SABRI; Neurol., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: This study sought to determine whether declining speech-in-noise perception in older adults with normal hearing thresholds is associated with cognitive performance (specifically attention and working memory) and structural integrity of cortical gray matter. 18 younger adults (ages 20-41, mean= 26.1, SD= 5.7) and 18 older adults (ages 57-72, mean= 62.4, SD= 4.9) with normal hearing (audiometric thresholds ≤25 dB HL 500 - 4,000 Hz) were tested with the Montreal Cognitive Assessment, the Test of Everyday Attention, the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS), the Wechsler Adult Intelligence Scale, and the QuickSIN Speech-in-Noise Test. The QuickSIN involves 12 lists of 6 syntactically correct sentences spoken by a female and masked by four-talker babble presented binaurally through headphones. The sentences are presented at a range of signal-to-noise ratios (SNR) between 25 and 0 dB. Structural Magnetic Resonance Imaging (MRI) scans were acquired in all subjects. On average, older adults performed significantly worse on the QuickSIN 0 dB SNR than the younger

adults ($p < .05$). A multiple regression was performed across both groups with age and RBANS attention tasks as predictors for QuickSIN 0. For this model, raw scores of RBANS attention-digit span (working memory) and RBANS attention-coding (processing speed) were significant predictors of speech perception performance ($p < .001$). Structural analyses revealed, for older adults only, a significant relationship between QuickSIN 0 and bilateral gray matter thickness in regions of the frontoparietal attention network (middle frontal gyrus, superior frontal gyrus, superior parietal lobule, right intraparietal sulcus), semantic network (inferior frontal gyrus, angular gyrus, precuneus, middle temporal gyrus), and speech perception regions (superior temporal sulcus) ($p < .05$). Structural correlations were subject to false discovery rate correction ($q = .05$) for multiple comparisons. This study demonstrates that in aging, speech perception in noise does indeed decline despite normal hearing and that this can be attributed to declining executive function related to attention and working memory. In addition, deficits in speech perception are also associated with decreased gray matter thickness in cortical areas involved in executive cognitive control, attention, and language processing.

Title: Neural representations of subjective value across the human lifespan

Authors: *M. A. GRUBB[1], S. RASHID[1], P. W. GLIMCHER[1], I. LEVY[2];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Neurobio. and Neurosci., Yale Sch. of Med., New Haven, CT

Abstract: Humans often face decision scenarios in which the actual outcome of one or more of the available options is uncertain. Sometimes the probability that an event will occur is known (e.g., a 50% chance of gaining $10), while other times, only partial information is available (e.g., a 25%-75% chance of gaining $10), and our idiosynchratic attitudes to risk and ambiguity, respectively, guide our choices. How these attitudes change across the human lifespan, particularly in more vulnerable phases like adolescence and elderhood, and how the brain

incorporates features like value, risk, and ambiguity to arrive at a unified representation of the subjective value (SV) of a given option is of great interest to economics and neuroscience alike. Here, we evaluate the neural correlates of subjective value representation under uncertainty across the lifespan. 60 participants (12-88 y.o., 35 F) made choices between a fixed reference amount (certain gain of $5) and a lottery whose magnitude ($4-$120), probability of payout (0.25, 0.5, 0.75), and degree of ambiguity (0, 0.24, 0.5, 0.74) was systematically manipulated; neural activity was concurrently measured using fMRI. The SV for each option was modeled using a power utility function with an additional ambiguity-attitude parameter, and choice data were fit with a logistic function to obtain idiosynchratic risk and ambiguity attitudes. One of the choices was randomly selected at the end of the experiment and determined bonus earnings. We examined the timecourse of the BOLD signal in the ventral striatum and the ventral medial prefrontal cortex (vMPFC) using ROI masks from a 2013 meta-analysis of the neural correlates of subjective value. Using individual risk and ambiguity attitude parameters, we calculated the SV of each option and computed trial triggered averages of the BOLD response, separately for two SV conditions (High, Low). A mixed-design ANOVA was performed on the peak activation in each ROI, with SV condition as a within-subjects factor and age group (12-50, 51-90) as a between-subjects factor. In line with previous research, we found that subjective value modulates BOLD activity in the ventral striatum and the vMPFC. We found no evidence for an age x SV interaction, in either ROI, suggesting that SV representation is robust from adolescence to elderhood. We did find, however, some evidence for a main effect of age in the ventral striatum, with the 51-90 group showing a decrease in overall activation relative to the 12-50 group. No evidence for such age related differences were found in the vMPFC. Future analyses will assess more fine-grained age-related differences in the precision of the SV representation in both ROIs.

Title: Proactive interference as a source for age related navigational decline

Authors: ***M. MERHAV**[1], T. WOLBERS[2];
[2]Aging & Cognition Res. Group, [1]DZNE, Magdeburg, Germany

Abstract: Elderly people often report declines in navigational abilities, for example, problems in finding one's way in a new environment. Even though numerous studies have investigated spatial navigation impairments in old age, the mechanisms underlying such deficits are poorly understood. One such mechanism could be Proactive Interference (PI), a situation in which previous learning disrupts the ability to recall more recently presented information. PI could, for example, lead to problems whenever spatial information needs to be updated, for example when having to find your car in a parking lot you frequently visit. Age related PI has been observed both in working memory and in associative learning tasks, but whether such deficits also occur in the spatial domain is unknown. To address this question, we designed an incidental object-location task in which we presented 24 objects, one at a time, to healthy young and old participants (the encoding phase). Each object was presented in a distinctive location. There were no instructions to remember the locations of the objects, but participants were asked to judge the dimensions and colorfulness of each object. In the interference phase, which took place a day before encoding, half of the objects (12) were presented in a different set of locations. In the retrieval phase, which took place two hours after the encoding phase, participants had to indicate the location of each of the 24 objects, as placed in the encoding phase. The distances to the correct locations were calculated to measure retrieval accuracy for the interfered and the non-interfered associations. The results reveal an interaction between interference condition and age group, showing that older participants were selectively impaired at recalling interfered object-locations associations. This result presents PI as a potential source for navigational deficits in elderly people and provides an example for age related deficit in spatial updating.

Title: A modified-Sternberg paradigm measures load and delay components of working memory in cognitive SuperAgers

Authors: *A. H. COOK[1], E. LOYER[1], M.-M. MESULAM[1], S. WEINTRAUB[2], H. BREITER[2], E. ROGALSKI[1], J. REILLY[2];
[1]Cognitive Neurol. & Alzheimer's Dis. Ctr., [2]Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Objective: The Northwestern University SuperAging Program studies individuals over age 80 (SuperAgers) who perform at least as well as middle-age adults on tests of episodic memory in order to identify neurobiologic factors that contribute to successful cognitive aging. Previous research suggests that decline in working memory underlies age-related impairment in episodic memory, possibly due to reduced ability to hold information in working memory. Traditional working memory tasks do not differentiate components of working memory such as the amount of information held (load) and the duration over which it is held (delay). The present pilot study aimed to validate the use of a novel modified-Sternberg task that allows for the differentiation and quantification of working memory components in SuperAgers. **Method**: Four SuperAgers (ages 83-86) and 6 cognitively average Middle-age Controls (ages 57-63) completed a novel computer-based modified Sternberg task that consisted of 4 blocks of 32 trials over which arrays of 1-7 boxes (load) were briefly presented. After a variable delay (1-10 seconds), a probe box appeared and subjects indicated whether the probe was in the same or different location as any box in the preceding array. Response accuracy (hit and false alarm rates), d-prime (sensitivity to detect a correct target among noise), and beta (decision threshold to report a signal) were calculated at each load, as was response time for correct response trials (correct hit or rejection). Repeated Measures General Linear Models were used to compare the groups on each measure. **Results**: SuperAgers did not differ from Middle-age Controls with regard to response accuracy, d-prime, or beta (p's > 0.05). As expected, both groups demonstrated an increase in false alarm rate and beta with increasing load (p's < 0.001) as well as a decrease in d-prime ($p < 0.001$) and trend towards a decrease in hit rate ($p = 0.14$) with increasing load. Both groups demonstrated increased response time with increasing load ($p < 0.001$) yet SuperAgers were significantly slower overall ($p < 0.01$). **Conclusions**: Preliminary results from a novel working memory task suggest that SuperAgers perform as accurately as younger adults on tests of working memory. While performance accuracy was similar between the groups, SuperAgers took longer to make their response, consistent with literature that documents age-related decline in processing speed. Slower response time may reflect a compensatory mechanism that supports the maintenance of cognitive abilities with increasing age. Overall, task demands appear appropriate for continued use in SuperAgers as a means of investigating components of working memory.

Title: Cognitive performance and gait task difficulty are predictors of stride variability during dual-task walking

Authors: *L. A. ZUKOWSKI[1], P. PLUMMER[1,2];
[1]Dept. of Allied Hlth. Sci., [2]Human Movement Sci. Curriculum, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Difficulty of cognitive and gait tasks can influence dual-task interference during walking. However, it is currently unknown whether task difficulty can predict gait variability during dual-task performance. Therefore, the purpose of this study was to determine if reaction time variability and/or accuracy during the dual-task performance of gait and cognitive tasks of varying difficulty levels are predictors of spatiotemporal stride variability in young and older adults. METHODS: Twenty-eight healthy, young adults (21.9±1.4 years) and 12 healthy, older adults (73.1±5.6 years) performed six dual-task conditions that included all combinations of two cognitive tasks (from easier to harder: auditory Stroop task, clock task) and three walking tasks (from easiest to hardest: walking at preferred speed, walking at fastest comfortable speed, fast walking while crossing an obstacle). Two linear regressions were utilized with stride time coefficient of variation (CV) and stride length CV as the dependent variables and cognitive task accuracy, reaction time CV, walking condition, cognitive condition, and age group as the independent predictors (α=0.05). To further explore the regression results, a repeated-measures ANOVA was then utilized to compare stride variability for the different age groups, walking conditions, and cognitive conditions (α=0.05). RESULTS: The independent predictors accounted for 55.5% of the variance in stride duration CV. Accuracy in the cognitive tasks (β=-4.868, $p<0.001$) and crossing an obstacle (β=4.846, $p<0.001$) were the strongest predictors of stride duration CV, but age group (β=0.961, $p=0.002$) was also a significant predictor. In the ANOVA, main effects for age ($F=12.177$, $p=0.001$) and walking condition ($F=102.045$, $p<0.001$) were observed as well as an interaction effect between walking condition and age ($F=6.054$, $p=0.005$).

Reaction time CV, walking speed, and cognitive condition did not predict changes in stride duration CV. Finally, stride length CV was not significantly related to any of the tested predictors. CONCLUSIONS: Cognitive performance accuracy, age group and walking task difficulty are significant predictors of temporal but not spatial gait variability. Greater temporal gait variability is associated with lower cognitive performance accuracy, older age, and the performance of a more demanding gait task. This last relationship is true for younger and older adults, but the impact on gait variability is even greater for older adults. The greater temporal variability observed during more demanding gait and cognitive tasks may have important implications for young and older adults ambulating in the community.

Title: Association between medial temporal lobe microstructure and cognitive function in healthy community-dwelling older adults

Authors: E. T. REAS[1], D. J. HAGLER, Jr.[1], N. S. WHITE[1], A. M. DALE[2], E. BARRETT-CONNOR[3], *L. K. MCEVOY[1];
[1]Dept Radiology, [2]Depts of Neurosciences, Radiology, and Cognitive Sci., [3]Dept Family Med. and Publ. Hlth., UCSD, La Jolla, CA

Abstract: The brain's medial temporal lobe is essential for declarative memory and undergoes structural alterations during the early stages of neurodegenerative memory disorders. Although memory decline is a common feature of typical aging, it remains unclear whether medial temporal lobe structural changes track cognitive function in normal aging, as they do under pathological conditions such as Alzheimer's disease and mild cognitive impairment. This study examined the association of medial temporal lobe microstructural organization and morphometry with cognitive function in healthy, community-dwelling older adults. Participants (N = 60; age range 60-99 years, mean 75 years; 63% women), with no history of neurological disorders or

stroke, completed a neuropsychological test battery and underwent structural magnetic resonance imaging (MRI) and diffusion weighted imaging. Regional cortical thickness and subcortical volume measures were extracted from MRI data using FreeSurfer software (www.FreeSurfer.net). Diffusion metrics for selected temporal lobe fiber tracks were derived using a probabilistic atlas of fiber tract locations and orientations (AtlasTrack; Hagler et al. Hum Brain Mapp. 2009;30:1535-1547). T1-weighted images were used to nonlinearly register the brain to a common space, and diffusion tensor orientation estimates were compared to the AtlasTrack atlas to obtain a map of the relative probability that a voxel belonged to a particular fiber given the location and similarity of diffusion orientations. These probability values were used to calculate weighted averages of the diffusion measures for each fiber tract. Results of FreeSurfer's automated brain segmentation were used to exclude voxels in fiber tract regions of interest that were primarily gray matter or CSF. After controlling for age, sex and education, lower global cognitive and memory scores correlated with reduced thickness in entorhinal and parahippocampal cortices and with altered microstructure in the fornix and parahippocampal cingulum. These findings suggest that even among healthy, community-dwelling older adults, microscopic and macroscopic changes in the medial temporal lobe may contribute to decline in cognitive function with age.

Title: Aging contributes to grey matter volume and attentional impulsivity correlates in frontoparietal functional connectivity

Authors: *J. J. CASTRELLON[1], L. C. DANG[1], S. F. PERKINS[1], G. R. SAMANEZ-LARKIN[2], D. H. ZALD[1];
[1]Psychology, Vanderbilt Univ., Nashville, TN; [2]Psychology, Yale Univ., New Haven, CT

Abstract: Background: Attentional impulsivity (AI) is a trait marked by the inability to focus one's attention on a given task observed in psychopathology such as ADHD but prevalent in healthy individuals as well. The Barratt Impulsiveness Scale (BIS) assesses AI, motor impulsivity and nonplanning, and is among the most commonly used self-report measures of impulsivity. Given its role in attention, features of frontoparietal network (FPN) may be associated with age changes in AI. Past studies have suggested associations between grey matter volume (GMV) and functional connectivity (FC) in the FPN and impulsivity, although the studies have been limited to young (YA) and middle-aged (MA) samples, and have shown inconsistent relations. Little research address whether FC and GMV in the FPN are related to AI in the context of healthy aging. We aimed to determine whether FPN FC and GMV related to age and AI in a healthy adult sample. Method: Resting-state fMRI and T1-weighted structural images were acquired in 69 healthy adults (22-81). Independent component analysis (ICA) identified a FPN across all subjects. Dual regression analysis identified subject-specific temporal dynamics and linked spatial maps correlated with age and BIS, identifying relationships in the FC strength within a network. For follow-up analyses using voxelwise GMV as covariate, GMV values were derived from voxel-based morphometry. Results: Age and AI BIS were negatively correlated. FPN FC showed a positive correlation with age and a negative correlation with AI BIS. The age correlation remained after controlling for AI BIS. When controlling for age, however, the FPN FC relationship with AI BIS was lost. Remodeling the age effect with GMV as a covariate rendered it insignificant. A final analysis between GMV and FPN FC revealed a trending relationship. Conclusion: The findings demonstrate that decreasing AI and increasing age have overlapping correlates with FPN FC and that these associations were largely accounted for by age, but dependent on GMV effects. The GMV FPN FC trend further suggests that GMV may contribute to FPN FC. Together, the findings suggest that age may mediate AI and GMV changes in FPN FC, stressing the importance of age on attention networks.

Abstract: Personal past events may be remembered along with the spatiotemporal context or source information present when we experienced the event or may be remembered without this information. The ability to retrieve contextual details is termed recollection, and it declines with advancing age, while the ability to remember the event without contextual information, known as familiarity, is only slightly affected in old age. Age effects on regional brain activations and deactivations have been identified during the encoding of information that will be remembered later through recollection or familiarity. However, how the interaction among these regions accounts for the decline of these two types of memories is still unknown. We used dynamic causal modeling (DCM) to analyze functional magnetic resonance imaging (fMRI) data. Neural connectivity during encoding of subsequent successful and unsuccessful spatial source memory retrieval was examined in young and old adults. DCM analyses were performed in brain regions that showed significant activity differences between age groups in the contrast between study items that were later recognized and assigned a correct source judgment with those whose sources were subsequently forgotten. Neural connectivity in the reverse contrast was also analyzed. Effective connectivity between the left medial orbitofrontal gyrus and left hippocampus was reduced in old adults relative to young adults during the encoding of subsequent source retrieval. The results suggest that age effects on recollection are not only due to local under-recruitment activity but also to less efficient interactions between brain regions.

Title: Classification of age–related brain connectivity using resting state fMRI and the support vector machine

Authors: *T. IIDAKA[1], E. BAGARINAO[1], S. KOYAMA[2], M. KUNIMI[2], T. NAKAI[2]; [1]Nagoya University, Grad. Sch. of Med., Nagoya, Aichi, Japan; [2]Natl. Inst. for Geriatrics and Gerontology, Obu, Japan

Abstract: Age-related changes in brain function of healthy young and old subjects have been investigated with fMRI and cognitive tasks. Recently, functional connectivity analysis using fMRI in resting rather than task conditions has emerged as an important tool for understanding brain aging and dementia. A classification approach using machine learning such as the support vector machine (SVM) could therefore significantly contribute to this field of research. In the present study, we classified healthy young and old subjects' resting–state (rs–) fMRI activity by the SVM. We achieved high classification accuracy with relatively few features. Study participants included 53 young (mean age, 22.6 years, male/female, 25/28) and 57 old (mean age, 68.6 years, male/female, 24/33) healthy subjects. None of the subjects had cognitive impairment (MMSE > 24) or clinical depression. Whole brain echo planar images were obtained during the resting state with eyes open (3T, Siemens, Trio, TR = 3000 ms, TE = 30 ms, 64 × 64 matrix, 39 slices, 135 volumes). The images were preprocessed with SPM8. The mean signal time courses in 90 cerebral regions were then extracted with the Data Processing Assistant for Resting-State fMRI (DPARSF) software. A 90 × 90 correlation matrix of functional connectivity was created for each subject. The connectivity matrices were subjected to an in-house SVM program (linear SVM, C parameter = 1) that implemented principal component analysis and permutation tests to classify the groups. The results showed that the accuracy was 100% when using all subjects and 96.4% when subjects were split into training and test sets (10-fold cross validation). Of 4005 possible connections, high classification accuracy was obtained from only 66 pair-wise connectivities. The connected regions were mainly located in the frontal (29%), subcortical (23%), and temporal (20%) areas. A connectivity value between the anterior cingulate gyrus and olfactory gyrus in the left hemisphere significantly correlated with the age of old subjects ($r = –0.45$, $p < 0.05$, Bonferroni correction). Thus, we achieved high classification accuracy between the young and old subjects by using rs–fMRI and SVM. The age-related difference in connectivity was distributed across the whole brain; however, majority of the connectivities were in the frontal, subcortical, and temporal regions. In the future, the present study could be extended to develop a biomarker of aging and dementia by including subjects with cognitive impairment.

Title: Integrity and selectivity of functional activation maps predict behavioral performance and successful aging

Authors: *C. G. HABECK, Y. GAZES, H. OH, Y. STERN;
Taub Inst., Columbia Univ., New York, NY

Abstract: For cognitive neuroimaging a self-evident idea postulates that similarity of cognitive processes implies corresponding similarity of neuroimaging substrates. A disruption of the relationship between similarity of cognitive processes and the corresponding similarity of neural substrates might signal “de-differentiation”, resulting in cognitive processes that are distinct sharing unduly similar activation maps. We operationalized a simple measure of such functional integrity and selectivity in two data sets: data set 1 contained 291 participants (age 20-77) who were imaged while performing 12 tasks, with 3 tasks for each of the following cognitive domains: episodic memory, fluid reasoning, perceptual speed, and vocabulary. The functional-integrity and selectivity measure is computed for each participant as the difference of the average Fisher-Z coefficient of the 12 possible WITHIN-domain task pairings vs. the average Fisher-Z coefficient of the 54 possible BETWEEN-domain pairings. Higher values in this measure were associated with better neurocognitive profiles, as it correlated negatively with age ($p=0.0036$), but positively with mean cortical volume ($p=0.0007$) and thickness ($p=0.0112$), years of education ($p=0.0022$), and verbal intelligence ($p=0.0180$). It also correlated positively with task performance in 10 of 12 tasks at $p<0.05$. A second data set contained 123 participants (age 20-70) performing a verbal Sternberg visual working-memory task with 3 memory loads in 3 task phases, yielding 9 task-activation maps per participant. The functional-integrity and selectivity measure was similarly computed as the difference of average Fisher-Z spatial correlation of activation maps WITHIN task phase (9 possible pairings) vs. BETWEEN task phases (27 possible pairings). While the measure did not correlate with age or years education, it positively correlated with verbal intelligence ($p=0.0023$), mean cortical volume ($p=0.0127$), neuropsychological measures of fluid reasoning ($p=0.0107$), perceptual speed ($p=0.0391$), vocabulary ability ($p=0.0055$). It also correlated negatively with the task reaction times in fMRI scanner ($p<0.01$ for all 3 memory-load conditions). Future research might assess to what extent

the functional-integrity and selectivity measure investigated in this report can provide diagnostic information about successful aging above and beyond structural brain measures and neuropsychological performance. The measure is computationally easy to implement, does not involve specially tailored group-level derivations and is particularly feasible for rich multi-task data sets.

Title: Visual search performances does not predict age- related performance differences in an everyday memory task

Authors: *M. KEMPE[1,2], O. L. BOCK[1], D. MEMMERT[2];
[1]Inst. of Physiol. and Anat., [2]Inst. of Cognitive and Team/Racket Sport Res., German Sport Univ. Cologne, Cologne, Germany

Abstract: The age-related decline in memory tasks is well documented within the literature. However, it is still unclear how those results transfer into everyday life and what might impair memory performance of older adults in everyday life memory tasks. To explore age related differences, we used a shopping task to measure memory performance of sixteen younger (23.88 ± 4.15 years, 10 male) and sixteen older adults (71.19 ± 4.02 years, 12 male). Eye-movements were recorded to clarify if the reduced visual search performance of older adults is accountable for reduced memory performance. Older adults performed worse than younger adults in the everyday memory task. In line with previous findings, the age effect in the everyday memory task was more pronounced than in laboratory memory tasks. Further they showed a decrease in their visual search performance via increases in the number of fixations, number re-fixations and fixation time for target items. To check if impaired visual search and/or inhibition performance might be accountable for the age effect a linear regression analysis was conducted. Inhibition performance, but not visual search performance could predict the performance in the everyday memory task via the regression analysis. Therefore, we conclude that memory performance in everyday life might not be explained by the performance of searching for target items but by the performance to inhibit irrelevant visual information.

Title: Life-time stability of reference ability neural networks

Authors: ***Y. STERN**, C. HABECK, Y. GAZES;
Cognitive Neurosience Division, Columbia Univ., New York, NY

Abstract: Analyses of large test batteries administered to individuals ranging from young to old have consistently yielded a set of latent variables representing reference abilities (RAs) that capture the majority of the variance in age-related cognitive change: Episodic Memory, Fluid Reasoning, Perceptual Processing Speed, and Vocabulary. The Reference Ability Neural Network Study administers 12 cognitive neuroimaging tasks (3 for each RA) to healthy adults age 20 -80 in order to derive unique neural networks underlying these 4 RAs and investigate how these networks may be affected by aging. We used a multivariate approach, linear indicator regression, to derive a unique covariance pattern or Reference Ability Neural Network (RANN) for each of the 4 RAs. RANNs were derived from the neural task data of 64 younger adults of age 30 and below. We then prospectively applied the RANNs to fMRI data from the remaining sample of 227 adults of age 31 and above in order to classify each subject-task map into one of the 4 possible reference domains. Overall classification accuracy across subjects was 0.82 ± 0.17. Classification accuracy by RA domain, was also very good; memory: 0.83 ± 0.25; reasoning: 0.89 ± 0.24; speed: 0.82 ± 0.30; vocabulary: 0.73 ± 0.35. Classification accuracy did not decline with age, suggesting that these networks remained intact throughout the age range. Higher mean brain volume was correlated with increased overall classification accuracy. Higher expression of any particular RANN was associated with the corresponding classification accuracy for that reference ability. Conversely, expression of a RANN for one domain was not associated with classification accuracy of any other domain. Despite the absence of behavioral performance in the derivation of these networks, expression of the fluid-reasoning network correlated with performance. While age did not influence the expression of the FLUID RANN in participants age 31 and above, this association declined with increasing age. These results provide support for the hypothesis that a set of specific, age-invariant neural networks underlies

these four RAs, and that these networks maintain their specificity with aging. The relationship between network expression and fluid reasoning performance was unexpected, since the RANNs were derived with no reference to task performance. Our eventual goal is to derive RANNS that are unique to each RA and whose expression correlates with the associated RA performance. We will then be in a position to evaluate how network expression or topographic composition may be affected by age-related brain changes in order to produce performance differences with aging.

Title: Unique white matter tract covariance patterns predict age-declining cognitive abilities

Authors: *Y. GAZES, Q. R. RAZLIGHI, D. O'SHEA, Y. STERN, C. G. HABECK;
Taub Inst., Columbia Univ., New York, NY

Abstract: Previous studies investigating the relationship of white matter integrity to cognitive abilities and aging and have either focused on a global measure or a few selected white matter tracts. Ideally, contribution from all of the white matter tracts should be evaluated at the same time. However, the high collinearity among white matter tracts precludes systematic examination of white matter tracts simultaneously without sacrificing power due to stringent multiple-comparison corrections. Multivariate covariance techniques enable comprehensive simultaneous examination of all white matter tracts without being penalized for high collinearity among observations. Method: In this study, Scaled Subprofile Modeling (SSM) was applied to the mean integrity of 18 major white matter tracts to extract covariance patterns that optimally predicted four cognitive abilities (perceptual speed, episodic memory, fluid reasoning, and vocabulary) in 346 participants across ages 20 to 79 years old. Using expression of the covariance patterns, both age by white matter interaction and mediation of white matter integrity on age-related differences in cognition were tested separately, but inferences from the mediation analyses were cautiously made given cross-sectional data set was used in the analysis. Results: A covariance pattern was identified that significantly predicted all cognitive abilities except vocabulary. Age by white matter pattern interactions were not significant for any of the three abilities. The

expression of the corresponding white matter pattern accounted for a significant portion of the variability in each of the three abilities after partialling for age. Furthermore, each of the patterns mediated the effect of age on the respective cognitive ability. A distinct set of white matter tracts was most influential in each of the three patterns. The white matter pattern accounting for fluid reasoning showed the most number of influential white matter tracts whereas the episodic memory pattern showed the least number. Conclusion: Specific patterns of white matter tracts make significant contributions to the age-related differences in perceptual speed, episodic memory, and fluid reasoning but not vocabulary. Other measures of brain health will need to be explored to reveal the major influences on the vocabulary ability.

Title: Relation of white matter hyperintensity volume to cognitive performance in older adults

Authors: *L. A. NGUYEN[1,6,7], P. K. BHARADWAJ[1,6,7], K. A. HAWS[1,6,7], M. C. FITZHUGH[1,6,7], T. P. TROUARD[2], G. A. HISHAW[3], G. E. ALEXANDER[1,6,7,4,5]; [1]Dept. of Psychology, Univ. of Arizona, Tucson, AZ; [2]Biomed. Engin., Univ. of Arizona, University of Arizona, AZ; [3]Univ. of Arizona, Department of Neurology, AZ; [4]Physiological Sci. Grad. Interdisciplinary Program, [5]Neurosci. Grad. Interdisciplinary Program, Univ. of Arizona, Tucson, AZ; [6]Evelyn F. McKnight Brain Inst., Tucson, AZ; [7]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: Greater prevalence of cerebral white matter abnormalities, which appear as hyperintense regions in T2 FLAIR magnetic resonance imaging (MRI) scans, have been associated with increasing age, diminished cognitive performance, and cardiovascular risk factors, such as hypertension. We investigated the relation between white matter hyperintensity (WMH) volume and cognitive performance in a group of community-dwelling, elderly adults

with and without histories of hypertension to further evaluate the role of WMH in cognitive aging. A sample of 74 neurologically healthy older adults, 75-89 years of age, with treated hypertension (N = 32) and without hypertension diagnosis or treatment (N = 42) completed a battery of neuropsychological tests. T1-weighted volumetric and T2 FLAIR MRI scans were acquired on a 3T GE Signa Excite scanner. The volumes of WMHs were computed with a multispectral, automated lesion segmentation method to produce probability maps using Statistical Parametric Mapping (SPM8) and a lesion segmentation toolbox (LST; Schmidt et al., 2012). The results indicated that greater WMH volume was related to poorer performance ($0.001 \leq p \leq 0.018$) on several measures of memory (Selective Reminding Test: Sum Recall, Long-Term Storage, Long-Term Retrieval, and 30-minute Delayed Recall), executive functions (Paced Auditory Serial Addition Test, Trail Making Test - part B, and Wisconsin Card Sorting Test categories completed), and visuo/psycho-motor processing speed (Trail Making Test - part A and Grooved Pegboard), but was not related to performance on general measures of intellectual function (Wechsler Adult Intelligence Scale-IV - Full Scale IQ). After individually controlling for age ($0.006 \leq p \leq 0.049$) and the combination of age and hypertension status ($0.007 \leq p \leq 0.048$) in the cohort, these specific associations with cognitive performance remained significant. In a sample of generally healthy, community-dwelling older adults, having greater WMH volume is associated with poorer memory, executive functions, and processing speed, even after controlling for age and hypertension status. Together these findings suggest that WMH volume may be an important factor contributing to the individual differences observed in cognitive aging. Further research is needed to evaluate the longitudinal impact of white matter lesion volumes on cognitive decline in the context of healthy aging.

Abstract: Worldwide nearly 44 million people currently live with Alzheimer's disease or related dementias. Before the signs and symptoms of dementias are seen, older adults may have a decrease in their cognitive abilities or cerebrovascular functioning. To prevent these pre-clinical symptoms modifiable lifestyle factors such as physical activity (PA) must be studied to determine how to attenuate or improve brain health. The aim of this cross-sectional study is to determine if total lifetime PA is associated with better cognitive functioning with aging and if cerebrovascular function mediates this association in a sample of 226 (118 females, 52.2%) community dwelling older adults aged 55-90 years (66.5±6.4 years) in the *Brain in Motion* Study. Each participant completed the Lifetime Total Physical Activity Questionnaire, a neurophysiological assessment and a non-invasive cerebral blood flow velocity test of the middle cerebral artery. Multiple robust linear regressions were used to model the associations between lifetime PA and global cognition after adjusting for age, sex, North American Adult Reading Test results (i.e. estimated IQ), maximal aerobic capacity, body mass index and interaction terms (age, sex, lifetime physical activity). Mediation analysis was used to assess the effect of cerebrovascular measures on the association between lifetime physical activity and global cognition. Post-hoc analyses were performed assessing past year physical activity and current fitness levels (maximal aerobic capacity) relation to global cognition and cerebrovascular measures. Better global cognitive performance was associated with higher lifetime PA ($p=0.03$), recreational PA ($p=0.018$), vigorous intensity PA ($p=0.013$), PA between the ages of 0 and 20 years ($p=0.028$), between the ages of 21 and 35 years ($p<0.0001$) and for past year PA ($p=0.0.19$). Cerebrovascular measures did not mediate the association between PA and global

cognition scores ($p>0.5$). Cerebrovascular measures partially mediated the relation between current fitness (O_2max) and global cognition. This study revealed statistically significant associations between higher levels of PA (i.e., total lifetime, recreational, vigorous and past year) and improved cognitive function in later life that did not appear to be mediated by cerebrovascular function. Current fitness levels were also associated with global cognition and these relations were partially mediated by measures of cerebrovascular health.

Title: Contributions of age and Alzheimer's pathology to hippocampal memory network function in healthy elderly

Authors: *S. M. MARKS[1], S. N. LOCKHART[1], K. L. ARNEMANN[1], J. W. VOGEL[1], H. D. SCHWIMMER[1], W. J. JAGUST[1,2];
[1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, CA; [2]Life Sci. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: As part of a larger neural network, the hippocampus is central to successful memory processes and relies on pattern separation to orthogonalize similar events. Memory deficits are often the first indicator of cognitive decline with respect to Alzheimer's disease (AD) and there is reason to believe that AD pathology uniquely impacts the memory network beyond changes that occur with normal aging. The aim of this study was to investigate the impact of AD pathology on hippocampal function and its associated network during episodic memory. Thirty-seven cognitively normal elderly and 14 young controls participated in a functional MRI paradigm designed to emphasize pattern separation. A subset of elderly participants underwent

Pittsburgh Compound B and AV-1451 PET scans to measure beta-amyloid (Aβ) and tau neurofibrillary tangles, as well as structural, diffusion and resting-state MRI. Aβ was quantified globally and locally in the retrosplenial cortex (RSC). Tau was quantified locally in the entorhinal cortex. Connectivity of posterior parietal regions and medial temporal lobes (MTL) was assessed using seed-based correlation of RSC and parahippocampal resting-state time series, in addition to average cingulum fractional anisotropy (FA). Manually segmented hippocampal subfield ROIs were used to measure task activation and volume. Older adults performed worse on the memory task ($F = 28.4$, $p < 0.001$) and showed increased activation in right dentate gyrus/CA3 (DGCA3) compared to young controls ($F = 5.3$, $p = 0.026$), confirming previously published reports. Increased DGCA3 activity was associated with worse performance at trend levels ($t = -1.8$, $p = 0.076$). Additionally, larger hippocampal volumes predicted better performance in older adults ($t = 2.1$, $p = 0.046$). Average cingulum FA was associated with DGCA3 activity ($t = -2.1$, $p = 0.052$), suggesting that worse performance may result from inefficient network communication. AD biomarkers had no direct relation with task performance or activation, but did influence local structure and connectivity. Specifically, RSC Aβ was associated with reduced connectivity between RSC and parahippocampus ($t = -2.5$, $p = 0.023$); and, tau in entorhinal cortex was marginally associated with DGCA3 volume ($t = -1.9$, $p = 0.075$). These preliminary results suggest that in addition to age-related changes, AD pathology may influence memory in two distinct ways. First, MTL tau accumulation leads to focal neurodegeneration, altering the structure of the hippocampus. Second, Aβ alters long-range communication within the network, inhibiting efficient information flow to the hippocampus. Further work needs to be done to confirm these findings.

Title: Transcranial direct current stimulation over the right prefrontal cortex leads to time-dependent enhancement of sustained attention in ageing

Authors: *M. BROSNAN[1], M. ARVANEH[2], P. M. DOCKREE[2], I. ROBERTSON[2];
[1]Sch. of Psychology and Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland;
[2]Trinity Col. Inst. of Neurosci. and Sch. of Psychology, Dublin, Ireland

Abstract: Sustained attention can be described as maintaining a goal-directed focus in the face repetitive nonarousing tasks. The right dorsolateral prefrontal cortex appears to play a crucial role at endogenously maintaining attentional focus. Here we explored the potential of transcranial Direct Current Stimulation (tDCS) over the right prefrontal cortex to enhance sustained attention in an ageing population. Cognitively healthy older adults (aged 64-84) received tDCS while performing a sustained attention task, the Sustained Attention to Response Task (SART). A tDCS-induced reduction in RT variability was observed during real stimulation, exclusively during the first half of stimulation. RT variability on the SART is a sensitive measure of fluctuations in sustained attention, as the high frequency of response requirements allow an almost constant monitoring of attention. This time-dependent enhancement of sustained attention during stimulation may be suggestive of a 'homeostatic-like' response to tDCS over the prefrontal cortex. Analysis of spectral electroencephalogram (EEG) and event related potentials (ERPs) recorded during stimulation is currently underway.

Title: Medial temporal lobe representational pattern similarity during encoding predicts episodic memory performance among healthy older adults

Authors: *V. A. CARR[1], A. M. KHAZENZON[1], J. D. BERNSTEIN[1], C. P. LITOVSKY[1], G. A. KERCHNER[2], A. D. WAGNER[1];
[1]Psychology, [2]Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

Abstract: Healthy aging is often accompanied by impairments in episodic memory - memory for events in our daily lives. Individuals differ in the degree to which they experience such impairments, and the underlying factors contributing to this variability remain unclear. Computational models posit that age-related memory impairments are related to synaptic loss and weakening among perforant path inputs to the hippocampus, a region known to play a key role in episodic memory. These models suggest that such age-related changes reduce the capacity of the hippocampus to engage in pattern separation, a process allowing for the encoding of separable memory representations. As a result of impaired pattern separation, the retrieval of details specific to a given learning episode will also be impaired, leading to deficits in episodic memory. Emerging univariate fMRI findings provide initial support for this notion, demonstrating that impairments in item memory in healthy older adults are associated with dysfunction in hippocampal subfield DG/CA3, a region known to play a key role in pattern separation. Here, we extend these findings in two ways. First, given the importance of the hippocampus in forming associations between features of an event, we evaluated hippocampal subfield function in healthy older adults using high-resolution fMRI as they performed an associative memory task. Second, using representational pattern similarity analyses, we evaluated the degree to which trial-specific patterns of encoding activity were dissimilar or similar to one another, indicating a bias towards separation or generalization, respectively. Linear regression analyses revealed that measures of encoding pattern similarity were predictive of subsequent memory performance. Such results provide novel evidence that age-related alterations in hippocampal computations during encoding contribute to impairments in episodic memory.

Title: Structural and functional hippocampal changes underlying age-related memory retrieval impairment

Authors: *A. M. KHAZENZON, V. A. CARR, J. D. BERNSTEIN, C. P. LITOVSKY, G. A. KERCHNER, A. D. WAGNER;
Stanford Univ., Stanford, CA

Abstract: Healthy older adults frequently perform worse on tests of episodic memory relative to younger adults, even in the absence of memory complaints. The neural mechanisms underlying such age-related memory decline remain underspecified, though extant evidence highlights the potential contributions of medial temporal lobe changes with age. Hippocampal circuit function is critical for episodic retrieval. Computational models and initial data suggest that, when presented with a partial cue for an episode, the hippocampus performs pattern completion to retrieve associated elements. This hippocampal completion process is further thought to drive activity in neocortex, where event features are reinstated. Selective atrophy and functional changes in hippocampal subfields that affect pattern completion processes might therefore contribute to age-related episodic retrieval impairment. Here, we examined whether focal changes in hippocampal subfield structural integrity (measured using 7T MRI) along with functional alterations (measured using 3T high-resolution fMRI) contribute to age-related changes in associative memory. We evaluated both univariate measures of hippocampal subfield activity as well as multivariate measures of ventral occipitotemporal activity to determine whether individual differences in associative memory performance can be explained by differences in hippocampal pattern completion-mediated cortical reinstatement. Initial analyses suggest that performance during an associative memory task can be successfully predicted by these functional measures along with measures of hippocampal subfield thickness, providing support for the notion that age-related changes in hippocampal computations contribute to age-related memory decline. Title: A deficit-compensation brain activation pattern common to working memory and functional mobility in older adults

Authors: ***T. KAWAGOE**[1], M. SUZUKI[1], S. NISHIGUCHI[2], N. ABE[3], Y. OTSUKA[3], R. NAKAI[3], M. YAMADA[4], S. YOSHIKAWA[3], K. SEKIYAMA[1];

Abstract: Functional mobility and cognitive function often declines with age. We previously found that functional mobility measured by Timed Up and Go Test (TUG) is associated with cognitive performance for visually-encoded (i.e. for location and face) working memory (WM) in older adults. It suggests a common neural basis between TUG and visual WM. To elucidate this relationship further, the present study aimed to examine the neural basis for the WM-mobility association. According to one of the well-known neural compensation models in aging, we hypothesized that "attentional" brain activation for easy WM would increase for participants with lower mobility. The data from 32 community dwelling healthy older adults (MMSE > 26) were analyzed, which include brain activation during easy WM tasks via functional Magnetic Resonance Imaging (fMRI) and mobility performances via both TUG and a simple walking test. WM performance was significantly correlated with TUG but not with simple walking. Some prefrontal brain activities during WM were negatively correlated with TUG performance while positive correlations were found in internal structures including thalamus, putamen, and cerebellum. Moreover, the activation of "automatic" internal regions was significantly correlated with WM performance, with less activation for lower WM performers.These results indicate that older adults with lower functional mobility used more "attentional" and less "automatic" resources for easy WM tasks. To date, the frontal compensation has been proposed separately in motor and cognitive domain, which was assumed to compensate for deficit of other brain areas, however such deficit (deactivation) was less clear in the previous studies.The present study observed such deactivation associated with lower functional performance, which was found in "automatic" regions. We conclude that a common deficit-compensation activation pattern is likely the neural basis for the association between visual WM and functional mobility.

Title: The role of medial temporal lobe regions in incidental and intentional retrieval of relational and item information in aging

Authors: *W.-C. WANG[1], K. S. GIOVANELLO[2];
[1]Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC; [2]Dept. of Psychology, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Considerable neuropsychological and neuroimaging work indicates that the medial temporal lobes are critical for both item memory and relational memory retrieval. However, there remain outstanding issues in the literature, namely the extent to which medial temporal lobe regions are differentially recruited during incidental and intentional retrieval of relational and item information, and the extent to which aging may affect these neural substrates. The current fMRI study sought to address these questions; participants incidentally encoded word pairs embedded in sentences and incidental item and relational retrieval was assessed through speeded reading of intact, rearranged, and novel word-pair sentences, while intentional item and relational retrieval was assessed through old/new associative recognition of intact, rearranged, and novel word pairs. Results indicated that, in both younger and older adults, anterior hippocampus and perirhinal cortex support incidental and intentional item retrieval, but parahippocampal cortex differentially supports these two forms of item retrieval. In contrast, posterior hippocampus supports incidental and intentional relational retrieval in both age groups and an adjacent cluster in posterior hippocampus was recruited during both forms of relational retrieval for older but not younger adults. Our findings suggest that there are both shared and distinct roles for medial temporal lobe regions in incidental and intentional retrieval of item and relational information, and further indicate that these regions may, under certain conditions, be overrecruited in healthy aging.

Title: Investigating linear and nonlinear age-related changes in the functional neural correlates of context memory across the adult lifespan

Authors: *E. ANKUDOWICH[1,2], S. PASVANIS[2], M. N. RAJAH[1,2];
[1]McGill Univ., Montreal, QC, Canada; [2]Cerebral Imaging Center, Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: In healthy aging, larger reductions in context or source memory relative to item memory have consistently been found. Previous functional neuroimaging studies have revealed age-group differences in the prefrontal (PFC) and posterior regions supporting context memory in older vs. younger adults. More recently, studies have found that differential activation in PFC regions associated with context memory arises as early as midlife. However, little is known about the trajectory of functional brain changes across the adult lifespan that contribute to context memory decline with age. It is possible that some functional brain changes across the adult lifespan are linear and others nonlinear. The current study used functional magnetic resonance imaging (fMRI) to investigate linear and residualized quadratic (parabolic) changes in context memory networks across young (ages 20-35), middle-aged (ages 40-58) and older (ages 60-76) adults. Two context memory tasks tested for the spatial and temporal information of faces, and participants completed an easy and difficult version of each task in order to help characterize performance effects vs. age effects. Behaviorally, a Task (spatial, temporal) x Difficulty (easy, difficult) x Group (young, middle-aged, older) ANOVA revealed that, across tasks, young adults outperformed both middle-aged and older adults and that middle-aged adults performed no differently from older adults ($p<.05$). Using a multivariate behavioral partial least squares (B-PLS) approach, our fMRI results identified a whole-brain network of regions showing linear increases and decreases in activation with age, as well as a network of regions showing increases and decreases in activation specific to midlife relative to young and older adulthood. Our results suggest that some network regions may differentially contribute to context memory across the adult lifespan.

Title: Factors modifying longitudinal change in white matter tract integrity in healthy midlife and older adults

Authors: *A. BILLIG[1], K. M. KENNEDY[2], P. R. A. W. ROBINSON[3], K. SCHAIE[4], S. L. WILLIS[4];
[1]Integrated Brain Imaging Ctr., Seattle, WA; [2]Psychology, The Univ. of Texas at Dallas, Dallas, TX; [3]Integrated Brain Imaging Ctr. (IBIC), [4]Psychiatry and Behavioral Sci., Univ. of Washington, Seattle, WA

Abstract: Studies examining longitudinal change in white matter (WM) tracts are limited, particularly those including modifiers of change. We examined 4-year change in white matter tract diffusivity over 3 occasions in participants of the Seattle Longitudinal Study: N = 212; Mean Age=69 at first scan, Range=56-91, SD=7.71; Mean education: 16 yr; Male: 43%, Female=57%. Tract data were processed with FSL software (eddy correction, skull stripping, tensor computation). Probtrackx was used for probabilistic fiber tracking in native diffusion space using starting and wayfinding seeds for each tract of interest. Fractional anisotropy (FA), axial diffusivity (AD), and radial diffusivity (RD) were measured in 5 tracts: superior longitudinal fasciculus (SLF), inferior longitudinal fasciculus (ILF), uncinate fasciculus (UNC), fornix (FNX) and cingulum (CING). Multivariate multilevel models using a stepwise modeling procedure estimated longitudinal change. A baseline model of change in the aforementioned tracts was used to predict cross-sectional age differences (AGE) and individual differences in rate of change (TIME) in WM integrity. This model was followed by the introduction of explanatory variables (APOE genotype, Hypertension (HBP), Education (EDUC), and Sex). Significant ($p < .05$) longitudinal TIME effects were found for: AD(SLF, UNC); RD(ILF). AGE had a significant effect on the mean FA along the ILF, UNC, CING, FNX tracts ($p<0.001$). A significant Sex by TIME interaction was found only for RD in UNC, with the females showing a steeper increase in slope than the males. Significant gender differences were found for FA in the CING ($p<0.01$) and FNX ($p<.05$) tracts with higher FA for males. No significant effects for APOE were found, though an effect of HBP on FA in SLF was discovered ($p <0.05$). A significant effect of education occurred on FA in the FNX ($p<0.05$). These findings indicate that axial and radial diffusivities along these tracts are mostly affected by TIME with Sex as a

modifier, while fractional anisotropy is affected by AGE with Sex, Hypertension, and Education as modifiers.

Title: Neural correlates of loneliness in younger and older adults

Authors: *A. D'AGOSTINO, T. CANLI;
Stony Brook Univ., Stony Brook, NY

Abstract: Loneliness, defined as the subjective experience of social isolation, has been linked to poor health outcomes including depression and cardiovascular disease. To improve upon current treatments, the interaction between genetic and environmental risk factors for loneliness and their effect on the brain must be better understood. The current study investigated the brain basis of loneliness in both younger (mean age = 20.35) and older adults (mean age = 62.88). We used functional magnetic resonance imaging (fMRI) and an emotional valence picture task to address this question. FMRI data were collected on a 3T Siemens Trio Scanner, with functional whole-brain images acquired using a gradient echo T2*-weighted EPI scan (TR=2.5 s; TE=30 ms; flip angle=90; FOV=256mm). 100 subjects (49 older, 51 younger) viewed positive and negative social and non-social images in the scanner followed by completion of questionnaires including an objective measure of loneliness, the Social Network Index, and a subjective measure of loneliness, the UCLA loneliness scale. Saliva samples were collected from all subjects for genotyping analysis of single nucleotide polymorphisms (SNPs) in two genes of interest (*OXTR* and *AVPR1A*). Questionnaire results indicated that compared to younger adults, older adults were significantly less lonely, trait anxious, shy and emotionally suppressive. Furthermore, fMRI results indicated that older adults showed significantly less activation in the precentral gyrus (BA6), inferior parietal lobe and precuneus during viewing of negative social images compared to fixation ($p< 0.05$, FWE corrected). Gender differences were also seen in response to viewing of negative social images compared to negative non-social images, with females showing

significantly greater activation in the cingulate gyrus ($p < 0.05$, FWE corrected). Finally, genetic analyses demonstrated that across all subjects, those with the G/G genotype for the rs53576 SNP of the oxytocin receptor gene (*OXTR*) scored significantly lower on the shyness scale compared to the A/G genotype ($p < 0.005$). The present findings indicate age, gender and genetic differences in social and emotional processing. In addition to the results presented here, functional connectivity analyses will be performed to explore whether putative neural circuits of social behaviors show different patterns of connectivity in lonely and non-lonely adults.

Title: Age-related differences in networks of brain activation across two executive functioning domains - updating and task-switching

Authors: *K. KAWA[1,2], M. B. SCHMIT[2], J. A. CARDOZA[2], A. M. STICKEL[2], E. L. GLISKY[2], L. RYAN[2];
[1]Psychology, [2]Univ. of Arizona, Tucson, AZ

Abstract: Introduction. Miyake et al. (2000), using factor analysis, identified three relatively independent, yet related executive function processes. These included: 1) shifting between multiple tasks or mental sets, 2) updating and monitoring information in working memory, and 3) inhibition of prepotent or dominant responses elicited by a task. While previous studies have investigated the age-related differences in neural mechanisms underlying a single measure of executive functioning such as task-switching (Madden et al., 2010), fewer studies have investigated the mechanisms underlying age-related differences on multiple measures of executive functions in the same individuals. Methods. Older adults (n = 20; 60-79 years) and younger adults (n = 11; 18-31 years) were tested on two fMRI paradigms measuring updating and shifting. In the running span (updating) paradigm, the participants were presented with series of numbers and asked to continually remember the last three numbers. The length of the series of

numbers ranged from 3 to 5 to 7 in order to test task difficulty. In the task-switching paradigm (shifting), participants were presented with letters of the alphabet in either a square shape or diamond shape. If the letter was presented in a square, they responded whether the letter was printed in upper case or lower case. If the letter was presented in a diamond, they responded whether the letter was a consonant or a vowel. Results. In the running span paradigm, we observed a similar network of activation between older and younger adults. However, with increasing task difficulty, the older adults showed a greater extent of activation than the younger adults in this network, particularly in the right middle temporal gyrus, right inferior parietal lobule, and the middle frontal gyrus bilaterally. In contrast, during task-switching the two groups showed different networks of activation. The younger adults engaged greater frontal, parietal, and basal ganglia regions, while older adults engaged lateral frontal and visual cortices. Conclusion. Our results suggest that older and younger adults recruit similar or distinct networks of activation dependent upon the type of executive functioning task being performed. The differential recruitment highlights the importance of examining multiple executive functions within the same cohort to gain a greater understanding of the neural mechanisms underlying executive functioning and how these mechanisms change with age.

Title: Dietary zinc serum levels: preventing memory decline and depression in late adulthood

Authors: *A. A. OLIVEIRA, JR[1], T. JACOBSEN[2], T. FONSECA[3], M. FIEGENBAUM[2], F. ANDRADE[4];
[1]UFCSPA - Univ. Federal De Ciencias Da Saúde, Porto Alegre, Brazil; [2]Post-Graduate Course in Hlth. Sci., [3]Psychology, UFCSPA, Porto Alegre, Brazil; [4]Inst. de Ciências da Saúde, Feevale, Porto Alegre, Brazil

Abstract: The micronutrient Zinc is an essential molecular marker for several neurobiological functions. Its deficiency may affect neurogenesis, increase neuronal apoptosis and represent a

risk factor for the development of several neuropsychiatric disorders. Recent reports have suggested that a zinc diet treatment could significantly improve memory performance and reduce depression. Memory impairment and depression are among the most frequent complaints during aging. The progressive natural decline of memory produces lesser problems than more serious conditions observed on late adulthood. It is, however, a condition that worries most of the elderly population. Although widely studied as a psychopathology, depression is a pathological condition in increasing need of attention on aging with less biological comprehensive information available. There are unclear relationships between dietary zinc, memory deficits and depression. They share however a strong link with aging. In this study, we investigate the zinc serum levels and its relationship with depression and memory decline in late adulthood. For this purpose, 200 individuals over 50 years of age were evaluated for depression and memory. From these subjects, 16 indicated depression and were matched to 16 individuals without depression. All participants were examined regarding their zinc serum levels. Finally, the relationships between depression and memory deficits were analyzed. The results suggested that dietary zinc serum levels have a role important role preventing deficits such as memory impairment and depression.

Title: The effects of Omega-3 fatty acid supplementation on cognitive abilities in healthy adults

Authors: *D. LEHMAN, G. LECKIE, K. ERICKSON, S. SEREIKA, D. KUAN, S. MANUCK, M. MULDOON;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Long-chain, omega-3 fatty acids (LCn-3FAs) have several important biochemical roles in the brain, including modulation of synaptic plasticity. Mammals fed diets deficient in LCn-3FAs have behavioral abnormalities and reduced neuronal growth and synaptic proliferation. Western diets contain a median of just 100 mg/day of LCn-3FAs, and observational studies link low consumption with decrements in cognitive performance. To test for a causal relationship in humans, we conducted a randomized and double-blind clinical trial in

mid-life adults 30-55 years of age. Subjects were 271 adults (118 men, 153 women) consuming no more than 300 mg/day of LCn-3FAs. Each was randomized to 17 weeks of supplementation with 1400 mg/day of LCn-3FAs as fish oil (n = 134) or placebo capsules containing 1400 mg/day of soybean oil (n = 137). A neuropsychological test battery was completed at baseline and at study completion. Outcome measures included 11 cognitive tests categorized into domains such as fluid intelligence (Matrix reasoning, Block Design) and psychomotor speed (Stroop Word Time, Trails A Time). At baseline, there were no significant group differences in gender, age, education or IQ. Participant blinding was verified, and capsule adherence was over 90% in both groups. Effects of supplementation on multiple cognitive domains, relative to baseline performance and adjusted for placebo-effects, will be reported. Differences in any cognitive domain in favor of the treatment group at follow-up would constitute strong evidence that LCn-3FA consumption affects cognitive functioning during middle-adulthood and potentially impacts risk for cognitive impairment with aging.

Title: Lutein and zeaxanthin are related to neurobiological efficiency during cognitive performance: An fMRI study

Authors: *C. A. LINDBERGH, D. TERRY, C. MEWBORN, M. BELLO, E. BOVIER, L. M. RENZI, B. R. HAMMOND, L. MILLER;
Univ. of Georgia, Athens, GA

Abstract: Objective: While historically studied in relation to eye health, an emerging literature suggests that lutein (L) and zeaxanthin (Z) may benefit cognitive functioning, possibly through antioxidant and anti-inflammatory effects. The present study sought to evaluate the mechanisms by which L and Z impact cognition using functional magnetic resonance imaging (fMRI). It was

hypothesized that greater levels of L and Z would predict increased neurobiological efficiency (i.e., reduced activation) in older adults during learning and memory performance. **Methods**: 43 community-dwelling older adults (64-86 years) participated in an fMRI-adapted verbal learning task that involved learning pairs of unrelated words (mean age = 71.55, mean education = 16.66 years, 58% female, 100% Caucasian). The paradigm was comprised of several repetitions of learning trials and recall trials interspersed with distractor trials. L and Z levels were measured via two standard, validated procedures: blood serum concentrations and macular pigment optical density (MPOD). FMRI data were processed in SPM12 using the distractor trials as the imaging contrast for learning and recall trials ($p < 0.05$, family-wise error corrected, minimum voxel cluster = 8). L and Z serum concentrations and MPOD values were then entered, separately, as covariates in regression-based analyses of blood-oxygen-level-dependent (BOLD) signal. **Results**: L and Z measures were not significantly related to behavioral measures of verbal memory performance ($p > 0.05$). However, fMRI covariate analyses revealed that L and Z serum concentrations were negatively related to BOLD activation during learning and memory processes in several relevant brain regions, including left central and left parietal operculum cortex, left superior parietal lobule, left postcentral gyrus, left precentral gyrus, and lateral occipital cortex bilaterally ($p < 0.01$). Greater MPOD significantly predicted attenuated BOLD signal in left insular cortex, left inferior frontal gyrus, left supramarginal gyrus, left planum polare, left cerebellar regions, right middle temporal gyrus, right middle frontal gyrus, and occipital pole bilaterally ($p < 0.01$). **Conclusions**: To our knowledge, this is among the first attempts to shed light onto the neural mechanisms underlying the relationship of L and Z to cognition in humans. Results suggest that dietary intake may improve brain efficiency during memory encoding and retrieval by promoting more honed neural networks and reducing need for compensatory recruitment in regions commonly associated with age-related deterioration.

Title: Attentional regulation training is associated with flexible engagement of frontal control and default brain networks in older adults

Authors: *A. ADNAN[1], G. R. TURNER[2], A. CHEN[3], T. NOVAKOVIC-AGOPIAN[3], M. D'ESPOSITO[4];
[1]Psychology, [2]York Univ., Toronto, ON, Canada; [3]Veteran's Admin. Med. Ctr., San Francisco, CA; [4]Univ. of California, Berkeley, San Francisco, CA

Abstract: The ability to attend to relevant information and filter out distracting information is crucial for goal-directed cognition (GDC). Older adults show pronounced deficits in this ability. Neuroimaging evidence suggests that this might arise from an age-related decline in top-down modulatory influences from prefrontal cortices to posterior perceptual regions (e.g. visual association cortices). There is evidence that young adults flexibly recruit frontal-parietal control network (FPN) and default network (DN) brain regions to enhance and suppress goal-relevant and irrelevant information respectively. We recently demonstrated that attentional regulation training leads to enhanced functional engagement of fronto-parietal and dorsal attention regions during GDC. Here we implement an event-related fMRI analysis to investigate whether improved GDC post-training is associated with flexible engagement of FPN and DMN. Specifically, we asked whether training was associated with (i) FPN activation during enhancement of relevant information and (ii) DN activation during suppression of irrelevant information. Healthy older adults were randomized to a 5-week cognitive training (N=12) or an equivalent education based control intervention (N=13). Participants completed a visual attention task for faces and scenes while undergoing an fMRI scan where task demands required them to attend to goal-relevant stimuli and ignore goal-irrelevant stimuli. Preprocessing of this data was carried out with AFNI and multivariate event-related analyses were conducted using Partial Least Squares (PLS). Post-attention training, we observed (i) increased recruitment of brain regions overlapping with the FPN during task trials requiring enhancement of goal relevant

information and (ii) increased recruitment of DMN regions during task-trials requiring suppression of goal-irrelevant information. In summary, our results support our previous findings of enhanced functional engagement of frontal and parietal brain regions associated with executive control post-training. Here we provide novel evidence for broader network changes following attention training. Specifically we observed a differential pattern of functional activation during enhancement (FPN) or suppression (DMN) of stimuli based on the current goal state. These findings suggest that attention regulation may impact modulation of large-scale brain networks based on goal relevance. Future work will investigate the relationship between this enhanced functional engagement post-training and measures of cognitive performance and real-world functioning in older adults.

Title: Comparing in-Person and Telephone Approaches to Videoconference - based cognitive assessment - an exploratory study with older individuals

Authors: *T. C. CASTANHO, L. AMORIM, P. MOREIRA, J. MARIZ, A. SILVA, J. PALHA, N. SOUSA, N. SANTOS;
Life and Hlth. Sci. Res. Inst. (ICVS), Sch. of Hlth. Sci., Braga, Portugal

Abstract: The increase in average life expectancy is a worldwide phenomenon responsible for a raise in the elderly population. Screening for cognitive impairment in older adults is still a difficult practice, but significant for clinicians and researchers who work with geriatric patients. In neuropsychological evaluation, in-person testing is considered the most effective mode of assessment however it can be limiting in reaching those with functional or other limitations. Taking these into consideration, feasible and rapid assessment tools are needed to assist in

cognitive diagnosis in clinical and psychological practice. The Telephone Interview for Cognitive Status Assessment (TICS), with a delayed recall item (modified, M), is one of the most widely used instruments to this end. Here the purpose of the current study was to determine whether cognitive testing via video-conferencing (VC; Skype®) using the TICSM provided comparable results with its application by telephone and with the Mini-Mental State Examination (MMSE) administered face-to-face. Fifty community dwellers aged 57 to 95 (mean = 71.90, SD = 1.298), still residing full-time in the community or institutionalized in day care centers, were randomly selected from registries of local health centers and day care centers. All participants were tested on cognitive performance under three experimental conditions: VC, face-to-face and telephone. Significant associations were obtained between the three administration methods, with the VC administration method yielding comparable results to the traditional telephone application and face-to-face evaluations of the MMSE. The linear regression model analysis indicated that age, gender, education and provenience explained 43.4% of the variance of the TICSM total score via VC, and 35.5% of the variance of the TICSM total score administered by telephone. This study demonstrates that TICSM scores obtained via VC are similar to those obtained via telephone evaluation and the "gold standard" (MMSE) in the face-to-face manner. The results also support the range of settings where the TICSM can be applied and its good acceptability. An alternative to travel to remote centers for routine or specialized services, health services via technologies can provide those in rural areas and nursing homes with substantial support.

Abstract: The hippocampus experiences significant anatomical and functional change during aging. Tasks that can be administered repeatedly with stable performance are needed for reliably assessing hippocampal functioning as a reference for detecting decline in performance due to aging or disease or improvement from change in lifestyle behaviors. The goal of the current study was to determine age-related performance differences and reliability of repeated testing of two tasks that have been proposed to measure hippocampal functioning. Fifty-four young (18-30 yrs; 28 F) and 30 older participants (60-80 yrs; 21 F) completed 4 experimental visits. All individuals completed a tablet-based spatial reconstruction (SR) task and a computer-based spatial pattern separation (SPS) task. The SR task involves delayed spatial reconstruction of unique layouts of novel objects. Error measurements include misplacement metrics and a relation-dependent swap metric, primarily targeting item-pair relation memory. The SPS task involves presentation of a target stimulus followed by two cues, one of which matches the location of the target. Smaller distances between cues leads to greater memory representation interference between, thus targeting the resolution of memory representations. Half of the participants performed the SR once and the SPS three times, while the other half performed the SPS once and the SR three times. As expected, young adults performed better than older adults on the SR task on all error metrics (swap metric: $F(1,81)=11.062$, $p<.001$). However, there was no main effect of age on the SPS task ($F(1,328)=2.319$, ns). No session effect was found for either the SR task (swap metric: $F(2,76)=.582$, ns) or the SPS task ($F(2,82)=1.635$, ns), nor was an age by session interaction found for either task. Interestingly, the SR task swaps error metric was negatively correlated with SPS task accuracy at lower levels of spatial interference across all individuals (Young: $r=-.279$, $p=.043$; Older: $r=-.445$, $p=.016$), and at higher levels of spatial interference only for older adults ($r=-.571$, $p=.019$). However, swap error rate on the SR task was not correlated with processing speed as measured by Trails A (Younger: $r=-.152$, ns; Older: $r=.150$, ns), supporting the idea that the association between SPS and SR performance is due to a commonality in spatial memory processing. These results indicate that both tasks can be administered repeatedly for both young and older adults with good test-retest reliability. The results also indicate that while the SR and SPS task may both tap memory constructs, item-pair swap rate in the SR task is more sensitive to age-related differences in hippocampal function.

Title: Functional correlates of personality & facial perception in old and young adults

Authors: *N. PERSSON[1,2], N. C. EBNER[3], T. LIN[3], H. FISCHER[2,4];
[2]Dept. of Psychology, [1]Stockholm Univ., Stockholm, Sweden; [3]Dept. of Psychology, Univ. of Florida, Gainesville, FL; [4]Aging Res. Ctr., Karolinska Institutet, Stockholm, Sweden

Abstract: Daily social interaction involves perception of emotional faces. Individual personality is of vital importance for how we perceive and interact with the outer world. Personality has been associated with age sensitive structures in the frontal cortices, and emotional perception. The literature investigating the link between personality, facial perception and BOLD activation is scarce. We assessed the influence of personality on peak fMRI BOLD activation in fronto-parietal areas in response to happy, neutral, and angry faces in a sample of younger (n= 30, 20-31 years) and older (n=31, 65-74 years) men and women. A series of Structural Equation Models was specified to evaluate the influence of age and personality on BOLD activation to emotional faces, contrasted with neutral faces. The behavioral measures included aspects of neuroticism (N), extraversion (E), and openness (O), assessed by a standard questionnaire (NEO-PI) during a first session. During the second session (fMRI), participants worked on the Facial Expression Identification Task that presented them with photos of old and young neutral, happy, and angry faces, randomly intermixed. Images were acquired using a 3T scanner (Siemens Magnetom Tim Trio). Onehundred and sixty functional images each were acquired with a T2*-weighted echo-planar sequence. Thirty-nine oblique axial slices were positioned parallel to the AC-PC line and acquired interleaved. A 1 × 1 × 1 mm T1-weighted image was used for co-registration with functional images. Processing of emotional faces was associated with increased activation in the medial frontal gyrus (MFG) and the post central gyrus (PCG), (FWE corrected). Older adults showed lesser degree of N and O than their younger counterparts. There were no reliable group differences in E. Older age predicted greater activity in PCG to angry faces compared to neutral faces, but there was no significant association for MFG. Extraverted subjects showed greater activity to angry than neutral faces after age was accounted for. E also predicted greater activity in MFG in response to happy than neutral faces, but the association was gone after age was taken into account. A trend was present for lesser activity in the PCG to angry than neutral faces for more neurotic subjects, but the association did not hold when adjusting for age. O was not related to activation to emotional faces in any of the ROIs.Our findings suggest that higher degree of extraversion is particularly important for BOLD activation in age-sensitive key structures in emotional processing. Greater activation of fronto-parietal networks to emotional faces in extroverted subjects may reflect increased use of cognitive control.

Title: Fatigue and fatigability in young and older adults

Authors: ***S. BURKE**[1], I. SAMUEL[2], B. KLUGER[3], M. DING[2];
[1]Univ. of Florida, Gainesville, FL; [2]Univ. of Florida, GAINESVILLE, FL; [3]Univ. of Colorado Denver, Denver, CO

Abstract: Fatigue is associated with increased mortality in older adults and is the leading cause of activity restrictions in this population. Unfortunately, our understanding of the causes of fatigue in older adults is quite limited and there are no proven treatments. Typically, fatigue is assessed by questionnaires. Cognitive fatigability, in contrast, is defined as changes in behavioral performance that occur during a sustained cognitive activity and is a more objective measure. The goal of this study is to compare cognitive fatigability in young and older adults. Naively, one expects that older adults are more fatigable than young. However, considering that during cognitive performance, older adults tend to adopt the resource-preserving strategy of taking longer to respond, we hypothesized that the opposite is true. To test the hypothesis we recruited a group of 18 healthy older subjects between the ages of 60 and 87 and a group of healthy young adults between the ages of 18 and 33. They were asked to perform a 3 hour continuous cued Stroop task. Two results were found. First, at the baseline (first 30 minutes of the task), the young group had faster reaction times but committed more errors than the aged group. Second, the aged group did not show markedly decreased performance (i.e., slowed reaction time and increased error rate) as time-on-task increased, whereas the young group exhibited significantly slowed reaction times and higher error rate as time-on-task increased, giving rise to higher cognitive fatigability. These results, consistent with our hypothesis, suggest that a conservative behavioral strategy that trades speed for accuracy helps to minimize resource depletion in the face of prolonged cognitive performance. Key words: Cognitive fatigability, fatigue, aging.

Title: Dynamics of resting state functional connectivity through the human adult lifespan

Authors: *D. BATTAGLIA[1,2], E. C. A. HANSEN[1,3], P. RITTER[4,5,6], V. JIRSA[1];
[1]INS, Univ. Aix-Marseille, Marseille, France; [2]BCCN, Goettingen, Germany; [3]FIAS, Frankfurt, Germany; [4]Neurol., Charité Univ. Hosp., Berlin, Germany; [5]Bernstein Focus State Dependencies of Learning and BCCN, Berlin, Germany; [6]Minerva Res. Group BrainModes, MPI for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: The aging brain undergoes anatomical alterations, but also transformations of the flexible way in which brain regions interact during cognition. In particular, functional connectivity in the resting state, describing spontaneously emergent correlations between the activity of different areas, distinctly displays age-related changes. Here, we show that aging also profoundly impacts on the dynamics of this functional connectivity. We reveal a characteristic switching, markedly slowing down with age, between epochs of meta-stable functional connectivity and transients of fast functional network reconfiguration. Furthermore, we identify communities of functional links, rather than network nodes, whose temporal fluctuations become increasingly anti-correlated in elderly subjects. Such manifest remodeling of functional connectivity dynamics discloses aspects of cognitive aging that cannot be captured by variations of structural and time-averaged functional connectivity. Its statistical parameterization allows then predicting a subject's age with superior accuracy, opening the way to the design of performing biomarkers with perspective clinical relevance. In particular, exploiting positive synergies between information about Functional Connectivity Dynamics, structural connectivity and time-averaged FC, we are able to predict the age of a single subject with an unprecedented precision of ±5 years, over an age span between 18 and 80 years. We finally show preliminary evidence that our Functional Connectivity Dynamics analyses predict also performance in simple

tasks, correlating thus to subject-specific cognitive flexibility beyond general trends due to anagraphic age.

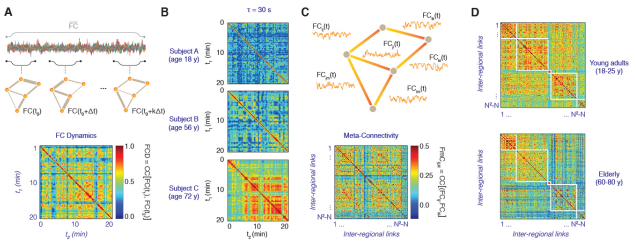

Figure caption: A. Functional Connectivity Dynamics (FCD) analysis, i.e. correlation between functional networks observed at different times. B: FCD slows down and "crystallize" with aging. C: Meta-Connectivity (MetaFC) analysis, i.e. correlation between time variation of functional links strenghts. D: anticorrelated meta-links develop with aging.

Title: Contributions of hippocampal and striatal tract integrity to mnemonic discrimination across the lifespan

Authors: *I. J. BENNETT[1,2], C. E. L. STARK[2,1];
[1]Ctr. for the Neurobio. of Learning and Memory, [2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: The striatum (caudate, putamen) is traditionally implicated in implicit forms of learning and memory (Squire, 1992). However, converging evidence indicates that the striatum also contributes to explicit, episodic memory. For example, individuals with striatal dysfunction exhibit episodic memory deficits (e.g., Parkinson's disease; Elgh et al, 2009) and striatal lesions

can produce memory impairments that mimic hippocampal damage (Yin & Knowlton, 2004). Moreover, functional neuroimaging studies have shown both hippocampal and striatal engagement during item recognition (Scimeca & Badre, 2012) and paired-associate learning (Mattfeld & Stark, 2010). Successful performance on these tasks requires discrimination of novel events from previously encountered events. This type of mnemonic discrimination is thought to rely on pattern separation, a computational process by which unique representations are generated for each event (Yassa & Stark, 2011). Using diffusion tensor imaging (DTI), our lab has previously shown that mnemonic discrimination is related to integrity of hippocampal tracts, including the fornix (Bennett et al, 2014), in healthy adults across the lifespan. In the current study, we tested the hypothesis that striatal tract integrity also relates to mnemonic discrimination. Participants (n = 112, 20-89 years) underwent whole-brain DTI to obtain measures of hippocampal (fornix) and striatal (caudate-frontal) tract integrity (fractional anisotropy, mean diffusivity). They also performed a modified item recognition task, the Mnemonic Similarity Task (Kirwan & Stark, 2007), which provides measures of mnemonic discrimination (correct "similar" responses to lure objects that are similar to memory set objects) and traditional recognition memory (correct "old" responses to repeated memory set objects). Results revealed age-related declines in fornix and caudate-frontal tract integrity, and in mnemonic discrimination, but not recognition memory. Separate regression analyses further revealed that increased fornix and caudate-frontal tract integrity was related to better mnemonic discrimination. After controlling for the effect of age on white matter integrity, however, only the relationship between fornix integrity and mnemonic discrimination remained significant. These preliminary findings indicate that mnemonic discrimination is mediated by integrity of tracts within the hippocampal, but not striatal, memory system. Additional research will be necessary to determine if integrity of other striatal tracts relate to mnemonic discrimination, or if the striatal network mediates other components of episodic memory.

Title: Discovery and characterization of potent biphasic a5GABAA receptor modulators

Authors: *M. SOH[1], R. MCGEARY[2], J. LYNCH[1];
[1]Queensland Brain Inst., Brisbane, Australia; [2]Sch. of Pharmacy, The Univ. of Queensland, Brisbane, Queensland, Australia

Abstract: Therapeutic drugs targeting $GABA_AR$s are used as anxiolytics, sedatives, and antiepileptics. These drugs are allosteric positive modulators of $GABA_AR$s that enhance GABA activity. As these drugs non-selectively target many $GABA_AR$ subtypes causing unwanted side effects, subunit-specific drugs are now desirable. Positive modulators selective for α_5GABA_ARs have shown promising results in treating cognitive symptoms of schizophrenia and age-related dementia, whereas α_5GABA_AR negative modulators have proven worth as cognition enhancers, in post-stroke recovery and prevention of general anesthetic-induced amnesia, without causing sedation and anxiety. The aim of this project is to discover and characterize novel α_5GABA_AR selective compounds. This was accomplished by screening a library of synthetic compounds on HEK cell-transfected $\alpha_5\beta_3\gamma_{2L}$ $GABA_AR$s using high-throughput YFP-based anion influx assay. Modulation on other $GABA_AR$ subtypes ($\alpha_1\beta_2\gamma_{2L}$, $\alpha_5\beta_2\gamma_{2L}$) and drug binding sites were also explored using functional studies on two-electrode voltage clamp electrophysiology (TEVC). To prepare for TEVC, *Xenopus borealis* frogs were anesthetized with MS-222 and surgically incised to obtain the oocytes, which were digested and injected with $GABA_AR$ mRNAs. TEVC recordings revealed that isomeric compounds RM 68, RM 69 and RM 70 are potent $GABA_AR$ modulators. These isomers, except RM 69, demonstrated biphasic modulation, selectively potentiating α_5GABA_ARs in the nM (sometimes pM) range, but inhibiting $GABA_AR$s non-selectively at higher μM concentrations. Removing mercaptoacetaldehyde from RM 68 to give RM 96 eliminated its α_5GABA_AR selectivity. Flumazenil managed to neutralize the potentiation of GABA responses by the 4 compounds, suggesting that the potentiating effect of these compounds was modulated via the benzodiazepine site. RM compounds can be potential leads to design novel subtype specific drugs for $\alpha_5$related disorders and to study the pharmacology of α_5GABA_ARs.

Title: Age differences in regional myelin content and white matter organization in healthy adults: Comparing myelin water fraction and diffusion tensor imaging

Authors: *M. ARSHAD[1], J. A. STANLEY[2], N. RAZ[3];
[1]Wayne State Univ., Detroit, MI; [2]Psychiatry and Behavioral Neurosci., Wayne State Univ. Sch. of Med., Detroit, MI; [3]Psychology, Inst. of Gerontology, Wayne State Univ., Detroit, MI

Abstract: Much of the extant literature relies on indices derived from diffusion tensor imaging (DTI), e.g., fractional anisotropy (FA), radial diffusivity (RD), and axial diffusivity (AD), to characterize age related differences in cerebral white matter. Despite growing evidence, differences in FA or RD are frequently interpreted as differences in myelination. In this study we compare FA to a more specific index of myelin content, Myelin Water Fraction (MWF), across multiple regions of interest representing association, projection and commissural pathways in a sample of 40 healthy adults (mean age = 52.0, SD = 18.9 years). Regions of interests were mapped from standard space to subject space, where all DTI and MWF measurements were made. The relationship between MWF and age was quadratic and the largest age differences were noted in the superior longitudinal fasciculus (SLF) and internal capsule anterior limb (ALIC), followed by inferior fronto-occipital fasciculus (IFOF), genu and splenium of corpus callosum, alhough the effect sizes do not differ significantly. No age differences were observed in the posterior limb of IC (PLIC). In contrast, the FA analysis revealed linear age differences, largest in IFOF and Genu, moderate in the Splenium and ALIC, lesser in the SLF and none in the PLIC. RD showed linear and quadratic age differences in ALIC and splenium. AD evidenced uniform linear and quadratic age differences across all regions. Correlations between MWF and DTI indices, after Bonferroni corrections, were not significant, except for SLF AD-MWF pairing. Thus, we find different relationships of MWF and DTI indices with age, across the white matter regions sampled here. The quadratic relationship between MWF and age is consistent with the continuing myelination of sub-cortical white matter tracts into adulthood. These results support the growing awareness that DTI indices are not a reflection of a myelination and caution should be taken when interpreting age differences in DTI indices.

Title: Physical activity levels and white matter microstructure in community-dwelling older adults

Authors: *C. SEXTON[1], N. FILIPPINI[1], E. ZSOLDOS[1], A. MAHMOOD[1], S. SABIA[2], A. SINGH-MANOUX[2], M. KIVIMAKI[2], H. JOHANSEN-BERG[1], K. EBMEIER[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Univ. Col. London, London, United Kingdom

Abstract: Cross-sectional studies have previously shown that cardiorespiratory fitness is positively correlated with white matter volume and integrity within the corpus callosum (1,2). Here, we use Diffusion Tensor Imaging to examine the relationship between physical activity (PA) levels and the corpus callosum in 306 members of the Whitehall II cohort (72 females, age 68.9 ± 4.9 years). PA was measured using a modified version of the Minnesota leisure-time PA questionnaire at 4 time-points (1997-99, 2002-04, 2007-09, 2012-13), and DTI acquired at a single time-point (2012-14) (3). For prospective and cross-sectional analyses, PA was classified at each time-point as low, medium or high and assigned a score of 0, 1 or 2, respectively. Low PA corresponded to < 1 hour moderate and < 1 hour vigorous PA per week, and high PA to ≥ 2.5 hours moderate or ≥ 1 hour vigorous PA per week. For cumulative analyses, PA score was summed across all time-points, and classified as low (total score 0-2), medium (3-5) or high (6-8). Analysis of DTI data was carried out using Tract-Based Spatial Statistics, with voxel-wise statistics performed using Randomise. F-tests were used to examine the overall effects of PA on fractional anisotropy (FA) values within the corpus callosum, and post-hoc t-tests used to assess group differences. Age and gender were included as covariates in all analyses, and the significance threshold set at $p<0.05$ using threshold-free cluster enhancement. At each individual time-point, PA was not found to be significantly associated with FA. In cumulative analyses, though, FA values were significantly different between PA groups. Post-hoc t-tests demonstrated that FA was significantly greater in both the medium and high PA groups compared with the low PA group (Figure). In conclusion, our results support the hypothesis that cumulative levels of PA are associated with white matter integrity in older adults. References 1. Johnson et al. Title: Age-related changes in cerebral correlates of voice processing

Authors: ***J. ZHANG**[1,2], F. W. SMITH[3], B. L. GIORDANO[2], M.-H. GROSBRAS[2], G. A. ROUSSELET[2], P. BELIN[2];
[1]Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX; [2]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom; [3]Sch. of Psychology, Univ. of East Anglia, Norwich, United Kingdom

Abstract: Pervasive age-related brain atrophy, including in auditory cortex, creates the necessity of studying whether and how voice processing changes with age. To address this issue, in an fMRI study we manipulated vocal and non-vocal signals and measured the relationship between age and brain functions for voice processing by applying both univariate and multivariate analysis. Sixty healthy adults (20-86 years, M = 51.2 years, SD = 18.2) passively listened to sounds with eyes closed while being scanned. The paradigm consisted of a classical voice localizer scan (Belin et al., 2000) contrasting blocks of vocal vs non-vocal sounds to identify the temporal voice areas (TVA), which mostly cover the middle and anterior parts of the bilateral superior temporal sulcus (STS) (Belin et al., 2000). The stimuli had 40 8-sec blocks of sounds. Half of the blocks had only vocal sounds, and the other half had only non-vocal sound. Both univariate (General Linear Model, GLM) and multivariate approaches were used. For the

multivariate analysis, we used leave-one-trial-out cross validation to train and test a linear support vector machine (SVM). Results showed that TVAs were responsive to voice processing across the whole age range in both univariate and multivariate analysis. To study how voice processing changes with age, we conducted correlations of activity/classification accuracy with age for the univariate and multivariate approach respectively. Univariate analysis did not show significant negative correlation of activity with age for the vocal vs non-vocal contrast. In contrast, multivariate analysis showed that the vocal minus non-vocal accuracy in bilateral TVAs declined with increasing age. Both the univariate and multivariate analysis had a significant positive correlation in activity/accuracy with age, with univariate analysis showing that activity in bilateral postecentral regions increased with age whereas multivariate analysis showing that the classification accuracy difference between vocal and non-vocal in medial frontal and right precentral regions increased with age. The results suggest that multivariate and univariate analysis had different sensitivity to age-related changes in voice processing. Multivariate pattern analysis had an age-related decline in voice processing, with less sensitivity to differentiating vocal from nonvocal sounds in bilateral temporal regions in response to aging. Univariate analysis seems to be less sensitive to detecting age-related impairment in voice processing. Both multivariate and univariate seem to be sensitive to the age-related increasing recruitment of regions in the non-auditory cortex.

Title: Arterial spin labelling (ASL) may be useful for diagnosing various types of Parkinson's disease with dementia

Authors: *K. ABE[1], T. HAYASHI[2], M. YAMAMOTO[2], N. AKIYAMA[2], M. FUJITA[2]; [1]Dept. of Community Hlth. Med. and Neurol., Hyogo Col. of Med. Grad. Sch. of Medic, Nishinomiya-Shi, Japan; [2]Neurol., Fujita Shinkeinaika Clin., Higashiosaka, Japan

Abstract: Purpose: To determine whether arterial spin labeling (ASL) can be used to evaluate regional cerebral blood flow (CBF) patterns in various types of Parkinson's disease (PD) with

dementia. Subjects and Methods: Thirty five PD patients (15 Male/19 Female, Age 73.1±6.5 (mean±SD) years, disease duration7.55±3.3) who met a Japanese PD diagnosis criteria and 35 age and sex normal controls were scanned by using a pseudo-continuous arterial spin labeling (PCASL) method with a 1.5 Tesla MRI unit (Achieva A-series; Philips Medical Systems, Best, The Netherlands). Clinical signs were evaluated by unified Parkinson's disease rating scale (UPDRS), minimental state exmination (MMSE), frontal assessment batery (FAB), Montral cognitive assessment (MOCA). Regional cerebral blood volume (CBF) was compared in the frontal, the parietoposterial, and the posterior cortex using region-of-interest analysis. Results: PD patients had UPDRS with 33.9±5.2 MMSE with 24.0±3.9, FAB with 13.5±3.7, MOCA with 21.7±5.7. PD patients showed four regional CBF patterns. The first group had normal regional CBF patterns comparing with those of normal controls. The second group had reduced frontal cortex regional CBF patterns comparing with those of normal controls. The third group had reduced parietoposterial cortex regional CBF patterns comparing with those of normal controls. The fourth group had reduced posterial cortex regional CBF patterns comparing with those of normal controls. Conclusion: This is a study to detect four patterns of hypoperfusion in the cortex in PD patients using ASL perfusion MRI. Because ASL perfusion MRI is completely noninvasive and can, therefore, safely be used for repeated assessments, this method can be used to monitor treatment effects or disease progression in PD.

Title: Anatomical substrate of fatigue in Parkinson's disease

Authors: *Q. ZHAO[1], H. HUANG[1], J. TANNER[2], C. PRICE[2], B. KLUGER[3], M. DING[1]; [1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Dept. of Clin. and Hlth. Psychology, Univ. of Florida, Gainesville, FL; [3]Univ. of Colorado, Denver, CO

Abstract: Nonmotor symptoms in Parkinson's disease (PD) are increasingly recognized as a significant source of suffering and disability. In particular, fatigue affects approximately half of all PD patients and is reported by one third to be their single most disabling symptom. The pathogenesis of fatigue in PD remains unknown, however, and we have no effective treatments. Here, we performed a voxel-based morphometry (VBM) analysis to examine the neuroanatomical basis of fatigue in PD. Forty nine patients clinically diagnosed with idiopathic tremor dominant PD without dementia (42 male, 7 female) and forty two age- and sex- matched controls (37 male, 5 female) enrolled. Imaging included T1-weighted structural scans acquired with trait-level fatigue assessed by Fatigue Severity Scale (FSS) within 24 hours of the MRI. Dividing PD patients into two groups: with fatigue (FSS>4, 25 subjects) and without fatigue (FSS<4, 24 subjects), we found that PD patients with fatigue had reduced gray-matter volume in caudate and putamen relative to PD patients without fatigue ($P<0.05$ FDR corrected). The involvement of insula in fatigue was further revealed by a ROI-based multiple regression analysis. In contrast, no fatigue-related structural atrophy was found in controls. These results provide evidence for a central origin of fatigue involving the frontal-striatal network and insula within PD.

Title: Validation of olfactory identification deficit as a biomarker of Alzheimer's disease

Authors: *E. LAZAR[1], M. WOODWARD[1], C. AMRUTKAR[1], J. HAGEMEIER[1], H. SHAH[1], R. BENEDICT[1], S. RAJAKRISHNAN[1], R. DOODY[2], L. YAN[1], K. SZIGETI[1];
[1]SUNY At Buffalo, Buffalo, NY; [2]Baylor Col. of Med., Houston, TX

Abstract: Importance: With increased longevity the prevalence of AD in the elderly represents a major public health problem. Olfactory identification deficit (OID) may represent a parallel neurodegenerative process preceding the AD disease trajectory thus may have utility 1) as a screening tool in the primary care setting, 2) in identifying presymptomatic individuals for disease modifying therapy,3) in enriching aMCI trials with conversion as the primary outcome measure. Objective: To evaluate smell identification as a biomarker for AD by assessing its utility in differentiating normal aging from an amnestic disorder and determining its predictive value for conversion from aMCI to AD. To correlate the clinical olfactory deficit with neuroanatomical changes assessed by structural MRI. Design: There are three components: 1) it is powered as a cross-sectional case-control study to evaluate the sensitivity and specificity of OID in differentiation normal aging from an amnestic disorder; 2) an exploratory longitudinal study of aMCI subjects with at least one year follow up to evaluate the utility of OID in predicting conversion from aMCI to probabale AD by NINCDS-ARDA criteria; 3) a subset of subjects (27 NC, 15 aMCI and 37 AD) had structural MRI analysis. Participants: 566 participants 65 years or older were consented to participate (AD=262, aMCI=110, Controls=194). Results: Correlation trend test between odor identification and disease status was significant after correcting for age, sex, and ApoE in the model (p=1.52x10-59). ROC/AUC was similar for the 40 item UPSIT, the top 10 smells in our study, and the 10 item subset previously proposed. Smeller/non-smeller based on the 10 item subset with a cutoff of 7 (< = 7, non-smeller; > 7, smeller) had a sensitivity and specificity of 88% and 71% for identifying AD, and 74% sensitivity and 71% specificity for identifying an amnestic disorder. 36.4% of subjects with impaired olfaction and 17.3% with intact olfaction converted to AD (p=0.03).Volumetric analysis revealed differences in right hippocampal volumes between smellers and non-smellers in the aMCI stage. Olfactory memory is coded in the right hippocampus suggesting disease relevance and a central mechanism. OID measures a pure memory deficit and does it earlier. Conclusion: OID has sensitivity and specificity that are comparable or slightly inferior to other established biomarkers, with benefits such as ease of administration and low cost. Longitudinal studies exploring the time relationship between the trajectory of decline in olfactory identification and the development of an amnestic disorder are needed to further characterize the relationship.

Title: Identification of initial visit factors predictive of cognitive maintenance or cognitive decline in memory clinic patients

Authors: W. D. DUNN, Jr.[1], R. CHEN[5], L. ZHANG[2], E. E. HECHT[3], A. I. LEVEY[6], *D. A. GUTMAN[4];
[1]Dept. of Neurol., [2]Dept. of Biostatistics, [3]Dept. of Anthrop., [4]Dept Psychiatry & Behavioral Sci., Emory Univ., Atlanta, GA; [6]Dept. of Neurol., [5]Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Objective: Alzheimer's disease (AD) is a devastating neurodegenerative condition that currently has no cure. Due to significant personal and financial costs associated with treatment, it is of critical importance to identify the disease in its most incipient stages. Here, we use clinical assessment records to study characteristics of patients who either decline mentally or stay relatively stable over several years. We hope our findings will offer more insight into the probable trajectories of various patient groups, which could shed light towards more targeted treatment decisions from the very first visit. Methods: More than 10,000 record visits were initially extracted from the Emory University memory clinic database. Records were next grouped by patient and those with an initial Mini Mental State Examination (MMSE) of at least 24 and at least two years between first and last visits were divided into "Stable" and "Declining" groups representing patients whose MMSE scores changed less than 2 points and those whose scores decreased by more than 5 points respectively. The demographic and first cognitive testing variables of these Stable and Declining patient groups were characterized. Significant differences between these groups were tested using t-test or chi-squared statistics. In addition, to identify factors that influence changes between Stable and Declining groups, we performed logistic regression and Akaike information criterion (AIC) - based stepwise variable selection. Results: Descriptions of demographic and initial cognitive testing variables and significance of

differences between Stable and Declining groups are given in Table 1. Chi-squared proportions test revealed no differences in biological sex, handedness, or race between the two groups. Finally, logistic regression results indicate five baseline cognitive test scores that significantly predict decreasing mental state. Conclusion: Early diagnosis is a critical first step towards the goal of delaying the progression of dementia-related diseases. Our results shine light on initial visit demographic and cognitive scoring factors associated with stable or decreasing condition that may be capitalized upon to reduce the overall burden of the disease.

Table 1: Stable vs Declining patient characteristics

Demographic/Cognitive Initial Factor	Stable Patients (N=113)	Declining Patients (N=103)	P value
Handedness (%RH, %LH, %AMB)	90.27, 7.965, 0.885	90.29, 8.738, 0	N/A

Title: PDE4 inhibition in young healthy adults improves memory: a translational approach

Authors: ***M. VAN DUINEN**[1], A. SAMBETH[2], A. BLOKLAND[2], J. PRICKAERTS[1]; [1]Psychiatry and Neuropsychology, [2]Neuropharm. and Neuropsychology, Maastricht Univ., Maastricht, Netherlands

Abstract: Selective phosphodiesterase (PDE) inhibition has been considered as an interesting target for cognition enhancement. There are 11 different PDEs and only some PDEs have been related to memory enhancement: PDE1-5 and PDE9. The classic PDE type 4 inhibitor rolipram has repeatedly shown to enhance memory performance in rodents, yet its clinical application is limited due to severe emetic side effects. More recently, PDE4-Is have been found with a far more favorable side effect profile. After we showed memory improvement in rodents after treatment with the selective PDE4 inhibitor roflumilast, we initiated a trial with roflumilast to evaluate its cognition enhancing potential in young healthy adults. Memory and attention performance were assessed and EEG was recorded simultaneously. Acute oral roflumilast administration (100 mcg, 300 mcg and 1000 mcg) was applied in a double-blind cross-over placebo controlled design. Healthy adults (n=20) receiving a single oral dose of 100 mcg of roflumilast showed a statistically significant improvement with respect to the number of correct words recalled in the verbal learning task (VLT) after the third learning trial as compared to placebo. Roflumilast did not improve delayed recall scores in the VLT. Evaluation of the EEG

measurements (event-related potentials) during the VLT testing revealed a higher P600 amplitude after receiving a single oral dose of 100 mcg of roflumilast as compared to placebo. The P600 has repeatedly been related to memory processes and supported the effects on the improved memory performance. No effects of roflumilast on attention were discovered as assessed with the Stroop. Side effects were reported in some subjects with the higher doses (e.g. nausea), in particular after 1000mcg roflumilast. No side effects were found with the effective dose. We are the first to show that PDE4-I can improve memory performance in unaffected healthy young adults. This finding implies that roflumilast, by preventing the breakdown of cAMP by specific phosphodiesterases, optimizes memory. This data offers a promising pharmacological perspective for the treatment of memory impairment. Moreover, PDE-4 remains present in the older brain, which renders PDE4-Is an attractive target for memory impairment related to aging.

Title: The effect of chronic consumption of purple grape juice on memory, bdnf and histone h4 acetylation levels in elderly residents in southern Brazil

Authors: *V. ELSNER[1], P. CAÑETE DA COSTA[2], G. REINALDO[4], C. ARAUJO[5], I. REICHERT VITAL DA SILVA[3], P. DAL LAGO[6], C. FUNCHAL[3], C. DANI[3];

Abstract: Purple grape juice consumption by presenting phenolic compounds, has been described as an important strategy able to improve cognitive functions, especially during the aging process. However, the molecular bases associated with these beneficial effects are not yet elucidated. The present study aimed to investigate the effect of chronic consumption of purple grape juice on memory, plasma levels of brain-derived neurotrophic factor (BDNF) and histone H4 acetylation levels in leukocytes of healthy elderly residents in Porto Alegre city, Rio Grande do Sul, Brazil. This study was approved by the Ethics Committee on Human Research of the Methodist University with IPA on 04/12/2014, number 900.767. Forty one volunteers of both genders (4 male and 37 female) were recruited to take part in this experiment. They were instructed to consume 400ml daily of red purple juice, provided by the researchers, for 30 days in time not specified. For BDNF and histone H4 acetylation levels analyses, the volunteers underwent to two blood collections: before the intervention and after 30 days of juice consumption. These assays were performed using commercial kits (ELISA), according to the manufacturer's instructions. The Mini Mental State Examination test (MMSE) was also applied before and after the intervention in order to assess the memory. The Wilcoxon test revealed that there was no statistically significant change in BDNF and acetylation of histone H4 levels ($p > 0.005$) in the pre and post intervention periods. However, the paired t-test showed statistically significant difference, with higher scores in the post intervention period ($p = <0.001$). Conclusion: Chronic consumption of purple grape juice shown to improve memory of elderly people, which is not seem to be associated with the modulation of peripheral BDNF and histone

H4 acetylation levels. Additional work will be required to investigate the molecular mechanism behind this phenomenon.

Title: Age-related differences in the salience network: behavioral implications for executive function and affect

Authors: *A. TOUROUTOGLOU[1,2], J. ANDREANO[3], L. FELDMAN BARRETT[4], B. DICKERSON[2];
[1]Athinoula A. Martinos Center, Massachusetts Gen. Hosp., Harvard Med. Sch., Charlestown, MA; [2]Neurol., [3]Harvard Med. Sch., Boston, MA; [4]Northeastern Univ., Boston, MA

Abstract: The salience intrinsic connectivity network is comprised by two dissociated subsystems, implicated in a variety of psychological phenomena that are critical for healthy aging. The dorsal salience subsystem includes regions important for executive function such as dorsal anterior insula and mid cingulate cortex; the ventral salience network includes regions implicated in affective experience such as ventral anterior insula, anterior cingulate cortex and amygdala (Seeley et al., 2007; Touroutoglou et al., 2012). In this study, we examined the age-related differences in the two salience subsystems and the behavioral implications of these differences. We found that the intrinsic connectivity within the dorsal salience subsystem decreases with age. In contrast, the connectivity within the ventral salience subsystem is preserved with age, and even increased between some of its nodes such as the ventral anterior insula and amygdala. Furthemore, using mediation analysis, we found that age-related declines in executive function are mediated by decreased connectivity within the dorsal salience subsystem, whereas age-related changes in negative affect are mediated by altered connectivity within the ventral salience subsystem. Taken together, these findings show that the aging brain

has preserved circuitry for allocating attention to information that it finds evocative and homeostatically important, even if the circuitry for allocating attention to information on a cognitive basis is diminished with age.

Title: Neural mechanisms supporting successful speech comprehension in normal aging

Authors: *Y. .-S. LEE[1], C. ROGERS[2], N. MIN[1], A. WINGFIELD[3], M. GROSSMAN[1], J. PEELLE[2];
[1]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA; [2]Otolaryngology, Washington Univ. in St. Louis, St Louis, MO; [3]Volen Natl. Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Although declines in hearing ability typically occur during normal aging, many older adults retain high levels of speech comprehension ability. However, older listeners differ in their degree of success, and the reasons for this variability are unclear. In the present fMRI study we recruited a group of 39 older adult listeners (mean age=65.9 years). Participants underwent scanning while listening to sentences varying in both syntactic complexity (subject-relative vs. object-relative embedded clause) and acoustic richness (acoustically rich vs. acoustically degraded using noise vocoding). For each sentence, participants indicated the gender of the character performing the action via button press. We split the older adults into better-performing (n=19) and worse-performing groups (n=20) based on their behavioral performance. The better performing older adults show accuracy scores and reaction times comparable to those of the young adults (n=26). Hearing acuity is well matched across the two groups of older subjects, while significantly worse than that of young adults (Figure 1A). Neural activity for these groups of subjects is shown in Figure1B. The good-performing older adults show activity that is statistically indistinguishable from the young adults. By contrast, the poor-performing older

adults show increased activity in frontal cortex and cerebellum compared to their good-performing counterparts. Because these patterns of activity were associated with correct responses, we conclude that these additional regions are recruited to maintain high levels of speech comprehension in the poor-performing older group (Figure 1C). Taken together, our findings demonstrate more dynamic interplay of task demands, neural recruitment, and behavioral performance during spoken language comprehension.

Title: Age-dependent community dynamics and brain system organization in human functional brain networks

Authors: *K. J. SCHLESINGER[1], B. O. TURNER[2], B. LOPEZ[2], M. B. MILLER[2], J. M. CARLSON[1];
[1]Physics Dept., [2]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: As humans age, cognition and behavior change significantly, along with associated brain function and organization. Aging has been shown to decrease variability in functional magnetic resonance imaging (fMRI) signals [1], and to affect the modular organization of human brain function [2]. In this work, we use complex network analysis to investigate the dynamic community structure of large-scale brain function, asking how evolving communities interact with known functional systems, and whether the dynamics of communities and brain systems are affected by age. We analyze networks derived from fMRI scans of 105 human subjects (53 female; not analyzed separately by sex) performing a word memory task. Network nodes are 94 anatomical brain regions, and dynamic edge weights are defined as the low-frequency (0.06-0.125 Hz) wavelet coherence of activity between pairs of nodes, computed within each of a set of sequential time windows. We determine the time-evolving modular structure of these networks by maximizing the multislice modularity [3], thereby identifying distinct communities, or sets of brain regions with strong intra-set functional coherence. To describe changes in community structure over time, we use flexibility, or the probability that brain regions will switch between communities [4]. We find a significant positive correlation between age and flexibility: brain regions of younger subjects tend to change communities less often during the memory task. We characterize the relationship of community structure to known brain systems by the recruitment coefficient, or the probability of a brain region being grouped in the same community as other regions in the same system [5]. We find that subcortical regions and regions associated with fronto-parietal and cingulo-opercular circuits have a significantly higher recruitment coefficient in younger subjects. This indicates that the within-system functional coherence of these specific systems during the memory task declines with age; such a correspondence does not exist for other systems (e.g. visual and dorsal attention), whose recruitment coefficients remain relatively uniform across ages. These results confirm that the dynamics of functional community structure vary with age, and demonstrate methods for investigating how aging differentially impacts the functional organization of different brain systems. Title: Gray matter volumes related to body fat predict executive functions differentially in males and females

Authors: ***A. STICKEL**, E. RODRIGUEZ, A. MEYER, L. RYAN;
Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Obesity is associated with brain structure and cognitive functioning in some studies but not others. Typical measures of obesity, like body mass index, may be limited in their ability to operationalize body fat, especially in males and older adults. The current study investigated the impact of percent body fat, measured with an impedance scale, on brain structure and executive functioning and sought to determine if there were different impacts on males versus females. Males (n = 18) and females (n = 18), ages 60-80, were matched on age, education, and hypertensive status. Voxel-based morphometry was used to identify gray and white matter regions that decreased as percent body fat increased ($p < .001$), controlling for age, intracranial volume, and gender. Decreasing gray matter regions included bilateral fusiform, right medial temporal, left occipital, bilateral parietal, left cingulate, and left middle frontal areas. White matter volumes decreased in the left occipital, left medial temporal, and right parietal regions as percent body fat increased. Volumes were extracted from each significant cluster to create regions of interest (ROIs). ROIs were residualized to take into account the effects of age and intracranial volume. Separate univariate general linear models were used to predict executive function tasks (Global-Local, Stroop, and Keep Track tasks) from ROIs, gender, and the interaction between ROIs and gender. In males higher gray matter volumes in the left occipital lobe were associated with better performance on the Keep Track Task but were not associated in females. In females, but not males, better performance on the Stroop was associated with higher

volumes in the left cingulate and the right parietal lobe. No associations were found for white matter volumes. Results suggest that higher body fat may be affecting different aspects of cognition for males versus females.

Title: Characterizing population EEG dynamics throughout adulthood

Authors: ***A. HASHEMI**[1], L. J. PINO[2], G. MOFFAT[2], K. J. MATHEWSON[1], C. AIMONE[2], L. A. SCHMIDT[1], P. J. BENNETT[1], A. B. SEKULER[1];
[1]Psychology, Neuroscience, & Behaviour, McMaster Univ., Hamilton, ON, Canada; [2]InteraXon, Toronto, ON, Canada

Abstract: For decades, electroencephalography (EEG) has been a useful tool for investigating the underlying neural mechanisms of human psychological processes. However, traditional laboratory investigations are limited by the time-consuming nature of running human EEG studies, which constrains the numbers of participants included in most studies. Using InteraXon's Muse, a portable and wireless 4-channel EEG headband, we obtained EEG recordings from 6029 (1650 women) consenting users worldwide who ranged from 18 to 88 years in age (M = 41.7 years old, SD = 13.0) while users completed a category exemplar task followed by a mindfulness-based stress reduction exercise. Here, we report age-related changes in EEG power at a very fine chronological scale. EEG was recorded from prefrontal and temporoparietal locations in each hemisphere while users completed a one-minute category exemplar task followed by a three to 20-minute session of a mindfulness-based stress reduction exercise. Because some participants had completed hundreds of sessions, our initial analyses were limited to just five sessions per unique user, to avoid overrepresentation of single users. All artifact-free EEG data from each prefrontal and temporoparietal electrode site were subjected to a Fourier transform to yield estimates of EEG power in five traditional frequency bands (delta, theta, alpha, beta, and gamma). We also calculated the peak alpha frequency at temporoparietal

sites, and separate alpha asymmetry measures for the prefrontal and temporoparietal sites. We found that EEG power changed as a function of age depending on sex and frequency band. Prefrontal alpha and beta power increased with age, and overall EEG power increased more for women than men. We also found a gradual (year-by-year) slowing of the peak alpha frequency with increased age, for both sexes. Finally, our analysis of alpha asymmetry revealed a linear increase in right frontal activity (EEG alpha power is inversely related to activity) with age. Our results replicate a number of previous findings such as increased alpha power and slowing of the peak alpha frequency with age. We also found a shift towards greater relative right frontal EEG activity with age, possibly reflecting a bias toward negative affect. Unlike previous age-related EEG studies which have been limited by sample size and restricted age ranges, our work highlights the advantage of using "Big Data" to address questions about developmental brain changes with large and representative samples. Findings are also discussed in terms of their relevance to brain-based models of emotional well-being and illness related to aging.

Title: Dual-task functional connectivity changes induced by exercise in the elderly

Authors: *L. T. K. VO[1,2], M. N. N. TO[1], A. F. KRAMER[2];
[1]Electrical Engin., Tan Tao Univ., Tan Duc E.City, Duc Hoa, Viet Nam; [2]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: While physical training seems to affect only some cognitive tasks on elderly people, its influence is explained via changes in intrinsic or task-independent resting state functional connectivities (FC) (1, 2, 3). In contrast, we use a Bayesian network algorithm to examine the change in dual-task (DT) FC of 55 healthy seniors (mean age = 66.6 ± 6.7) as they discriminate

letters and/or numbers (details in 4) at before and after 6 months of exercise training. Mean response time of DT is significantly improved after exercise training (p=.012) (Fig. 1). We use a high-level generalized linear model to find DT activated regions within frontal, temporal and parietal areas (5, 6, 7). The identified regions are then considered as nodes of the graphical model analysis. fMRI time series at those nodes are fed into IMaGES (8) to determine inter-region FC during DT processing. This step is done separately for the fMRI data collected on the same set of regions before and after the exercise intervention. Thus, by comparing the two networks, we can observe exercise training-induced FC changes (Fig. 2). After 6-months of exercise training, inter-hemisphere connectivity appears between left and right pars opercularis in the Broca's area. Given that DT performance suffers greatly by age (9), this exercise-induced FC likely helps to compensate for neural deficiency by employing homologous contralateral regions (10) and thus boosting the performance. Furthermore, there appear two more FC within the fronto-parietal network - a core of task initiation and coordination (11, 6). Given the age-related connectivity disruptions (12, 13), these newly exercise-induced FC may support significant improvement in DT performance after 6 months of exercise via an increased number of connections. Future analysis will include the 3rd data sets acquired after 12 months of exercise. The 6-month and 12-month induced FC connective strength will be related to corresponding DT improvements. This analysis will provide further insight into the neural mechanism through which exercise training can positively affect DT performance.

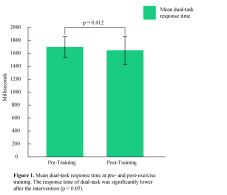

Figure 1. Mean dual-task response time at pre- and post-exercise training. The response time of dual-task was significantly lower after the intervention ($p < 0.05$).

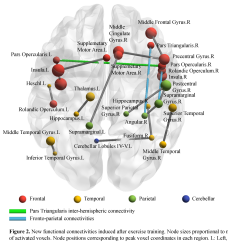

Figure 2. New functional connectivities induced after exercise training. Node sizes proportional to number of activated voxels. Node positions corresponding to peak voxel coordinates in each region. L: Left, R: Right.

Title: Brain metabolism, amyloid, vascular disease: anterior cingulate cortex and cognitive aging

Authors: *J. V. PARDO[1], J. T. LEE[2];
[1]Psychiatry, Univ. of Minnesota & VAMC, Minneapolis, MN; [2]Cognitive Neuroimaging Unit, VAMC, Minneapolis, MN

Abstract: The anterior cingulate cortex (ACC) is a critical nexus for declining glucose metabolism during healthy aging. The decline in glucose metabolism correlates with age-associated decline in cognitive function particularly executive functions. Healthy elders from the ADNI database were examined for changes in brain metabolism, amyloid, and vascular disease risk (Hachinski, "Hach") that correlated with age. Data included FDG and amyloid PET both normalized to the cerebellum. The significance of voxel-wise, whole-brain, Z-scores was adjusted ($p < 0.05$) dividing by resels. Several comparisons are shown in the figure showing voxel-wise correlations with age: a) 46 healthy normals (18-90 y) reported in Pardo et al 2008 (*Neuroimage* 35:1231); b) 210 ADNI normal (age 56-90 years); c) 103 ADNI normal (56-90 y) Hach = 0; d) 107 ADNI normal (63-89 y) Hach = 1-3. For the ACC region, the correlation of metabolism with age was $r = -0.49$ ($p < 10^{-6}$), while for amyloid the correlation with age was $r = +0.01$ ($p = 0.88$). The robust decline in metabolism of the ACC with age was replicated in the ADNI dataset and occurred even in those without major vascular risk factors. ACC metabolism decreased at a much greater rate than did amyloid deposition. These findings suggest the need to consider alternative pathophysiological mechanisms for aging-associated ACC dysfunction.

Title: Healthy children with Apolipoprotein E4 carriers showed a stronger connectivity between nodal regions of default mode networks that linked to weakened functional connections between hippocampus and default mode networks

Authors: *A. ARINO[1,2], M. ABE[2], D. MICHIMATA[1,2], S. YOKOTA[3], T. HASHIMOTO[3], K. FURUKAWA[4], M. KAMADA[4], H. ARAI[4], H. TAKEUCHI[2], R. KAWASHIMA[3], Y. TAKI[2]; [1]Fac. of Med., Tohoku Univ., Sendai-Shi, Japan; [2]Nuclear Med. and Radiology, [3]Inst. of Aging, Develop. and Cancer, Tohoku Univ., Sendai, Japan; [4]Geriatrics and Gerontology, Inst. of Development, Aging and Cancer, Sendai, Japan

Abstract: Apolipoprotein E epsilon4 allele (Apo E4) is an established genetic risk factor for late-onset Alzheimer's disease. It is known that Apo E4 proteins can modulate development and maturation of neural circuits in animal models. However, whether a genetic variant of Apo E4 allows organizing different brain networks in childhood in humans is unknown. Here, using functional magnetic resonance imaging (fMRI) techniques, we examined different interregional brain networks during rest, called resting networks, in healthy children with a genetic variant of Apo E4 (i.e. carriers, age 13.8 ± 2.5 n = 31 [male 19, female 12]) compared with age-matched, non-carrier children (age 13.8 ± 2.5, n = 31 [male 19, female 12]). We hypothesized that impaired functions of hippocampus in Apo E4 carriers would involve a compensatory overfunction of default mode networks that have known functionally declined in an early stage of late-onset Alzheimer's disease. Functional brain imaging was acquired while subjects were lying on a bed with their eyes open and were not engaged in any tasks in a 3 Tesla MRI scanner (Fillips, xxxxx). Wechsler Intelligence Scale for Children-Revised was also performed to ensure comparable IQ scores between the carries and noncarriers. Imaging data was realigned, normalized and smoothed with use of SPM (http://www.fil.ion.ucl.ac.uk/spm) in each subject. Functional connectivity between hippocampus and nodal regions of default mode networks, and between regions within default mode networks were computed in each subject using a simple regression model and then compared between carriers and noncarriers in group analysis. Our results revealed a stronger functional coupling between posterior cingulate cortex (PCC) and other nodal regions within default mode networks when functional connections between hippocampus and PCC showed weaker in carriers but not in noncarriers. Healthy children with

Apolipoprotein E4 carriers showed a stronger connectivity between nodal regions of default mode networks that linked to weakened functional connections between hippocampus and PCC.

Title: Evidence that decreased system segregation observed across the healthy adult lifespan does not result in differences in resting-state defined system topology

Authors: ***M. Y. CHAN**[1], F. ALHAZMI[1], N. K. SAVALIA[1], D. C. PARK[1,2], G. S. WIG[1,2]; [1]Ctr. for Vital Longevity and Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Dallas, TX; [2]Dept. of Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Functional brain networks exhibit a modular organization in young adulthood. Modular organization is characterized by dense within-system connectivity and sparser between-system connectivity (i.e., the presence of segregated but not disconnected brain systems). Recent work from our laboratory has demonstrated that the segregation of brain systems decreases with increasing age, and that the degree of segregation in association systems predicts memory ability independent of age (Chan et al., 2014). While our initial report began to explore distinctions in segregation as a function of system type (sensory-motor vs. association), it was unclear how differences in segregation related to the connection patterns of specific nodes. Further, as decreasing system segregation reflects increases in connections between systems, it was also unclear how age-related differences in segregation influenced the overall network topology of functional systems across adulthood. We analyzed data from the Dallas Lifespan Brain Study (N=238; age: 20-89 years). Following thorough data cleaning and quality-control procedures, we analyzed participants' resting-state functional connectivity (RSFC) to both probe the source of age-related de-segregation on a node-level, and understand the community structure of functional systems across four different age groups (YA=20-34 years, ME=35-49 years, ML=50-64 years,

OA=65-89 years). Brain network nodes were defined with a biologically plausible parcellation of area features (Wig et al., 2014); edges were defined by the pairwise Fisher's z-transformed Pearson correlation between the average resting-state time series of every node with one another, in each participant. We found non-uniform increases in between-system connections in the nodes of both sensory-motor and association systems. Nodes with lesser connections to systems outside of their own in younger adults exhibited the greatest increases in between-system connections across older adulthood. We then examined the topology of functional brain systems as revealed by community detection algorithms. Despite the observed differences in patterns of connections across age, community-detection revealed that while minor shifts in community structure occur, most of the 'canonical' brain systems (e.g., frontal-parietal control, visual, default) are present across the healthy adult lifespan. These results serve to further illuminate our understanding of differences in segregation observed across healthy adulthood.

Title: Effect of chronic plus acute prolonged stress on expression of platelet derived growth factor in the rat orbitofrontal cortex

Authors: *K. SMITH[1], D. A. CRUZ[2], B. BINGHAM[2], R. R. BURSON[3], D. A. MORILAK[2], D. E. WILLIAMSON[2];
[1]UT Hlth. Sci. Ctr. San Antonio, San Antonio, TX; [2]Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX; [3]San Antonio Military Med. Ctr., San Antonio, TX

Abstract: In a cohort of active military personnel, we have observed an increase in protein levels of platelet derived growth factor (PDGF) associated with prior deployment that is further elevated if they also have posttraumatic stress disorder (PTSD). In parallel, we have also

observed a significant decrease in DNA methylation and an increase in gene expression of the PDFGα receptor gene in the medial orbital frontal cortex (OFC) of human postmortem brain tissue in PTSD patients compared to controls. To further investigate how exposure to traumatic stress may underlie these differences, we utilized a rat preclinical model of PTSD, the Chronic plus Acute Prolonged Stress (CAPS) model, which induces PTSD-like behavioral changes. Groups of rats were first fear-conditioned to a tone and then subject to control or CAPS treatment (14 days cold stress, 4°C 6 hr/day, then 3 acute stressors on day 15). We then examined mRNA levels of PDGF ligands (A,B,C, and D) and their receptors (α and β) in the OFC on day 21 following extinction retention testing in one group, and following two days of rest in the home cage in another group. In animals that were exposed to CAPS without fear extinction training, we observed significantly lower mRNA levels in CAPS treated rats for both PDGF α ($p<.05$) and β ($p<.01$) receptors but no differences between the groups for any of the four PDGF ligands. In the group that received fear extinction training, there was no difference in mRNA expression of either receptor between the CAPS treated and control rats, however, mRNA levels of PDGF C were decreased in CAPS treated rats compared to controls ($p<.02$). These preliminary results suggest that CAPS treatment following fear conditioning reduces the expression of the PDGF α and β receptors in the OFC of rats, and that this difference is not seen following fear extinction. Our data could serve as a model to investigate the importance of this gene in fear learning and how it may contribute to changes induced by behavioral interventions, such as exposure therapy. Understanding the convergence of gene expression in clinical PTSD and preclinical models of fear conditioning and extinction will ultimately aid in uncovering the root causes of this debilitating condition.

Title: Effect of time-of-day on mouse behavior measured in a comprehensive behavioral test battery

Authors: *K. TAKAO[1], H. SHOJI[2], S. HATTORI[2], T. MIYAKAWA[2,1];
[1]Natl. Inst. For Physiological Sci., Okazaki, Japan; [2]Fujita Hlth. Univ., Toyoake, Japan

Abstract: Mouse behavior is analyzed in laboratories to elucidate the effects of various experimental manipulations, including gene mutation and drug administration. When the effect of a factor (manipulation) of interest is assessed, other factors, such as age, sex, temperature, apparatus, housing, etc., are controlled for in the experiments by matching, counterbalancing, and/or randomizing. One of such factors that has not received much attention is the effect of time-of-day when the mice are subjected to the tests. Here we evaluated the effects of time-of-day on mice behaviors by analyzing the combined data of approximately 2000 C57BL/6J mice that we collected using our comprehensive behavioral test battery including the light/dark transition test, open field test, elevated plus maze, hot plate test, social interaction test rotarod test, prepulse inhibition, Porsolt forced swim test, tail suspension test, cued and contextual fear conditioning test, and 24-hour homecage activity monitoring test. The mice were maintained under a 12-h light:12-h dark cycle (lights on at 7:00), and subjected to the tests included in the battery from 9:00 to 18:00, during the light phase. Locomotor activity in the open field test, pain sensitivity in the hotplate test, anxiety-like behavior in the light/dark transition test, and prepulse inhibition of acoustic startle response were significantly influenced by time-of-day of testing. On the other hand, we failed to detect significant effects of time-of-day of testing on the results of the elevated plus maze test, social interaction test, Porsolt forced swimming test, tail suspension test, or cued and contextual fear conditioning test, except for some indices related to locomotor activity in these tests. The results of the present study suggest that time-of-day of testing affects locomotor activity, a certain type of anxiety-like behavior, pain sensitivity, and prepulse inhibition in mice. Thus, the time-of-day of testing should be carefully counterbalanced between groups to be compared in behavioral tests.

Title: Study of anxiolytic effects of kami kihi to (gui pi tang) in rats

Authors: J. V. CIANCAGLINI, Jr[1], *B. B. SILVA[1], M. POLLY, Jr[1], R. S. DE LIMA, jr[1], F. S. GUIMARÃES, Jr[1], P. L. LANNI, Jr[2], L. C. D. NETO, Jr[1], D. FEDER, Dr[2], C. D. NASSIS, Dr[3]; [2]Farmacologia, [3]Famarcologia, [1]Faculdade De Medicina Do ABC, Santo Andre, Brazil

Abstract: INTRODUCTION: Kami-kihi-to (KKT, gui pi tang) is a medicinal herbal mixture used in traditional japanese and chinese medicines. Some of its components like ginseng, astragalus, longan (Longanae arillus), angelica and polygata have proved therapeutic effects in the treatment of central nervous system disordes. KKT has been prescribed by traditional oriental medicine phisicians to treat anxiety, but this use lacks experimental validation. In addition to being effective for central nervous system disorders (such as amnesia and cognitive disturbances of learning and memory), the KKT has proven an effective anxiolytic. Previous studies have shown that after anxiogenic induction by the use of reverse agonist of benzodizepine in animals, the gui-pi-tang proved to be a competent anxiolytic (per share antagonist to benzodiazepine receptors) when compared to a benzodizepine agonist (diazepam). OBJECTIVES: Experimental validation of the traditional use of KKT in anxious diseases and the comparison between eventual kkt effects to fluoxetine effects on anxiety. MATERIAL AND METHODS: 30 Wistar male rats were divided in 3 groups (n=10) and received, for 21 days, orally, the following treatment: group A (control): 0,5ml saline/day; group B: fluoxetine 10mg/kg/day; group C: KKT (aqueous extract) 1,66 ml/kg/day. In the 22nd day animals were submitted to elevated T maze, and withdrawal (WL) and escape (EL) latency times (s) were assessed to each group. In the first step (WL), animals were placed on the distal end of the maze closed, and the time took for each animal to get out of that arm with the four paws was assessed. In the second step (EL), each animal was placed on the end of the maze's open arm and the time measures were carried out like the ones made in the first step. Results intergroups were compared by means of variance analysis (p</= 0,05) and Kruskal Wallis test. RESULTS (mean of each group +/- sdm): WL: A 250,17 +/- 86,52 ; B 137,7 +/-75,50* ; C 241,26 +/-89,2. EL: A 194,72 +/-125,1 ; B 19,1 +/-12,91* ; C 115,36 +/-113,27 . * = statistic significance (p</= 0,05) when compared to control group. Reduction of withdrawal time can be related to an anxiolytic effect on generalized anxiety disease (GAD), while reduction of escape time indicates a panicolytic effect. Fluoxetine, has both of these effects, and our results did confirm it. KKT, however, did not show any significant effect on withdrawal or escape latency times. CONCLUSION: KKT treatment, in rats, did not show any significant effect on anxious behaviors of rats submitted to elevated T maze. Our results, therefore, do not support the traditional use of KKT on anxiety.

Title: Effects of Lippia alba on animals submitted to the elevated t-maze test

Authors: *J. E. PANDOSSIO, N. M. MARTINS, P. M. MARTINS;
Univ. of Brasilia, Brasília, Brazil

Abstract: Anxiety disorders represent prevalent psychiatric condition in clinical practice and are associated with important social and functional impairment, comorbidity, disability and reduced quality of life. Among the theories proposed to explain the neurobiology of anxiety disorders, it is highlighted the dual role of serotonin (5-HT), based on the mechanism of action of drugs that act on serotonergic neurotransmission. In spite of the clinic pharmacological options available, only a small number of patients has adequate response to treatment. Therefore, new therapeutic approaches can ensure higher response rates, greater therapeutic adherence, with lower losses associated with these disorders. In this sense, Lippia alba (L. alba), a plant species widely used in folk medicine, has been investigated as to their anxiolytic properties. Thus, it was intended to evaluate the effects of aqueous extract of L. alba on the behavior of animals submitted to the elevated T-maze model (ETM). Female Wistar rats (n = 58) were divided in the groups saline, fluoxetine, buspirone, flurazepam (controls) and extracts of L. alba at doses of 25, 50 and 75mg/kg (experimental groups), all with intraperitoneal administration, in order to verify the latency of inhibitory avoidance and escape, with three trials each. After the ETM, it was verified, in the open field, the frequencies of crossings, rearings and grooming, evaluating the possibility of sedation in this model. The ANOVA one-way repeated measures, followed by Student Newman-Keuls test showed that treatment with the extract of L. alba facilitated inhibitory avoidance (anxiogenic effect) and impaired escape (panicolytic effect) in ETM, specially at doses of 50 for escape ($F(2,6) = 5,35$; $p = 0,02$) and 75mg/kg for avoidance ($F(2,8) = 23,74$; $p = 0,00003$) and escape ($F(2,8) = 4,40$; $p = 0,03$), compared with controls. In the open field it was not observed induction of sedation by any plant doses. These observations suggest that the extract of L. alba can exert anxiolytic effect on a set of defensive behaviors implicated in panic, but not on generalized anxiety, resembling found for buspirone, a drug that acts selectively on 5-HT1A receptors, possibly implying the involvement of serotonergic neurotransmission.

School, Kochi University, Dept. of Neuropsychiatry, Nankoku, Kochi, Japan

Abstract: Posttraumatic stress disorder (PTSD), a complex disorder associated with an intricate biological and psychological symptom profile, is induced by exposure to life-threatening trauma. Although the detailed mechanisms are not fully uncovered, results of the clinical studies of PTSD, such as the enhanced negative feedback of the hypothalamo-pituitary-adrenal axis, hippocampal atrophy, and fear memory extinction, suggest the functional as well as morphological abnormalities in the hippocampus in response to severe stress are closely involved in the pathophysiology of this disorder. In this context, it is important to examine the alteration of hippocampal gene expression through glucocorticoid receptor (GR) in an animal model of PTSD to elucidate the pathophysiology of PTSD. In a series of studies, we validated the single prolonged stress (SPS) as a model for PTSD. So, we first examined whether SPS changed the nuclear levels of GR in the rat hippocampus 1, 2, 4, 24 hours and 7days after the exposure to SPS by using Western blot. Nuclear levels of GR were significantly increased 1, and 2 h after SPS, suggesting that the transcription of gene expression mediated by glucocorticoid response element (GRE) may be activated. In second, we are examining the GR binding to the GRE at the promoter of the Bcl-2 and Bax gene by ChIP-qPCR assay. Simultaneously, we examined the spine abnormalities of the CA1 and CA3 pyramidal cells in the hippocampus of SPS rats by Golgi staining. There were no changes in the length and density of spine in CA1 or CA3 region, but a significant decrease in the diameter of spine was found in CA1 pyramidal cells. In addition,

we will demonstrate the involvement of apoptotic pathway in the spine abnormalities in the hippocampus of SPS rats.

Title: Modulation of the Endocannabinoid System within the Nucleus Accumbens shell elicits anxiolytic effects in rats

Authors: T. PARDO-GARCÍA[1], N. YUSIF[2], *C. S. MALDONADO-VLAAR[3];
[1]Biol., [2]Psychology, [3]Univ. Puerto Rico, San Juan, PR

Abstract: Preclinical investigations have demonstrated that the endocannabinoids and its receptor CB1 can modulate emotional responses. In addition, studies point to a modulatory role of the transient receptor potential vanilloid 1(TRPV1) within the brain endocannabinoid system. In mice, previous immunocytochemical findings reported a high density of co-localized CB1 and TRPV1 receptors within the NAc shell. In addition, the NAc shell is found to also regulate anxiogenic responses in animal models. To our knowledge, the functional role of the co-localization of the CB1 endocannabinoid receptor and (TRPV1) receptor within the Nucleus Accumbens (NAc) has not been studied. Thus, the present study seeks to elucidate the effects of this receptor interaction within NAc Shell subregion on anxiety states. We hypothesized that blockade of this interaction within the NAc shell will elicit and anxiolytic response in rats. In order to test our hypothesis we conducted the present experiment in which male Sprague Dawley rats were implanted with bilateral brain cannulae aimed at the NAc shell. Following recovery from surgery, animals received pre-treatment of microinfusions (0, 0.125, 0.25 nmol/0.4µl) of N-arachidonoyl-serotonin (AA-5-HT), a dual blocker of the endocannabinoid-inactivating enzyme, fatty acid amide hydrolase (FAAH) and a TRPV1 antagonist, within the Nac shell. After the treatment, animals were tested in an elevated plus maze paradigm for a period of 5 minutes. Behavioral parameters measured were: Time Spent in Open Arms, Time Spent in Closed Arms, Rearing, Flatback and Grooming. At the end of the experiment, animals were sacrificed and their

brains collected for histological analysis. Results showed that the pre-treatment with the antagonist significantly increased the time spent in the open arms in animals compared to vehicle injections ($p < 0.0005$). Significant differences were also found in time spent in closed arms and grooming parameters following antagonist treatment. The present findings suggest that the endocannabinoid system modulates anxiety within the NAc shell and that co-localization of CB1 and TRPV1 receptors may play a role in mediating emotional responses.

Title: Effect of COMTval158met polymorphism on sensitivity to long-term effects of trauma in the predator stress model of PTSD

Authors: ***J. DESLAURIERS**[1,2], M. TOTH[1,2], D. HOPPENER[3], M. A. GEYER[1,2], V. B. RISBROUGH[1,2];
[1]Psychiatry, Univ. of California San Diego, San Diego, CA; [2]Ctr. of Excellence for Stress and Mental Health, VA, La Jolla, CA; [3]Pharmacol., Utrecht Inst. for Pharmaceut. Sci., Utrecht, Netherlands

Abstract: Posttraumatic stress disorder (PTSD) affects 7-8% of the American population while rates are up to 20% in military veterans. The val158met polymorphism in the COMT gene has been associated with a greater risk of neuropsychiatric disorders, including PTSD. Our hypothesis is that the COMTval158met polymorphism modulates the response to a severe trauma, increasing the risk to develop a PTSD-like phenotype. To test this hypothesis we examined the sensitivity of mice “humanized” for the COMTval158 to the predator stress model of PTSD. Our previous studies suggest that this mouse line has similar cognitive phenotypes as reported in human COMTval158met carriers, with Met/Met mice exhibiting increased working memory, sensorimotor gating and reduced fear extinction compared to Val/Val littermates. In the current study male and female Val/Val or Met/Met carriers were grouped into stress or control groups, with stressed groups being exposed to a cat for 10 minutes while control mice were handled, but were not exposed to the cat. One week after the predator stress, avoidance behaviors

(open field; light/dark box) were evaluated. Two weeks after the predator stress, mice were underwent a ”trauma-reminder test” in which their avoidance of cat litter was assessed. A composite avoidance score (average of Z-scores across the 3 tests) was calculated for each animal, with negative scores reflecting greater avoidance behavior. Overall, male Val/Val mice exhibited a decreased Z score, (i.e. increased avoidance behavior) compared to Met/Met mice, suggesting baseline anxiety differences across Val and Met carriers. Predator stress also significantly decreased Z scores, resulting in the greatest avoidance behavior being in the Val/Val-stressed mice. In females, there was a significant robust effect of predator stress regardless of COMT genotype, which may have resulted in ceiling effects. These results suggest that the COMTval158met polymorphism modulates the response to a severe trauma in males, here mimicked by the predator stress, and support the double-hit hypothesis of PTSD. This two-hit model may be useful to understand the mechanisms implicated in the risk for development of PTSD-like symptoms. Results from a second experiment using a milder form of predator stress (no physical contact), will also be presented.

Title: Altered cognitive and motivational nociceptive processing in an animal model of post-traumatic stress disorder

Authors: ***J. D. VEGA-TORRES**, P. KALYAN-MASIH, T. HEERS, J. D. FIGUEROA; Basic Sci., Loma Linda Univ. Sch. of Med., Loma Linda, CA

Abstract: The nature of recent conflicts in Iraq and Afghanistan has resulted in a higher prevalence of comorbid chronic pain (CP) and post-traumatic stress disorder (PTSD) in veterans of Operations Enduring Freedom and Iraqi Freedom (OEF/OIF). Treatment of comorbid CP and PTSD remains a major challenge, as patients who suffer from both CP and PTSD experience greater pain, affective distress, and disability than patients with either condition alone. However, preclinical studies delineating the shared neurobiology of comorbid CP and PTSD are lacking.

This study was designed to investigate co-occurring pain-like and PTSD-like behaviors in a well-established predatory threat model of PTSD. Lewis rats (post-natal day 57-62) were placed on soiled cat litter for 10 min in a standard plastic mouse cage. Pain-related behaviors were assessed using both thermal (Hargreaves) and mechanical (von Frey) evoked reflex responses and a novel operant mechanical conflict-avoidance test (MCS). The responses of animals in both the elevated plus maze (EPM) and the acoustic startle response (ASR) tests served as tools for classifying rats as exhibiting PTSD-like behaviors. Testing sessions were performed one-week before (baseline) and one-week after exposure to predatory threat stress. Markers of neuroinflammatory activation (GFAP, Iba-1) were investigated in the thalamus and spinal cord using immunohistochemistry and Western blot. We found that animals exhibiting PTSD-like behaviors showed significant alterations in cognitive and motivational aspects of pain-like behaviors when compared to baseline responses ($p = 0.0022$). No significant differences were observed in thermal and mechanical evoked reflexes ($p > 0.05$). Interestingly, these behavioral results were not correlated with changes in the expression of astrocytes or microglia astrocyte assessed by glial fibrillary acidic protein and ionized calcium-binding adapter molecule immunohistochemistry. Together, our data demonstrates impairments in motivational nociceptive processing in PTSD-like rats, thus providing a useful model for elucidating supraspinal mechanisms and investigating potential treatments for comorbid chronic pain and PTSD.

Title: Effects of familiarity on emotional contagion in rodents

Authors: *M. C. CARRILLO[1], F. MIGLIORATI[2], R. BRULS[2], T. VAN LIERDE[3], Y. HAN[2], M. HEINEMANS[4], I. PRUIS[4], V. GAZZOLA[2], C. KEYSERS[2];

Abstract: Witnessing of conspecifics in pain has been shown to elicit vicarious freezing in rodents. To date, however, it is unknown how the vicarious response is modulated by repeated exposure to a conspecific experiencing painful stimuli. A series of experiments were conducted in long Evans rats to investigate: 1) how the affective response of observers is modulated in a repeated witnessing paradigm, and 2) the role of familiarity in such paradigms. For the repeated witnessing experiments, shock-experienced observer rats repeatedly witnessed (6 times) familiar demonstrators experience painful footshocks. For experiments examining the role of familiarity, observer-demonstrator pairs were subdivided into 4 conditions: unfamiliar or familiar for either 1, 3 or 5 weeks by testing day. Familiarity was examinedfollowing a single or repeated witnessing of demonstrators experiencing painful footshocks. The results showed that vicarious freezing levels were gradually reduced as the tests progressed, reaching minimallevels by test 6. In contrast, the appearance and increase in the frequency of yawning, as the tests progressed, the fact that yawning mainly occurred during the shock period and that only observers expressed this behavior suggest that yawning was related to the distress of the demonstrators. This indicates that although vicarious freezing levels were reduced, perhaps, rats still share the emotional state of the other but they modify the expression. Moreover, results from the familiarity studies showed that in rats, the level of familiarity between the observer and demonstrator doesn't appear to modulate the vicarious response. Given, that familiarity between the observer and the demonstrator has been identified as a key modulator of the vicarious freezing response in mice, it is possible that the differences in the natural social structure between mice and rats determines its effect in the vicarious response.

Title: Sex differences in kappa opioid receptor-mediated negative affective states in rats

Authors: *M. MAVRIKAKI, J. MAYS, D. PUTTICK, E. CHARTOFF;
Harvard Med. School, McLean Hosp., Belmont, MA

Abstract: Dynorphin, an endogenous ligand at kappa opioid receptors (KOR), is required for the expression of stress-induced depressive-like states in male rats. Previously we demonstrated that female rats are less sensitive to the depressive-like effects of KOR activation in the intracranial self-stimulation (ICSS) paradigm. The present study was designed to assess the role of KORs in the ability of an ethologically relevant stressor, social isolation (SI), to produce negative affective states in male and female rats. Adult male and female rats were either group housed (GH) or socially isolated (SI) for 5 weeks. The elevated plus maze (EPM) was used to assess the effects of SI on anxiety-like behavior. Place conditioning was used to assess the effects of SI on the aversive effects of the KOR agonist U50,488. In separate rats, effects of SI on brain region-specific levels of dynorphin and KOR mRNA expression were measured. SI reduced the amount of time spent in the open arms of the EPM in males but not females, suggesting that SI stress during adulthood produces greater anxiogenic effects in males. Female rats exposed to SI were less sensitive than males to U50,488-induced conditioned place aversions. Finally, levels of KOR mRNA in the bed nucleus of the stria terminalis (BNST), a brain region critical for anxiety-like behavior, depended on sex and housing condition: GH females had less, whereas SI females had more, KOR mRNA than similarly housed males. Our results are consistent with previous work demonstrating depressive-like effects of SI in males and they suggest that SI acts to modulate sensitivity to the anxiogenic effects of KOR activation through regulation of KOR levels in the BNST. Taken together, our findings raise the possibility that KOR ligands could be effective, gender-specific pharmacotherapies for anxiety and depressive disorders.

Title: Establishment of a behavioral-pharmacological evaluation on social interaction behavior using a 3-chamber system for rats

Authors: T. YAMAGUCHI[1], R. FUKUMORI[1], *M. YOSHIOKA[2], T. YAMAMOTO[1]; [1]Dept. of Pharmacol., Nagasaki Intl. Univ., Sasebo, Nagasaki, Japan; [2]Hokkaido Univ. Sch. Med., Sapporo, Hokkaido, Japan

Abstract: Social interaction test has been generally evaluated as index of social behaviors performed between two experimental animals. In this study, we established a new social

interaction test using a 3-chamber openfield system to examine the social behavior of rats. We used square-shaped openfield apparatus with 3-chamber system for social interaction test. A rat had been acclimated for 2 days in the openfield apparatus in which two stranger cages without rats were installed. After acclimation to the openfield apparatus, we measured the time required for the rat to approach the stranger cage in which a rat was placed by visual observation or video tracking analysis in the test trial. For measuring effects of lighting conditions, social behavior was examined under dark (5 lux) and bright conditions (350 lux). Under the dark condition, the time required for the rat to approach the stranger cage in which a rat was placed based on active contact was significantly longer than that measured under the bright condition, by visual observation. In addition, video tracking analysis using imaging data also showed a similar tendency. Briefly, this result was similar to that obtained by visual observation. In the social interaction test using the 3-chamber system, the time required for the rat to approach the stranger cage in which a rat was housed (social interaction time), which was measured by visual observation, was correlated with that by video tracking analysis. On the other hand, anxiolytics, tandospirone (3 mg/kg, i.p.) and diazepam (0.3 mg/kg, i.p.), significantly increased the time required to approach the stranger cage in which a rat was housed, without influencing spontaneous locomotor activity. In conclusion, this study revealed the behavioral-pharmacological validation of this social interaction test to evaluate innate anxiety and social behavior using a 3-chamber system in a single rat. In addition, this evaluation system may contribute to the elucidation of neural basis in social behaviors and the development of new therapeutic drugs for psychiatric diseases, including anxiolytics

Title: Anxiolytic effect of Diferuloylmethane on rats exposed to ozone

Authors: ***L. HERNANDEZ**, J. J. RAMIREZ-VAZQUEZ, S. NERY-FLORES, G. CAMARGO, A. HERNANDEZ-CHAVEZ, M. MALDONADO-RUBIO, S. RAMOS CALZADA, M. L. MENDOZA-MAGAÑA, M. A. RAMIREZ HERRERA;
Univ. de Guadalajara, Guadalajara, Jalisco, Mexico

Abstract: Background: Outdoor air pollution contains ozone, a pollutant that can harm our health when there are elevated levels in the air we breathe. High up in the atmosphere, ozone forms a layer that shields the Earth from ultraviolet rays. However, at ground level, ozone is considered a major air pollutant. This "bad" ozone is not emitted directly into the air, but is created by chemical reactions between oxides of nitrogen (NOx) and volatile organic compounds (VOC) in the presence of sunlight. Accumulating evidence suggests that outdoor air pollution may have a significant impact on central nervous system (CNS) health and dis ease. Particularly, short term ozone exposure in rodents has been reported to result in cerebral edema, neurodegeneration in the hippocampus, striatum, and substantia nigra, and altered behavior. A well-known damage mechanism of ozone is the oxidative stress and recently, oxidative stress has also been implicated in depression, anxiety disorders and high anxiety levels. In this work we explore the anxiety-like behavior in rats induced by ozone exposure and if this condition could be inhibited in rats treated with the phytochemical Diferuloylmethane (DFM), which has well documented antioxidant properties. Methods: 15 male Wistar rats (21-day old) housed in a standard 12::12 light-dark cycle and with ad libitum access to food and water, were divided in three study groups: an intact control group (CTL), a group of animals exposed during 15 days to ozone at 0.7 ppm for 4 h (OZO) and another group exposed to the same condition than OZO and fed with food supplemented with 5 mg/Kg/day Diferuloylmethane (OZO+DFM). All groups of rats were submitted to Force Swimming Test (FST) as described by Porsolt et al. Data was analyzed by one way Anova followed by the Dunnett`s test. The significance level was set at $p< 0.05$. Preliminary results and conclusions: OZO group shows a decrement of immobility time of 25% and an increment of climbing time to 110% in relation to CTRL group. OZO+DFM group only decrease 12% the immobility time and increase 24% the climbing time. These results suggest the Diferuloylmethane reduces the anxiety-like behavior induced by ozone exposure in rats.

Title: Sex matters: Anxiolytic effects of diazepam and BDNF and parvalbumin protein levels

Authors: B. MASON[1], R. RAVENELLE[2], A. K. BERMAN[3], *S. DONALDSON[4];
[1]Developmental and Brain Sciences, Psychology, Univ. of Massachusetts Boston, Boston, MA; [2]CUNY Neurosci. Collaborative, City Univ. of New York, New York, NY; [3]Psychology, Western Michigan Univ., Kalamazoo, MI; [4]Univ. Massachusetts, Boston, Boston, MA

Abstract: In humans and animal models, those showing moderate to high anxiety-like behavior are more sensitive to anxiolytic drugs. In the present study, we examined whether there were any dose-dependent differences in the responses to diazepam (DZ: 0, 0.1 and 1.0 mg/kg, i.p.) in adult male and cycling female rats (tested while in proestrus, when estradiol (E2) was high) phenotyped as showing high- (HAn) and low anxiety (LAn)-like behavior. Further, we assessed parvalbumin (stains a subpopulation of GABA neurons) and brain-derived neurotrophin protein (BDNF) levels in forebrain and limbic structures implicated in anxiety/stress. At baseline, we saw significant differences between HAn and LAn animals, with HAn displaying less time on the open arms of the EPM, and less open arm entries, regardless of sex. Using three-week inter-trial intervals, we observed significant sex and trait differences in the anxiolytic effects of diazepam treatments on EPM, with proestrus, HAn females showing *less anxiety-like behavior* (ALB) at 0.1 mg/kg DZ and E2-rich LAn females displaying *less ALB* at 0.1 and 1.0 mg/kg DZ relative to males. Twenty-four hours after the completion of the DZ treatment, animals were sacrificed and brain tissue was harvested for immunohistochemistry analysis of protein levels of BDNF and parvalbumin in the medial prefrontal cortex (mPFC) and the hippocampus. BDNF protein was elevated in females and in the HAn line in mPFC, as was the number of PV immunoreactive cells (mPFC, CA2 and DG) relative to males from the same line. Taken together, our data demonstrate levels of estradiol influence ALB in the presence of the anxiolytic, diazepam, and that this may relate to increases in neuroplasticity and GABA neuron density in corticolimbic structures.

Title: Sex-dependent increase in myocardial sensitivity to ischemic injury in an animal model of post-traumatic stress disorder

Authors: *P. R. ZOLADZ[1], A. KRIVENKO[1], M. E. FRY[1], J. D. LAWSON[1], L. E. STONER[1], E. D. EISENMANN[1], B. L. JOHNSON[1], M. L. HEMBREE[1], R. M. ROSE[1], C. J. LOMBARDI[1], M. R. HUNTLEY[1], S. SEELEY[2], A. D. BUI[2], B. R. RORABAUGH[2];
[1]Psychology, Sociology, & Criminal Justice, [2]Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: Traumatized individuals who develop post-traumatic stress disorder (PTSD) are at increased risk for developing cardiovascular disease and exhibit greater mortality following cardiovascular-related events. Despite the link between PTSD and cardiovascular health, little work has examined the cardiovascular consequences of animal models of PTSD. Thus, in the present study, we examined the influence of a well-validated, psychosocial predator-based animal model of PTSD on myocardial sensitivity to ischemic injury. Male and female Sprague-Dawley rats were subjected to chronic psychosocial stress or control conditions for a period of 31 days. Rats in the psychosocial stress groups were given two 1-hr cat exposures, separated by a period of ten days, and experienced daily social instability throughout the experimental timeline. Rats in the control (no stress) groups were handled briefly each day and remained with the same cage mates throughout the 31-day period. On Day 32, anxiety-like behavior in the rats was assessed on the elevated plus maze, and on Day 33, rat hearts were isolated and subjected to 20 min ischemia and 2 hr reperfusion on a Langendorff isolated heart system. Psychosocial stress had no effect on pre-ischemic contractile function. However, post-ischemic recovery of rate pressure product and +dP/dT were attenuated in hearts from psychosocially stressed male, but not female, rats. In addition, psychosocial stress led to greater post-ischemic diastolic blood pressure and larger infarct sizes in male rats. These findings are the first to demonstrate increased myocardial sensitivity to ischemic injury in an animal model of PTSD and suggest that such effects are more pronounced in males. Thus, the present model may be used to explore sex differences in the development of PTSD-like sequelae and to better understand the mechanisms by which PTSD increases risk for cardiovascular disease and myocardial damage following cardiovascular-related incidents.

Title: Modeling the effects of paternal lifestyle on the mental health of offspring

Authors: *A. K. SHORT[1], T. Y. PANG[1], A. J. HANNAN[1,2];
[1]Behavioural Neurosci., Florey Inst. of Neurosci. and Mental Hlth., Parkville, Australia; [2]Anat. and Neruoscience, Univ. of Melbourne, Melbourne, Australia

Abstract: The extent of paternal influence was thought to be limited to inherited genetic material. Recent studies have provided evidence that developmental traits may be passed on from the paternal lineage, possibly via non-genetic inheritance through the sperm. To study how paternal stress might influence offspring, a model of chronic heightened hypothalamic pituitary adrenal (HPA) axis activation in male C57Bl/6 mice was used. Mice were supplemented with oral corticosterone (CORT) in drinking water for four weeks before mating with untreated females. Sperm was collected from the epididymis for RNA sequencing. Offspring were then tested for a variety of anxiety and depression-related behaviors starting at PND3 and during young adulthood. Small RNA sequencing revealed that sperm collected from CORT-treated mice had different small RNA distribution profiles. Selective microRNAs predicted to regulate genes involved in anxiety behavior were found to be altered. Male offspring had altered vocalization patterns at PND3 and as adults had increased anxiety-like phenotypes on both the elevated-plus maze and the light-dark apparatus. Changes in expression of anxiety-associated genes in the brains of the male offspring were also observed. This demonstrates that CORT may be instrumental in the transmission of paternal stress induced traits across generations by causing changes in the small RNA populations of sperm. These altered small RNA environments may be having effects in specific offspring tissues, leading to altered phenotypes

Title: The effect of bimodal value representation on goal directed behavior and reflective choice in behaving macaque

Authors: *M. YASUDA[1], S. NAKAMURA[2], K.-I. OKADA[3], Y. KOBAYASHI[3], K.-I. TSUTSUI[2], K. NAKAMURA[1];
[1]Dept. of physiology, Kansai Med. Univ., Hirakata, Japan; [2]Lab. of Systems Neurosci., Grad. Sch. of Life Sciences, Tohoku Univ., Miyagi, Japan; [3]Labs. for Neurosci. Visual Neurosci. Group, Osaka Univ. Grad. Sch. of Frontier Biosci., Osaka, Japan

Abstract: Gaze is attracted by valuable objects based on past reward learning. During learning, objects may be associated with relative value within local behavioral context, or with absolute value which maintains across contexts. Previous studies investigated behavioral and neuronal correlates of either one of these value representations. However, little is known how those value representations affect our automatic choice of visual object. Here we developed an experimental procedure to test the effect of relative and absolute values on monkey's automatic choice under free viewing. First, the monkey performed a button press task with two fixed sets of 6 visual objects to learn their values. In each trial, one of 6 objects was presented in a pseudorandom order. The monkey was required to react to it by pressing a button, keep pressing for a certain time period, and then release it to obtain a reward. The amount of reward was determined by the object. In the high-valued block (HVb), 3 objects were associated with large (0.11ml); the other 3 with middle reward (0.07ml). In the low-valued block (LVb), 3 were associated with middle (0.07ml); the other 3 with small reward (0.04ml). After performance of this button press task, we tested monkey's gaze in the free-viewing task. In each trial, 4 of trained objects were presented simultaneously, and the monkey was free to look at anywhere. In the button press task, the button-release reaction times (RTs) reflected relative value; shorter in large (middle) reward trials than in middle (small) reward trials in HVb (LVb) (L(mean:562ms) vs. M(653) in HVb, p=5.9x10-16, M(592) vs. S(666) in LVb, p=6.1x10-12, t-test). On the other hand, the button-press RTs represented absolute value across two blocks: shorter in large, intermediate in middle, and longest RTs in small rewarded trials (L(739ms) vs. M(841) in HVb, p =1.5x10-6, M(841) in HVb vs M(859) in LVb, p=0.4, M(859) vs. S(1078) in LVb, p=2.3x10-13). In free viewing, the monkey so far tended to see the objects associated with large reward in HVb more often than the object associated with middle reward in LVb, suggesting the automatic choice represents absolute value of visual objects. The free-viewing tasks which place a few demands on participants would be an ideal tool to investigate cognitive characteristics of psychiatric disorders in humans. Applying this method for the animal may open the way to investigating underlying neural mechanism, and evaluating therapeutic effects of drugs and brain stimulation, such as repetitive transcranial magnetic stimulation and deep brain stimulation.

Title: Midbrain dopamine stimulation enhances perceptual sensitivity

Authors: ***A. LAK**[1], S. SCHRÖDER[1], E. JACOBS[1], S. SOARES[2], C. P. BURGESS[1], J. J. PATON[2], K. D. HARRIS[1], M. CARANDINI[1];
[1]Univ. Col. London, London, United Kingdom; [2]Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: Midbrain dopamine (DA) neurons are involved in a variety of cognitive functions such as learning and value-based decision making. In contrast, less is known about how they influence sensory perception and the resulting decisions. We addressed this question by optogenetically stimulating DA neurons in mice, at different stages of a visual decision task. We expressed Channelrhodopsin-2 in midbrain DA neurons via an AAV virus in DAT-Cre mice, and implanted an optical fiber over the ventral tegmental area. Mice were trained to perform a head-fixed visual two alternative forced choice task. In each trial, a grating was presented on the left or right side of monitor, and mice indicated its position by turning a wheel with their forepaws, receiving liquid reward for correct choices. Task difficulty was manipulated by varying stimulus contrast across trials, resulting in high-quality psychometric curves, and reaction times that decreased as a function of stimulus contrast. We first confirmed that DA stimulation at the end of the trial acted as a reward. In alternating blocks of trials, correct choices toward one but not the other response side (left or right) were rewarded not only with liquid but also with phasic optical stimulation of DA neurons. The psychometric curves became markedly biased towards the response side paired with DA stimulation. Moreover, the corresponding reaction times became significantly shorter. These behavioral changes resembled the effects of increasing the amount of

water reward on one side. In animals with unilateral fiber implantation, the behavioral effects were stronger for choices contralateral to the stimulated hemisphere. We then asked how DA stimulation at the time of the visual stimulus would affect perceptual sensitivity. To do so, in randomly chosen trials we phasically stimulated DA neurons prior to or at the onset of the visual cue presentation. Such a manipulation improved performance in difficult trials involving medium to low contrasts, thus resulting in steeper psychometric curves. This improvement in perceptual sensitivity was accompanied by a decrease in reaction time. Together, these results suggest that stimulation of DA neurons during different stages of a perceptual decision task has diverse effects on choice behavior, depending on when such a manipulation is applied. In particular, stimulation of DA neurons during stimulus presentation increased both the speed and the accuracy of detection, effects that resemble those seen with increased attention.

Title: Amelioration of working memory deficits induced by prefrontal cortical GABA hypofunction by D1 receptor stimulation

Authors: ***M. AUGER**[1], N. S. CHAN[1], S. B. FLORESCO[2];
[1]Dept Psychology, [2]Psychology and Brain Res. Ctr., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Perturbed prefrontal GABA signalling has been proposed to contribute to cognitive dysfunction associated with schizophrenia. In recent years, work from our group has shown that antagonism of prefrontal GABA-A receptors reproduces many cognitive abnormalities relevant to schizophrenia in rodents, including impairments in working memory as assayed with radial arm maze and delayed non-match to position (DNMTP) tasks. Identifying compounds that can ameliorate these effects may elucidate novel strategies in treating cognitive impairment associated with schizophrenia. D1 receptor agonist drugs have been shown to enhance attention and working memory function at moderate doses. Furthermore, such drugs augment interneuron

excitability and GABAergic inhibition of PFC pyramidal cells, which could potentially reverse the effects of dampened inhibitory neurotransmission. Thus, the goal of this study was to ask whether working memory impairments induced by diminished prefrontal GABA signalling could be rescued by stimulation of dopamine D1 receptors. To this end, male Long Evans rats were trained on an operant version of a DNMTP task. The task consisted of a sample phase in which one lever is extended, and a choice phase in which the subject must select the opposite lever, separated by a variable delay (1-24s). Well-trained animals were implanted with bilateral cannulae in the medial prefrontal cortex (PFC). On test days, animals received counter-balanced infusions of either saline or the GABA-A receptor antagonist, bicuculline (50 ng) and injections of either saline or the D1 agonist SKF 81297 (0.1-0.3 mg/kg, i.p.). Similar to what we have observed previously, antagonism of PFC GABA receptors induced delay-independent impairments in the DNMTP task. However, impairments in working memory performance induced by intra-PFC bicuculline were reversed by concomitant administration of the lower dose of the D1 agonist. Future studies will examine the dose-dependence of these effects and whether D1 agonists rescue impairments induced by prefrontal GABA antagonism in other cognitive tasks. In conclusion, this work suggests that working memory impairments induced by insufficient prefrontal GABA transmission may be reversed by pharmacological stimulation of D1 receptors. As such, pharmaceutical agents that enhance D1 receptor signalling may represent novel treatment strategies for cognitive deficits observed in schizophrenia.

Title: The influence of acute stress on individual differences in probabilistic reversal learning

Authors: ***C. A. BRYCE**[1], S. B. FLORESCO[2];
[2]Psychology and Brain Res. Ctr., [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The stress response is a normal physiological reaction that occurs when a threat from the environment causes a disruption in internal homeostasis. Unlike the well-characterized influence of acute stress on learning and memory, the manner in which stress affects more

complex forms of decision-making and cognitive flexibility is poorly understood. Different forms of cognitive flexibility include relatively simple reversal learning, requiring shifts between different stimulus reward contingencies, wherein correct/incorrect responses are always or never reinforced. More complex forms of flexibility are required when "correct" actions are not always reinforced, and may be assessed with probabilistic reversal learning (PRL) assays in both humans and animals. These tests require subjects to keep track of changes in probabilistic reward contingencies, wherein a "correct" choice elicits a reward the majority of the time (80% chance of reward), but an "incorrect" choice also elicits a reward occasionally (20% chance of reward), with these contingencies switching repeatedly over a session. Previous studies have shown that acute stress can either facilitate or impair affects simple reversals, depending on a variety of factors (e.g.; duration, context and timing of the stressor). In comparison, we found that one-hour of restraint stress can differentially affect PRL depending on individual differences in baseline levels of performance. Rats were well trained on a PRL task and then on the test day, were subjected to 1 hr of restraint stress prior to a test session. Rats that displayed "Good" baseline levels of performance (indexed by the number of reversals completed per session) displayed a slight impairment in performance following restraint stress, accompanied by a selective increase in the sensitivity to negative feedback (reward omissions), as indexed by an increase in lose shift behavior. In contrast, in "poor" performers, acute stress reduced negative feedback sensitivity and improved reversal performance. Acute manipulations of serotonin modulates negative feedback, such that decreasing serotonin levels causes an increase in lose-shift behavior in PRL, whereas long-lasting serotonin treatments affect reward sensitivity (Bari et al., 2010). Therefore, ongoing experiments aim to identify the mechanisms underlying the individual differences in PRL following acute stress. These data suggest that acute stress can differentially modulate probabilistic learning, negative feedback sensitivity and cognitive flexibility and may have relevance to understanding abnormalities in these processes that are associated with depression.

Title: Non-aggressive resolution of conflict between two male mice by resource split behavior

Authors: *I. CHOE, K.-K. KIM, S. PARK, I. KIM, H.-S. SHIN;
Ctr. for Cognition and Sociality, Inst. For Basic Sci., Daejeon, Korea, Republic of

Abstract: The goal of dyadic contest is maximizing the acquisition of the resource while minimizing the cost, such as injury from battle. While it has been theoretically suggested that non-aggressive strategy would be rational when the expected cost exceeds the value of resource, little experimental evidence supports this idea. Therefore, little is known how animals resolve conflict without aggression. Here we show how two freely interacting male mice compete for reward by wireless intracranial electrical stimulation (WICS) on the medial forebrain bundle, a pleasure center. In a test arena equipped with two reward zones, a mouse was able to obtain WICS if it occupied the visually denoted zone first. Contrary to the general expectations in competition, where animals try to monopolize reward, using aggression when necessary, we found that mice resolved conflict non-aggressively using the resource split behavior (RS-behavior), where each mouse obtained reward in different zones and did not intrude the other's zone. The degree of RS-behavior increased over time, and was associated with both the amount of WICS acquired and the equality of acquisition. These suggest that mice learned how to non-aggressively resolve conflict in a mutually benefiting way grounded on economic concerns. This provides insights into when and how non-aggressive resolution can occur during competition.

Title: Sex differences measured using a novel paradigm to assess approach and avoidance behaviors

Authors: *T. G. CHOWDHURY[1], N. W. SIMON[1], R. DUTTA[2], J. T. WOOD[1], B. MOGHADDAM[1];
[1]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Scripps Col., Claremont, CA

Abstract: Men and women have differing incidence rates of various psychiatric illnesses. For example, men are more vulnerable to schizophrenia, autism, and addictions while women are

more susceptible to depression, anxiety, and other mood disorders. The biological basis for these sex differences is unknown. To study sex differences in behaviors that are relevant to psychiatric illnesses, we have developed a novel paradigm for simultaneously testing two different motivated behaviors, namely reward approach and active punishment avoidance, in rats. Rats are first trained on two separate tasks: (1) to perform a nose-poke action to obtain a reward during presentation of a cue, and (2) to perform a lever-press action to avoid an impending foot-shock during a different cue. The identities of the cues and actions were counterbalanced across subjects. After achieving criterion, rats entered the testing phase in which both reward seeking and punishment avoidance behavior were assessed concurrently. On average, male rats obtained a greater proportion of successful responses for reward attainment than females. Females acquired the avoidance behavior faster than males, but upon entering the testing phase, males and females did not differ in the proportion of trials in which they successfully avoided the shock. These results highlight interesting differences between males and females that mirror vulnerability to psychiatric illnesses. Male rats show greater reward-seeking motivation, correlating with the greater incidence of addiction disorders in men. Female rats show more rapid acquisition of avoidance behavior, and this correlates with the greater vulnerability of women to depression and anxiety disorders. These preliminary behavioral data also reveal a great deal of inter-animal variability in both male and female rats. In the future, we are interested in exploring neural and pharmacological correlates of this task, and how these differ as a function of sex.

Title: Effect of social peers on risky decision making in male sprague dawley rats

Authors: *V. WEISS[1], M. T. BARDO[2];
[2]Psychology, [1]Univ. of Kentucky, Lexington, KY

Abstract: Adolescence is a time associated with increased risk taking, as well as prominent peer relations. Extensive work has shown that adolescents are more vulnerable to peer pressure and advice compared to adults, which leads to exacerbated risk taking. Preclinical research has suggested that these clinical findings may also be applicable to rodents, as adolescent rats find social interaction rewarding and are more prone to risky behavior than adults. There is, however, little research on the effect of social interaction on rodent models of risky decision-making. Recently, an apparatus has been designed by connecting two operant chambers with wire mesh, which allows for two rats to have social contact while performing operant tasks. The current study utilized these social chambers to evaluate the effects of a social peer on behavior in a novel Risky Decision-Making Task (RDMT). In this task, rats were given a choice between a small, safe reward of a single food pellet that is delivered immediately following a response, and a large, risky reward of three food pellets delivered immediately following a response; however, the large reward was also associated with a mild footshock, with the probability of the shock increasing across the session by block (0, 25, 50, 75, & 100%). Adolescent male rats (PND 28 upon start of experiment) were trained in the RDMT either alone (controls) or with their cage mate as a social peer every session until stable responding occurred. Results revealed a main effect of group, such that rats exposed to a social peer were riskier than controls ($p = 0.02$). Rats were then divided into high and low risk-takers within their groups. In controls, high and low risk-takers showed significant differences in risk-taking during all blocks, except for the block associated with 0% chance of shock. In contrast, high and low risk-takers in the social group only showed a significant difference when the chance of shock was 100%. Furthermore, when comparing high and low risk takers across groups (controls vs. social), there were no differences between the high risk-takers, but the low risk-taking rats in the social group were significantly more risky than low risk-taking rats in the control group ($p = 0.01$). These results support clinical work showing that social peers lead to increases in risk taking, and also provide evidence for the ability of social risk-taking to be modeled in rodents. The future goal is to determine the neural systems involved in social facilitation of risky behavior.

Title: Bayesian approach can help analyze and design cognitive flexibility tasks

Authors: J. WANG, *D. S. TAIT, E. M. BOWMAN, V. J. BROWN;
Univ. of St Andrews, St Andrews, United Kingdom

Abstract: Bayesian analysis has recently been used to analyze the data from an intradimensional/extradimensional (ID/ED) attentional set-shifting task in rats, showing that the traditional n-correct-in-a-row learning criterion for the task may cause overtraining or undertraining - and that overtraining may affect rats' performance at the ED shift stage. Here we show two more applications of Bayesian analysis. First, Bayesian analysis can help analyze the detailed learning process in individual rats. In particular, Bayesian analysis of rats' behavior at the ED shift stage of a four consecutive ID task has shown that impaired ED performance in orbital prefrontal cortex-lesioned rats (data from Chase et al., 2012) may result from different causes in different rats, including not only the expected difficulty in shifting attentional set, but also the lack of set-formation in preceding stages, and a lack of attentional focus on either dimension at the ED stage. This suggests that, in future studies of ED shifting ability, researchers may be able to exclude those rats that showed a lack of set-formation or poor attentional focus by investigating individual rat's performance using Bayesian analysis. Second, which bowls contain which perceptual stimuli (e.g., the various odors and media) are traditionally pre-determined pseudo-randomly. Using Bayesian analysis of the previous trials, we can adaptively determine which bowl should contain which stimuli in the current trial by putting the rewarded stimulus into the bowl that the rat is least likely to choose based on preceding choices. Such adaptive design can potentially improve the efficiency of rats' learning by helping rats more quickly focus on the rewarded stimulus. Our investigation suggests that Bayesian analysis, and adaptive-design learning tasks, are powerful tools for data collection and analysis in behavioral studies.

Title: Context cues disambiguate the meaning of an extinguished stimulus to guide choice between actions

Authors: *V. LAURENT, B. C. CHIENG, B. W. BALLEINE;
Brain & Mind Res. Inst., Camperdown, Australia

Abstract: Context cues are known to disambiguate the meaning of an extinguished stimulus and control the amount of conditioned responding that such a stimulus can evoke. The present series of experiments examined whether context cues can also control the influence that an extinguished stimulus exerts over choice between actions. We found that a stimulus tested outside of its extinction context acted as a positive predictor of its previously associated outcome, as it biased choice toward an action delivering that same outcome. Extinction cues produced the reversal of this choice. When tested in its extinction context, the stimulus functioned as an inhibitor of its previously outcome, as it biased choice away from an action delivering that same outcome toward an an action earning a different outcome. This reversal of choice was removed by silencing neurons in the infralimbic cortex, consistent with the well-established role of this brain region in the retrieval of extinction. In contrast, silencing of the hippocampus was found to disrupt choice irrespective of the context in which the extinguished stimulus was being tested. Taken together, these experiments indicate that extinction spares the ability of a stimulus to bias choice between actions but the direction of that choice is under the control of the context cues present during extinction training. Interestingly, these extinction cues appeared to imbue the stimulus with net inhibitory properties, which required neuronal activity in the infralimbic cortex to be expressed.

Title: Multi-site optogenetic inactivation of the rat frontal orienting fields and posterior parietal cortex during evidence accumulation

Authors: *C. D. KOPEC[1], J. U. KASDIN[1], C. D. BRODY[2];
[1]Princeton Univ., Princeton, NJ; [2]Princeton Neurosci. Inst., HHMI / Princeton Univ., Princeton, NJ

Abstract: The gradual accumulation of evidence is a fundamental component of decision making, yet the location of the circuit responsible for its implementation remains a mystery. Both optogenetic (Hanks and Kopec et al. Nature 2015) and pharmacological (Erlich et al. eLife 2015) unilateral inactivation of the rat Frontal Orienting Field (FOF, a region of prefrontal cortex) have suggested that while the FOF is required for decisions based on accumulating evidence, it is not part of the accumulation process per se. Instead the data suggested that the FOF is a requisite node that lies downstream of the actual accumulator. Nevertheless, bilateral pharmacological inactivation of the FOF hints at a potential role for it in the accumulation process itself (Erlich et al. eLife 2015). Furthermore, although many neurons in the FOF have firing rates patterns consistent with the FOF being downstream of the graded accumulator, other individual FOF neurons have patterns consistent with encoding graded accumulation itself (Hanks and Kopec et al. Nature 2015). Finally, although bilateral and unilateral pharmacological inactivations of the posterior parietal cortex (PPC) indicated that the PPC plays a minimal role in decisions driven by accumulation of auditory evidence, a behavioral effect of unilateral PPC inactivation could be revealed when combined with simultaneous bilateral FOF inactivation. Here we investigate whether the graded accumulation process is distributed in a redundant fashion across multiple brain areas, with the inhibition of any one region being insufficient to affect the animal's response. The long timescale associated with pharmacological inactivation (~hours) makes it difficult to distinguish effects due to the graded accumulation process from effects due to processes occurring immediately downstream and subsequent to it. We therefore turned to the high temporal resolution afforded by optogenetic inactivation. Using halorhodopsin (eNpHR3.0) in rats performing an auditory accumulation of evidence decision task (the Poisson Clicks Task, Brunton et al. 2013), we probe the effect of simultaneously silencing, only within the graded accumulation period of each trial, either (a) both hemispheres of the FOF; or (b) both FOF and PPC in the same hemisphere. If the circuit responsible for accumulation of evidence is distributed across the two cortical regions probed in each experiment, then simultaneous inactivation of the two should impact the animal's choice, regardless of when during the accumulation period the inactivation occurs.

Title: Temporal integration in a vibrotactile delayed comparison task: From sensory coding to decision in humans and rats

Authors: A. FASSIHI[1,2], A. AKRAMI[3,4], V. H. SCHÖNFELDER[1], *M. E. DIAMOND[2]; [1]SISSA, Trieste, Italy; [2]Intl. Sch. for Advanced Studies, Trieste, Italy; [3]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [4]Howard Hughes Med. Inst., Princeton, NJ

Abstract: We carried out studies to elucidate how an uncertain tactile stimulus is integrated over time to produce a percept and how that percept is transformed into a decision. Earlier work showed that rats can perform a tactile delayed comparison task with performance overlapping that of human subjects. Subjects discriminate between two vibrations (v1 and v2) delivered either to their whiskers, in rats, or fingertips, in humans. Vibrations are normally distributed velocity noise. The subject must evaluate the two vibrations' relative velocity standard deviations, $\sigma1>\sigma2$ or $\sigma2<\sigma1$. In the present study, vibration duration was varied to investigate how signals are integrated over time. The number of velocity samples grows linearly with vibration duration; the distribution of sampled values approaches the distribution from which they are sampled. Therefore, an ideal observer's estimate of σ will improve with the square root of duration. RESULTS: Both rats and humans showed progressive improvement as vibration duration increased from 100 to 600 ms, provided v1 and v2 were of equal duration. In contrast, unequal duration of v1 and v2 led to a perceptual bias corresponding to an overestimate of σ of the longer stimulus. To account for these observations, we posited that the vibration percept could be approximated by the weighted (exponentially decaying function) sum of speed values over time. Guided by this supposition, we formulated a model that was able to replicate both (i) the subjects' improvement in performance as stimulus duration increased (ii) the bias by which subjects judged longer stimuli as having a greater value of σ. We recorded neuronal activity from rat primary somatosensory (S1) and premotor (PM) cortices. For >30% of S1 neurons, firing rate increased monotonically with σ. PM neurons were heterogenous in their association with various task parameters. About 30% of PM neurons predicted the upcoming decision as the rat integrated v2. Importantly, about 20% of premotor PM neurons encoded v1 during the inter stimulus interval, and their firing was better correlated with weighted sum model than with σ itself. Such neurons appear to encode the animal's percept. These results suggest that a single model,

applicable both to rats and humans, can account for the evolution of the percept of an uncertain stimulus. Moreover the neuronal activity in PM cortex highlights the previously unknown role of this region in stimulus integration and decision making.

Title: Causal contribution and neural encoding of the rat superior colliculus in an accumulation of evidence decision-making task

Authors: ***T. D. HANKS**[1], M. M. YARTSEV[1], C. D. BRODY[2];
[1]Princeton Univ., Princeton, NJ; [2]Princeton University, HHMI, Princeton, NJ

Abstract: Many decision-making behaviors depend on the gradual accumulation of evidence over time. A long line of research has identified neural responses that may be involved in gradual accumulation and subsequent choice categorization over a wide range of brain regions, including multiple cortical areas, the striatum, and the superior colliculus (SC). Here, we used a combination of approaches including electrophysiological recordings, causal perturbations, and computational modeling to examine the role of the rat superior colliculus in an auditory accumulation of evidence decision-making task. We compared these results to those we have obtained previously in other brain regions, such as the frontal orienting fields (FOF) in prefrontal cortex, and the anterior dorsal striatum. Causal perturbations demonstrated that the SC is necessary for decisions driven by accumulation of evidence. Electrophysiological recordings showed that many neurons in the SC exhibit strong pre-movement side-selective responses that gradually develop as the trial unfolds. Furthermore, these firing rate modulations depended on the strength of accumulated evidence, one of the primary identifying characteristics that has been used to suggest a possible role in evidence accumulation. However, when we applied a recently developed computational method to examine the relationship between the firing rates and the value of accumulated evidence (Hanks*, Kopec*, et al. Nature 2015), we instead found that these SC neurons have a more categorical encoding of accumulating evidence. These results suggest

that rather than having a critical role in the graded accumulation process itself, the rat SC may have a more important role in transforming accumulated evidence into a categorical choice, a conclusion similar to one we previously found for the FOF (Hanks*, Kopec*, et al. 2015; Erlich et al. eLife 2015). These results for the FOF and SC stand in contrast to recent findings applying the same toolkit to neurons in the rat anterior dorsal striatum, which were consistent with a role for anterior dorsal striatum in the accumulation process itself (Yartsev*, Hanks*, and Brody Cosyne 2015). Given the direct connectivity of the dorsal striatum through basal ganglia pathways to the superior colliculus, our data suggest a possible route of information flow at the circuit level between neural components that support evidence accumulation and those that support choice categorization based on that accumulated evidence.

Title: Time dependent involvement of Posterior Parietal and Prefrontal cortex in a rat auditory parametric working memory task

Authors: *A. AKRAMI[1,2,3], A. EL HADY[1,3], C. D. KOPEC[1,3], C. BRODY[1,2,3];
[1]Princeton Neurosci. Inst. (PNI), Princeton, NJ; [2]Howard Hughes Med. Inst., Princeton, NJ;
[3]Mol. Biol., Princeton Univ., Princeton, NJ

Abstract: Working memory (WM) refers to the ability to store and manipulate information across time intervals of a few seconds. A particular example of working memory task is the sequential comparison of two graded stimuli separated by a delay period of a few seconds, which forces the subject to maintain an analog value in memory. This form of WM is called Parametric Working Memory (PWM) and its neural correlates have been studied in primates (Romo and Salinas 2003). The prefrontal and posterior parietal cortices (mPFC and PPC) have been proposed to be involved in working memory (Pasternak and Greenlee 2005, Harvey et. al 2012, Crowe et al. 2010), but no inactivation experiments probing whether these areas are necessary for parametric working memory have been performed. Moreover, it remains unknown whether the involvement of these brain regions is affected by memory retention time. We have developed

an auditory delayed comparison task in rats, adapted from a tactile task (Fassihi and Akrami et. al 2014). In this task, rats compare two sequential auditory stimuli, 'f1' and 'f2', separated by a variable delay. Stimuli consist of broadband noise (2K-20K Hz), generated as a series of Sound Pressure Level (SPL) values sampled from a zero-mean normal distribution. The rats' task is to decide which of f1 and f2 had greater SPL standard deviation, thus requiring them to hold the analog value of f1 in memory during the delay period. Training steps were formalized into semi-automated computer code, requiring minimal human intervention. Rats show a remarkable ability to hold information about f1 stimulus in their memory for up to 10s (the longest tested). We carry out the first local reversible inactivations of cortical regions to probe their role in PWM, and we show that inactivations of either PPC or mPFC impact this auditory behavior. Interestingly, only PPC inactivation leads to delay-duration dependent impairment. To precisely chart the timecourse of PPC involvement, we optogenetically silenced it, using halorhodopsin (eNpHR3.0), during different time points of the trial. Using a logistic regression model to analyze the specific task components impacted by inactivations, together with electrophysiological recordings, our data suggest distinct roles played by PPC and mPFC in auditory PWM.

Title: Transient, localized disruption of neural activity in posterior parietal cortex reduces accuracy of visual decisions

Authors: A. M. LICATA, D. N. RAPOSO, *A. K. CHURCHLAND;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Integration of uncertain sensory evidence can improve decision accuracy. Pharmacological and chemogenetic inactivations have identified candidate areas that support

evidence integration, including posterior parietal cortex (PPC). However, the slow timescale and large spatial extent of the inactivations mean that PPC has not yet been firmly established as critical for visual decisions requiring evidence integration. Here, we aim to determine the role of PPC in these 'integration decisions' via localized disruption of PPC activity on a fast timescale. We disrupted PPC activity in rats trained to integrate evidence about the rate of visual or auditory events presented over 1000 ms. Rats were injected to express channelrhodopsin-2 (ChR2) pan-neuronally in PPC and were implanted with fibers to allow optical stimulation. Normally, individual PPC neurons are either suppressed or elevated during decision formation, so pan-neuronal stimulation disrupts a dynamic population code. In 2 rats, optical stimulation presented over the 1000 ms decision period reliably reduced accuracy on visual, but not auditory trials. Optical stimulation in an uninjected control rat had no effect. Stimulation could reduce decision accuracy either by weakening the influence of visual evidence on choice or by allowing irrelevant task features to more strongly influence choice. To distinguish these, we fit a logistic regression model to the behavioral data. This revealed that sensitivity to visual evidence was weaker on stimulation trials, while bias and trial history dependence were overall unchanged. Finally, to define the temporal dynamics governing PPC's involvement in integration decisions, we disrupted neural activity during restricted epochs of the decision. Surprisingly, when stimulation took place during the first 250 ms of the decision, accuracy was reduced to the same extent as observed during full 1000 ms stimulation. By contrast, accuracy was largely unaffected when stimulation took place during the last 250 ms of the decision. The effect on accuracy during the middle of the decision (250-500 ms; 500-750 ms) was intermediate. Taken together, our results suggest that PPC activity is required for visual integration decisions, but that the integrated evidence is maintained outside PPC throughout the trial duration. The long-lasting effect of brief stimulation early in the trial suggests that stimulation interrupted an ongoing process that could not recover within the timescale of the trial. This suggests that several hundred milliseconds may be required for the network to re-establish a state that is receptive to visual evidence for decisions.

Title: A behavioral task for quantitative assessment of impulsivity in mice

Authors: ***H. PI**[1], T. SIKKENS[3], A. KEPECS[2];
[1]Neurosci., [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [3]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Impulsivity, a failure of cognitive inhibition in decision-making process, is implicated in diverse psychiatric symptoms including addiction, attention deficit hyperactivity disorders, mania, and borderline personality disorder. The progress has been made in our understanding, yet it remains elusive which neural circuits are involved and how impulsivity is regulated by these circuits. Our long-term goal is to understand neural circuit mechanisms underlying impulsive behavior. As an initial step, we sought a quantitative behavioral assay to assess impulsivity on a trial to trial basis. Therefore we designed a lick withholding task suitable for head-restrained mice. In each trial, in order to receive water reward mice are required to withhold licking until the end of a temporally uncertain delay, signaled by an auditory cue. If the mice lick during the cue presentation, an airpuff is delivered as a punishment. To dissociate impulsivity from temporal and reward expectations we introduce three distinct waiting and reward size contingencies predicted by the auditory cue. The three different trial types are pseudo-randomly interleaved: type 1 - short wait (1.5s) and small reward (3uL); type 2- long wait (3s) and large reward (8uL); type 3 - long wait (3s) and small reward (3uL). Our preliminary behavioral results show that mice could be trained to perform the task reliably. The trained mice (n=2) preferred short wait to long wait (mean performance: type 1 = 0.59+/-0.150; type 2 = 0.47+/-131; type 3 = 0.32+/-0.082; mean +/- standard deviation). Mean reaction times for correct trials were 0.29+/- 0.269 sec (type 1), 0.30+/-0.243 sec (type 2) and 0.79+/-0.627 sec (type 3). Currently, we are designing a computational model for this task to fit the waiting times so that we can extract trial-to-trial impulsivity measures useful for neural studies.

Title: Integration of visual and tactile signals in behaving rats

Authors: *N. NIKBAKHT[1], R. QUIAN QUIROGA[2], D. ZOCCOLAN[1], M. E. DIAMOND[1]; [1]SISSA, Trieste, Italy; [2]Univ. of Leicester, Leicester, United Kingdom

Abstract: Our experience of the world depends on integrating cues from multiple senses to form unified precepts. How the brain merges information across sensory modalities has been the object of debate. To measure how rats bring together information across sensory moralities, we devised an orientation categorization task that combines vision and touch. Rats encounter an object-comprised of alternating black and white raised bars-that looks and feels like a grating and can be explored by vision (V), touch (T), or both (VT). The grating is rotated to assume one orientation on each trial, spanning a range of 180 degrees. Rats learn to lick one spout for orientations of 0±45 degrees ("horizontal") and the opposite spout for orientations of 90±45° ("vertical"). Though training was in VT condition, rats could recognize the object and apply the rules of the task on first exposure to V and T conditions, suggesting that the multimodal precept corresponds to that of the single modalities. Quantifying their performance, we found that rats have good orientation acuity using their whiskers and snout (T condition); however typically performance is superior by vision (V condition). Performance is always highest in the VT condition, indicating multisensory enhancement. Is the enhancement optimal with respect to the best linear combination? To answer this, we computed the performance expected by optimal integration in the framework of Bayesian decision theory and found that most rats combine visual and tactile information better than predicted by the standard ideal-observer model. To confirm these results, we interpreted the data in three additional frameworks: Summation of mutual information for each sensory channel, Generalized linear models, and probabilities of independent events. All three analyses agree that rats combine vision and touch better than could be accounted for by a linear interaction. To study the neuronal correlates of visuo-tactile integration, we are performing electrophysiological recordings in somatosensory, visual and parietal association areas.

Title: Anxiolytic-like effects of n-sustituted melatonin analogues on mice

Authors: *A. ALMARAZ, E. B. NARANJO-RODRIGUEZ, A. S. LIRA-ROCHA, A. M. VÁZQUEZ;
Univ. Nacional Autonoma De Mexico, Mexico City, Mexico

Abstract: Melatonin (MT) is a Pineal hormone that regulates several physiological processes, circadian rhythms, reproductive and modulates neuroendocrine function. And anticonvulsivant, sedative, hypnotic, anxiolytic and antidepressive-like pharmacological effects. On the other hand, Diazepam (DIAZ) has been used for long time as a treatment, however; produces several adverse effects. For this reason this research is aimed to find alternative therapies at anxiety treatment with modified molecules at functional groups, such as MT Analogues. This study was carried out in CD1 male mice (22±3g) with Marble-Burying Test as a model of anxiety and, ED50 were calculated by statistical analysis. All the mice were administrated with DIAZ (0.25,0.5 mg/kg), MT (0.5,1.0,2.0 mg/kg) and 1-N substituted Analogues [(M6A and M7A) (0.125,0.25,0.5,1.0,2.0 mg/kg)] . The results obtained showed that MT Analogues had more effectiveness as anxiolytic-like that MT and DIAZ. This project was supported by DGAPA-PAPIIT-UNAM. Key IT201112-2

Title: Rapid and refined screening of behavioral flexibility, impulsivity and attention in mice using different types of automated home-cage tasks

Authors: *E. REMMELINK[1,2,3], M. VERHAGE[3], A. B. SMIT[2], M. LOOS[1];
[1]Sylics, Amsterdam, Netherlands; [2]Mol. and Cell. Neurobiology, CNCR, [3]Functional Genomics, CNCR, VU Univ., Amsterdam, Netherlands

Abstract: Several brain disorders, such as schizophrenia, autism and Alzheimer's disease, are characterized by deficits in cognitive flexibility, attention and inhibitory control. The majority of currently available behavioral tests to assess these executive functions in animal models of brain disorders are labor intensive, require imposed food-restriction regimes and involve extended training periods. Therefore, we investigated whether in a home-cage setting, with 24-hour access to an operant task and without imposed food-restriction regimes, mice would reach similar performance levels in a shorter training period. We describe 3 new operant protocols for automated home-cages that measure behavioral flexibility, sustained attention, impulsivity, and attentional set-shifting. 1. First, we developed a reversal learning task that effectively measures initial discrimination learning and behavioral flexibility within 4 days in an automated home-cage. C57BL/6J mice were able to attain the performance criterion of 80% correct within 1 day. Reversal learning requires suppression of the initially acquired response, while learning a new, competing rule. As expected, mice took significantly longer to attain the performance criterion during the reversal phase, confirming the idea that we tested behavioral flexibility. In line with previous studies, lesions of the orbitofrontal cortex led to a specific reversal learning deficit. 2. We adapted a five choice serial reaction time task (5CSRTT) for mice towards a home-cage setup. Typically, 10 - 14 weeks of daily training sessions are required to measure performance in a conventional setup. Automation significantly reduced total training time to 2 weeks with levels of accuracy, omissions, and premature responses comparable to those obtained in the conventional setup. 3. We designed a novel attentional set-shifting protocol for an operant home-cage setup, in which mice successfully completed 2 reversals and 1 dimensional shift within 2 weeks. We observed impairments in mouse lines with well-known deficits in executive function (e.g. APP/PS1, Fmr1 and some BXD strains) in these automated tasks, replicating as well as extending previous results. In all tasks, activity was predominantly limited to the dark phase, suggesting that 24-hour access to the task had no impact on circadian rhythm. In conclusion, we show that various tasks measuring executive functions can be implemented effectively in automated home-cage setups without imposed food-restriction regimes, providing an efficient, robust and improved way of testing mice for executive abilities.

Title: Eco-HAB - fully automated and ecologically relevant assay for individualized measurement of social impairments in mouse models of autism

Authors: *A. PUSCIAN[1], S. ŁęSKI[1], M. WINIARSKI[1], P. BOGUSZEWSKI[1], G. KASPROWICZ[2,3], E. KNAPSKA[1];
[1]Nencki Inst. of Exptl. Biology, PAS, Warsaw, Poland; [2]Ctr. for Theoretical Physics, Polish Acad. of Sci., Warsaw, Poland; [3]Inst. of Electronic Systems, Warsaw Univ. of Technol., Warsaw, Poland

Abstract: Impairments of social interactions are a key feature of autism spectrum disorders. Although there exist behavioral assays designed for evaluation of conspecific-related behavior in mice, available tasks do not allow for longitudinal observations of spontaneous interactions between littermates. Furthermore, the experiments are usually carried out on isolated animals and require their handling by an experimenter. These factors may exert confounding, anxiety-related effects on obtained data and result in large between-laboratory variability. In order to alleviate these problems, we designed Eco-HAB - a fully automated, stress-reducing tool for an individualized assessment of voluntary social interactions in group-housed mice. Using Eco-HAB, we assessed social approach of male and female Fmr1 knock-out mice of the FVB strain. Expansion of the CGG trinucleotide repeat affecting the Fragile X mental retardation 1 gene is the most widespread single-gene cause of autism. We determined that in accordance with previously documented deficits, Fmr1 knock-out male subjects show less social approach behaviors than respective controls. On the contrary, Fmr1 knock-out females display an enhanced pattern of exploration oriented towards olfactory stimuli of the conspecific-provenience. Besides sex differences, we were also able to assess individual level of social approach behavior for each investigated subject, due to an RFID-based animal tagging. We argue that when utilizing mouse models of autism for developing therapeutic strategies, one should focus on particular behavioral impairments, corresponding to individual symptoms in patients, rather than try to address a rarely appearing all-inclusive phenotype. Eco-HAB enables such research, asserts high reliability and reproducibility. It imitates natural habitat by taking into account specific features of murine behavior. Therefore, we claim that Eco-HAB is a valuable and reliable tool for the assessment of social interactions and gathering knowledge of social relations in-group housed mice.

Title: Low level lead exposure differentially impairs cognitive flexibility in an attentional set shifting task dependent upon sex and developmental period of exposure

Authors: *L. S. NEUWIRTH, D. W. ANDERSON, J. S. SCHNEIDER;
Pathology, Anat. and Cell Biol. Med., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Low level lead (Pb) exposure impairs a variety of cognitive processes. Children exposed to Pb developmentally present with cognitive impairments that include deficits in learning, memory, language and executive functioning, yet experimental work on Pb toxicity in rats has focused mostly on hippocampal dependent learning and memory deficits and less on executive functions. However, detrimental effects on executive functioning could result in or even underlie a variety of other cognitive problems attributed to Pb exposure. We examined the ability of Long Evans male and female rats (control and Pb-exposed: 150ppm Pb-acetate in food given perinatally (Peri, gestation through weaning) or early postnatally (EPN, birth through weaning) to acquire and perform an attentional set shifting test (ASST) that requires locating a food reward by discriminating between digging materials and odors. The tasks consisted of simple (SD) and compound (CD) discriminations and reversals, intra-dimensional (ID) and extra-dimensional (ED) shifts followed by reversals (Rev). The performance of control females differed from males only at the ID-Rev stage. Pb-exposed male and female rats exhibited sexually distinct cognitive impairments depending on the developmental time period of Pb exposure. EPN Pb-exposed male rats were unable to perform the SD with odors and were incapable of performing the CD tasks to complete the ASST. In contrast, Perinatal Pb-exposed males were able to complete the entire ASST, but had deficits in the ID and ID-Rev stages compared to controls. EPN Pb-exposed females, unlike EPN Pb-exposed males, were able to complete the ASST and had impairments in the ED and ED-Rev stages. Perinatal Pb-exposed females also were able to complete the ASST and had deficits in the ED and ED-Rev stages. These data suggest that fronto-executive functions may be regulated in a sex dependent manner. Moreover, low level Pb exposure results in executive dysfunction dependent upon sex and the developmental exposure period. In particular, Pb may impair the ability to form, maintain and shift response sets contributing to deficits in cognitive flexibility.

Title: Moderate prenatal alcohol exposure alters hippocampal functional network connectivity and social behavior in adult long evans rats

Authors: ***C. I. RODRIGUEZ**[1], S. DAVIES[2], V. CALHOUN[3,4], D. SAVAGE[2], D. HAMILTON[1];
[1]Psychology, [2]Dept. of Neurosciences, [3]Dept. of Electrical and Computer Engin., The Univ. of New Mexico, Albuquerque, NM; [4]The Mind Res. Network, Albuquerque, NM

Abstract: It is well established that heavy ethanol exposure during prenatal brain development leads to profound cognitive and behavioral consequences. In contrast, the effects of moderate prenatal alcohol exposure (MPAE) are less severe yet persistent. Prior research has showed alterations of hippocampal functioning as a result of MPAE. Additionally, the hippocampal complex has been implicated in a number of social behaviors. Here we investigate whether MPAE alters functional network connectivity (FNC) in the hippocampus and its association to social behavior. To accomplish this, we applied independent component analysis (GICA) to functional MRI data gathered from Long-Evans rats exposed to 5% ethanol or saccharin throughout gestation. In adulthood, rats were anesthetized (1.0-2.3% isoflurane) and BOLD signals were acquired during a 10 min echoplanar imaging sequence in a 4.7T Bruker Biospin scanner. Following motion correction, spatial normalization and smoothing, spatial independent component analysis (ICA) was performed using the Infomax algorithm implemented in the GIFT toolbox (http://mialab.mrn.org/software/gift). A total of 17 non-artifactual components were retained for analysis of connectivity measured through component cross-correlations. Components were observed in cortical, hippocampal, striatal, thalamic, and cerebellar structures. We focused our analyses on the correlations between the frequency of wrestling behavior and FNC between components localized in the hippocampus and other brain regions. Saccharin controls and ethanol-exposed animals showed more negative correlations between measures of wrestling and hippocampal FNC. When compared to saccharin animals, ethanol animals also displayed a slight increase in the number of positive associations between FNC and behavior.

When examining males, more negative rather than positive correlations between FNC and behavior were observed. Ethanol-exposed males also displayed a decrease of negative associations between FNC and behavior. Saccharin and ethanol-exposed females displayed more positive, associations between FNC and behavior. In contrast to males, however, female animals displayed more positive associations between FNC and behavior for both treatment conditions. These results indicate that moderate fetal ethanol exposure can have long-lasting consequences on hippocampal functional connectivity, and these alterations are predictive of alterations in social behavior.

Title: Elevated brain cytokine levels associated with cognitive vulnerability of CHT+/- mice following repeated mild traumatic brain injury

Authors: *A. KOSHY CHERIAN[1], N. C. TRONSON[1], V. PARIKH[2], R. D. BLAKELY[3], M. SARTER[1];
[1]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Psychology and Neurosci., Temple Univ., Philadelphia, PA; [3]Pharmacol. and Psychiatry, Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Repetitive mild traumatic brain injury (rm-TBI), as sustained by athletes and military personnel, is one of the most common types of brain injury resulting in persistent, particularly attentional, impairments. Loss of or attenuated cholinergic functioning has long been hypothesized to greatly contribute to rm-TBI-induced cognitive symptoms. Because choline transporter (CHT) heterozygosity limits the capacity of cholinergic neurons to sustain elevated levels of cholinergic activity, we hypothesized that rm-TBI yields more severe attentional-

cholinergic consequences in CHT+/- mice. CHT+/+ and CHT+/- mice acquired the mouse version of the Sustained Attention Task (SAT; St.Peters et al., 2011) and then were subjected to rm-TBI using a modification of the method described by Kane et al. (2012). Mice practiced the SAT 5 - 6 days a week and received five TBI events distributed over 35 days. Rm-TBI did not impair the performance of WT mice but, beginning after the 3rd impact and persisting thereafter, greatly impaired the detection rates of CHT+/- mice. In a separate group of mice, 7 days/SAT sessions after the final impact we harvested frontal cortical tissues for saturation analyses of hemicholinium-sensitive choline uptake in synaptosomes. Choline uptake (Vmax) was mildly but significantly reduced in WT mice subjected to rm-TBI. Rm-TBI nearly completely abolished choline uptake in CHT+/- mice. However, this effect was not associated with a loss of total CHTs, cholinergic terminals or synaptic contacts in general, suggesting a regulatory silencing of CHTs following rm-TBI in CHT+/- mice. To determine a potential mediator of this effect of rmTBI, and guided by hypotheses linking cholinergic activity with inflammatory mechanisms, we determined brain cytokine/chemokine levels in tissues harvested 7 days after the final impact. Compared with CHT+/+ mice subjected to rm-TBI, levels of IL-2, CCL3, CCL4, IL-9, and IL-13 were significantly elevated in CHT+/- mice. These results suggest that elevated cytokine levels may interfere with normal CHT function and therefore mediate the attentional-cholinergic vulnerabilities of subjects expressing subcapacity variants of cholinergic neurons or with declining cholinergic systems.

Abstract: Early life traumatic experiences or exposure to stressful environments may predispose an individual to develop a neuropsychiatric disorder or health problems later in life, including schizophrenia (SZ) or depression. Animal models have played a critical role in understanding how adverse events early in life may evoke changes in biomarkers of altered brain function and altered behavioral phenotypes that resemble these neuropsychiatric disorders. However, SZ is a complex condition with a multifactorial etiology, which makes it difficult to model the breadth of this condition in a single animal model. Considering this, it is necessary to develop rodent models that model clearly defined subsets of pathologies observed in the human condition and their developmental trajectory. One of the most widely used animal models to induce SZ-like symptoms is the maternal deprivation (MD) model. This models an early life traumatic event via exposure to a stressful event in the postnatal period. The current study assessed how an early life traumatic event alters cognition and brain function to better understand what neural systems might be compromised following these events. On postnatal day (PD) 9, male rat pups were maternally deprived (MD) for 24-hours or were left undisturbed. In Experiment 1, recognition memory was tested in adulthood using the novel object recognition task. Then, tissue was extracted and expression of catechol-o-methyl transferase (COMT) and glutamic acid decarboxylase (GAD67) were quantified in the prefrontal cortex (PFC), striatum, and temporal cortex (TC). In Experiment 2, electrophysiological recordings were obtained from the PFC, vertex, and TC during a paired-click paradigm to assess the effects of MD on sensory gating. Locomotor activity, root mean squared (RMS) voltage signal, and a gating ratio were quantified between groups. Impaired recognition memory was observed in MD animals. Compared to shams, MD animals had lower expression of COMT in the PFC and TC, and lower expression of GAD67 in the TC only. No differences were observed in the striatum. In Experiment 2, MD animals had an increased RMS voltage in all three recording sites and increased locomotor activity compared to shams. Lastly, MD animals had a blunted gating response during the paired-click paradigm compared to shams, which was most pronounced in the TC. These data suggest that neurodevelopmental perturbation early in life was associated with long-lasting alterations in cognition and brain function in adulthood. As such, this model may provide a useful tool to further explore the neural basis of early life trauma that may result in mental psychiatric disorders, including SZ.

Title: Sensitivity to delay of reinforcement, but not sensitivity to amount, correlates with impulsivity in Spontaneously Hypertensive Rats

Authors: *V. ORDUÑA, O. ZAMORA;
UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, MEXICO, Mexico

Abstract: In previous reports, we have shown that Spontaneously Hypertensive Rats (SHR), an animal model of Attention Deficit Hyperactivity Disorder (ADHD) show higher levels of impulsive behavior in a free operant choice task, are more sensitive to the delay of reinforcement, and are equally sensitive to the amount of reinforcement than Wistar (WIS) rats. These results were obtained from experiments using separate groups of experimental subjects. In the present report, 9 SHR and 9 WIS rats participated in three tasks: one of them measured impulsivity, while the other two were short versions of the tasks measuring sensitivity to amount and sensitivity to delay. The results replicated the results reported before: SHR were more impulsive and more sensitive to delay, but equally sensitive to amount. In addition, we found a positive correlation between the degree of impulsivity and the degree of sensitivity to delay; impulsivity and sensitivity to amount were found to be no correlated.

Title: The significance of highly basic C-terminal region of Reelin for behavior

Authors: K. SAKAI[1], H. SHOJI[2], T. KOHNO[1], T. MIYAKAWA[2,3], *M. HATTORI[1];
[1]Nagoya City Univ., Nagoya, Japan; [2]Fujita Hlth. Univ., Toyoake, Japan; [3]Natl. Inst. Physiol. Sci., Okazaki, Japan

Abstract: Reelin is a large secreted glycoprotein that is required for normal brain formation. In adult brain, Reelin malfunctions have been suggested to play critical roles in the pathogenesis of neuropsychiatric disorders, including schizophrenia, bipolar disorder, and autism. Reelin protein is composed of N-terminal domain, Reelin repeats, and highly basic C-terminal region (CTR). The primary sequence of the CTR is conserved in most vertebrates, suggesting its importance. We generated knock-in mice lacking Reelin CTR (ΔC-KI mice, Kohno et al., J. Neuosci. 35, 4776 (2015)). In the ΔC-KI mice, layer structures of the cerebral cortex and the hippocampus are partially abnormal. To reveal functions of the CTR in adult brain, we analyzed behavior of the ΔC-KI mice by comprehensive behavioral test battery. Between the ΔC-KI and wild-type mice, there was no difference in sociability, spatial memory, depression-like behavior, prepulse inhibition of acoustic startle response, and cued and contextual fear memory. ΔC-KI mice fell from a wire lid earlier than wild-type mice in wire hang test, while they remained longer on a wheel in rotarod test. We assume that results of wire hang and rotarod tests derive from hyperactivity of ΔC-KI mice (see below). The ΔC-KI mice were hyperactive and exhibited reduced anxiety-like behavior in open field test and elevated plus maze test, respectively. There was no difference in reference memory between the ΔC-KI and wild-type mice, while working memory of the ΔC-KI mice was impaired compared with the wild-type mice in T-maze test. These observations suggest that the CTR of Reelin is required for normal locomotor activity and working memory function. Thus, the ΔC-KI mice may be useful as a model of psychiatric disorders characterized by hyperactivity and working memory deficits, such as autism and attention deficit hyperactivity disorder.

Title: Situational and age-dependent decision making during life threatening distress in myotis macrodactylus

Authors: X. HUANG[1], T. JIANG[1], Z. LONG[1], B. LUO[1], X. YUE[1], Y. GU[1], J. FENG[1], *J. S. KANWAL[2];
[1]Jilin Provincial Key Lab. of Animal Resource Conservation and Utilization, Northeast Normal Univ., Changchun, China; [2]Neurol., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Echolocation and audiovocal communication have been studied extensively in bats. The manner in which these abilities are incorporated within escape behaviors during life-threatening distress is largely unknown. Here we tested whether behavioral response profiles expressed during distress are relatively stereotypic or vary with the individual, the context and the animal's age. We subjected juvenile and adult big-footed Myotis (Myotis macrodactylus) to a sequence of three types of life threatening distress: 1) trapping them in a mist-net (environmental threat), 2) approaching them when trapped (predator threat), and 3) partially restraining their freedom to move (arrest), and made audio-video recordings of their escape behaviors in each condition. Response profiles differed across individuals and with the context in which they were expressed. During environmental and predator threat, bats displayed significantly more biting and wing-flapping behaviors and emitted more echolocation pulses than during arrest. Response profiles also varied with age. During arrest, juveniles were more likely than adults to emit distress calls and vice-versa for biting and wing flapping during environmental and predator threat. Overall, individualized response profiles were classified into ten clusters that were aligned along two divergent response trajectories when viewed within two-dimensional, multifactorial decision space. Juvenile behaviors tended to follow a predominantly “social-dependence” trajectory, whereas adult behaviors were mostly aligned along a “self-reliance” trajectory. We conclude that bats modify their vocal behavior and make age-appropriate and contextually adaptive decisions when distressed. This decision-making ability is consistent with observations in other social species, including humans.

Title: EP4 receptor-associated protein (EPRAP) deficient mice exhibited behavioral abnormalities

Authors: *R. FUJIKAWA, M. MINAMI, S. HIGUCHI, M. YASUI, T. IKEDO, M. NAGATA, M. YOKODE;
Kyoto Univ., Kyoto, Japan

Abstract: Background and aims: EP4 receptor-associated protein (EPRAP) is a newly identified molecule regulating macrophage activation. Recently we have demonstrated that EPRAP exists abundantly in the brain; however, little is known about the function of EPRAP in the brain. EPRAP specifically localized in glial cells: therefore, we hypothesized that EPRAP may be involved in emotion or behavior. Methods: Behavioral tests were performed with 5-month-old, male EPRAP deficient mice (KO) and wild-type C57BL/6 mice (WT) (n=16, each). First, we examined general health and neurological screening including wire hang test. Motor coordination and balance were tested with rotarod test. Locomotor activity and anxiety-like behavior were measured using open field test, plus maze test and light/dark transition test. Porsolt forced swim test was performed to evaluate despair-like behavior. Working memory performance was tested with radial maze. Social behavior was assessed by Crewley's social interaction test. Startle response was tested in pre-pulse inhibition test. Finally, EPRAP-KO and WT mice were injected intraperitoneally with methylphenidate (MPH), a dopamine reuptake inhibitor, at a dose of 30mg/kg. The effect of MPH on locomoter activity was examined by open field test. Results: EPRAP-KO mice didn't show abnormality in general health. In wire hang test, latency to fall was significantly decreased in EPRAP-KO mice compared to WT mice. There were no significant differences in despair-like behavior and working memory and motor coordination between WT mice and EPRAP-KO mice. However, compared to WT mice, EPRAP-KO mice showed increased locomoter activity in some tests. Furthermore, EPRAP-KO mice decreased anxiety-like behavior and startle response. Social novelty preference is increased in EPRAP-KO mice. After MPH administration, locomoter activity in EPRAP-KO mice was less increased compared to WT mice. Conclusion: EPRAP-KO mice exhibited behavioral abnormalities including locomotor activity, abnormal anxiety-like behavior, and startle response, which partially recapitulate the symptoms of attention deficit hyperactivity disorder (ADHD) or schizophrenia. Additionally, we demonstrated that EPRAP-KO mice decreased the response to MPH. Because dopamine signaling is closely related to the symptoms of ADHD or schizophrenia, dysfunction of dopamine could be a cause of these behavioral abnormalities in EPRAP-KO mice. EPRAP may participate in the pathogenesis of behavioral disorders and could be a novel therapeutic target for mental diseases.

Title: Behavioral and biochemical consequences of simulated vehicle exhaust exposure

Authors: ***A. A. SALVI**[1], G. PATKI[2], H. LIU[2], S. SALIM[2];
[2]Pharmacol. and Pharmaceut. Sci., [1]Univ. of Houston, Houston, TX

Abstract: Air pollution from vehicle exhaust leads to 800,000 premature deaths annually. While most attention is focused on air pollution-related pulmonary and cardiovascular complications, its impact on mental health is often ignored. Carbon dioxide (CO2), carbon monoxide (CO) and nitrogen dioxide (NO2) present in exhaust are pro-oxidants. Our laboratory has established that increased oxidative stress in the brain leads to behavioral deficits such as anxiety-, depression-like behaviors and cognitive impairment in rats. Thus prolonged exposure to pro-oxidants present in vehicle emissions also might increase levels of oxidative stress ultimately leading to behavioral deficits. Here, we simulated vehicle exhaust exposure in a laboratory setting and observed that sub-chronic exposure to this simulated system induced behavioral deficits in rats. Adult male Sprague Dawley rats were exposed to a mixture of 1.3% CO2, 100 ppm NO2 and 0.06% CO with air as a base in regulated whole body exposure chambers. This mixture resembles the composition of pro-oxidants in vehicle exhaust diluted in a ratio of 1:10 with air. The exposure was performed for 30 min daily for a period of 2 weeks. A separate control group of rats was exposed to normal air for the same duration. Following exposure, behavioral analysis was performed to assess anxiety-like behavior (open-field, elevated plus maze and light-dark tests), depression-like behavior (forced swim test) and cognitive impairment (Morris water maze test). This was followed by biochemical analysis to measure the increase in oxidative stress (Enzyme Immunoassay based tests) following exposures. We observed increased anxiety-like and depression-like behavior as well as impaired short-term and long-term memory in rats exposed to simulated exhaust. Biochemical analysis showed elevated levels of corticosterone (systemic stress marker) and 8-isoprostane (oxidative stress marker) in the plasma of exposed rats indicating an increase in oxidative stress following exposure to simulated exhaust. In

conclusion our study identifies sub-chronic simulated vehicle exhaust exposure-induced behavioral and biochemical deficits. This study is expected to reveal the negative impact of vehicle exhaust exposure on the brain and its repercussions on mental health.

Title: Touchscreen tasks for cognitive phenotyping of rats exposed to a chronic mild stress model of depression

Authors: ***L.-S. MARTIS**[1], S. KROG[1], C. BRISION[1], A. MØLLER[2], O. WIBORG[1]; [1]Translational Neuropsychiatry Unit, Aarhus Univ., Risskov, Denmark; [2]Dept. of Clin. Med., Ctr. of Functionally Integrative Neurosci., Aarhus University, Denmark

Abstract: Background: Major depressive disorder (MDD) affects 350 million people worldwide designating it as the second leading cause for disability. Patients suffering from depression show cognitive impairment and anhedonia, one of the core symptoms indicating diminished anticipation and feelings of pleasure. To further develop, optimize and verify antidepressant treatment and therapeutic strategies, valid animal models are essential. Since stress is the main environmental risk factor for developing depression, we aim to model MDD by applying the chronic mild stress (CMS) paradigm, in which rats are exposed to a series of unpredictable stressors over weeks. Following stress exposure, rats are defined as stress-susceptible or resilient based on their consumption of a palatable sucrose solution, which is used as a measure of their reward sensitivity. Methods: We apply the Bussey-Saskida touchscreen (TS) operant platform in combination with the CMS paradigm to evaluate possible alterations in cognitive functions, specifically regarding memory consolidation, perseveration, stimulus-reward association and paired-association learning. Advantages of the TS technique include automation, diminution of experimenter's bias, objective and standardized readouts, good translatability to the human CANTAB (Cambridge Neuropsychological Test Automated Battery) test, countless modifications of the visual stimuli and a test battery for more precise cognitive phenotyping. Results and Perspectives: Preliminary results show that memory retrieval is impaired in the CMS group after a period without TS training, whereas non-stressed controls keep a consistent performance. Stress exposure alone does not seem to have an effect on simple executive

functions like stimulus-reward association learning. Therefore, we are currently investigating the CMS subgroups of anhedonic-like and resilient animals separately to accentuate potential phenotypic differences. Furthermore, advanced and more cognitive demanding TS tasks are applied to detect even subtle cognitive alterations in dependence of the rats' phenotype.

Title: Bone marrow-derived mesenchymal stem cells improve diabetes-induced cognitive impairment by secreting exosomes and repair neurons and astrocytes

Authors: *M. NAKANO, K. NAGAISHI, N. KONARI, T. CHIKENJI, Y. MIZUE, M. FUJIMIYA;
Sapporo Med. Univ., Sapporo City, Hokkaido, Japan

Abstract: BACKGROUND: Diabetes is a risk factor for cognitive decline. It is known that diabetes impairs neurons and astrocytes in hippocampus leading to learning and memory disturbance. Recently we found that intravenous injection of bone marrow-derived mesenchymal stem cells (MSCs) ameliorate diabetes-induced cognitive impairment and these cells are potent to repair damaged neurons and astrocytes. In this study, we aim to investigate why intravenously injected MSCs can reverse the damaged cells by focusing the exosomes secretion from injected MSCs. METHODS: Diabetes mouse model was produced by an intraperitoneal (ip) injection of streptozotocin (STZ, 150 mg/kg). MSCs were isolated from bone marrow of rats and administered via the tail vein at 12, 14, 16, 18 weeks after STZ injection. After 20 weeks of STZ injection, learning and memory behavior was measured using Morris Water Maze (MWM) test and mice were sacrificed for morphological study. We also injected PKH-labeled MSCs intravenously to evaluate distribution of MSCs in the brain. On the other hand, exosomes (0.5 μg of protein) were isolated from the culture media of MSCs and injected intracerebroventricularly (icv) for 5 successive days at 12 weeks after STZ injection. Two days after last icv injection, MWM test was conducted and mice were sacrificed for analyses. We also injected PKH-labeled exosomes icv to evaluate their distribution in the brain. RESULTS: The MWM test demonstrated that cognitive impairment induced by diabetes was completely recovered by both MSCs and

exosomal treatment. In the CA1 region of the hippocampus, degeneration of neurons and astrocytes as well as synaptic loss were prominent in diabetes, however MSCs and exosomal injection successfully normalized them. After injection of PKH-labeled MSCs, very few MSCs were detected in the brain parenchyma although amounts of labeled MSCs were detected in the lung or other organs. On the other hand, a large number of injected PKH-labeled exosomes were found in the brain parenchyma and they were internalized into astrocytes and neurons. CONCLUSIONS: The results suggest that exosomes derived from MSCs may contribute to repair the damaged neurons and astrocytes in diabetes and subsequently recover the cognitive impairment. This study provides a new therapeutic strategy for diabetes-induced cognitive impairment.

Title: Cerebellar neuropathology influences cerebellar-nucleus accumbens, striatum, and prefrontal cortex pathways in modulating dopamine release in the Fmr1 strain: Relevance to Autism Spectrum-related behavioral disorders

Authors: *E. MCKIMM[1], D. M. COOMES[1], Z. R. HOLLOWAY[1], M. CALTON[1], D. GOLDOWITZ[2], G. MITTLEMAN[1], C. D. BLAHA[1];
[1]The Univ. of Memphis, Memphis, TN; [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Autism spectrum disorders are neurodevelopmental disorders that traditionally encompass autism, Asperger's syndrome and pervasive developmental disorders not otherwise specified (APA, 2013). Autism is characterized by at least two neural abnormalities: cerebellar pathology including Purkinje cell loss or dysfunction as well as dopaminergic (DA) and glutamatergic changes among multiple cerebellar-prefrontal cortex (PFC) pathways. Electrical stimulation of the deep cerebellar dentate nucleus (DN) is attenuated in Lurcher (Lc) mutant mice lacking Purkinje cells (Mittleman et al. 2008). Fmr1 knockouts (mutants) are a commonly used model of Fragile X syndrome and exhibit cerebellar abnormalities such as elongated

Purkinje cell spines and decreased cerebellar nuclei volume (Ellegood et al., 2010; Koekkoek et al., 2005; Goodrich-Hunsaker et al., 2011; Verkerk et al., 1991). Rogers and colleagues (2011) have shown PFC DA transmission elicited by electrical stimulation of the DN in Fmr1 knockouts produces similar results to the Purkinje cell absent Lc mutants. The Fmr1 strain also has projections from the DN to the striatum and the nucleus accumbens (NAc), as well as DA transmission in both of these pathways (McKimm et al., 2014). Individuals with Autism often exhibit cognitive and behavioral deficits with regards to movements, executive functions, and reward learning, such as habitual actions and preoccupation of specific obsessions. In the present study we explore the potential influence of dysfunctional Purkinje cells within the Fmr1 strain on the behavioral and cognitive abnormalities of the striatum and NAc, specifically in the dorsomedial (DMS) and dorsolateral striatum (DLS) as well as the NAc core (NAcc) and NAc shell (NAcsh). The striatum is associated with learning and performance associated movement as well as some executive functions. The NAc is associated with motivation, pleasure, and reward-reinforcement based learning. Fixed potential amperometry in combination with carbon fiber electrodes in urethane anesthetized Fmr1 mice (1.5g/kg i.p.) was used to explore DA transmission. Electrical stimulation of the DN (20 pulses; 50 Hz every 60 sec) elicited DA release in all aspects of the striatum and NAc that were explored. Expected results based on preliminary findings suggest significant differences between the Fmr1 wildtype and knockout strains in the DMS, NAcc and NAcsh, however no difference was found in the DLS. The current findings suggest influence of aberrations in the DN-striatal and DN-NAc pathways with regards to the cognitive and behavioral deficits seen in Autism.

Title: Effect of sub-anesthetic ketamine on behavior in Cynomolgus Macaques

Authors: *G. J. DEMARCO[1], X. CHEN[1], B. DEREK[2], C. CHRISTOFFERSEN[2]; [1]Comparative Med., [2]Neurosci. Res. Unit, Pfizer Inc., Cambridge, MA

Abstract: Sub-anesthetic ketamine, a non-selective NMDAR antagonist, has been reported to induce hallucinatory-like behaviors in rhesus and squirrel monkey. The purpose of this study was

to test the hypothesis that sub-anesthetic ketamine would induce hallucination-like behaviors in Cynomolgus monkey. Animals were video-recorded for 20 min pre-dose, chaired for drug administration, immediately returned to their home cage and videoed for approximately 30 min. Captured video was reviewed and scored by a trained scientist using an in-house NHP Behavioral Scoring System. Ketamine at 0.05-0.3 mg/kg IV induced significant transient behavioral changes including extinguishing stereotypic behaviors and increased staring, self-inspection, star gazing, grooming, lipsmacking and gum chewing. At doses of 0.5 and 1.0 mg/kg IM ketamine induced significant sedation and ataxia which obscured many behaviors. These data suggest the behavioral response to sub-anesthetic ketamine in Cynomolgus Macaques is distinct from other monkeys and may represent a species specific form of hallucination-like behaviors.

Title: Biting the hand that feeds you: Heart rate variability as a correlate of aggression

Authors: *L. A. CRAIG, E. P. WIERTELAK, J. E. MEYERS-MANOR;
Macalester Col., Saint Paul, MN

Abstract: Canine aggression affects many, with nearly 5 million dog bites reported each year in the United States alone. It is of considerable interest to determine the physiological factors that may lead to aggression and could be targeted for treatment. One factor that has been used in order to measure autonomic nervous system (ANS) function and inhibitory control is heart rate variability (HRV), the beat-to-beat change in the heart rate. Low HRV has been associated with impaired emotional and behavioral regulation and stress in both humans and animals and may reflect the balance between sympathetic and parasympathetic activation.The present study examined HRV differences between dogs with bite histories and dogs without bite histories using a Polar H7 heart rate monitor that was applied to subjects (male and female adults) at rest. Significantly lower HRV was found in the aggressive group. These results suggest that aggressive dogs may have physiological differences that reflect ANS dysregulation, which could

influence aggressive reactivity. Understanding these differences may be useful in order to develop and assess treatments for canine aggression.

Title: Methamphetamine withdrawal inflates reward valuation by enhancing corticostriatal plasticity

Authors: ***A. B. THOMPSON**[1], A. STOLYAROVA[1], Y. ZHUANG[2], F. GOMEZ-PINILLA[3], A. IZQUIERDO[1];
[1]Psychology, [2]Integrative Biol. and Physiol., [3]Integrative Biol. and Physiology, Neurosurg., UCLA, Los Angeles, CA

Abstract: Exposure to drugs of abuse can induce changes in choice behavior that persist long into protracted withdrawal and abstinence. These changes include increased valuation of rewards and an enhanced ability to learn from positive feedback (Stolyarova et al. 2014, 2015), which may contribute to reinstatement of drug-seeking behavior when drug use is an option. Increased reward valuation after withdrawal may represent a successive positive contrast effect, in which responses to obtain reward are invigorated when reward value is unexpectedly increased. A recent computational model proposes that increased effort expenditure for rewards can occur when opportunities for reward procurement are presented to an animal with a belief that it is in a reward-impoverished environment (McNamara et al. 2013). Learning about the environment requires plasticity in corticostriatal pathways which link motor programs to outcomes. Brain-derived neurotrophic factor (BDNF) is released in the striatum by cortical afferents in an activity-dependent manner, where it signals through the TrkB receptor and interacts with dopamine to induce LTP at cortical inputs active during reward procurement (Altar et al. 1997, Jia et al. 2010, Wickens et al. 1996). In this way, conditions in the environment when TrkB signaling is elevated can influence subsequent behavior by changing an animal's belief about its environment. During withdrawal, negative somatic and psychological conditions may be 'stamped in' to the animal's memory, allowing for positive contrast effects and increased reward

valuation during protracted abstinence. We measured phosphorylation of the TrkB receptor (pTrkB) via western blot in the striatum of male Long-Evans rats (n=40) after methamphetamine. Tissue was collected either immediately after methamphetamine experience (escalating doses, culminating at 6.0 mg/kg over 2 weeks) or six weeks after the last dose. Expression of pTrkB was elevated in the immediate group, but had returned to baseline after six weeks, suggesting that a transient window of corticostriatal plasticity is opened during withdrawal from methamphetamine. A separate group of rats (n=14) was treated with the same dosing regimen then tested on a cognitively effortful 3-way visual discrimination task. Methamphetamine-, but not saline-treated rats, were able to learn the task to an 85% criterion, providing functional evidence of this enhanced plasticity. Experiments are designed to assess the effects of withdrawal on effort-based reward seeking behavior and uncover neural substrates.

Title: Investigating the role of catecholamines in cognitive dysfunction associated with Parkinson's disease

Authors: ***S. L. SIMMS**[1], L. KEIBEL[1], V. VELLA[2], J. S. SHUMSKY[1], B. D. WATERHOUSE[1], S. KORTAGERE[2];
[1]Neurobio. and Anat., [2]Microbiology and Immunol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Parkinson’s disease (PD) is a progressive neurodegenerative disorder that produces debilitating motor and cognitive impairments. The disease is characterized by a loss of dopaminergic neurons in the substantia nigra, and a subsequent reduction of dopamine and norepinephrine levels throughout the brain. The influence of dopamine deficiencies on motor disturbances has been well-studied. However, its effect on cognitive performance has not been well characterized. We have previously investigated the role of catecholamines, particularly norepinephrine and dopamine, in facilitating cognitive function in naïve animals. We designed

the compound, SK609, with dual activity as a selective dopamine D3 receptor agonist and a norepinephrine transporter reuptake inhibitor. In naïve animals tested on a sustained attention task, SK609 improved performance similar to the psychostimulant methylphenidate (MPH - Ritalin®). This improvement could be reversed with the D2/D3 receptor antagonist raclopride as well as the alpha-1 adrenergic receptor antagonist prazosin, implicating both dopaminergic and noradrenergic mechanisms. Conversely, naïve animals tested on a task of flexible attention showed no difference in performance when treated with SK609. However, performance of the task was disrupted by raclopride, suggesting involvement of dopamine in mediating flexible attention. Given these findings, our present study investigated the effects of SK609 on the mild cognitive deficit observed in PD. Hemiparkinsonian rats were put through a battery of tests to assess sustained attention, flexible attention and working memory. In the attention set-shifting task, treatment with SK609 normalized performance of PD rats, which previously showed significant impairments in simple and reversal discriminations relative to naïve animals. By contrast, in a cross maze task of working memory, animals treated with SK609 displayed impaired performance relative to naïve controls, a result consistent with the reported actions of other dopamine receptor agonists. While these outcomes suggest some potential therapeutic value for SK609 in treating Parkinson's cognitive deficits, they also indicate that dopamine's involvement in executive functions is task-dependent. Furthermore, our finding that SK609 selectively modulates sustained and flexible attention tasks suggests that different catecholaminergic pathways could be mediating these cognitive tasks.

Title: Chronic pramipexole treatment influences motor and impulse control in a rat model of Parkinson's disease

Authors: *S. TEDFORD[1], N. A. HOLTZ[1], S. A. GRASSO[1], A. L. PERSONS[1], T. C. NAPIER[1,2];
[1]Dept. of Pharm., and Ctr. for Compulsive Behavior and Addiction, [2]Dept. of Psychiatry, Rush Univ., Chicago, IL

Abstract: Pramipexole (PPX) is a dopamine agonist commonly used to treat motor disturbances observed in Parkinson's disease (PD). Subsets of treated patients develop impulse control disorders (ICDs), e.g., problem gambling. In hopes of providing more stable motor benefits, PPX has been prepared as an extended release formulation. The consequence of this formulation on ICD propensity is currently being studied. To advance this effort, we determined the effects of chronic PPX administration on motor function and risk-taking in a rat model of PD and ICDs. Rats with 6-OHDA-induced lesions of the dorsolateral striatum (to model PD) were implanted with stimulating electrodes in the lateral hypothalamus. This allows for an intracranial self-stimulation-mediated probability discounting task as measure of risk-taking to indicate ICDs. We used subcutaneously implanted osmotic minipumps to continuously release PPX for 14 days. Discounting task outcomes were compared to the ability of PPX to improve lesioned-induced deficits in forelimb stepping adjustments, a task that emulates PD-like postural instability. We reveal that within 24hr of pump insertion, motor deficits were fully reversed by 0.3, 0.6 and 1.2mg/kg/day PPX. These improvements occurred in all lesioned rats and were stable throughout the 14 day experimental timeframe. In contrast, discounting was not altered until several days of PPX exposure, and significance occurred only at the 1.2mg/kg/day dose. A subset of rats showed decreased discounting (i.e., increased risk-taking) at all doses tested. These results reveal the utility of a novel model of PD with ICDs wherein, like treated human PD patients, a subset of rats showed risk-taking behavior. These findings demonstrate the differential influence of PPX on motor benefits and ICD development.

Title: Rodent models of delirium and encephalopathy: Behavioral and neurophysiological studies in aging

Authors: *E. Y. KIMCHI[1,3], B. F. COUGHLIN[2], S. S. CASH[2,3];
[1]Dept. of Neurol., [2]Neurol., Massachusetts Gen. Hosp., Boston, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Delirium is an acute disturbance of attention and awareness commonly seen in elderly patients. Delirium heralds the possibilities of not only sustained brain dysfunction but also dependence and death. Epidemiologic studies have suggested that the most prominent predisposing risk factors for delirium are aging and dementia and that common precipitating risk factors include anticholinergic medications, inflammation, and anesthesia. We are developing animal models of delirium by studying the responses of aged (22-26 months) vs. young (3-6 months) rats to specific risk factors in order to determine the causal significance of each risk factor. We have developed a translational, rodent version of the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) scale, used to assess delirium in patients unable to give a verbal response (such as intubated patients). We evaluate delirium phenotypes using simultaneous measurements of electrophysiology, discrimination behavior, and locomotor activity. Both scopolamine and lipopolysaccharide (LPS) injections cause EEG changes consistent with slowing seen in clinical delirium: increased power at lower frequencies and decreased power at higher frequencies (n=18 scopolamine, n=10 LPS). Both scopolamine and LPS injections also cause decreased discrimination accuracy on a flexible Go/Nogo auditory discrimination, consistent with impaired attention. Scopolamine increases locomotor activity consistent with a hyperactive delirium phenotype, whereas LPS decreases locomotor activity, consistent with a hypoactive delirium phenotype. Our results demonstrate that aged rodents display the expected core translational features of delirium, providing evidence that animal models are likely to generate testable, clinically relevant hypotheses about the pathophysiology of delirium.

Title: Voluntary physical exercise improves the subsequent motor and cognitive impairments in Parkinson's disease model of rats

Authors: ***S.-C. HSUEH**[1,2], T.-H. HSIEH[3,2], J.-H. LAI[2], K.-Y. CHEN[2], Y.-W. YU[2], Y.-C. CHAN[2], C.-H. LI[2], Y.-H. CHIANG[2,4];

Abstract: Parkinson's disease (PD) is typically characterized by the impairments of motor function. Gait disturbances similar to those of human PD can be observed in animals after injection of neurotoxin 6-hydroxydopamine (6-OHDA) to induce unilateral nigrostriatal dopamine depletion. Exercise has been shown to be a promising non-pharmacological approach to reduce the risk of neurodegeneration disease. In this study, we investigated the long-term effects of voluntary running wheel exercise on gait phenotypes, rotational behavior as well as histology in a 6-OHDA-lesioned rat model of PD. In results, we observed that five weeks voluntary exercise alleviates and postponed the 6-OHDA induced gait deficits, as compared to non-exercise controls, including a significantly improved walking speed, step/stride length, base of support and print length. However, the rotational behavior and tyrosine hydroxylase (TH)-positive neurons in the substantia nigra in exercise group did not show significant differences when compared with non-exercise group. In conclusion, we first analyzed the detailed changes of gait pattern to investigate the potential benefits after long-term exercise in the rat model of PD, which could be useful for future objective investigation of locomotor function in PD or other neurological animal models. Also, these results suggest that long-term voluntary exercise reduces the aggravation of motor symptom but not exerts neuroprotection in PD rats model, which might be might be relevant for the development of potential treatment protocols for functional recovery in PD.

Title: High midbrain D3 receptor availability is related to inflexible decision-making processes in rats

Authors: *S. M. GROMAN[1], N. J. SMITH[1], J. R. PETRULLI[2], L. CHEN[1], B. MASSI[3], D. LEE[4], E. D. MORRIS[2], J. R. TAYLOR[1];
[1]Psychiatry, [2]Biomed. Engin., [3]Interdepartmental Neurosci. Program, [4]Neurobio., Yale Univ., New Haven, CT

Abstract: Decision-making processes are impaired in individuals with psychiatric disorders, such as addiction and schizophrenia. Converging evidence indicates that dysfunction of the dopamine D2/3 receptor underlies the inflexible, impulsive decisions that are observed in individuals with psychiatric disorders. However, it is unclear whether these behavioral effects are due to disruptions in the D2, the D3 or both receptor systems. To address this question, flexible decision-making processes were assessed in rats using a three-choice spatial discrimination and reversal task and compared to PET measurements of D3 receptor availability. Thirteen adult, male rats were trained to acquire and reverse three-choice spatial discrimination problems that were probabilistically reinforced (PRL). Choice behavior of rats was characterized using previously validated computational models to estimate learning rates and outcome sensitivity for each individual rat. PET scans, using the radioligand [11C](+)PHNO, were collected in the same rats to quantify D2/3 receptor availability in the dorsal striatum and midbrain and related to the behavioral performance of rats in the PRL task. [11C](+)PHNO binding potential in the midbrain, an area rich in D3 receptors, was related to the performance of rats in the reversal, but not the acquisition, phase of the PRL. Rats with greater midbrain [11C](+)PHNO binding potential (BPND) had more difficulty reversing a spatial discrimination and made more perseverative responses than rats with less [11C](+)PHNO BPND. Furthermore, midbrain [11C](+)PHNO BPND was inversely related to the learning rate and the sensitivity of rats to positive, but not negative, outcomes following a reversal. These data demonstrate a new role for midbrain D3 receptors in select aspects of reinforcement learning and suggest that individual variation in D3 receptors regulates flexible behavior. These results add to a growing body of work suggesting that midbrain D3 receptor abnormality may underlie the behavioral problems

observed in psychiatric disorders and implicate the D3 receptor as a target for the treatment of disorders that are associated with decision-making impairments.

Title: Response of medial prefrontal cortex to cues for behavioral restraint

Authors: *K. MANSON[1], J. D. ROITMAN[2];
[1]Psychology, [2]Univ. of Illinois At Chicago, Chicago, IL

Abstract: Environmental cues associated with rewards often prompt approach and consummatory actions that are difficult to override, even when restraint may lead to beneficial outcomes in the short- or long-term. The medial prefrontal cortex (mPFC) has been implicated in directing reward/value-based choices and dysfunction of the PFC has been extensively associated with impulsive actions. Control of goal-directed behavior may be executed through mPFC connections with the nucleus accumbens (NAc), which integrates information about environmental cues and rewards to influence motor behaviors via basal ganglia circuitry. The role of excitatory neural activity within PFC to engage inhibitory processes over approach behavior is still unclear. Recently, Roitman and Loriaux (2014) found greater increases in NAc neuronal firing when animals restrained behavioral action in a symmetric Go/NoGo task in which all correct responses – Go and NoGo – were rewarded. Animals' ability to restrain their approach behavior is substantially reduced when glutamatergic AMPA/kainate, but not NMDA, receptors are pharmacologically blocked in NAc, suggesting that excitatory inputs to the NAc allow the animal to inhibit approach behavior. We hypothesize that mPFC may serve as a source for this excitatory input. In support of this, bilateral inactivation of mPFC activity and disconnection of mPFC communication with NAc caused an increase in NoGo errors in the symmetric Go/NoGo Task (Manson et al. *In Prep*). To examine whether mPFC neuronal responses differentially encode Go and NoGo cues that are both reward-predictive, but require either approach or restraint, we implanted electrode arrays in the mPFC and recorded the activity of multiple single neurons while rats performed the Go/NoGo task. Neurons in mPFC showed transient responses at the onset of cues that were modulated by cue type and behavioral response.

These results support a role for mPFC providing a source of signaling for restraint of behavior in response to environmental cues.

Title: Effects of methylphenidate on prefrontal cortex and decision-making throughout development

Authors: *J. D. ROITMAN[1], E. JACOBS-BRICHFORD[2], M. MCMURRAY[2], C. SHORT[2], L. AMODEO[2];
[1]Psyc, [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: The psychostimulant compound, methylphenidate (MPH) is the most common treatment for ADHD, and is approved for administration to children in the US. At therapeutic doses, MPH treatment has been shown to reduce the severity of the core symptoms in ADHD, including cognitive impulsivity, without increasing an association with subsequent substance abuse. However, due to its wide availability, MPH is also one of the more highly misused and abused drugs in adolescence, in both clinical and general populations. Given that MPH works through the same pathways activated by other drugs of abuse, it is not surprising that the focus of the MPH literature is related to the potential risk of future drug addiction. However, the possible short and long-term effects of MPH on decision-making are not clearly understood. The goal of this research was to examine MPH actions on decision-making during a critical developmental period. Long-Evans rats (non-hyperactive) were injected with MPH (0, 1, 2.5, or 5 mg/kg IP) twice daily throughout late adolescence (PD35-50). During this period, rats performed Magnitude Discrimination and Delay Discounting tasks. In contrast to prior studies in hyperactive rats, we found that treatment with MPH did not decrease naturally impulsive behavior in normal (non-hyperactive) adolescent rats. After discontinuation of MPH, behavioral flexibility and risk-preference were subsequently assessed in adulthood. Behavioral flexibility was assessed using a Reversal Learning task, which revealed that animals previously treated with MPH showed improved acquisition, but no difference in reversal performance. Rats' preference

for probabilistic rewards/tolerance for reward omission was measured using a Risk Task in which they chose between small-certain and large-risky options. In this task, rats treated with MPH in adolescence showed increased risk preference in adulthood. Taken together, the results suggest that adolescent MPH-induced increases in risk-preference were not due to increased perseverative behavior. To determine whether these effects may be due to changes in dopaminergic signaling in prefrontal cortex, we quantified mRNA expression of D1 and D2 receptors in the orbitofrontal cortex (OFC) using qPCR. Results suggest a shift in the balance of D1/D2 receptor expression in the OFC of MPH-exposed rats. Overall these findings suggest that MPH administered during late adolescence can affect cognitive outcomes in adulthood.

Title: Neural markers of cognitive control, and their evolution during a pre-symptomatic monkey model of Parkinson's disease

Authors: *C. R. WILSON[1,2], F. STOLL[1,2], M. C. M. FARAUT[1,2], J. VEZOLI[1,2,3], V. LEVIEL[1,2], E. PROCYK[1,2];

Abstract: Beta oscillations (15-30Hz) are associated with top-down cognitive control, and modulated in Parkinson's disease (PD). We investigated whether frontal beta oscillations are differentially modulated by different parameters contributing to cognitive control, including exploration vs. exploitation, and time on the task, in 2 macaque monkeys. We then used these data as a baseline to characterize the progressive alteration of behavioural and electrophysiological markers under systemic dopaminergic system lesion, using a chronic low dose MPTP treatment in a longitudinal study. This approach contributes fundamental knowledge about the dopamine system in cognitive control, but in addition the detection of alterations in cognition or underlying neurophysiological mechanisms prior to the onset of the motor symptoms in PD constitutes a crucial prerequisite for the development of early diagnostic tools. The monkeys learned the Problem Solving Task by searching (SEA phase) amongst targets to find the target rewarded with juice, and then repeating that choice for several trials (REP phase). Problems were separated by a clear change signal, restarting the search phase. The contrast between SEA and REP phases provides an index of cognitive control. Monkeys were chronically implanted with at least 22 electrodes resting on the dura mater to provide electroencephalographic (ECoG) recordings. During a stable control period, frontal beta power was modulated both by cognitive control demands in the SEA and REP phases of the task, and also by within-session progression towards a final large bonus reward. Importantly, when the monkey spontaneously paused for several minutes during the session, these beta power modulations were reset. Feedback related potentials (FRPs) over medial frontal cortex differentiated the forms of feedback necessary for behavioural adaptation in the task. Monkeys then received a slow low-dose MPTP treatment whilst continuing to provide ECoG recordings and behaviour. Monkeys remained below the threshold for clinically significant motor symptoms throughout. FRPs were significantly modulated by MPTP treatment, to the point that they no longer reflected the contrast between correct and incorrect feedback, but despite this, cognitive performance was unchanged. Beta oscillatory power was maintained overall across treatment, and in contrast to the FRPs, beta power continued to reflect cognitive control. However, the within-session effect on beta power was diminished. Hence a slow dopaminergic lesion has contrasting effects on different neural markers of cognitive control.

Title: Pupillometric readouts of decision making in mice

Authors: *P. J. STEFFAN[1], M. MCGINLEY[2], D. LEE[3], D. MCCORMICK[2];
[1]Yale Sch. of Med. Dept. of Neurobio., [2]Dept. of Neurobio., Yale Univ., New Haven, CT; [3]Dept. of Neurobio., Yale Univ., New, CT

Abstract: Pupillometry has been used extensively for over 50 years as a window into mental states and cognitive processes in human studies of decision making. The development of molecular-genetic tools to study brain circuits in mice has made them an attractive model system to study neural mechanisms of decision making. However, sophisticated behavioral paradigms for mice have been lacking and pupillometric readouts of decision making remain unexplored. We recently developed a psychometric tone-in-noise detection task for head-fixed mice on a cylindrical treadmill and used pupillometry to measure arousal. We found that the pupil diameter immediately before each sound was highly predictive of the speed and accuracy of target detection, largely irrespective of locomotor state (McGinley et al., 2015). Pupillometry in humans is predominantly used to estimate latent cognitive variables (e.g., cognitive load; Beatty, 1982) based on task-evoked pupillary responses, rather than baseline effects. Thus, we have analyzed task-evoked responses in our detection task. We find that pupils dilate differently for hits, misses, and false alarms. Hits aree associated with large (~7% increase; from baseline to peak) and persistent (lasting > several seconds) dilations. Misses have the smallest dilations (~2%) whereas false alarms are associated with intermediate dilations (~5%). Pupil dilations (width at half maximum) for misses and false alarms lasted ~2 seconds. These results show that task-evoked pupillary responses in mice are sensitive to choices and outcomes. To further explore the utility of pupillometry in mouse decision making we have developed a behavioral task in which mice make stay-leave valuation decisions, based on the widely-used 'patch-leaving' task in behavioral ecology (Stephens and Krebs, 1987). Mice initiate and terminate blocks of trials, termed 'patches,' with their locomotor activity on the treadmill. Within a patch, animals lick for sugar reward upon detection of target tones in a background noise stream. The reward volume decreases gradually in a patch and is reset upon entry to a new patch. This head-fixed virtual patch-leaving task may provide a framework to study ethologically-relevant, sophisticated decision making strategies, and their pupillometric readouts, in mice. Title: Cocaine self-administration and incubation of craving exacerbates poor decision-making on a rat gambling task, exposing individual vulnerability to addiction

Authors: *J.-M. N. FERLAND[1], C. A. WINSTANLEY[2];
[1]Djavad Mowafaghian Ctr. for Brain Hlth., [2]Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Maladaptive decision-making is commonly found amongst substance abusers and is thought to play an integral role in the development and maintenance of addiction. Indeed, human studies using the Iowa Gambling Task (IGT), a validated measure of decision-making, have found that substance dependent individuals tend to choose the least advantageous option and are less likely to change their strategy following losses compared to controls. These deficits have been found to worsen following withdrawal. Animal studies using self-administration have found that cocaine use impairs a variety of executive functions including reversal learning and impulse control. However, little preclinical work has examined whether cocaine self-administration or prolonged withdrawal has an impact on cost/benefit decision-making. More critically, no animal models have focused on individual differences in decision-making, which may underlie the likelihood to abuse drugs and relapse. To investigate this relationship, we trained male Long-Evans rats on a cued or uncued Rat Gambling Task (rGT), rodent analogues of the IGT. In brief, animals were allowed to choose between 4 different nosepoke holes of an operant box, each associated with a different sugar pellet reward (1-4 pellets), penalty time out (5-40s), and probability of receiving a reward over a penalty (0.9-0.4). The advantageous options (those resulting in 1 or 2 sugar pellets) are commonly chosen while the disadvantageous options (3 and 4 sugar pellets) are often avoided. The cued version of the rGT utilizes win-paired light and tone cues that intensify in number and variability as the reward won increases, a method which has been found to increase the choice of the disadvantageous options. Following training, rats were implanted with jugular vein catheters and were allowed to self-administer cocaine for 10 days followed by 30 days of withdrawal. Decision-making was simultaneously measured by rGT performance throughout the experiment. Results indicated that a subgroup of animals with a baseline preference for the disadvantageous options in both the cued and uncued versions of the task performed worse (i.e. chose the risky options more) following cocaine self-administration

and withdrawal, took greater amounts of cocaine, and had potentiated levels of responding for drug-paired cues following withdrawal. These data demonstrate that cocaine self-administration intensifies poor decision-making within a vulnerable subgroup, providing a model by which we can begin to investigate the individual susceptibility to abuse drugs and relapse.

Title: Pupillary dynamics reflect behavioral states in head-fixed rats performing whisker direction discrimination tasks

Authors: *B. SCHRIVER, S. BAGDASAROV, Q. WANG;
Columbia Univ., New York, NY

Abstract: The use of pupillometry as a noninvasive means to gauge human behavior state has been well-established. In particular, change in pupil size has been successfully used as a reliable indicator of mental efforts, change in attention allocation, and arousal level in humans. However, little is known about the correlation between pupillary dynamics and behavioral states in awake, behaving rodents. We trained head-fixed rats to perform a whisker direction discrimination task using a Go/No-Go paradigm. The pupil of the rats was simultaneously imaged using a custom made infrared pupillometry system. The dorsal direction was selected as the Go direction (S+) while the ventral direction was the No-Go direction (S-). The rats preferentially responded to S+ at a probability of ~85% while responding to S- with a probability of only ~25%. The rejection rate of S- stimuli was dependent on their angular velocities. The higher the velocity, the less likely the animal rejected S- Stimuli. For S+ stimuli the response time decreased with increasing velocity. Pupillometry data showed that the pupil of the rats dilated for all behavior outcomes, i.e. Hit, Correct Rejection, False Alarm, and Miss. However, the pupil dilated approximately 3 times larger for Hit trials than for False Alarm or Miss trials. Furthermore, the baseline pupil size is tightly correlated with the behavioral performance. Specifically, the False Alarm trials had the largest baseline pupil size while the Miss trials had the smallest baseline pupil size. The baseline pupil sizes for both the Hit and Correct Rejection trials were around average. More interestingly, the pupillometry data, when aligned with stimulus onset for the miss trials, showed that the pupil began to dilate prior to the window of opportunity closing. This suggests that the pupil dilation is

not due to motor output. Our preliminary data also demonstrated that the pupil dynamics are dependent on the behavioral outcome of previous trials. Taken together, our data suggest that, similar to human subjects, pupillary dynamics in awake behaving rats are a reliable indicator of their behavior state.

Title: Assessing cognitive flexibility in the social home-cage

Authors: *T. J. BURTON[1,2], A. SAWATARI[2];
[1]Bosch Inst., [2]Phsyiology, The Univ. of Sydney, Sydney, Australia

Abstract: "Cognitive Flexibility" is an Executive Function that allows an organism to inhibit previously learned strategies or rules that are no longer currently relevant so that new and appropriate patterns of behaviour can be developed and applied. This process of adapting to changes in the environment is compromised in patients with neuropsychiatric disorders such as schizophrenia and Alzheimer's disease. Much is still unknown about the mechanisms that control complex and integrative higher order functions in the brain. Traditionally, assays of cognitive flexibility in the rodent have been conducted in the cross maze, where rats can be trained to use egocentric response strategies, allocentric spatial strategies or visual cues to guide choice behaviour. While much has been learned about the neural circuitry underlying executive function using this approach, these paradigms are labour intensive, require regular operator-animal interaction and necessitate animals to be removed from their home cage and social setting. These latter two features can be sources of unwanted stress and anxiety which may interfere with normal behaviour. Developing more naturalistic and species-relevant behavioural tasks is essential for improving our understanding of intact and disordered neural systems. Using the IntelliCage system for mice, we have developed a novel and fully automated method for investigating cognitive flexibility in the home cage - a more naturalistic social setting for this species than a cross maze or operant box. Mice were required to learn one of two tasks (either a Visual cue-Dependent [VD] task or a Response-Dependent [RD] task) before the task contingencies were changed (either an Extradimensional Shift [EDS; between-task switch] or a Rule Reversal [RR; within-task change]). Robust learning was observed in both the VD and RD

tasks. However, the RD task was acquired more rapidly than the VD task. A significant reduction in performance was observed for all animals immediately after the task contingencies were changed. Moreover, these particular results were remarkably consistent with theoretical expected performances after such task changes. This automated approach also allowed for a detailed examination of the evolution of choice behaviour during all phases of learning and adaptation to contingency changes. We show that the IntelliCage is a promising tool for developing reliable and species-relevant assays of specific cognitive functions in mice.

Title: ΔFosB regulation of hippocampal physiology and learning

Authors: *A. L. EAGLE[1], P. A. GAJEWSKI[2], M. YANG[1], P. J. KENNEDY[3], H. WANG[1], A. J. ROBISON[1];
[1]Dept. of Physiol., [2]Genet. Program, Michigan State Univ., East Lansing, MI; [3]Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: The hippocampus (HPC) is essential for memory consolidation, a process dependent on synaptic plasticity and gene expression in HPC neurons. However, the transcriptional machinery underlying HPC-dependent learning has yet to be wholly delineated. The transcription factor ΔFosB is induced throughout the brain by chronic exposure to drugs or stress and regulates synaptic plasticity in the nucleus accumbens (NAc), suggesting it drives activity-dependent gene expression, but the role of HPC ΔFosB in plasticity and learning is currently unknown. Here, we find that ΔFosB is induced in HPC by spatial learning, suggesting it may be important for transcription-dependent changes in HPC synaptic plasticity associated with learning. We used viral tools to demonstrate that HPC-targeted ΔFosB inhibition in mice impairs

HPC-dependent learning and memory. Interestingly, HPC ΔFosB viral overexpression also impairs HPC-dependent learning and memory. We also demonstrate here that ΔFosB overexpression increases immature dendritic spines on HPC CA1 pyramidal cells. Ongoing studies are currently investigating the role of ΔFosB in synaptic and cellular physiology, as well as downstream gene targets of ΔFosB. These findings suggest that endogenous ΔFosB is crucial for normal HPC function and that cell-specific ΔFosB expression is required for memory formation, while general overexpression introduces noise that prevents establishment of a memory trace. Finally, these data support the hypothesis that ΔFosB exerts its behavioral effects through modulation of HPC synapses, and ongoing studies will address this hypothesis directly.

Title: Epigenetic regulation of the FosB gene in hippocampus

Authors: ***P. A. GAJEWSKI**[1], A. L. EAGLE[2], E. A. HELLER[3], I. MAZE[4], A. J. ROBISON[2]; [1]Genet., [2]Physiol., Michigan State Univ., East Lansing, MI; [3]Neurosci., [4]Pharmacol., Mount Sinai Sch. of Med., New York, NY

Abstract: Elucidation of the molecular mechanisms of memory formation is critical for the development of a cohesive theory of memory. However, the patterns of gene regulation that occur during learning remain unknown. Consolidation of explicit memories occurs through synaptic plasticity in the hippocampus, and some of the molecular mechanisms of this process are well characterized, but epigenetic regulation underlying changes in hippocampal gene expression and the distribution of gene expression through the hippocampus is poorly understood. The transcription factor DeltaFosB is an important arbitrator of activity-dependent gene expression in nucleus accumbens (NAc) underlying maladaptive changes in reward processing. Previous studies demonstrate that drugs of abuse and stress also upregulate DeltaFosB in hippocampus, but its role in this brain region is uncharacterized. Here, we demonstrate for the first time that DeltaFosB is upregulated in the dorsal hippocampus in

response to novel environment exposure, spatial learning, and cocaine exposure, and we are currently determining whether the expression pattern of DeltaFosB differs throughout hippocampal subregions. Furthermore, we use chromatin immunoprecipitation to demonstrate that dimethylation of lysine 9 at histone H3, a repressive histone modification, is decreased at the FosB gene promoter in hippocampus after exposure to either cocaine or a novel environment. Studies are ongoing to examine the effects of learning and drug exposure on other histone modifications, such as acetylation of lysine 9, as well as global levels of histone modifications in hippocampus. Furthermore, experiments using viral-mediated gene expression are ongoing to investigate the relationship between these histone modifications and DeltaFosB expression and learning behavior. These findings collectively suggest that specific salient stimuli, such as spatial learning or drug exposure, induce epigenetic changes in the hippocampal FosB gene promoter that regulate DeltaFosB induction, which in turn may control the transcription of genes that underlie hippocampal cell function, plasticity, and learning.

Title: Hippocampal Arc protein expression in male C57BL/6J mice is exploration dependent in the novel object recognition task

Authors: *D. A. CINALLI, JR[1], S. J. COHEN[2], R. W. STACKMAN, Jr.[2];
[1]Florida Atlantic Univ., Jupiter, FL; [2]Florida Atlantic Univ., Boca Raton, FL

Abstract: Transcription and translation of proteins are required for the consolidation of episodic memory. Arc, an effector immediate early gene, has been linked to synaptic plasticity which occurs following learning and memory. It is well established that the rodent hippocampus is essential for processing spatial memory, but its role in processing object memory is a point of contention. This study seeks to elucidate hippocampal processing of object memory using the Novel Object Recognition (NOR) task. Using immunohistochemical techniques, we stained for arc proteins in pyramidal neurons in the CA1 region of the dorsal hippocampus in C57BL/6J

mice following two variations of the NOR task. Mice were placed into a familiar high-walled square enclosure that contained two novel 3D objects during the sample session. During the test session 24 h later, one of the objects was replaced with a novel object. Results of arc-positive neuron counts suggest that in mice that accumulated 30s of exploration of each object during the sample session, a substantial hippocampal ensemble was activated. In contrast, in mice that accumulated only 10s of exploration on each object during the sample session, hippocampal activation was not significantly different from controls that were not exposed to any objects. Arc expression was also examined in neurons of other hippocampal subregions, as well as in medial temporal lobe cortical regions such as the perirhinal cortex. Taken together, these results suggest that the mice must acquire a threshold amount of object information during the sample session before the hippocampal CA1 region is engaged in object memory processing. These data support that the view that the rodent hippocampus processes object memory.

Title: Involvement of hippocampal diaschisis in mediating stroke-induced hippocampal hypofunction and memory deficits

Authors: ***G. RABILLER**[1], Y. NISHIJIMA[2], J.-W. HE[2], X. LEINEKUGEL[1], V. ANDJELKOVIC[1], A. HAMBUCKEN[1], B. BONTEMPI[1], J. LIU[2];

Abstract: The cognitive consequences and the underlying mechanisms leading to cognitive impairments after cerebrovascular occlusive diseases are still unclear. In addition to the infarct zone that suffer the deadly consequence of ischemic stroke, the penumbra surrounding the lesion site and some brain regions remote to the ischemic areas can be functionally affected by the insult. This phenomenon is referred to as diaschisis. In light of the importance of interactions between hippocampus and cortex during memory processing, we hypothesized that the cognitive impairments observed following ischemic stroke could occur in the absence of direct

hippocampal insult, possibly via impaired connectivity within cortico-hippocampal networks leading to diaschisis-induced hypofunctioning in specific hippocampal subregions. To test this possibility, we used the distal middle cerebral artery occlusion (dMCAO) in rats which induces restricted cortical infarct in the somatosensory (SS) cortex in the absence of direct hippocampal injury. dMCAO rats exhibited reduced expression of the activity-dependent gene c-fos in the hippocampus when exploring a novel environment, indicating neuronal hypoactivation. Some of these rats also exhibited impaired associative olfactory memory when tested in the social transmission of food preference (STFP) task. To confirm that the ischemic-induced hippocampal hypofunctioning resulted from reduced afferent inputs (i.e. deactivation) originating in the damaged cortex, we performed region-specific pharmacological inactivation of SS and entorhinal cortices using the sodium channel blocker lidocaine or the AMPA receptor antagonist CNQX. Fos imaging revealed that these treatments induced hippocampal hypoactivation and impaired memory performance as measured in the STFP task. We additionally recorded hippocampal activity in anesthetized rats during acute stroke or after SS cortex inactivation and found an increase in the occurrence of ripples during reperfusion after stroke and a shift of the theta phase between the hippocampus and cortex, suggesting alteration in the dynamics of hippocampal-cortical interactions. Taken collectively, these findings identify hippocampal diaschisis as a crucial mechanism for mediating stroke-induced hippocampal hypofunction and associated memory deficits.

Title: The design and application of a flexible parylene-based multi-electrode array for *in vivo* recording from the rat hippocampus

Authors: ***H. XU**, M.-C. HSIAO, D. SONG, T. W. BERGER;
USC, Los Angeles, CA

Abstract: The hippocampus is a deep brain structure critical for the formation of new long-term declarative memories. Hippocampal malfunctions can be caused by various diseases and pathological conditions. The hippocampus is anatomically composed of three main sub-regions, i.e., dentate gyrus, CA3 and CA1. Lesion studies have indicated that damages to different sub-regions of the dorsal hippocampus of rats can result in distinct impairments in detecting spatial novelty. Because of the regular intrinsic connections within the hippocampus and the highly structured anatomical organization of the hippocampus sub-regions, it has become a model structure for the studies of cognitive functions in particular and various forms of synaptic plasticity in general. Understanding how the hippocampus is involved in declarative memory and studying its neural plasticity require simultaneous recordings of neural activities from multiple sub-regions of the hippocampus in behaving animals. Parylene C is a highly biocompatible and flexible polymer. Based on histological results from brain slices and neural activities recorded from behaving animals, we have designed a multi-shank electrode which uses Parylene C as base and has multiple recording sites specifically positioned along the longitudinal axis to conform to the curvy shape of the rat hippocampus. This Parylene probe can be implanted into the rat hippocampus for multi-site chronic recordings of unitary activities. Spike trains from multiple sub-regions of the hippocampus will be recorded and examined under complex behavioral conditions. Responses of single cell activities to the manipulation of spatial cues as well as neural functional connectivities will be investigated to identify the roles of hippocampus sub-regions in spatial information processing.

Title: Consequences of altered dendritic arborization in hippocampal networks -linking molecular signaling and neuronal morphology

Authors: J. MAURER[1], D. MAUCERI[2], H. BADING[2], A. DRAGUHN[1], *M. BOTH[1];
[2]Dept. of Neurobio., [1]Heidelberg Univ., Heidelberg, Germany

Abstract: Dendrites of neurons receive multiple synaptic inputs and transmit information to the soma. Thus, they provide powerful options for active modulation and integration of signals arriving at different dendritic segments. The morphology of dendrites plays a crucial role in this context. Here, we investigate alterations of information processing due to dendritic arborization changes in mouse hippocampal CA1 pyramidal cells. Previous findings showed that the vascular endothelial growth factor D (VEGFD) is involved in the maintenance of dendritic arborization. After downregulation of VEGFD in hippocampal neurons, a reduction in the length and the complexity of basal dendrites was observed (Mauceri et al., 2011)1. We have studied the role of VEGFD for arborization and synaptic input to basal and apical dendrites of CA1 pyramidal neurons. Following suppression of the growth factor, we performed 3D reconstructions of apical and basal dendritic trees (covering stratum oriens, stratum radiatum and stratum lacunosum-moleculare). In line with the former findings, basal dendrites became shorter and less complex. Surprisingly, we found no hint for similar changes in apical dendrites. Preliminary data do even indicate increased dendritic arborization in stratum lacunosum-moleculare. Passive membrane properties and action potential firing were unchanged. In summary, these findings indicate a shift in the balance of synaptic inputs to CA1 pyramidal cells following downregulation of VEGFD. Regulation of dendritic morphology by VEGFD follows different mechanisms in apical and basal dendrites, suggesting specific effects of this growth factor on input integration in the hippocampal network. ___ 1 Mauceri D, Freitag HE, Oliveira AM, Bengtson CP, Bading H (2011) Nuclear calcium-VEGFD signaling controls maintenance of dendrite arborization necessary for memory formation. Abstract: The balance between excitation and inhibition in the brain is highly dependent on the functional integrity of gamma-amino-butyric acid (GABA)-releasing interneurons. Though these cells represent only ~ 20% of all neurons in the CNS, they exert a powerful activity in the brain by synchronizing principal neuron output. Studies indicate that aberrant function of GABAergic interneurons especially parvalbumin (PV) interneurons is strongly associated with cognitive deficits in psychiatric disorders. However, the mechanisms leading to GABAergic interneurons dysfunction in the brain disease context are not yet completely understood. Here, we show that fibroblast growth factor 14 (FGF14), a component of the voltage-gated Na+ channel complex and a regulator of the presynaptic neurotransmitter release machinery, plays a critical role in regulating structure and function of GABAergic interneurons. In Fgf14-/- animals we found that the total number of PV interneurons in the CA1 hippocampal region is reduced significantly and that these changes are associated with a reduction in the expression of synaptic GABAergic markers. These phenotypes coincide with alterations in the CA1 inhibitory tone, reduction of *in vivo* gamma frequency oscillations and working memory deficits. Bioinformatics analysis of schizophrenia transcriptomics reveals functional co-clustering of FGF14 and genes enriched within the GABAergic pathway along with correlative reduced expression of FGF14, glutamic acid decarboxylase 67 (GAD67) vesicular GABA transporter (VGAT) in the disease context. This study highlights a new potential role of FGF14 in regulating the excitation/inhibition tone in the filling knowledge gaps in mechanisms underlying cognitive dysfunction in neuropsychiatric disorders.

Title: Hippocampal and perirhinal cortex BOLD responses to familiar and novel odors in awake rats: just a start..

Authors: *C. CHWIESKO[1], B. BOULAT[1], D. WIEDERMANN[2], M. HOEHN[2], M. SAUVAGE[1];
[1]Ruhr-Universität Bochum, Bochum, Germany; [2]Max-Planck- Inst. for neurological research, Cologne, Germany

Abstract: The specific nature of information processing in the hippocampus and the perirhinal cortex, and thus the precise mechanisms by which these structures support cognitive processes like memory is still not well understood. In humans, these questions are most often addressed using functional magnetic resonance imaging (fMRI). This technique has only rarely been used in awake animals, never in the medial temporal lobe in relation to memory function, principally because of the major technical challenges it encompasses. Indeed, animal studies often adopt more invasive approaches, which offer striking advantages on the one hand, but also render results less readily comparable between species. Therefore, investigating memory with fMRI in awake animals and combining it with the advantageous invasive techniques, would address the comparability problem and offer a great potential for the research of hippocampal function in memory. For this reason, we aimed at developing a translational human to animal fMRI compatible cognitive task by adapting a Memory paradigm to awake rats, which requires the recognition of familiar and novel odors. This involved an extensive habituation of the animals as well as the development of new hardware such as a 40 odor- olfactometer, a head fixation system and a new scanning bed, Prior to the experiment, rats underwent a surgery for head fixation and

were thoroughly habituated to the fMRI experimental condition in order to minimize stress levels and maximize attention to the stimuli. During the experiment, a set of familiar and novel odors was presented in a block design to awake rats while hippocampal and perirhinal cortex activity was measured with fMRI. We found for the first time BOLD signals in the rat hippocampus and perirhinal cortex in relation to a fMRI cognitive paradigm in awake rats. The rat hippocampus showed a greater BOLD effect for the familiar odors in contrast to the novel odors, the perirhinal cortex showed the reverse pattern, a greater BOLD effect for the novel odors. The results match well human reports using a similar design. In conclusion, we have successfully adapted a fMRI cognitive paradigm to awake rats, which allows us now to adopt a translational approach with the aim of contributing to solve major debates in memory research by using a combination of fMRI and invasive approaches in awake rats.

Title: Spatiotemporal synaptic input pattern sensitivity of persistent firing in hippocampal CA1 neuron model

Authors: *K. TAKADA[1], K. TATENO[2];
[1]Dept. of Life Sci. and Systems Engin., [2]Dept. of Human Intelligence Systems, Kyushu Inst. of Technol., Kitakyushu, Japan

Abstract: The hippocampus is considered that is basis of construction of the episodic memory. In addition, in a manner that supports the hypothesis, place cells and time cells have been discovered in the hippocampus, the cells that express the space or time. In the receptive field, place cells and time cells show persistent activity. Hippocampal CA1 region is one of the main target of experimental study of place cells and time cells. However, it is difficult to maintain the persistent activity in the network-based in the CA1 region, because of poor recurrent connections. On the other hand, intrinsic persistent firing under cholinergic activation has been discovered in hippocampus. Intrinsic persistent firing potentially supports the activity of place cells and time cells. *In vitro*, intrinsic persistent firing is caused by the perfusion of acetylcholine agonist carbachol and the brief current injection. If the activity of place cells and time cells are

based on intrinsic persistent firing, these need appropriate spatiotemporal pattern of activity of CA3 region that depolarizes CA1 pyramidal cells. In our study, using a network model of hippocampal CA1 and CA3 region, we investigated the spatiotemporal activity patterns of the CA3 network model that leads to the intrinsic persistent firing in the CA1 network model. The present CA1 network model consisted of 100 conductance based pyramidal neuron models and 100 inhibitory interneuron models. The pyramidal neuron model had the calcium-activated non-selective cationic current which is known to underlie intrinsic persistent firing. The stimulation pattern to the CA1 pyramidal neuron models was generated by a Markov chain model. To quantify the input pattern to CA1 pyramidal cells, we used the coefficient of variation (CV) and the local variation (LV) of interspike intervals. In our results, occurrence of intrinsic persistent firing in the CA1 network model was strongly dependent on the LV of input patterns and its duration strongly depended on the CV. Under the low LV condition, spatial coherence of synaptic input to CA1 pyramidal cell models was relatively high. Consequently, intrinsic persistent firing was frequently triggered. In addition, an asymmetric spike timing dependent plasticity rule for the Schaffer collateral synapses reduced the duration of the persistent firing. Our results indicate that, under the poor recurrent connections, the persistent firing of CA1 pyramidal cells are induced by spatially coherent synaptic input generated by the CA3 region. The spatiotemporal activity patterns of the CA3 region may adjust a condition for appearance of place and time cells in the CA1 region.

Abstract: We previously demonstrated that rats that receive dorsal third ventricle (3V) streptozotocin (STZ) injec- tions (STZ-3V-rats) exhibit cognitive decline as measured by the Morris Water Maze (MWM) and can be used as an animal model of Alzheimer's disease (AD). Immunohistochemical studies of the hippocampal formations of these animals have revealed significant changes in cerebral insulin signalling pathways, as well as marked increases of amyloid beta (Ab) deposition. Here, we performed Sholl analyses of granule cell layer dendrites and measured dendrite spine densities to assess the effect of STZ on hippocampal morphology. In STZ-3V rats as the results, more branching, complex dendrite arborisation, and increased soma size of the granule cells were observed, while spine densities were decreased in all three spine types. An intraventricular injection of a long-acting insulin analogue improved STZ-induced behavioural and immunohistochemical changes. Nevertheless, dendrite spine densities remained diminished, pre- sumably due to overall null changes since new spine formation due to insulin stimulation has been compensated by loss of old spines. It is concluded that cognitive decline in the "Brain Diabetes" rats is primarily due to impaired intracerebral insulin signalling and the ultimate results were injured excitatory inputs through the perforant pathway.

Title: Tau-dependent loss of cell cycle repressors in a mouse model of Alzheimer's disease

Authors: *S. IPPATI;
UNSW, Unsw Sydney, Australia

Abstract: Recent studies reported that a high amount of neurons located in brain regions at risk in Alzheimer's disease, ectopically express proteins related to the cell cycle and proliferation. The re-activation of this process that is normally arrested in mature neurons has been linked to the presence of amyloid-β (Aβ), and the phosphorylation of specific sites of tau. Despite this, the molecular mechanisms that lead to this aberrant cellular process remain poorly understood, and it has not been clarified whether they play a role in the neuronal loss, which characterizes the disease. In the present study, we analyze the elements possibly involved in this molecular process in a transgenic model of Alzheimer's disease. Furthermore, we investigate the direct

effect of Aβ and the involvement of tau on primary hippocampal neurons of mice in the re-activation of the cell cycle. We found that Aβ expression in mice is associated with expression of several cell cycle proteins in neurons surrounding plaques, but more importantly already in the brains of mice before the onset of an overt Aβ pathology. The occurrence of these changes coincides with the onset of memory deficits. Mechanistically, we found that the expression of cell cycle repressors, p27 and p21, was markedly reduced in the brains of APP transgenic mice. This was absent in APP transgenic mice that lack tau expression. Therefore, Aβ may induce cell cycle reentry in neurons by reducing expression of cell cycle repressors in a tau-dependent manner.

Title: Neuroprotective effects of placenta-derived mesenchymal stem cell for rat model of dementia

Authors: *J. LEE[1], D. JEONG[1], W. CHANG[2], J. CHANG[1,2];
[1]Dept. of Neurosurg, Brain Korea 21 Plus Project Me, Seodaemun-gu,Seoul, Korea, Republic of;
[2]Dept. of Neurosurgery, Yonsei Univ. Col. of Med., Seodaemun-gu,Seoul, Korea, Republic of

Abstract: Introductions The neuroprotective effects of mesenchymal stem cell (MSC) in neurodegenerative disease have been recently reported. In contrast of the transplantation effect of MSC derived from bone marrow, adipose tissue and human umbilical cord blood, the study of placenta-derived mesenchymal stem cell (pMSC) is still little known. In this study, we studied the effective method of placenta-derived mesenchymal stem cell (pMSC) transplantation by comparing intracerebroventrical (icv) with intravenous (iv) injection. In addition, we also tried to compare the effect of pMSC transplantation and standard treatment for dementia. Materials and Methods We used the rat model of dementia by damaging basal forebrain cholinergic neurons

using 192 IgG-saporin. 1 week after administration of 192 IgG-saporin, pMSC was injected via intraventricular route (icv, 1.2 x 106cells/8μl) or intravenous route (iv, 5 x 106cells/200μl). And Cyclosporine (immunosuppressant drug) were administrated at peritoneal cavity for preventing immune reaction by innate immunity (daily / 5 weeks). To compare the effect of stem cell therapy and standard therapy, some rats were treated with donepezil and 5 weeks after transplantation, all animals were tested visuo-spatial cognitive functions by Morris water maze. Results The probe test of water maze, performance of pMSC transplantation group and donepezil group increased time spent in target quadrant and in platform zone. Also acetylcholinesterase(AChE) activity was increased in the hippocampus and medial prefrontal cortex(mPFC). Interestingly, iv group showed more improved behavior performance and acetylcholinesterase(AChE) activity than icv group. Immunohistochemistry of stem121 marker of stem cell and iba1 maker of microglia and Western blot of DCX and BDNF were also suggested the beneficial effect of both stem cell therapy and standard donepezil treatment. Conclusions Our result show that pMSC recover spatial memory of dementia model by increasing acetylcholinesterase(AChE) activity. Intravenous injection of pMSC seemed to be more beneficial route for both risk managing and symptom improvement. And pMSC transplantation also showed similar efficacy of the donepezil for improving cognitive function. For determining the superiority of both treatment, further investigation should be needed. Title: Neuronal responses to conspecifics and social facial touch in the ventral hippocampus

Authors: *R. P. RAO, M. BRECHT;
Humboldt Univ. of Berlin, Berlin, Germany

Abstract: Animals exhibit a range of social interactions (dominance hierarchies, mating and parental behaviours) that rely on their ability to recognize conspecifics. The hippocampus has been demonstrated to be involved in the higher order representation of social signals in humans (Quian Quiroga et al, 2012) and monkeys (Sliwa et al, 2014). However in rodents, the dorsal hippocampus was only weakly modulated by the presence of other rats (von Heimendahl et al, 2012; Zynyuk et al, 2012). This lack of modulation in the dorsal hippocampus could possibly be explained due to the functional segmentation of the hippocampus with the primate anterior hippocampus corresponding to the rodent ventral hippocampus (Moser & Moser, 1998). In our study, we investigate the representation of social signals in the rat ventral hippocampus using a combination of low- and high-speed videography, extracellular neuronal data acquisition and ultrasound recordings. Firing patterns of putative single units were analysed specifically during facial interactions (associated with whisker-to-whisker contacts) in awake, behaving rats while freely interacting with a conspecific across a gap. Social modulation was observed in many ventral hippocampus CA1 stratum pyramidale units (>85%). A large fraction of these (80%) were strongly modulated, with most showing inhibition while a few showed excitatory responses. While some cells responded directly to facial contact, we also observed cells that showed long term modulation of firing that is contingent on the presence of the conspecific. Some cells show individual- and sex-specific responses, and we are currently investigating these aspects of the responses. In summary, the responses in ventral hippocampus appear to be very different from the dorsal hippocampus and also distinct from sensory cortices where firing is seen upon contact (Bobrov et al, 2014). The large fraction of strongly socially modulated neurons implicates the ventral hippocampus in social information processing.

Title: Neurodevelopmental insult by neonatal ventral hippocampal lesion alters periodic activity of dorsal hippocampal neurons in adult rats

Authors: *H.-Y. KAO, A. A. FENTON;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Neonatal ventral hippocampal lesion (NVHL) is a neural excitotoxic lesion that disrupts neurodevelopment. NVHL rats have cognitive deficits and weak hippocampal synchrony of theta and beta oscillations between the two dorsal hippocampi (Lee et al., 2012). Both cognitive ability and the weak synchrony were normalized after NVHL rats received early cognitive training. These observations motivated us to investigate whether NVHL rats have abnormal hippocampal neuronal discharge properties that could be normalized with early cognitive training. Long-Evans male pups were infused with ibotenic acid (NVHL) or ACSF (control) at postnatal day 7. Adult rats were either naïve (control, n = 8; NVHL, n = 8) or tested in the two-frame active place avoidance task (control, n = 6; NVHL, n =3) at postnatal days 56-60. On postnatal days 60-70, spontaneous single unit discharge was recorded from the dorsal hippocampus for 60 min under urethane anesthesia. In some cases, we recorded bilaterally from the hippocampus (control, n = 18; NVHL, n = 16 hippocampus recordings). We first compared the population activity of NVHL and control rats. The spectral power analysis of spiking activity at frequencies from 0 to 12 cycles/hour was calculated. Peaks of activity at any frequency that were greater than two standard deviations from average activity at all frequencies were considered periodic. Six of 16 NVHL, and 3 of 18 control recordings showed periodic spiking activity. Periodicity ranged from 4-5 cycles/hour in NVHL rats, while the periodicity was 6 cycles/hour for control rats. After establishing that the population activity was periodic, we examined single cell activity. In NVHL rats, 24 of 33 (72.7%) cells were periodic and 13 of 24 (54.1%) cells had a periodicity (~4 cycles/hour) similar to the population. For control rats, 17 of 29 (58.6%) cells were periodic and 7 of 17 (41.2%) cells had a periodicity (~6 cycles/hour) similar to the population periodicity. We computed the relationship between single cells and the population by calculating the Person's correlation coefficient (r). The cell-to-population r-values larger than the critical value (0.25) were considered to be significant and were selected from the populations which themselves were periodic. There were 20 of 33 (60%) of cells significantly correlated to the population in NVHL rats and 22 of 29 (76%) in control rats. However, cells from NVHL rats had stronger correlation to the population than cells from control rats. These data indicate that the population dynamics of hippocampal discharge is less stable in NVHL rats. We will determine the effects of early experience on these properties.

Title: Cognition-sensitive discoordination of local field potentials and place cell spike-field coupling in Fmr1 knockout mice

Authors: *A. A. FENTON[1,3], F. SPARKS[1], Z. TALBOT[2], B. RADWAN[1], D. DVORAK[1,4]; [1]Ctr. for Neural Sci., [2]Sch. of Med., New York Univ., New York, NY; [3]Physiol. & Pharmacol., SUNY, Downstate Med. Ctr., Brooklyn, NY; [4]SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Fragile X syndrome (FXS) patients do not express the fragile X mental retardation protein (FMRP). Absence of FMRP causes dysregulated translation, abnormal synaptic plasticity and intellectual disability. But FMRP loss has minimal effects on memory itself, making it difficult to understand why absence of FMRP impairs memory discrimination and exaggerates responses to environmental changes, which is characteristic of FXS patients. While Fmr1 knockout (KO) and wild-type (WT) mice perform cognitive discrimination tasks, we find abnormal coupling between theta and gamma oscillations in distinct perisomatic and dendritic hippocampal CA1 local field potentials of the KO. Perisomatic CA1 theta-gamma phase-amplitude coupling (PAC) decreases with familiarity in both the WT and KO, but activating an invisible shock zone, subsequently changing its location, or turning it off, causes KO but not WT mice to increase PAC at specific dendritic compartments depending on if the cognitive challenge is to learn a new shock location or that shock has turned off. Place cells recorded from WT and Fmr1 KO mice express similar time-averaged firing field properties. But place cell discharge is also organized by a temporal structure that is defined by the phase and frequency of ongoing LFPs at specific perisomatic and dendritic compartments. Thus, on the one hand, we find that the basic electrophysiological properties of individual place cells and frequency band-defined oscillations in the LFP poorly discriminate between WT and Fmr1 KO mice. On the other hand, we find that dynamic patterns of coordinated LFP and related LFP-structured spike-field activity across perisomatic and dendritic CA1 locations are sensitive to the cognitive challenge determined by task demands, as well as cognitive ability expressed as adaptive behavior. This neural coordination provides an electrophysiological basis upon which to differentiate and

mechanistically define the cognitive abilities WT and Fmr1 KO. These findings suggest that hippocampus circuit specific patterns of neural coordination and discoordination provide a pathophysiology that can explain how dysregulated translation leads to intellectual disability in FXS.

Title: Coordinated slow and fast gamma oscillations predict recollection success and failures in wild-type and Fragile X Syndrome model mice

Authors: *D. DVORAK, B. RADWAN, A. A. FENTON;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Active behaviors are standardly used to assess memory and identify memory deficits in animal models of mental dysfunction, but behavior is only a proxy for the neural events that define cognitive variables like recollection. We identified an electrophysiological signature of memory recollection in the dorsal CA1 hippocampus of mice, while they were not actively moving during a place avoidance task. Although both slow (30-50 Hz) and fast (60-100 Hz) gamma oscillations were decreased before mice initiated avoidance movements, the slow gamma events transiently dominated the fast events about two seconds before successful shock avoidance, but not before failure to avoid shock. These recollection events increased with learning in wild-type as well as Fmr1 mutant mice that model the intellectual disability in Fragile X Syndrome. Wild-type but not mutant mice quickly adapted to relocating the shock zone as well as turning it off. This cognitive flexibility coincided with decreased recollection events in the wild-type but in the mutants the recollection events persisted, consistent with their cognitive inflexibility. Thus recollection is signaled by domination of slow gamma oscillations over fast gamma oscillations in CA1.

Title: Do cortical head-direction cells preserve both directional tuning and temporally-coordinated neural discharge during cognitive control of information in two spatial frames?

Authors: *E. PARK, S. KEELEY, A. A. FENTON;
New York Univ., New York, NY

Abstract: During a two-frame place avoidance task on a rotating arena, spatial information dissociates into a spatial frame of stationary information and a rotating frame of local information. Hippocampus CA1 place cell discharge transiently organizes into same-function groups of coactive cells such that the discharge occurs in temporally-coordinated patterns that switch between representing stationary and rotating locations. We wondered whether other spatially-tuned cells would remain tuned to spatial variables and if so in which spatial frame during the two-frame task. We thus recorded hippocampal place cells and cortical spatially-tuned cells simultaneously while animals performed a one-frame active place avoidance task on a stationary arena and a two-frame task variant on a rotating arena. The notion that spatially-tuned cells (head-direction and grid cells) signal spatial variables for guiding behavior predicts that spatial tuning will be preserved throughout the tasks. Furthermore, notions that the discharge of these cells are governed by strong attractor-like dynamics predicts preserved, coordinated, temporal discharge relationships within the networks of these cells. We find that the fundamental physiological characteristics like the firing rates of directional cells were stable across the stationary and rotating conditions. Despite good spatial cognition performance, directional preference was lost in the rotating condition. In contrast, the temporal organization of discharge was preserved. Estimates by correlating pairs of spike trains showed preserved pair-wise correlations across the stable and rotating conditions. These findings are support for the notion that directional cells are organized by attractor dynamics and those responses to azimuthal inertial direction is secondary to these network dynamics.

Title: Hyperactivity, short- and long-term memory impairments during otherwise intact cognitive control in the gestational day 17 methylazoxymethanol acetate (MAM) rat model of neurodevelopmental insult

Authors: *K. C. O'REILLY, A. A. FENTON;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Like diverse forms of mental illness, schizophrenia is increasingly considered to have a neurodevelopmental origin. *In utero* exposure to the mitotoxin methylazoxymethanol acetate (MAM) at gestational day 17 results in altered hippocampus morphology and function and impaired spatial memory in rats. Because cognitive impairments are the most debilitating for schizophrenia patients, we asked if MAM rats displayed cognitive deficits during adolescence (36/37 days old), when symptoms of schizophrenia first emerge, or during adulthood (60-70 days old). We assessed cognitive control, short- and long-term memory, and locomotor behavior, using the hippocampus-dependent two-frame active place avoidance task, during which rats avoid a stationary shock zone on a rotating arena. The rats were tested over two days (eight 10 min trials/day). We measured locomotor activity (distance actively moved), ability to learn (learning curve over 16 trials), short-term memory (entrance latency, time to the first error for each trial), and long-term memory (entrance latency on the first trial of the second day). Adolescent and adult MAM rats were hyperactive during all trials. Both adolescent and adult MAM rats made significantly more errors than controls on the first day of testing. However, normalizing the errors by locomotor activity (errors/m), revealed that MAM rats were not different from control rats. Additionally, the learning curves of MAM rats, which could be described by exponential decay, were not different from controls. MAM rats showed impaired short-term memory: in contrast to control rats, MAM rats did not increase their entrance latency by the end of the first day. Hyperactivity is unlikely to account for shorter entrance latencies because the rats remained hyperactive on the second day of testing, but their entrance latencies increased to the same levels as controls. The distance walked prior to the first error was shorter in adolescent and adult MAM rats, which further confirmed that hyperactivity did not account for the short entrance latency. During all trials, adolescent and adult MAM rats were able to avoid the shock zone for the same maximum time as control rats, indicating that within trial

memory was not impaired. Adolescent and adult MAM rats have impaired long-term memory, indicated by shorter latency to enter and shorter entrance distance on the first trial of day two. We conclude that adolescent and adult MAM rats are hyperactive and have impaired short-term and long-term memory. Because MAM rats are able to learn the shock zone and do not make more errors when hyperactivity is accounted for, we conclude that there is no evidence of impaired cognitive control.

Title: Neural discoordination within the hippocampus place cell network during cognitive control in the Fragile X mouse model of Autism Spectrum Disorder

Authors: *F. T. SPARKS[1], Z. N. TALBOT[2], D. DVORAK[3], A. A. FENTON[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]New York Univ. Sch. of Med., New York, NY; [3]SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: The hippocampus (HPC) is the model neural system facilitating high-order cognitive functions such as autobiographical memory, spatial navigation, and cognitive control. Though much focus has been placed on dedicated spatial tuning properties of individual place cells, the HPC also exhibits dynamic functional grouping of place cells that are temporally organized such that subpopulations collectively participate in representing information. We hypothesize that abnormalities in neural coordination underlie dysfunctional cognitive control, the ability to selectively use relevant information while ignoring distraction. Cognitive control deficits are a core feature of Fragile X syndrome (FXS) the most common form of intellectual disability and a syndromic form of Autism Spectrum Disorder (ASD). Assessment of this hypothesis was performed using a Fragile X mutant mouse model (Fmr1-KO) that lacks the Fmr1 gene. Mice performed two-frame active place avoidance tasks to evaluate cognitive control. To assess neural

coordination, we characterized first-order features of individual place cells, and then analyzed higher-order features of place cell ensemble dynamics. Place cells were recorded concurrently with local field potentials from dorsal CA1 region of HPC in Fmr1-KO and wild-type (WT) mice. During pre-training with no shock on the stationary arena, individual Fmr1-KO place cells formed normal place fields compared to WT place cell properties such as inter-spike interval, firing rate map coherence, number of place fields, and field size. During slow continuous rotation of the arena, place cells in both genotypes maintained place fields anchored to distal cues. Ensemble coordination was estimated by Kendall's correlation (tau) across short time scales in pairs of place cell spike trains. Arena rotation had minimal effect on tau calculated up to 1 sec. Analysis of place cell spike trains prior to and following active place avoidance training revealed differences in coordinated ensemble activity across genotype. Following active place avoidance, the number of significant discordant cell pairs is silenced in the KO on various time scales < 1sec, whereas WT maintains proportion of discordant pairs. Overdispersion, a measure of within-field firing variability is significantly increased in the Fmr1-KO but only following task training. Together, these results illustrate normal properties of individual place fields in Fmr1-KO mice and abnormal neural coordination within the Fmr1-KO place cell network during cognitive control, supporting the hypothesis that abnormal neural coordination contributes to cognitive control deficits found in FXS and ASD.

Title: Characterization of the postnatal loss of mef2c selectively in the brain

Authors: ***M. MAHGOUB**[1], M. ADACHI[2], P.-Y. LIN[1], L. M. MONTEGGIA[1];
[1]Dept. of Neurosci., UTSW Med. Ctr. At Dallas, Dallas, TX; [2]Astellas, Chicago, IL

Abstract: Myocyte enhancer factor 2 (MEF2) transcription factors are crucial for cell differentiation and development in peripheral tissues as well as in brain. In the mammalian genome the MEF2 family is comprised of 4 genes that share high homology with the family of MAD (MCM1-Agamous-Deficiens-Serum response factor) box transcription factors. The Mef2c

gene member of the family is expressed the earliest in embryonic brain development and maintains high levels of expression in adult brain including the cortex, striatum and hippocampus, particularly the dentate gyrus subregion, suggesting potential roles in adult brain function. In previous work we had generated conditional Mef2c knockout mice in which Mef2c was deleted embryonically selectively in brain and observed an increase in the number and function of synapses that was accompanied by deficits in learning and memory. However, the embryonic deletion of Mef2c could result in compensation effects that impact the resulting phenotypes. Therefore, in this study we generated conditional Mef2c knockout mice using the calcium/calmodulin-dependent protein kinase II (CaMKII)-Cre93 driver line that targets broad forebrain regions including hippocampus to examine whether the postnatal deletion of Mef2c impacts behavior and synaptic plasticity. We find that postnatal deletion of Mef2c in the brain results in a significant increase in spine numbers. Data will be presented on the behavioral and synaptic characterization of these conditional knockout mice to examine the role of endogenous Mef2c expression in CNS function.

Title: Spatial representation of place cells of APPswe/PSEN1dE9 Alzheimer's mouse model

Authors: *M.-J. PARK[1,2], H. RHIM[1,2], J. CHO[1,2];
[1]Korea Inst. of Sci. and Technol., SEOUL, Korea, Republic of; [2]Korea Univ. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: The hippocampus plays an important role in spatial learning and memory and also is known to be susceptible to neurodegenerative disorder, such as Alzheimer's disease (AD). APP/PS1 transgenic mice model is used to mimic the pathological and physiological impairments in AD. Our previous study has shown that APP/PS1 mice (at 10-12 months of age) were impaired hippocampal dependent learning and memory in Morris water maze and passive avoidance test. Although hippocampal dependent memory impairments in AD have been well studied, much less is known about neurophysiological mechanism related to memory deficits in AD. The hippocampal place cells are believed to be a neural substrate for spatial memory and encode the animal's location in a given environment. Here, to examine the function of

hippocampal neurophysiology in AD, we conducted a hippocampal dependent place recognition memory test and CA1 & CA3 place cell recordings using APP/PS1mice (at 10-12 months of age). APP/PS1 mice showed impaired place recognition memory performance compared to WT mice by showing no preference to the object that has been moved to a new location. In addition, both CA1 and CA3 place cells recorded in APP/PS1mice showed decreased place cell stability in a familiar environment, which accompanied with decreased spatial coherence and decreased selectivity of place field. Furthermore, ratio of intra-burst spikes to total spikes and mean inter and intra-burst intervals were significantly altered, whereas mean firing rates were not altered in both CA1 and CA3 place cells in APP/PS1 mice. These results suggest that reduced place cell stability and altered physical properties of spiking in both CA1 and CA3 place cells may provide the neuronal basis underlying the impaired hippocampal dependent learning and memory in AD.

Title: Learning and memory induced CA1 activity *in vivo* and its deficiency in a mouse model of Alzheimer's disease

Authors: *S. POLL, L. C. SCHMID, J. STEFFEN, D. EHNINGER, M. FUHRMANN; German Ctr. for Neurodegenerative Dis. (DZNE), Bonn, Germany

Abstract: The hippocampus is critically involved in learning and memory processes and one of the first regions affected in Alzheimer’s disease (AD). Pyramidal neurons of the hippocampal CA1 region substantially contribute to memory acquisition and retrieval of recent and remote memories. Memory retrieval in part involves the same neuronal ensemble that is active during acquisition - a process called reactivation of a memory trace. We asked whether memory trace formation was altered in a mouse model of AD. For this purpose we performed repetitive *in vivo* two-photon imaging of individual hippocampal CA1 pyramidal neurons combined with contextual fear conditioning. Neuronal activity was monitored by tracing expression of the immediate early gene c-fos in a transgenic FosGFP mouse. The mouse model was crossbred to APP/PS1 transgenic mice that served as a model for AD. We revealed a major fraction of continuously fosGFP expressing cells indicating a regularly active subset of CA1 pyramidal neurons. A minor but specific neuronal ensemble was identified to be active after fear

conditioning and reactivated during memory retrieval potentially representing a memory trace. This learning- and memory-specific change of neuronal activity was absent in the mouse model of AD. Our data suggest that aberrant learning-dependent activity of pyramidal CA1 neurons contributes to contextual memory impairments in APP/PS1 mice and potentially in AD.

Title: Hippocampal inactivation impairs object-in-place associations and delay-dependent recognition in rhesus monkeys

Authors: *A. R. WEISS, J. BACHEVALIER, M. C. ALVARADO;
Emory University/YNPRC, Atlanta, GA

Abstract: The present study compared the effects of transient hippocampal inactivation on delay-dependent recognition memory and spatial relational memory, as measured by the visual paired-comparison paradigm (VPC), a task known to be impacted by permanent hippocampal lesions (Nemanic et al., 2004, *J. Neuroscience*, *24*; Bachevalier & Nemanic, 2008, *Hippocampus, 18*). Using modified techniques developed by Malkova and colleagues (Forcelli et al., 2014, *PNAS, 111*), we infused either 2-4µl muscimol, a GABA-A agonist (1µg/1µl) or the same volumes of vehicle (saline), or no infusion into the hippocampi of two awake, behaving, adult monkeys (M1 and M2). For each subject, the infusion targeted one anterior and one posterior coordinates of the hippocampus in each hemisphere, allowing for three inactivation Conditions: A) anterior + posterior; B) anterior only; C) posterior only. Monkeys were tested using two versions of the VPC paradigm: 1) Object-in-Place, in which the comparison is

between a 5-object array and the same 5-object array but with the spatial positions of 3 of the objects rearranged; a short 5s delay was used; or 2) Object-Replace, in which the comparison is between a 5-object array and the same array with 3 of the objects replaced with novel ones; short (5s) and long (60s) delays were used. Here, we report preliminary results from Condition A (combined infusion in anterior and posterior regions). Object-in-Place: For M1, bilateral infusions of muscimol, but not saline or no infusion, reliably lowered its novelty preference to chance levels (test-value=50%) [muscimol: $t(21)=0.87$, $p=0.395$; saline: $t(35)=2.66$, $p=0.012$; No infusion: $t(39) = 2.80$, $p = .008$]. Object-Replace: for M2, muscimol injections decreased its novelty preference scores to chance levels at the long delay [muscimol: $t(9)=0.71$, $p=0.46$; saline: $t(8)=3.20$, $p=0.01$; No infusion: $t(23) = 4.88$, $p < .001$; drug effects ANOVA [$F(2,40) = 3.30$, $p < .05$], but not at the short delay [all $p > .05$; drug effects ANOVA $F(2,43) = 0.26$, ns]. These preliminary results suggest that hippocampal inactivation alters object recognition memory at long delays as well as spatial relational memory even at a brief delay. These impairments were similar to those observed after excitotoxic hippocampal lesions in adult monkeys. Future inactivations of hippocampal anterior vs posterior portions may help refine our understanding of its role in support of memory.

Title: Morphological analysis of CA1-CA3 neurons of dorsal hippocampus and evaluating the learning and spatial memory process in adult Taiep rats

Authors: F. MEDINA[1], *A. B. SILVA[2];
[1]Escuela de Biologia, [2]Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: The *Taiep* rat characterized by tremor, ataxia, immobility episodes, audiogenic epilepsy and hinlimb paralysis, is an autosomic recessive myelin mutant in which hypomyelination and progressive demylination of the central nervous system (CNS) is present during development, resulting in numerous molecular, morphological and functional abnormalities of the neurons. The aim of this study was determine the morphological characteristics of the CA1-CA3 of pyramidal neurons of dorsal hippocampus and the performance of learning and spatial memory process in adult *Taiep* rats. Forty-eight male adult

rats Sprague Dawley (SD) were used, they were divided in two lots of twenty-four rats each one, these in turn were divided in three groups: 1) *Taiep,* 2) carries and 3) SD (n=8). One lot was used for the morphological analysis and the second lot was used for the object recognition task (OR). For the dendritic morphological characteristics, coronal cuts of dorsal hippocampus were studied using the Golgi-Cox staining technique followed with Sholl analysis. The OR task evaluates the spatial memory in rats, based on the time of exploration of familiar and novel objects. In the first trail (T1), the rat explored four objects (familiar objects) during five minutes, after a delay of five minutes, the second trail (T2) was performed, three objects used in T1 and a novel object was used; all the objects were changed of position. We evaluated the time of exploration for the objects in T1 and T2, when the rats explore the novel object for a greater time period, suggest memory for the familiar object, or when they explore the novel and familiar objects indistinctly, suggest a lack of recall or loss of memory for the familiar objects. As a result we observed that the carried rats showed a decrease in the concentric circles 14-21 of the apical dendritic arborization of CA3 neurons and a diminution in the concentric circles 11-13 and 15 of basal dendritic arborization in CA3 neurons of *Taiep* rats. For the dendritic length for order of branching, the *Taiep* rat showed a diminution of the dendritic length of fourth order (basal branch) and first order (apical branch) of CA1 neurons and a diminution in third order (basal branch) in CA3 neurons. The results obtained in the OR task, there were not significant differences between the groups. Due to the myelinic alterations presents in the *Taiep* rat in the CNS, the severity of symptoms presenting in adulthood and the alterations in the dendritic arborization of dorsal hippocampus, the learning and memory task were performed efficiently.

Title: A computational model of the ‘what’ and ‘where’ of episodic memory

Authors: *A. BICANSKI, N. BURGESS;
Inst. of Cognitive Neurosci., London, United Kingdom

Abstract: The Byrne, Becker and Burgess (Psych Rev, 2007; 'BBB') model of spatial memory provides a plausible account of high-level, cognitive phenomena such as imagery and neglect, at the level of the responses of individual neurons. In the model, allocentric spatial representations consisting of place cells, boundary vector cells and perirhinal texture/identity neurons, are stored as attractors in the medial temporal lobe (MTL). These representations are translated to/from corresponding egocentric representations in parietal areas, via an intermediate 'gain field' circuit, thought to reside in retrosplenial cortex. We present an updated version of the BBB-model, extended in two ways. First, we include an agent model, allowing the network to be driven by the current perceptual input, allowing for sensory driven self-localization (as opposed to pattern completion in the MTL). Second, we incorporate representations of discrete objects into the egocentric parietal and the allocentric medial temporal representations. Previously the BBB-model was only capable of representing extended topographical features (e.g., buildings), via boundary vector cells. We propose that this geometrical representation can be furnished with content (i.e. discrete objects) via place cells (firing in response to a given object in a given location) and object-specific cells akin to boundary vector cells (see e.g., landmark-vector cells, Deshmukh et al. 2013; object trace cells, Tsao et al. 2013). Crucially these object representations can be encoded on the fly (as the agent explores the environment) and updated (e.g. after displacement) without affecting the transformation between reference frames. The model can also recall the locations of objects by re-instantiating a view of them in imagery and retrieving the place linked to the object in the pattern-completing MTL network. Finally, embedding object information into the MTL representations for spatial memory allows us to explore the item-context dichotomy in a mechanistic, neural-level model of memory and imagery. Title: Learning-related single-neuron activity changes in the nidopallium caudolaterale and hippocampus

Authors: *S. STAROSTA[1], O. GUNTURKUN[1], M. C. STÜTTGEN[2];
[1]Ruhr Univ., Bochum, Germany; [2]Univ. Med. Ctr. Mainz, Inst. of Pathophysiology & Focus Program Translational Neurosci., Mainz, Germany

Abstract: Adapting behavior to changing circumstances frequently entails both the acquisition and the extinction of conditioned responding. While acquisition is intuitively regarded as learning, the reduction of responding is often seen as a behavioral signature of forgetting. However, decades of research show that the reduction in responding following the repeated omission of an expected reinforcement (extinction) is far better described as a consequence of a second inhibitory learning process. Studies employing Pavlovian fear conditioning in rodents identified the hippocampus as well as the prefrontal cortex as two key players involved in the acquisition and extinction of a fear response. By contrast, the involvement of these structures in the acquisition and extinction of appetitive, operantly conditioned responses is not well characterized. To investigate the time course of neuronal plasticity during acquisition, extinction, and reacquisition in an operant conditioning paradigm with positive reinforcement, we established a behavioral paradigm enabling us to monitor single-neuron activity across these learning stages in a single experimental session lasting >1,000 trials. We subjected pigeons to a visual discrimination task with two stimulus pairs. One pair was familiar to the animals; thus, they knew how to respond to these stimuli. This condition served as a control. The other pair of stimuli consisted of pictures which the animals had never seen before. Thus, in each behavioral session, animals had to learn how to respond to either of two stimuli. After reaching a pre-defined performance criterion, responding to one of the novel stimuli was no longer reinforced. Once responding to this stimulus had decreased (i.e., had been extinguished), the response was reinforced again, leading to its reacquisition. While animals were performing this task, we recorded the activity of single neurons in two regions of the avian brain: nidopallium caudolaterale (an associative forebrain structure thought to be functionally analogous to mammalian prefrontal cortex); hippocampus (the avian homolog to mammalian hippocampus). The observed highly dynamic response patterns during learning are discussed in regard to similarities and differences between learning processes, brain regions, and species.

Title: Mesopontine median raphe regulates hippocampal ripple oscillation and memory consolidation

Authors: *D. V. WANG, S. IKEMOTO;
NIH, Baltimore, MD

Abstract: Memory consolidation integrates newly acquired information into preexisting neural network without confusing it with old memories. To accomplish this, a precise regulation of the consolidation process is essential. Converging evidence suggests that sharp wave-associated field oscillations (~200 Hz) of the hippocampus, referred to as ripples, are important for consolidation of explicit memory. We have recently shown that the mesopontine median raphe (MnR) plays an important role in regulating hippocampal ripple activity and memory consolidation. In particular, when a group of MnR neurons (type I) was active, ripples were absent. These neurons display tonic and burst activity in pacing ripple activity. We also found that these type I neurons were not serotonergic or GABAergic using electrophysiological recording combined with optogenetics in transgenic mice (known as 'phototagging'). To test the hypothesis that type I neurons are glutamatergic, we performed phototagging of VGlut3-positive MnR neurons. Preliminary results showed that MnR type I neurons, identified by its correlation with hippocampal ripple activity, responded to photostimulation with short latency (5 ms or less), confirming that they are VGlut3-positive. We are currently examining how photoactivation and photoinhibition of the MnR VGlut3-positive neuron would affect hippocampal ripple activity and memory consolidation processes. We are also examining how MnR neurons regulate ensemble of hippocampal place cells, using the *in vivo* calcium imaging technique

Title: Upregulation of estrogen receptor alpha restores spatial memory and NMDA receptor synaptic function

Authors: *L. A. BEAN[1], A. KUMAR[2], A. RANI[2], M. GUIDI[3], P. CRUZ[2], T. C. FOSTER[2]; [1]Neurosci., [2]Univ. of Florida, Gainesville, FL; [3]Noldus Information Technol., Leesburg, VA

Abstract: The decline in the therapeutic effects of estradiol (E2) on cognition during aging is thought to result from a loss of neural plasticity due to altered expression of estrogen receptors. We tested the hypothesis that upregulating hippocampal expression of estrogen receptor alpha (ERα) or estrogen receptor beta (ERβ) would restore the therapeutic potential of E2 treatment on cognition and rejuvenate E2 induced hippocampal plasticity in aged animals that experienced prolonged hormone deprivation. We employed adeno-associated viral (AAV) vectors to enhance expression of ERα, ERβ, or green fluorescent protein (GFP) in the CA1 region of dorsal hippocampi of female Fisher 344 rats (18.5 months.) whose ovaries had been removed 14 weeks earlier. One week after virus injections, animals were treated for five weeks with cyclic injections of 17β-estradiol-3-benzoate (EB, 10 μg) or oil (GFP+EB: n=13, GFP+Oil: n=12, ERβ+EB: n=11, ERβ+Oil: n=11, ERα+EB: n=13, ERα+Oil: n=12). Spatial water maze performance was examined forty-eight hours following EB/oil treatment. EB failed to improve cognition in GFP animals, consistent with the idea that long-term hormone deprivation in older animals is associated with closing of the E2 therapeutic window. Increased expression of ERβ was associated with a modest learning impairment, regardless of treatment. In contrast to GFP and ERβ groups, spatial memory was enhanced in animals that express ERα and received EB treatment indicating ERα expression reinstated E2 responsiveness. This idea was supported by examination of hippocampal synaptic transmission. EB treatment had no effect on N-methyl-D-aspartate (NMDA) receptor synaptic transmission in the GFP group confirming a decrease in hippocampal EB responsiveness with prolonged E2 deprivation. Enhanced NMDA receptor synaptic transmission was observed in animals expressing ERα and treated with EB compared to GFP animals treated with EB or ERα animals treated with oil. This is the first demonstration that the E2 therapeutic window and hippocampal responsiveness can be reinstated by enhanced expression of estrogen receptors, specifically ERα.

Title: Genetic activation of stathmin impairs adult hippocampal neurogenesis, spinogenesis, and NMDA receptor-dependent memory

Authors: *S. UCHIDA[1,2,3], I. CHÉVERE-TORRES[2], C. HEVI[2], Y. WATANABE[1], G. P. SHUMYATSKY[2];

Abstract: Activation of postsynaptic NMDARs triggers complex downstream signaling events, including cAMP-response-element binding protein (CREB)-dependent gene transcription, which is critical for memory in many species. To exert their physiological roles, NMDARs must be transported into dendrites and synaptic sites. Thus, dendritic transport of NMDARs along microtubules is a prerequisite for NMDAR activity. However, little is known about the mechanisms underlying microtubule-based dendritic transport of NMDARs. Among microtubule-associated proteins, stathmin, a negative regulator of microtubule formation, is highly expressed in certain regions of the adult mammalian brain, including the dentate gyrus (DG) of hippocampus. In this study, we examined the role of the DG stathmin in neurogenesis, dendritic development, and NMDAR-dependent memory formation. To this end, we employed transgenic mice expressing the unphosphorylatable constitutively-active stathmin4A (Stat4A) protein in the tetracycline-dependent manner in the DG of hippocampus. Expression of Stat4A led to impaired adult hippocampal neurogenesis and aberrant maturation of the DG granule neurons. It was associated with deficient intracellular transport of the NMDAR subunits GluN2A and GluN2B and a decrease in CREB-mediated gene transcription known to be dependent on NMDAR function. Consistent with the NMDAR signaling deficit, transgenic mice expressing Stat4A showed deficient NMDAR-dependent memory in contextual discrimination learning, which is also dependent on neurogenesis. In contrast, Stat4A mice had normal NMDA receptor-independent memory tested by contextual fear conditioning with upstairs/downstairs protocol. The deficits in neurogenesis and NMDA receptor-dependent memory in Stat4A mice were

reversed by suppression of transgene expression with doxycycline (dox). These results indicate a crucial role for stathmin in the DG maturation and hippocampus-dependent memory formation. Our results demonstrate the role of stathmin in controlling intracellular transport of NMDA receptors, neurogenesis, neuronal maturation, and contextual discrimination.

Title: Enhancing prefrontal neuron excitability enables the associative learning over an extended temporal delay

Authors: *X. YU[1], J. VOLLE[2], H. SUN[2], S. E. TANNINEN[2], N. INSEL[2], K. TAKEHARA-NISHIUCHI[1,2];
[1]Cell Systems and Biol., [2]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: The medial prefrontal cortex (mPFC) has been implicated in cognitive processes that involve the linking of multiple stimuli over temporal delays. When animals learn to associate a neutral conditioned stimulus (CS) with an aversive eyelid shock (US) in trace eyeblink conditioning, the mPFC exhibits several characteristic activity patterns during the CS-US interval, including increased amplitude of theta oscillations (Takehara-Nishiuchi et al., 2011) and persistent single neuron firing (Takehara-Nishiuchi and McNaughton, 2008). These neuron activity patterns indicate the sustained activation of mPFC network during the temporal delay; however, its causal relation to the proposed linking function remains unknown. Here, we artificially elevated neuron excitability in the mPFC and examined its effect on stimulus-evoked oscillatory activity and memory formation in trace eyeblink conditioning. Neuron excitability was manipulated by using a pharmacogenetic approach, in which either the evolved human M3-muscarinic receptor (hM3Dq rats) or, as a control, green fluorescent protein (GFP rats) was expressed, through viral transduction, in mPFC pyramidal neurons of adult rats. The hM3Dq-

expressing neurons were activated by systemic injection of the hM3Dq ligand, clozapine-N-oxide (CNO, 0.1 mg/kg body weight). All rats received a modified version of trace eyeblink conditioning with an extended CS-US interval (750 msec), during which local field potentials (LFPs) were recorded in the prelimbic region of mPFC. Each group was split into two sub-groups which received either CNO or saline thirty minutes before daily conditioning started. We found that while the majority of control rats could not acquire the CS-US association (15 non-learners/ 20 rats in the hM3Dq-saline, GFP-saline, and GFP-CNO groups), most rats with the enhanced prefrontal neuron excitability were able to acquire the association (11 learners/13 rats in the hM3Dq-CNO group). Moreover, LFP activity was elevated upon the CS presentation in all groups. After the offset of CS, the amplitude of theta (4-12 Hz), beta (12-30 Hz) and gamma (30-80 Hz) oscillations stayed high toward the US onset in the hM3Dq-CNO group and the learners in the control groups whereas in the non-learner controls it immediately dropped to a baseline level. Our results suggest that the enhancement of prefrontal neuron excitability is sufficient to extend the stimulus-induced activation of the mPFC network, which contributes to the linking of stimuli separated by a temporal delay.

Title: Parvalbumin cells in prefrontal cortex support working memory by modulating theta and gamma power

Authors: ***M. U. WOLOSZYNOWSKA-FRASER**[1], B. CROUCH[1], B. PLATT[1], P. WULFF[2], G. RIEDEL[1];
[1]Univ. of Aberdeen, Aberdeen, United Kingdom; [2]Christian Albrechts Univ., Kiel, Germany

Abstract: The inhibitory circuitry of the prefrontal cortex (PFC) is involved in working memory and modulation of brain oscillations. Alterations in this network, and especially GABAergic cells

that express calcium-binging protein parvalbumin (PV), are thought to determine some of the cognitive deficits observed in schizophrenia. To assess the involvement of PV+ interneurons in PFC-dependent behaviours, we selectively inactivated PV-cells in prelimbic and infralimbic PFC via virus-mediated expression of tetanus toxin light chain (TeLC). We found that functional removal of PV+ neurons leads to specific impairments in working memory and cognitive flexibility, and these represent the main cognitive domains affected in schizophrenia. PV-TeLC mice displayed Y-maze alternation index reduction of ~10% ($p<0.04$), while the number of arm entries was not different. For physiological recordings, the Y-maze was redrawn and each arm divided into two equal-sized zones - proximal (close to the central decision point) and distal (far end). Zone entry was event-mapped onto continues local field potential recordings from infra-limbic PFC and CA1. Globally, there was lower hippocampal power in theta band frequencies ($p<0.05$ for 6.5-9 Hz) and reduced PFC gamma power in distal and proximal (decision) zones in PV-TeLC mice ($p<0.05$). While controls showed heightened hippocampal power in the gamma range when in the proximal zone close to the decision point relative to the distal zone of each arm ($p<0.05$), PV-TeLC mice did not. This suggests that the PV-TeLC animals are unable to modulate neuronal activity depending on the cognitive demand. However, PV-TeLC mice showed normal anxiety (light/dark box) or anhedonia (sucrose preference test) phenotypes. These results show that prefrontal PV+ interneurons control task-relevant neuronal activity in different brain regions engaged with working memory such as hippocampus. Similar signalling anomalies may thus underlie cognitive deficits found in schizophrenia.

Title: A respiration-coupled rhythm in the rat hippocampus independent of theta and cortical slow oscillations

Authors: *A. B. TORT, A. L. V. LOCKMANN, R. N. LEÃO, D. A. LAPLAGNE;
Brain Institute, UFRN, Natal, Brazil

Abstract: During slow-wave sleep and deep anesthesia, the rat hippocampus displays a slow oscillation (SO; <1.5 Hz) that follows up-and-down state transitions in the neocortex (Wolansky et al, 2006). There has been some debate as to whether this local field potential (LFP) rhythm is entrained by respiratory inputs (Lockmann and Belchior, 2014). For instance, in ketamine-anesthetized rats, Fontanini et al. (2003) reported oscillations of similar frequency in the piriform cortex of rats, which were locked to the respiratory cycle. However, Vizcko et al. (2014) convincingly demonstrated that hippocampal and neocortical SO recorded from rats during either urethane or ketamine anesthesia, as well as during natural slow-wave sleep, were not coupled to respiration. In the mouse hippocampus, however, Yanovsky et al. (2014) have recently described a slow oscillation entrained by nasal respiration under urethane anesthesia; this rhythm, dubbed hippocampal-respiration rhythm (HRR), was most prominent in the dentate gyrus, and could be distinguished from simultaneously occurring theta waves (Yanovsky et al., 2014). Therefore, whether slow frequency oscillations in the rat hippocampus couple to respiration or not is at issue. Here we have concomitantly recorded respiration activity along with hippocampal, neocortical and olfactory bulb (OB) LFPs in rats anesthetized with urethane. During the course of anesthesia, time-resolved spectral analyses showed that hippocampal LFPs transitioned between activity states characterized by the emergence of different oscillations. By jointly analyzing multisite LFP recordings and respiratory cycles, we could distinguish 3 types of oscillatory activity: SO, HRR and theta. Moreover, we could find time periods in which all three oscillations co-existed. While theta oscillations tended to be faster (>3 Hz) than HRR and SO, these latter two were typically of similar peak frequency (~1 Hz). Our results therefore solve the apparent contradictions among previous studies (Fontanini et al., 2003; Vizcko et al., 2014; Yanovsky et al., 2014) by demonstrating that the rat hippocampus can produce two types of slow oscillations <1.5 Hz: one that is entrained to the respiration cycle (HRR), and another that phase-locks to neocortical up-and-down transitions (SO). In all, the results suggest caution when referring to "slow oscillations" in the rodent hippocampus, as there may be different oscillatory activities that can overlap in time of occurrence as well as in peak frequency. Since they synchronize with different brain circuits, however, we postulate that each activity pattern plays unique roles in information processing.

Title: Respiration-related rhythm and theta oscillations are both present in the olfactory bulb of awake mice

Authors: *V. NGUYEN CHI[1], C. MÜLLER[2], T. WOLFENSTETTER[2], W. ZHONG[2], Y. YANOVSKY[2], A. DRAGUHN[2], A. B. L. TORT[3], J. BRANKACK[2];

Abstract: The respiration-related rhythm (RR) in local field potentials (LFP) of the olfactory bulb (OB) has been known for decades. Mice breathe and sniff with frequencies near or within theta range (4-12 Hz). In fact, breathing-related rhythm in the olfactory system has been frequently referred to as theta oscillations. Recently, we demonstrated the existence of an RR in the hippocampus of urethane-anesthetized mice, with frequencies close to theta rhythms (Yanovsky et al., 2014). Respiration-related hippocampal rhythms (HRR) depend on nasal airflow and have a laminar profile and pharmacological properties, clearly distinct from typical theta oscillations. Moreover, RR are most prominent within the dentate gyrus while theta reaches peak power at the hippocampal fissure. Here, we recorded LFP from OB and hippocampus of freely behaving mice. We found two distinct low frequency rhythms (theta and RR) in both structures. Respiration rate, and consequently OB RR and HRR varied from 1.5 Hz during drowsiness to 12 Hz in sniffing mice. Frequently, RR and theta oscillations had overlapping frequencies. However, respiration-induced rhythms could be easily differentiated from theta when respiration rate was below or (in case of sniffing) above the frequency of theta. Furthermore, we observed that gamma oscillations in OB couple exclusively to RR but not to theta. The origin of theta rhythms in the OB is unknown. Our present data show, however, that it is clearly distinct from respiration-related rhythm, which entrain neuronal activity in widespread areas in the rodent brain. Title: Early learning comparison of CA1 and CA3 single-unit response profiles during theta-contingent eyeblink conditioning

Authors: *J. J. CICCHESE, S. D. BERRY;
Psychology and Ctr. for Neurosci., Miami Univ., Oxford, OH

Abstract: Trace eyeblink classical conditioning (tEBC) is known to require the hippocampus for successful acquisition. Our lab has developed a brain-computer interface (BCI) capable of initiating conditioning trials in the presence (T+) or absence (T-) of hippocampal theta, a prominent hippocampal oscillation thought to play a role in coordinating activity across subregions. Utilizing our BCI, previous research has shown theta-contingent changes in CA1 cellular responding during discrete periods of trace tEBC trials, such as the tone and trace intervals, but those studies have not addressed neural activity in hippocampal subregions known to provide essential input to CA1, such as area CA3. In the present study, custom-made drives were used to lower tetrode bundles simultaneously into areas CA1 and CA3 of rabbits (Oryctolagus cuniculus) to analyze response profiles of CA3 pyramidal cells and interneurons relative to CA1 theta-contingent training. When assessing neural spike rate data at different periods of acquisition, we see that both pyramidal cells and interneurons in the T+ condition are more likely to increase their firing than those in T- early in training. Interestingly, we also show that rate increasing CA3 pyramidal cells show a greater magnitude of response in the T+ condition than rate increasing pyramidal cells in the T- condition, a pattern not seen in CA1. These results demonstrate an important difference in cellular activity between areas CA1 and CA3 that could guide future research on how anatomical differences between the two regions contribute to differential roles in associative learning.

Title: Local field potential activity in the monkey hippocampus during virtual navigation and contextual learning

Authors: *R. A. GULLI[1,2], G. DOUCET[5,3], B. CORRIGAN[2,5], S. WILLIAMS[4], J. MARTINEZ-TRUJILLO[5,3];
[1]Integrated Program in Neurosci., Western Univ., London, ON, Canada; [2]Integrated Program in Neurosci., [3]Dept. of Physiol., [4]Douglas Mental Hlth. Univ. Institute, Dept. of Psychiatry, McGill Univ., Montreal, QC, Canada; [5]Dept. of Pharmacol. and Physiol., Robarts Res. Institute, Western Univ., London, ON, Canada

Abstract: The hippocampus is known to be critical for contextual learning and memory, wherein unrelated aspects of the environment are associated within a singular memory. Several studies in rodents have demonstrated that changes in the firing rate of hippocampal neurons, as well as theta and gamma power are correlated with the formation of these context-dependent associative memories [1,2]. However, activity in the hippocampus of non-human primates may diverge from rodents during contextual learning, since their rate of learning in is much faster than other animal models and they visually explore environments and foveate on objects of interest during comparison and choice processes. Despite this, there have been few examinations of non-human primate hippocampal single-neuron activity and local field potentials (LFPs) recorded during contextual learning. We have created a context-object associative memory task using an open-source video game engine (Unreal Engine 3, Epic Games) remotely controlled via Matlab (Mathworks, Inc.) and recorded hippocampal activity from rhesus monkeys as they freely navigate using a joystick. In this task, monkeys learn a context-dependent object-value hierarchy through trial-and-error while we record hippocampal activity. Similar to previous literature [3,4], we see phase resetting and power peaks in the theta range (4-12 Hz) immediately following saccades as animals navigate the virtual environment. Immediately prior to object presentation in the virtual reality task, hippocampal theta power is elevated, while low gamma (32-64 Hz) is depressed. However, as monkeys saccade between objects in the virtual environment, and navigate towards the ultimately chosen object, this trend is inverted; hippocampal theta power is depressed, with an elevation in low-gamma power. In future analyses, we will explore how these activity patterns evolve over the course of learning, and how they differ between successful and unsuccessful instances of contextual retrieval. These results validate virtual reality environments as learning paradigms for use in non-human primate electrophysiological studies, and provide valuable insight in to the neural dynamics that support context-dependent associative learning in the hippocampus. 1. Title: Reward expectancy modulates CA1 oscillatory dynamics and hippocampal-ventral striatal coupling

Authors: *C. S. LANSINK[1,2], G. T. MEIJER[1], J. V. LANKELMA[1], M. VINCK[1,3], J. C. JACKSON[1], C. M. A. PENNARTZ[1,2];
[2]Amsterdam Brain and Cognition, [1]Univ. of Amsterdam, Amsterdam, Netherlands; [3]Dept. of Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: The formation of place-reward associations depends on the integrity of the hippocampal-ventral striatal system but it is not clear how, at the functional level, the hippocampus connects to this target structure to behaviorally express these associations. When rats navigate through an environment, hippocampal neurons fire in a location-dependent manner, and their activity is temporally organized by a theta rhythm (6-12 Hz) in the local field potential (LFP). Firing patterns of hippocampal CA1 and ventral striatal ensembles during goal-directed navigation were shown to be strongly affected by the presence of reward-predicting cues. We hypothesized that changes in reward expectancy may also impact on rhythmic synchronization in the hippocampus and on the regulation of its long-range neural interactions, such as with the ventral striatum. We explored this hypothesis by analyzing LFPs and single unit activity

simultaneously recorded from the dorsal hippocampal CA1 pyramidal layer, near the hippocampal fissure and the ventral striatum when rats were navigating towards goal-locations. We contrasted goal-site approaches in which reward expectancy was temporarily raised by the illumination of an outcome-predictive cue light, with behaviorally similar approaches that occurred spontaneously; i.e. when cue lights were off. Cued approaches were characterized by a stronger increase in hippocampal oscillatory power in the theta (8-10 Hz) and beta band (16-20 Hz) compared to spontaneous approaches. Remarkably, this increase was not aligned to the onset of the cue but occurred when the rat was on its way towards the goal-site and declined to baseline levels before goal-site arrival. Cued goal-site approaches were furthermore marked by stronger increases in phase-synchrony between hippocampal recording locations and concomitant spike-field phase locking in both frequency bands compared to spontaneous approaches. Reward-expectancy dependent changes in hippocampal rhythmicity were also expressed in the ventral striatum by increased phase modulation of firing rate in both frequency bands in cued compared to spontaneous goal-site approaches. Thus, hippocampal rhythmicity intensifies when reward expectancy is raised by outcome predictive cues and has enhanced impact on ventral striatum, by which the hippocampus- ventral striatal circuitry may claim priority in structures modulating behavioral output to express place-reward associations.

Title: The crosstalk within theta rhythms between secondary auditory cortex and basolateral amygdala is essential during remote fear memory recall

Authors: ***M. CAMBIAGHI**[1], A. GROSSO[1], E. LIKTHTIK[3], R. MAZZIOTTI[4], G. CONCINA[2], A. RENNA[2], T. SACCO[2], J. A. GORDON[3], B. SACCHETTI[2];
[1]Dip. Neuroscienze, [2]Univ. degli Studi di Torino, Torino, Italy; [3]Columbia Univ., New York, NY; [4]CNR - Inst. of Neurosci., Pisa, Italy

Abstract: Negative experiences are quickly learned and long remembered. The secondary auditory cortex (Te2) and the basolateral amygdala (BLA) are both involved in long-term fear memory. Indeed, in auditory fear conditioned rats, secondary auditory cortex is essential for encoding the emotional valence acquired by the auditory stimuli at remote time points. Brain oscillations, particularly the theta rhythm (4-12 Hz), seem to play a crucial role in the memory coding process and connections with amygdala. The present study examined neural activity in Te2 and BLA during the recall of recent and remote fear memories. To this end, we obtained LFP and multi-unit activity (MUA) recordings in Te2 and BLA of rats that underwent recall at 24 hours and 30 days after the association of an acoustic conditioned (CS, tone) and an aversive unconditioned stimulus (US, electric shock). Power spectral analysis of Te2 activity during the recall of aversive memories showed modality-specific significant changes in the theta band, at both 24h and 30 days. In particular, whereas low-theta (3-7 Hz) power increased in both conditions, high-theta (7-12 Hz) power decreased at both recent and remote retrieval. Remote memory recall was also associated with a modality and region specific increase in Te2-BLA low-theta synchrony. Furthermore, MUA recordings confirmed that BLA synchrony with the Te2 correlates with better memory at the remote time-point. Our study demonstrates the functional involvement of Te2 in the expression of auditory fear memory at remote time point.

Title: Effects of α7 nicotinic acetylcholine receptor activation on neurophysiological markers of cognition

Authors: ***M. HAJOS**[1], C. KELLEY[1], D. NAGY[1], L. LEVENTHAL[2], M. STOILJKOVIC[1]; [1]Comparative Med., Yale Univ. Sch. of Med., New Haven, CT; [2]FORUM Pharmaceuticals, Watertown, MA

Abstract: Experimental and clinical findings demonstrate that pharmacological activation of α7 nicotinic acetylcholine receptors (α7 nAChRs) improves cognitive function. In the present study effects of the novel α7 nAChRs agonist, FRM-17874 ((R)-7-fluoro-N-quinuclidin-3-yl)benzo [b]thiophene-2-carboxamide), an analogue of encenicline, was evaluated on neurophysiological markers related to cognition. One of the particular aims was determining the effective dose-range of the compound, supporting its pharmacokinetic-pharmacodynamic analysis. Since it has been shown that α7 nAChR agonists modulate neuronal network oscillation, efficacy of FRM-17874 was determined on elicited hippocampal theta oscillation in C57BL/6 mice and Wistar rats under urethane anesthesia. Using this assay, previous studies showed that drugs disrupting cognitive function eliminate or decrease the power of elicited theta oscillation, whereas drugs used to treat Alzheimer's disease, including acetylcholinesterase inhibitors and memantine, augment the power of theta activity. FRM-17874, administered subcutaneously at 0.1, 0.3, 1, 3 and 10 mg/kg showed a dose-dependent facilitation of the power of stimulation-induced hippocampal theta oscillation both in mice ($F(5,26) = 10.64$, $p < 0.0001$) and rats ($F(4,29) = 6.297$, $p < 0.001$) compared to the saline control groups. FRM-17874 significantly enhanced theta power at 1 and 3 mg/kg doses in mice, and at 0.3 and 1 mg/kg doses in rats, resulting an approximately 30 - 40% increase in absolute theta power both in rats and mice. Although there was a slight difference in the effective doses between mice and rats, their drug exposure levels in the brain were fully overlapping, indicating a species difference in pharmacokinetics. In a subsequent study, efficacy of FRM-17874 was determined on synaptic plasticity within the subiculum-medial prefrontal cortex pathway. Long-term potentiation (LTP) was generated by tetanic stimulation of subiculum in urethane anesthetized male rats. Compared to saline controls, FRM-17874 significantly increased LTP ($F(3,16) = 10.388$, $p < 0.0005$) at 0.3 and 1 mg/kg, s.c. but not at 3 mg/kg. Considering the physiological role of hippocampal theta oscillation in mnemonic functions and memory formation, and the role of the hippocampal - prefrontal cortex pathway in working memory, the described neurophysiological effects could be contributing mechanisms underlying the cognitive effects of α7 nAChR activation. However, the relatively narrow effective dose-range in these assays further underscores the critical importance of pharmacokinetics and dose-selection for clinical treatment.

Title: Hippocampal theta phase -contingent memory retrieval across trace eyeblink conditioning in rabbits

Authors: *T. WASELIUS, M. PENTTONEN, J. WIKGREN, M. S. NOKIA;
Dept. of Psychology, Univ. of Jyvaskyla, Finland, Jyvaskyla, Finland

Abstract: The hippocampal theta oscillations (3-12 Hz) play a prominent role in learning in mammalian brain. According to the theory of Hasselmo, Bodelón and Wyble (Neural Computation, 14(4):193-817, 2002) the phase of the theta cycle determines the optimal time windows for encoding and retrieval of memories: Encoding is favored at fissure theta trough and retrieval at fissure theta peak. In line with this notion, in our recent study on trace eyeblink conditioning in rabbits we found that the timing of the conditioned stimulus (CS) based on the theta phase affects hippocampal responses and learning. Namely hippocampal responses to CS were most synchronized when presented on fissure theta trough. Learning was retarded when the CS was presented at theta peak. However in contradiction to the theory our results suggested that in well-learned subjects the memory retrieval and performance of the conditioned eyeblink is not dependent on the theta phase regardless of a clear effect on neural responses. Here, we tested the effects of hippocampal theta phase-contingent stimulus presentation on memory retrieval across the whole conditioning process. We trained adult female New Zealand white rabbits in trace eyeblink conditioning using a tone CS and a 100-ms air puff unconditioned stimulus. The trace period was 500 ms. Preliminary results indicate that the phase of theta at CS onset has no effect on the performance of the behavioral learned response in any stage of trace eyeblink conditioning, when a 200-ms tone is used as a CS. This result is consistent with our earlier finding and suggests that retrieval of recently acquired memories and consequently performing a learned response is moderated by neural mechanisms other than hippocampal theta. However, using a CS longer than the duration of a single theta cycle might not be optimal for the effects studied. The data presented will indicate whether the effects of theta phase on memory retrieval during trace eyeblink conditioning are dependent on the timing and/or duration of the CS.

Abstract: Hippocampal theta rhythm is the electrophysiological signature of active locomotion during spatial navigation. It is critically involved in spatial memory, both during a task and subsequent sleep, and also plays a role in hippocampal-cortical interactions. Using functional ultrasound imaging (fUS) we sought to reveal the metabolic events associated with locomotion theta in mobile rats. We recorded from rats walking along a linear maze, to address how brain-wide networks activate during periods of hippocampal theta rhythm. Healthy Sprague Dawley rats ran on a 2.25m long, 0.2m wide linear track for water reward. A single imaging plane included dorsal hippocampus, cortex with somatosensory areas, and thalamus. In order to temporally resolve hemodynamics as the animal crossed the maze fUS compound frames were acquired at 500Hz for 12s. Acquisition was triggered when the animal turned around, and was followed by a 40s lapse to collect the data. As expected, hippocampal theta was consistently associated with locomotion. Distance travelled over time was slower (56-64%) than in control, surgery-free, rats ($p<10^{-6}$). Yet, maximum speed was only slightly slower for the initial 15min, with the difference reducing to non-significant 1% thereafter. In order to analyze series of track crossing trials, we aligned them by setting each trial reference time when the rat crossed the middle of the maze. Hemodynamic changes ranged from -10 to +20%. As expected, theta band intra-hippocampal EEG power peaked at top animal speed, which was coincident with crossing the midline, with a mid-height theta peak width of 3.2+/-0.3s (n=8). In order to quantify functional activation during the task, we computed the maps of Pearson's correlation coefficient between power in the theta band and pixel intensity, for varying time lags. Averaging pixels across anatomical areas revealed hyper-perfusion in the somatosensory cortex, dorsal thalamus

and hippocampus, and hypo-perfusion in the ventral thalamus. These correlations were consistent with fUS signal time course. Hyperemia peaked at 0.7-1.5s following the peak of hippocampal theta, which is compatible with signaling cascades that adapt blood flow to processing activation. Our data reveal a pattern of combined hippocampal and widespread cortical activation in a short time window around the navigation task, with coordinated dorsal thalamic activation and ventral thalamus suppression.

Title: Laminar, sub-regional, areal and behavioral contributions to variability in the hippocampal speed-theta relationship

Authors: *L. L. LONG, J. J. CHROBAK;
Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Theta (6-12 Hz) rhythmicity in the local field potential (LFP) reflects a clocking mechanism that brings physically isolated neurons together in time, allowing for the integration and segregation of distributed cell assemblies. Variation in the theta signal has been linked to locomotor speed, sensorimotor integration as well as cognitive processing. Previous research has characterized the decrease in the speed-theta power relationship across the septotemporal axis of the hippocampus. Here, we take previous studies a step further and investigate other sources of variability in the speed-theta relationship including laminar, sub-regional (e.g., DG vs. CA1), as well as behavioral differences observed across experiments (e.g., linear track vs. open field running). Rats were simultaneously outfitted with septotemporal and entorhinal cortical placements and recordings were obtained over a wide variety of experimental settings. Previously published data as well as current findings indicate robust variability in the speed-theta relationship as a function of laminar, sub-regional, areal and behavioral output of the animal. While preliminary, the current findings suggest that the hippocampal theta signal is not a limited information source and exhibits significant variation as a function of the aforementioned. Here,

we speculate that the speed-theta relationship represents the flow of sensory input across hippocampal circuitry and it appears that speed "synchronizes" hippocampus circuits. Alterations in the strength and "scaling" of the speed-theta relationship across the septotemporal axis of the hippocampus could be reflective of hippocampus processing with high speed-theta relationships indicating efficient processing on shorter time-scales (e.g., septal hippocampus), whereas low speed-theta relationships indicating processing on longer time-scales (e.g., temporal hippocampus). These ideas are consistent with increases in place field size across the septotemporal axis of hippocampus along with the possibility that septal hippocampus processes details of the proximal spatiotemporal environment, while more temporal aspects process larger spaces and wider time-scales. Thus, emergent function across the three-dimensional expanse of the hippocampus varies with respect to spatiotemporal scale. Overall, a better understanding of the relative contribution of these quantifiable variables and their variation as a function of environmental conditions and electrode location should facilitate our understanding of the relationship between theta and sensorimotor/cognitive functions.

Title: Effects of adenosine A2A receptor activation on chronic intermittent hypoxia-induced changes in sleep architecture and synaptic plasticity in rat

Authors: *L. DU, L. XU, Y. KE, W.-H. YUNG;
Sch. of Biomed. Sci., The Chinese Univ. of Hong Kong, Shatin, NT, Hong Kong

Abstract: Intermittent hypoxia and sleep disturbance associated with obstructive sleep apnea (OSA) are known to contribute to central nervous system dysfunction, including learning and memory impairment. Based on an OSA model in which rats were subject to daily 8-hr cycles of oxygen between 18% and 8% every 90s, we investigated the impact of OSA-associated intermittent hypoxia (IH) per se on sleep architecture. We also studied the effects of activation of adenosine A2A receptor, which is known to be involved in sleep control as well as hippocampal synaptic plasticity, on our model. We found a decrease in total sleep time and increased sleep

fragmentation induced by chronic IH. Administration of the A2A receptor agonist CGS21680 tended to reduce sleep fragmentation index and increased power of theta rhythm during non-REM sleep. At the same time, CGS21680 could also rescue IH-induced impairment in hippocampal long-term synaptic plasticity. Together, these results suggest that severe IH could affect sleep architecture and activation of adenosine A2A receptor is beneficial in ameliorating OSA-associated neurocognitive deficits.

Title: Theta-rhythmic drive between medial septum and hippocampus during theta and non-theta states: A Granger causality analysis

Authors: *D. KANG[1], M. DING[1], I. TOPCHIY[2], L. SHIFFLETT[2], B. KOCSIS[2];
[1]J. Crayton Pruitt Family Dept. of Biomed. Engineering, Univ. of Florida, Gainesville, FL;
[2]Dept. of Psychiatry, BIDMC, Harvard Med. Sch., Boston, MA

Abstract: Medial septum (MS) plays a critical role in controlling the electrical activity of the hippocampus (HIPP). In particular, theta rhythmic burst firing of MS neurons is thought to drive lasting HIPP theta oscillations in rats during waking motor activity, and REM sleep. Less is known about MS-HIPP interactions in non-theta states such as slow wave sleep (SWS) and quiet waking, although it was noted in early reports that MS burst activity may remain unchanged during non-theta states when HIPP theta rhythm is temporally replaced by other type of activity. The present study used Granger causality (GC) to identify the direction of rhythmic influence between MS and HIPP within the theta frequency band during theta and non-theta states. We categorize REM sleep and exploration as theta states while SWS and quiet waking (QW) are categorized as non-theta states. MS neuron firing was recorded using three tetrodes connected to separate microdrives in freely moving rats, along with HIPP field potentials and neck muscle EMG. MS neurons (>50) were identified in 4 rats using principal component and K-means clustering algorithms. Spectral analysis included autospectra of HIPP field potentials, and MS neuron firing, as well as MS-HIPP coherence and GC in both MS->HIPP and HIPP->MS

directions using a non-parametric algorithm specifically developed for handling point processes (spike trains). We found that during non-theta states, while GC revealed a unidirectional MS->HIPP influence over a wide frequency band (2-10 Hz, maximum: ~8Hz), there was no theta peak in the hippocampal power spectra, indicating a lack of theta activity in HIPP. In contrast, during theta states, theta peaks were seen in both MS and HIPP power spectra, and were accompanied by bidirectional GC with MS->HIPP and HIPP->MS theta drives being of equal magnitude. Thus, GC in non-theta states vs. theta states primarily differed in the level of HIPP->MS. The present findings suggest a modification of our understanding of the role of MS as the ultimate theta generator in two regards. First, a MS->HIPP theta drive does not necessarily induce theta oscillations in the hippocampus, as found in non-theta states. Second, HIPP theta oscillations involve bidirectional rhythmic interactions between MS and HIPP during theta states.

Title: Activity of supramammillary nucleus neurons during theta and slow oscillations in anaesthetized rats

Authors: *A. SLEZIA[1,2], A. F. VICENTE[1,2], A. KASZAS[1,2], A. GHESTEM[1,2], P. P. QUILICHINI[1,2], C. BERNARD[1,2];

Abstract: Theta oscillations in the hippocampus, entorhinal and subicular cortices are critical in a variety of mnemonic processes. Theta oscillations are strongly modulated by the medial septum, and the supramammillary nucleus of hypothalamus. Theta oscillations are an emergent property of cortical and subcortical structures, and the exact role of the supramammillary nucleus of hypothalamus in theta genesis and modulation is not fully understood. In our study, we combined local field recordings and single cell recordings with silicon probes and juxtacellular

electrodes to assess the behavior of neurons from the supramammillary nucleus, together with silicon probe recordings in the hippocampus during theta oscillations, as well as during slow oscillations for comparison in anaesthetized rats. We characterized supramammillary nucleus neurons on the basis on their firing properties and on the basis on their phase correlation with respect to theta and slow oscillations. Our preliminary result shows that supramammillary nucleus contains cells with different firing properties and also different phase relationship to theta and slow oscillations. We suggest that such a heterogeneous collection of neuronal firings may be instrumental in the pacing of oscillatory activities.

Title: Altered synaptic and molecular mechanisms of memory formation in ageing

Authors: ***W. AZIZ**[1], I. KRAEV[2], K. MIZUNO[1], F. A. VIGIL[1], K. KASBI[1], S. ROTHE[1], A. AHMAD[1], M. STEWART[2], K. P. GIESE[1];
[1]Kings Col. London, London, United Kingdom; [2]Life, Hlth. and Chem. Sci., The Open Univ., Milton Keynes, UK, United Kingdom

Abstract: Normal ageing is associated with deficits in learning and memory, which depends on the hippocampus. Impairments in induction and maintenance of long-term potentiation (LTP) in hippocampal area CA1 are thought to contribute to age-associated learning and memory impairments. However, despite these age-related LTP impairments memories can be formed with repeated training trials. Little is known about alternate synaptic mechanisms underlying this memory formation in ageing when LTP is impaired. Here, we used a hippocampus-dependent task called contextual fear conditioning (CFC) and used aged (18 months) and young mice (3 months). We showed that by increasing the stimulus intensity (5 shocks) the aged mice can make a memory distinct from that when presented with 1 or 2 shocks. Despite their ability for memory formation, aged mice had impaired autophosphorylation of alphaCaMKII at site T286 (pT286 αCamKII), a molecular signature of LTP. Young mice showed normal up-regulation of pT286

αCaMKII after CFC training. Using electron microscopy we found that young animals show an increase in mushroom spines after training. These are considered to be mature spines recruited for stabilizing a LTP dependent memory. In contrast to young mice, we did not observe an increase in mushroom spines in aged mice after 5 training trials. Next, we investigated the role of postsynaptic density protein-95 (PSD-95), a critical protein for activity-dependent synaptic remodeling associated with synaptic plasticity, and its correlation with structural alterations in ageing synapse. We found a specific up regulation of PSD-95 in aged mice after 5 training trials. Moreover, electron microscopy revealed generation of special type of spines called multi-innervated spine (MIS) specifically in aged mice after training. MIS are formed by contact of one spine with typically two excitatory presynaptic partners. Our results showed in detail that LTP dependent memory mechanisms are indeed lacking at molecular and synaptic level in aged mice. We propose that PSD-95 dependent up-regulation of MIS provides an alternative mechanism to make memories during ageing.

Title: Region specific expression of aging and cognitive genes

Authors: ***L. IANOV**, A. RANI, A. KUMAR, B. S. BEAS, J. L. BIZON, T. C. FOSTER; Neurosci., McKnight Brain Institute, Univ. of Florida, Gainesville, FL

Abstract: Cognitive decline during aging and neurodegenerative disease are associated with senescence of specific brain regions including the hippocampus and the medial prefrontal cortex (mPFC). However, there is enormous variability in cognitive decline, suggesting differential aging of processes critical to memory. Similar to aging humans, aged rodents exhibit variability in behavioral performance on a number of tasks that depend on the hippocampus or mPFC. While it is understood that gene expression profiles differ with age, studies are needed to

determine if specific transcriptional profiles in these brain regions relate to cognitive function during aging. To address this question, the current study utilized a powerful combination of a battery of behavioral tasks that are sensitive to different cognitive processes that decline with age and next-generation sequencing of the transcriptome (RNA-seq) in young (5-7 months) and aged (23-25 months) male Fischer 344 rats. Age effects: The results indicate that aging in the mPFC was associated with a decrease in expression of genes for gene ontology clusters linked to synaptic markers and chromatin assembly and disassembly genes ($p<0.05$). For hippocampal genes, aging was related with an increase in immune response genes and a decrease in genes linked to synaptic transmission and neural activity. Cognition-related genes: Re-exposure to the light chamber, 24 hours after inhibitory avoidance acquisition, increased expression of stress response and immediate early genes in the mPFC and hippocampal CA1 region indicating that both regions are responsive to experience. Impairment in a mPFC-dependent task, set-shifting, was correlated with decreased expression of mitochondrial function genes in the mPFC of aged rats ($p<0.05$). Impaired spatial episodic memory (water maze) in aged rats was correlated with decreased expression of synaptic and neural activity genes (e.g. Grin2b, Lin7a, Gria1, Egr1-3). Overall, relatively, few genes in the hippocampus and mPFC correlated with set-shifting and water maze performance, respectively, indicating that differential expression correlated with behavior was specific for brain regions that mediate the behaviors examined. Together, these results show that the identified clusters of genes within specific brain regions may explain the variability present in cognitive decline during aging.

Title: The role of mTORC2 in age-associated memory loss

Authors: *J. L. JOHNSON[1,2], W. HUANG[2], G. ROMAN[3], M. COSTA-MATTIOLI[2]; [2]Memory and Brain Res. Ctr., [1]Baylor Col. of Med., Houston, TX; [3]Biol. and Biochem., Univ. of Houston, Houston, TX

Abstract: As our population ages, cognitive decline and dementia are becoming more prevalent. The fact that memory declines as a function of age indicates that there must be crosstalk between components of these two processes. Yet, the molecular mechanisms underlying these inevitable processes are not fully understood. Although the serine/threonine kinase mechanistic target of rapamycin (mTOR) has long been implicated in aging, its role in brain aging remains unclear. Given the evolutionary conservation of mTOR between fruit flies and humans, we investigated the specific role of the new mTOR complex 2 (mTORC2) in age-related memory impairment in both the fly and rodent. We show that the activity of mTOR complex 2 (mTORC2) declines with age in the brain of both fruit flies and mice Interestingly, treatment with a small molecule that activates mTORC2 restores mTORC2 activity and rescues long-term memory (LTM) deficits in both aged mice and flies. In addition, we found that pharmacologically activating mTORC2 or promoting actin polymerization enhances long-term memory. In contrast to the current approaches to reverse memory loss that have primarily focused on changes in gene expression at the epigenetic and transcriptional level, our data suggests a novel, evolutionarily conserved mechanism for restoring memory that is dependent on structural plasticity. Although we are only beginning to understand the unique functions of mTORC2 in the brain, therapeutic approaches targeting the mTORC2 signaling pathway may have a profound impact in the prevention and treatment of age-related neurological diseases.

Title: Dorsal but not ventral hippocampal volume predicts cognitive performance in age

Authors: *J. M. REICHEL[1], B. T. BEDENK[2], M. CZISCH[2], C. T. WOTJAK[2]; [1]Albert Einstein Col. of Med., Bronx, NY; [2]Stress Neurobio. and Neurogenetics, Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: Cognitive decline with progressed age is a common phenomenon as well as morphological changes in the CNS occurring over the life span. However, not all aged individuals or rodents develop cognitive decline regardless of morphological changes. Here, we performed repeated within-subject testing of male mice in spatial learning tasks and subsequent manganese-enhanced MRI analyses at the ages of 8, 16 and 24 months in order to establish a timeline and correlation between morphological changes in ageing CNS and cognitive performance. Based on their spatial learning abilities at the age of 24 months we separated the mice in good and bad performers. For both groups we observed an increase in absolute whole brain volume over time accompanied by a decrease in total hippocampal volume. However, when normalized to the whole brain volume, the relative hippocampal volume, in particular the relative dorsal hippocampal volume, decreased significantly more for mice with poor spatial learning abilities is age. Moreover, we found that good- and bad performer had an a priori difference in their relative dorsal hippocampal volume at 8 months. Interestingly, we observed no behavioral differences between the groups until the age of 16 months, indicating a possible threshold connecting dorsal hippocampal volume and spatial learning performance.

Title: Morphological changes in synapses during memory formation in ageing

Authors: *I. V. KRAEV[1], A. KIRBY[1], W. AZIZ[2], K. MIZUNO[2], H. A. DAVIES[1], P. GIESE[2], M. G. STEWART[1];
[1]The Open Univ., Milton Keynes, United Kingdom; [2]King's Col. London, London, United Kingdom

Abstract: Long-term memory formation is related to functional strengthening of synapses. If the functional strengthening is impaired, hippocampus-dependent memory formation depends on modification of neural circuits and in particular the generation of multi-innervated dendritic spines (MIS) (Radwanska et al., 2011). Aged-related memory decline is associated with synaptic strengthening impairment. Memory formation in older animals is slower and less flexible in

comparison to younger animals. We have analysed MIS generation in the hippocampus before and after contextual fear conditioning (CFC) in the following wild-type groups of C57BL6N female mice: •young adult (n=6, 3 months): (i) naïve and (ii) 24 hours after CFC; •aged mice (n=4, 18 months): (i) naïve,(ii) 2 hours and (iii) 24 hours after CFC. Mice were perfused intracardially and brain slices taken for electron microscopy, 3D reconstructions from serial ultrathin sections were performed to allow quantitative analyses of structural changes in dendritic spines and post-synaptic densities in hippocampal CA1 stratum radiatum. Two MIS types were analysed: excitatory, which has more than one excitatory input from different axons; and dual, has one excitatory and one inhibitory contact (see Fig.1). We showed that number of mushroom spines increased after training in young but not aged mice. Furthermore there was a greater overlap between classes of thin and mushroom spines in young mice after training indicating that maturation process has occurred. On the other hand, aged mice showed a separation between thin and mushroom spines and an increase in the number of large thin spines not yet transformed into mushroom spines. Excitatory MIS analysis showed that the number of MIS was significantly higher in aged naïve mice compared to young naïve mice. Moreover, training induced a significant increase in MIS number in aged but not young mice. Inhibitory synapse analyses showed that both aged and young mice had an increased percentage of inhibitory synapses after training, due to an increase in number of dual MIS, but not shaft inhibitory synapses.

Abstract: Background: Cognition is impacted by aging. However, the mechanisms that underlie aging-associated memory impairment are unclear. PKMζ is a crucial molecule involved in the maintenance of long-term memory. Experiential learning and environmental stimulation have powerful influence on individual learning ability by mediating epigenetic modification of genes and further transcription and translation. Nevertheless, the transcription regulating mechanisms of PKMζ in memory retention are unclear. Here we explored whether the aberrant methylation of PKMζ DNA in the prelimbic cortex (PrL) is involved in aging-related memory decline. Methods: Rats were divided into three groups: young rats, adult rats and aged rats. We confirmed aging-related cognitive impairment by three types of behavior models which include contextual fear memory, Morris water maze and novel object recognition. We detected the expression of relative proteins in PKMζ-GluR2 signaling pathway in mPFC when LTM retention was impaired in aged rats. Then, we detected mRNA and DNA methylation levels of pkmζ respectively, in mPFC during the time that LTM impairment in aged rats. Next, we explored the reversing effect of EE on aging-related cognitive impairment and detected relative proteins expression in PKMζ-GluR2 signaling pathway, pkmζ mRNA and pkmζ methylation levels. Results: We confirmed that aged rats exhibited cognitive impairment in memory retention test 24 h after training compared with adult and young rats and genetic overexpression of PKMζ in the PrL rescued cognitive impairment in aged rats. After fear conditioning, the protein levels of PKMζ and the membrane

expression of GluR2 increased in the PrL in young and adult rats but not in aging rats, and the levels of methylated pkmζ DNA in the PrL decreased in all age groups, whereas the levels of unmethylated pkmζ DNA increased only in young and adult rats. Next, we found that 16 weeks environmentally enriched housing restored cognitive performance in aged rats in the three different behavior models. Environmentally enriched housing augmented PKMζ and GluR2 protein levels and PKMζ mRNA levels in PrL area of aged rats. The methylated DNA levels of pkmζ were decreased and unmethylated levels of pkmζ were increased in PrL area of aged EE rats. These rescuing effect of environmentally enriched housing can be reversed by microinjecting DN-PKMζ or antisense oligodeoxynucleotide of PKMζ in PrL area in aged rats. Conclusion: These results indicated that PKMζ may be a potential target for the treatment of aging-related cognitive impairment.

Title: Gross anatomical correlates of age-related spatial-cognitive decline in homing pigeons (Columba livia)

Authors: *V. J. COPPOLA, A. J. SCHREIBER, N. KANYOK, V. P. BINGMAN; Psychology, Bowling Green State Univ., Bowling Green, OH

Abstract: There is a growing interest in age-related cognitive decline in birds. For example, we recently investigated spatial-feature reference memory ability in older pigeons (11-14 years) and younger pigeons (2-3 years). In this task, pigeons were to learn which feeder, in an array of eight feeders, contained a food reward. Feeders could be distinguished from one another by their unique feature cues *and* spatial location, both of which remained stable across all training trials. It was found that older pigeons required a greater number of choices and sessions to reach the training criterion, and were less accurate with their first choice on each trial. It was concluded that older pigeons are impaired in the acquisition of reference memory, even when afforded two reliable cues (one spatial; one visual) for encoding. In the current study we began the search for neural correlates of cognitive decline in ten homing pigeons (5 young; 5 old) that previously

served as subjects on the spatial-feature reference memory task. Three linear, orthogonal measurements (i.e., anterior-posterior, dorsal-ventral, and medial-lateral) were taken of the forebrain and cerebellum, and the smallest possible cubic volume that could contain each structure was calculated. Additionally, two orthogonal measurements (anterior-posterior and dorsal-ventral) were taken of both the left and right tectum to obtain the smallest possible squared area that could be formed around each structure. It was found that only the forebrain was significantly smaller in older pigeons; the average cubic volume of the older pigeons' forebrain was 5.6% smaller than that of the younger pigeons. Furthermore, when assessed independent of age, cubic volume of the forebrain significantly correlated with measures of spatial-feature reference memory acquisition. Taken together, these results suggest that a reduction in forebrain volume may in part explain observed age-related cognitive deficits in homing pigeons.

Title: Behavioral deficits in a mouse model of Alzheimer's disease are mediated by alterations in immediate early gene expression

Authors: *J. PERUSINI, S. CAJIGAS, S. C. LIM, C. A. DENNY;
Integrative Neurosci., Columbia University- NYSPI, New York, NY

Abstract: Alzheimer's disease (AD) is a highly prevalent neurodegenerative disorder characterized by amyloid-beta (Aβ) peptides (plaques) and tau (neurofibrillary tangles). Mice with both the APPswe and PS1dE9 mutant transgenes have been previously developed and are characterized by early plaque development, around 4-6 months of age. While this line has been commercially available for some time, little is known behaviorally about these mice. We have performed a battery of behavioral assessment tests in order to better understand these mice for use in Alzheimer's disease models at four different time points both pre- and post-plaque

development. We tested anxiety-like, depressive-like, social, spatial, and cognitive behaviors. While AD mice showed no anxiety or depressive-like phenotypes, social and cognitive deficits emerged around 6 months, as tested by social recognition (SR), novel object recognition (NOR), Y-maze, and contextual fear conditioning (CFC) paradigms. By 8 months of age, however, wild-type mice also showed deficits in these cognitive tasks. These studies show that with increasing plaque load in the hippocampus, cognitive impairments emerge earlier than do age-related impairments.

Title: Aged-dependent effect of histone deacetylase inhibition on synaptic plasticity and memory

Authors: ***G. RAMIREZ MEJIA**[1], P. MORENO-CASTILLA[1], L. RODRIGUEZ-DURAN[2], M. ESCOBAR[3], F. BERMUDEZ RATTONI[1];

Abstract: Epigenetic regulation, including histone acetylation plays an important role for long-term memory formation. The increase of histone acetylation using unspecific histone deacetylases inhibitors (HDACi) enhances memory consolidation for hippocampus-dependent tasks and rescues age-related memory impairments. However the effect of HDACi in non-hippocampal memory in age-related memory impairments remain unexplored. The aim of this work was to study the effect of HDACi MS-275 on neocortical synaptic plasticity and memory in young and aged mice. We used young- and aged- B6129SF2/J mice and we performed *in vivo* electrophysiological recordings in anesthetized animals receiving intracerebral injections of MS-275 at insular cortex (IC) prior induction of long-term potentiation (LTP) in the basolateral amygdala-insular cortex (BLA-IC) projection. High frequency stimulation was applied into the

BLA, responses were measured at IC. The effect of the HDAC inhibitor in memory performance was evaluated in animals administered with MS-275 or vehicle, bilaterally in the IC prior to acquisition of conditioned taste aversion (CTA) or prior to object recognition memory (ORM). We found that HDACi showed increase induction of LTP, this change was more pronounced in aged than young mice. Also the MS-275 showed age-dependent effect of HDAC inhibition over memory process. In young animals there were no changes in extinction of CTA while in aged animals the HDACi produced a delay in extinction process. In the case of ORM the HDACi impairs recognition memory in young animals while in aged animals reestablish this memory. Our findings suggest that there is age-dependent regulation about histone acetylation induced by specific HDAC inhibitor and study of this process could help to understand memory alterations in aging.

Title: A biophysical, minimal model to explore age-related changes in ion channel gene expression and excitability in CA1 pyramidal cells

Authors: *E. MCKIERNAN[1], M. A. HERRERA-VALDEZ[2], D. F. MARRONE[1];
[1]Wilfrid Laurier Univ., Waterloo, ON, Canada; [2]Natl. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstract: As we age, our brains undergo a variety of changes, and yet we understand relatively little about these processes. What does normal neurophysiological aging look like and what are the various stages? How does the electrical activity of neurons change? How do aging neurons respond to input from other cells? Answering these questions is not just fundamental to understanding aging as a neurophysiological process, but also to understanding how this process goes awry in age-related disorders of clinical importance such as Alzheimer's disease. Many studies of aging have focused on the hippocampus, an area of the brain involved in learning and memory formation. Studies indicate that behavioral impairments and plasticity changes result in part from altered excitability in aged pyramidal cells. Pyramidal cells from aged animals show decreased excitability, increased spike frequency adaptation, and larger afterhyperpolarization

currents compared to neurons from young animals. Despite extensive study, however, it is still not well understood how changes in hippocampal pyramidal cell excitability and ion channel gene expression may affect neuron responsiveness to inputs and microcircuit output. We present a biophysical, minimal mathematical modeling approach to understand more about the effects of aging on hippocampal cellular responses. We show how small changes in gene expression in model CA1 pyramidal cells can reproduce the electrophysiological markers of aging, and link these changes to a geometrical analysis of the bifurcation structure of these neurons. This bifurcation analysis allows us to demonstrate how shifting the balance of ion currents can lead to functionally equivalent and non-equivalent cells.

Title: Dissociation of memory and long-term potentiation performance in aged mice

Authors: *W. YANG[1], X. ZHOU[1], T. MA[1,2,3];
[1]Dept. Gerontology, Wake Forest Baptist Med. Ctr., Winston Salem, NC; [2]Dept. of physiology and pharmacology, Wake Forest Baptist Med. Ctr., Winston Salem, NC; [3]Dept. of Neurobio. and Anat. , Wake Forest Baptist Med. Ctr., Winston Salem, NC

Abstract: Long-term potentiation (LTP) is widely considered as a synaptic model for memory. In general, LTP can be divided into two distinct forms: early LTP (E-LTP), which is transient and requires posttranslational mechanisms; late LTP (L-LTP), which is dependent on new protein synthesis. To our knowledge, the relationships between different forms of LTP and memory performance during aging process have not been elucidated. In the current study, by taking approaches of electrophysiology and behavioral tests, we compared LTP and memory performance in young (5 - 6 months of age) and old (18 - 20 months of age) mice. Compared to young mice, the old mice exhibited impaired memory as assessed by hidden platform Morris Water maze, Y water maze, and novel object recognition tests. In contrast, hippocampal L-LTP

(induced by two-train high frequency stimulation, HFS) in old and young mice was not distinguishable. However, E-LTP (evoked by one-train HFS) was significantly reduced in old mice, compared to those in young ones. Our results suggest that dissociation of memory and L-LTP performance during aging.

Title: Phosphorylated tyrosine 1472 NR2B levels are elevated in select synaptic compartments in the hippocampus of young and aging rats but only partially reduced by the presence of estrogen in aging rats

Authors: *T. A. MILNER[1,2], S. MAZID[2], M. DODOS[1], R. PURI[3], W. G. M. JANSSEN[3], J. H. MORRISON[3], B. S. MCEWEN[2], E. M. WATERS[2];

Abstract: Estrogen modulation of synaptic plasticity in the adult rat hippocampus critically involves NMDA receptors. In the absence of estrogens, aging rats have lower NR2B subunit levels in the lateral portion of the active synaptic zone that are restored in the presence of estrogens (Adams et al. JCN 2004). This suggests that estrogens may impact the mobility of NMDA receptors across the synapse. Here, we examine whether phosphorylated tyrosine 1472 NR2B (pY1472), which is critically involved in the surface expression of NMDA receptors (Zhang et al., J. Neurosci. 2008), is altered in aged synapses in the absence and presence of estrogen. For this, young (2 mo old) and aged (~24 mo old) rats were ovariectomized (OVX) and treated with either 17β-estradiol or vehicle for 2 days and then dorsal hippocampus sections were embedded in plastic (same rats as used by Adams et al., 2004). Serial sections through the CA1 stratum radiatum were collected on formvar-coated slot grids (5-6/grid), labeled for pY1472

NR2B (Phosphosolutions) using immunogold and analyzed by electron microscopy. Overall, the number of pY1472 gold particles was greater in the pre- (terminals) and post-(spines) synaptic compartments of OVX vehicle-treated aged OVX rats compared to other groups. In aged rats, presynaptic pY1472 levels were elevated in regions containing the readily releasable and reserve pool of synaptic vesicles. Estradiol-treatment reduced the levels of pY1472 in both of these pools to levels seen in young rats. Postsynaptically, both young and aged OVX rats had high levels of pY1472 in the PSD and spine cytoplasm that were reduced similarly by estradiol. However, pY1472 levels in aged OVX rats were selectively elevated in the regions adjacent to the post-synaptic density and were not reduced by estradiol. Interpretation: NR2B endocytosis is blocked by phosphorylation at Y1472 and elevated pY1472 is detected during low estrogen states and with increased age. Because pY1472 is reduced by estradiol treatment, this suggests another mechanism through which estrogen promotes synaptic plasticity by facilitating endocytosis.

Title: The glutamate modulator riluzole alters hippocampal gene expression patterns associated with age-related cognitive decline

Authors: *J. KOGAN, J. D. GRAY, R. L. DAVIDSON, B. S. MCEWEN, A. C. PEREIRA; McEwen Lab., The Rockefeller Univ., New York, NY

Abstract: Decreased memory function with age often leads to poor quality of life in older adults. The neural circuits susceptible to aging are comprised of glutamatergic pyramidal neurons that furnish cortico-cortical connections between the association cortices as well as the excitatory hippocampal connections that subserve memory and cognition. Synaptic NMDA receptor activation is critical for learning and memory while extrasynaptic NMDA activity leads to long-

term depression and excitotoxicity. Riluzole is a glutamate modulator that increases glutamate-glutamine cycling and glutamate uptake, potentially increasing synaptic glutamatergic activity while preventing glutamate overflow to the extrasynaptic space. This drug has previously been shown to prevent age-related memory decline in rodents (Pereira et al PNAS 2014). This study seeks to evaluate the gene expression changes underlying this effect. Rats were given riluzole in the drinking water from 10 months to 14 months. Animals were sacrificed and the hippocampus was dissected out. RNA was extracted for sequencing on an Illumina Hi-Seq 2500 at a depth of 60 million reads. Differential expression analysis was conducted using Strand NGS software and gene lists were further analyzed for relevant Gene Ontology (GO) terms and pathway analysis using DAVID analysis tools. We found 233 genes significantly decreased in the riluzole group that were up-regulated with age and 95 genes showing the opposite pattern. GO analysis indicated that both these lists were enriched in genes associated with transmission of nerve impulse, synaptic transmission and ion transport. RNA was also used to create a cDNA library for qRT-PCR validation of these targets. A separate cohort of animals was tested for hippocampal-dependent memory using the Y-maze. These rats were subsequently perfused for immunohistochemical analysis. EAAT2 (Glt-1) is an astrocytic glutamate reuptake transporter and decreased levels of this gene are commonly associated with excitotoxicity. We observed a significant positive correlation between EAAT2 levels with riluzole treatment and y-maze performance, suggesting that riluzole may act to improve hippocampal function through regulation of the glutamatergic system. This study expands on previous work by revealing gene expression changes in the hippocampus that underlie the ability of riluzole to improve hippocampal memory in rodents. These gene patterns will allow us to gain a deeper understanding of the aging brain and potentially lead to development of novel drug targets for age-related cognitive decline and Alzheimer's disease.

Title: Conserved memory and hippocampal glutamate in a growth hormone receptor knockout model of extended life span

Authors: *K. N. HASCUP[1], P. J. FITZGERALD[1], S. O. BRODERICK[1], S. RANDALL[1], J. J. KOPCHICK[4], A. BARTKE[2], E. R. HASCUP[3];
[1]Neurology, Ctr. for Alzheimer's Dis. and Related Disorders, [2]Intrnl. Med., [3]Neurology, Ctr. for Alzheimer's Dis. and Related Disorders, Pharmacol., Southern Illinois Univ. Sch. of Med., Springfield, IL; [4]Biomed. Sciences, Edison Biotech. Inst., Ohio Univ., Athens, OH

Abstract: Growth Hormone Receptor Knockout (GHR-KO) mice present with increased longevity (30-36 mos) and healthspan as compared to normal aging littermates. Previous studies indicate hippocampal mRNA levels for vesicular glutamate transporters remain constant in GHR-KO, but decrease with age in normal aging littermate controls (Hascup *et al*, 2015). Because of glutamate's involvement in learning and memory, we examined cognitive performance and *in vivo* hippocampal glutamate dynamics in 20-24 mos female GHR-KO and normal aging littermate controls. Spatial learning and memory was assessed with the Morris water maze (MWM). By the 5th training session, GHR-KO and littermate controls traveled a similar duration (23.4 ± 4.6 and 27.0 ± 8.8 s, respectively) and distance (4.3 ± 0.8 and 4.7 ± 1.7 m, respectively) to locate the submerged escape platform (both significantly ($p<0.001$) decreased compared to the 1st training session), indicating no differences in learning between genotypes. During the probe challenge, GHR-KO mice took a more efficient path (Fig 1A) and less time (12.7 ± 2.3 s; $p<0.05$) to first platform cross compared to control littermates (28.7 ± 7.1 s), supporting retention of reference memory in GHR-KO mice. One week following MWM, mice were isoflurane anesthetized and a glutamate selective microelectrode array coupled with *in vivo* electrochemistry was used to examine glutamatergic neurotransmission (basal, evoked release, and uptake) in the dentate gyrus (DG), CA3, and CA1. Basal and stimulus-evoked (70 mM KCl, isotonic, pH 7.4, ~150nl) glutamate was significantly attenuated in all hippocampal subregions of GHR-KO compared to littermate controls (Fig 1B & C). No differences in glutamate uptake were observed in any subregion. Increased basal CA3 glutamate negatively correlated with path efficiency to first platform cross during MWM probe (Fig 1D). These data support elevated basal and evoked-glutamate release observed in normal aging littermate controls impairs reference memory, which was not observed in the GHR-KO mouse model of increased healthspan.

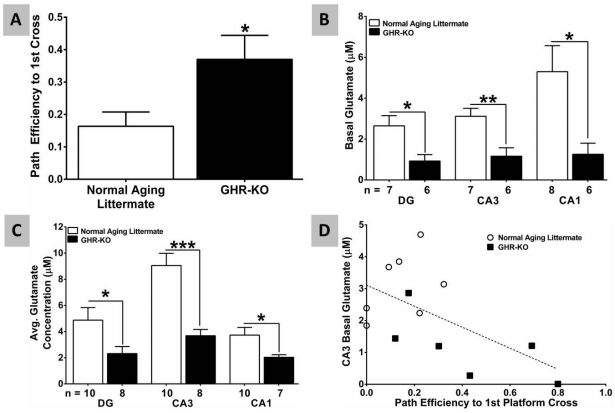

Figure 1: A) GHR-KO swam a more direct path to the first platform cross compared to normal aging littermates (n=10). B & C) Basal and stimulus-evoked glutamate release was elevated in all hippocampal subregions of normal aging mice. D) CA3 basal glutamate negatively correlates (Pearson r = -0.5741; p<0.05) to path efficiency. Figures A, B & C: Mean ± standard error; two-tailed t-test; *p<0.05, **p<0.01, ***p<0.001.

Title: Hippocampal glutamate and cognition is altered in normal aging C57BL/6J mice

Authors: *S. O. BRODERICK[1,2], K. N. HASCUP[2], E. R. HASCUP[2,3];
[2]Dept. of Neurology, Ctr. for Alzhiemer's Dis. and Related Disorders, [3]Dept. of Pharmacol., [1]SIU Sch. of Med., Springfield, IL

Abstract: Aging is an important issue as population distributions and life expectancies are changing, resulting in increased older populations living longer than previous generations. Understanding the aging process in the brain can give insight into normal age-related cognitive decline as well as accelerated decline common in disease states, such as Alzheimer's disease. Our goal is to present a comprehensive view of how normal aging alters cognition and hippocampal glutamate (Glu) neurotransmission in male C57BL/6J mice. Mice were divided into 2-4, 6-8, or 12-15 month age groups (n = 10-13) and evaluated for learning and memory using Morris Water Maze (MWM). During MWM, subjects underwent five training days (learning)

followed by a single probe trial (memory). We observed an age-related decline in learning when examining path efficiency on the final training day, with 12-15 month mice exhibiting decreased cognition compared to 2-4 month mice (0.31 ± 0.03 and 0.45 ± 0.04, respectively; $p<0.05$). Similarly, memory impairments were evident when comparing platform entries corrected for distance traveled, which were elevated in 2-4 month old mice compared to the 12-15 month group (0.38 ± 0.05 and 0.21 ± 0.05 platform entries/m traveled, respectively; $p<0.05$) and 6-8 month group (0.23 ± 0.04 platform entries/m traveled; $p<0.05$). Following a recovery period, *in vivo* Glu neurotransmission was measured in CA1, CA3 and dentate gyrus (DG) regions of isoflurane anesthetized mice. A microelectrode array selective for Glu and micropipette with 70 mM KCl (isotonic, pH 7.4) was stereotaxically placed in the hippocampal subregion of interest. We observed a trend of decreasing stimulus evoked Glu release with age in the DG of 2-4 month, 6-8 month and 12-15 month C57BL/6J mice (3.8 ± 1.1 μM, 2.8 ± 0.5 μM, and 2.0 ± 0.3 μM, respectively). Furthermore, increased Glu release in the DG positively correlated with platform entries per distance traveled when examining the three age groups (Pearson $r = 0.48$, $p<0.05$). These results demonstrate that hippocampal Glu neurotransmission varies with age and may influence cognitive decline associated with normal aging. Future studies are planned to add 18-20 and 24+ month old groups to better understand the relationship between hippocampal function and cognition in advanced age.

Title: A docosahexaenoic acid diet prevented cognitive decline in mice knock-in for human apolipoprotein e epsilon 4 allele

Authors: *M. PLOURDE[1], R. CHOUINARD-WATKINS[2], M. VANDAL[3], F. CALON[3]; [1]Res. Ctr. On Aging, Sherbrooke, QC, Canada; [2]Univ. de Sherbrooke, Sherbrooke, QC, Canada; [3]Univ. Laval, Québec, QC, Canada

Abstract: We previously showed that the metabolism of docosahexaenoic acid (DHA), an omega-3 fatty acid, is disrupted in humans and in transgenic mice carrying human apolipoprotein E epsilon 4 (APOE4) allele. Carrying APOE4 is recognized as being the most important genetic risk of developing Alzheimer's disease. Moreover, contrary to non-carriers of APOE4, carriers seem not protected against cognitive decline when consuming fatty fish. We have shown that brain DHA uptake is lower in APOE4 mice compared to APOE3 mice such that APOE4 mice might be more vulnerable to DHA deficiency, hence contributing to higher risk of developing cognitive decline. However, we have preliminary data in humans suggesting that with high doses of dietary DHA, its homeostasis can be rebalanced, hence potentially contributing to delay the onset of cognitive decline. The objective of this study was to evaluate whether dietary DHA intake prevent cognitive decline and whether proteins involved in neurotransmission are modified by the diet in APOE4 mice compared to APOE3 mice. To investigate this objective, four months old APOE3 (n = 32) and APOE4 (n = 38) mice were fed a control diet or a DHA diet for 8 months. At 12 months, animals were tested for visual and spatial memory using object recognition (OR) and Barnes maze (BM), respectively. A recognition index (RI) was calculated in the OR test whereas primary errors and escape latency were calculated in the learning phase of the BM. We also investigated by Western blot the following proteins in parieto-temporal cortex: SNAP25, synaptophysin, PSD95. Our results showed that APOE3 mice fed the control or the DHA diet recognised the new object whereas in APOE4 mice, only those fed the DHA diet recognised the new object. Escape latency was higher in APOE4 mice fed the control diet compared to APOE3 mice but there was no difference in escape latency between the genotypes when the mice were fed DHA. There was no difference in the synaptic protein levels in parieto-temporal cortex between genotypes and diets. These results support that DHA intake could be a nutritional strategy preventing cognitive decline in APOE4 carriers when provided at high doses. However, the mechanism behind this positive effect on cognition seems not related to synaptic protein content. Therefore, more investigations are needed to understand by which mechanism DHA intake prevented cognitive decline in APOE4 since these result could help designing therapeutic strategies for prevention of cognitive decline.

Title: Dietary supplementation with quercetin rejuvenates cognitive performance independent of adult hippocampal neurogenesis

Authors: *K. DU[1,2], S. D. PEREZ[1], P. T. KOZAK[1], A. A. SHERIFF[1], J. H. BAXTER[3], R. VAZHAPPILLY[3], J. S. RHODES[1];
[1]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois At Urbana Champaign, Urbana, IL; [2]Div. of Nutritional Sci., Univ. of Illinois at Urbana Champaign, Urbana, IL; [3]Abbott Nutr., Columbus, OH

Abstract: Nutritional supplementation with quercetin, phosphatidylserine-docosahexaenoic acid (PS-DHA) compound, CDP-choline (citicoline), 5-methyltetrahydrofolic acid (Metafolin), and α-tocopherol have been suggested to ameliorate cognitive aging, but mechanisms are not known. The objective of this study was to measure the effect of these micronutrients on adult hippocampal neurogenesis and cognitive performance in a mouse model. Aged female and male C57BL/6J mice 18 months old were fed 8 different treatment diets for 4 months, before being tested on a battery of cognitive behavioral tasks. The 8 treatment diets (n=10 males and 10 females per group) were: 1) control (AIN93M), 2) 50% deficient in vitamins and minerals, 3) 150% elevated vitamins and minerals, 4) 0.051 g/kg quercetin, 5) 0.102 g/kg quercetin, 6) PS-DHA, 7) a combined supplement of CDP-choline, 5-MTHF, and α-tocopherol, and 8) a diet containing all mentioned supplements. Animals were euthanized at the end of the study to quantify numbers of new neurons by immunohistochemical detection of doublecortin (DCX). Young (2 months old) mice were also measured without dietary manipulation to serve as a reference for the aging-induced decline in the outcome measures. Quercetin significantly rejuvenated cognitive performance on the active avoidance learning and memory task, and the effect was enhanced when combined with the other micronutrients. No differences in number of DCX-positive cells were observed. Results confirm pro-cognitive effects of quercetin in an aging population, but mechanisms appear independent of adult hippocampal neurogenesis and remain unknown.

Title: Dietary supplements with quercetin and micronutrients enhanced performance in active avoidance task in aged mice but no synergistic effect was found with voluntary wheel running

Authors: *P. PARK[1], T. K. BHATTACHARYA[1], C. RENDEIRO[1], B. D. PENCE[1], A. J. COBERT[1], J. L. RYTYCH[1], Y. SUN[1], K. W. KELLEY[1], R. W. JOHNSON[1], R. H. MCCUSKER[1], J. H. BAXTER[2], J. A. WOODS[1], J. S. RHODES[1];
[1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Abbott Nutr., Columbus, OH

Abstract: Dietary supplements and physical exercise have been widely examined in regards to their beneficial effects on cognitive function in aging. In particular, quercetin, a flavonoid found in fruits and vegetables, has been shown to alleviate age-associated cognitive deficits, potentially through its ability to modulate synaptic plasticity and inflammation status. Earlier studies from our lab showed that when combined with other micronutrients (citicoline, 5-methyltetrahydrofolic acid, α-tocopherol and PS-DHA), chronic intake of quercetin significantly enhanced cognitive performance in aged C57BL/6J mice compared to the intake of quercetin alone. In the present study, we further investigated the synergistic effects of the quercetin and micronutrients with physical exercise on cognitive function. Aged male Balb/c mice were provided with running wheels for regular voluntary exercise and/or a diet containing quercetin for 4 months and were tested in active avoidance and social recognition tasks. Our preliminary data suggest that Balb/c mice fed with the quercetin-containing diet performed significantly better on the active avoidance task in comparison to the control aged group, whereas no synergistic effect with exercise was observed. Neither quercetin nor exercise showed improvements in social recognition task. Overall, these results indicate that a diet containing a combination of quercetin, citicoline, 5-methyltetrahydrofolic acid, α-tocopherol and PS-DHA is efficacious at ameliorating learning impairments in aging across different strains of mice. The precise mechanisms underlying such effects are not clear and will be further investigated.

Title: Cognition and behaviour impairment: is oxidative stress the earlier change commanding senescence? Lessons from senescence accelerated P8 mice

Authors: *M. PALLÀS[1], M. PUIGDORIOL-ILLAMOLA[2], V. PALOMERA-AVALOS[2], A. CAMINS[2], C. GRIÑÁN-FERRÉ[2];
[1]Pharmacol. and medical chemistry, Univ. De Barcelona, Barcelona, Spain; [2]Univ. de Barcelona, Barcelona, Spain

Abstract: Understanding of the magnitude and physiological significance of earlier oxidative processes on cognitive and behaviour changes and its relationship with aging processes or pathological settings is a frontier to be crossed in order to prevent/treat neurodegenerative disorders. Senescence-accelerated mice P8 (SAMP8), has been postulated as a biological tool to study pathological ageing. Behaviour changes, cognitive impairment and molecular and cellular changes linked to neurodegenerative diseases were characteristic in this mouse strain. Orchestrating these challenges, oxidative stress is one of the main actors in SAMP8 mice. Here we went deep on the temporary evolution of oxidative stress and its correlation with cognitive and behaviour changes, including molecular and cellular changes associated to neurodegenerative processes Oxidative stress disturbances namely 8-OHdG, 4-HNE, NF-kB, SOD1 levels are present as earlier as 1 month in SAMP8, but at this age cognitive impairment was not significant, although anxiety and temerosity were. Aged SAMP8 showed cognitive impairment, less oxidative stress but elevated levels of neurodegerative markers as Bax in reference to age-mated SAMR1. Accordingly with cognitive results changes in hallmarks of cognitive impairment as tau phosphorylation or neurogenesis process were found in aged SAMP8 mice in reference to age-mated SAMR1. Hyperphosphorylation of tau was significant higher in 9 months SAMP8 in front of SAMR1, but were equal at young age. In reference to neurogenesis process doublecortin (DCX) levels were significant decreased in young and old SAMP8, indicating a reduced capability to respond in front to a APP processing, an increase in BACE, sAPPbeta protein levels, concomitantly with a decrease in sAPPalfa, indicating a neurodegerative process likely Alzheimer's dementia in 9 months SAMP8 mice. The correlation among levels of oxidative levels and behavioural changes between SAMP8 and SAMR1 at the

different ages studied indicated that oxidative stress gives the pathway of molecular and cellular mechanisms that landing in cognitive impairment and neurodegeneration. Oxidative stress reduction is therefore a main and easily strategy to prevent neurodegenerative diseases.

Title: Epigenetic changes mediated by miRNAs as a cause of rapidly aging and cognitive impairments in female SAMP8 mouse model

Authors: *C. G. FERRE, JR[1], V. PALOMERA-AVALOS, Jr.[1], D. PUIGDORIOL-ILLAMOLA, Jr.[1], D. ORTUÑO-SAHAGÚN, Sr.[2], A. CAMINS, Sr.[1], M. PALLÀS, Sr.[1]; [1]Univ. of Barcelona, Barcelona, Spain; [2]Univ. de Guadalajara, Guadalajara, Mexico

Abstract: The role of epigenetics in the control of transcriptional mechanisms is one of the earliest emerging fields in senescence processes. These age-associated transcriptional signatures seem to be controlled by non-coding RNAs, known as microRNAs (miRNA). These miRNAs are small molecules (22 nucleotides approximately) that regulate gene expression by binding to their target messenger RNA (mRNA) inhibiting its translation, or, less frequently, promoting its degradation. One miRNA could potentially regulate large numbers of target genes synchronously, which implies that miRNAs may be important sculptors of transcriptional networks. As such, they are attractive candidates for regulating development and pathological changes. Thus, we chose the spontaneous senescence-accelerated P8 mouse model (SAMP8) which exhibit age-related deterioration in learning and memory abilities, and SAMR1 as a control to explore AD-associated pathogenesis and the links between miRNAs and AD. It is feasible that the differences among SAM strains could be explained through the link between these factors and epigenetic changes. For this reason, we focus on SAMP8 epigenetic alterations

through screening of the expression of 84 mature miRNAs in hippocampus of females SAMR1 and SAMP8 (1 and 9 months) by using the *miScript®.* These miRNAs were chosen because they are expressed differently during the progression of neurological diseases. The results of microarray analysis showed that the family of let-7, miR-26b-5p, miR-29a-3p, miR-29c-3p, miR-146a-5p, miR-151a-3p, miR-181a-5p miR-191-5p, miR-298, miR-485-5p were all expressed differently depending on the strain and age. The mirDB is an online database for miRNA target prediction and functional annotations and its analysis showed that these miRNAs are also implicated in cell fate determination, senescence, apoptosis, proliferation, stress and regulation of epigenetical enzymes and β-amyloid processing. Results were validates by quantitative real-time PCR. The data obtained pointed out several miRNAs that participated as regulators of aging and neurodegeneration in female SAMP8 mice. Title: Reframing role of resveratrol in neurodegeneration: Oxidative stress, mitochondrial function and Wnt-pathway modulation in the brain of metabolically stressed SAMP8 mice

Authors: *V. PALOMERA[1], C. GRIÑÁN-FERRÉ, Jr[2], A. CAMINS[2], N. AMARO-UMBERT[2], M. PUIGDORIOL-ILLAMOLA[2], C. SANFELIU[3], A. M. CANUDAS[2], M. PALLÀS[2];

Abstract: Alzheimer´s disease (AD) results in an irreversible loss of neurons, especially in the associative cortex and the hippocampus. Senescence-accelerated mouse prone 8 (SAMP8) has been proposed as a model for studying both the earliest neurodegenerative changes associated with AD as well as the progression of this disease, as it includes the age-related cognitive deficits and neuropathological abnormalities. Growing evidence indicates that mitochondrial dysfunction is a common feature of neurodegenerative diseases and is observed at an early stage in the pathogenesis of AD. On the other hand, the activation of the Wnt signaling pathway has an essential role in synaptic maintenance and neuronal function, and its deregulation has also been implicated in AD. We examined the effect of resveratrol in neurodegenerative processes, studying changes in oxidative stress, mitochondrial dysfunction and Wnt signaling induced by a high fat diet (HFD) as a metabolic stressor in 4-month-old mice. The results show an increase of (active) β-catenin on HFD-mice treated with resveratrol, target of Wnt pathway. Significant changes in the expression of Dickkopf, Dvl3, Axin1 LRP6 and GSK3 β were observed. Furthermore, the HFD caused a significant decrease in the expression of the OXPHOS complex, which was blocked in resveratrol-treated animals. Levels of mitochondrial fusion proteins OPA and Mitofusin2 were modified by HFD. Resveratrol blocked these differential protein expressions, pointing to a reduction in the fusion process. Furthermore, resveratrol reverted changes in oxidative stress markers. These results suggest than the Wnt pathway was modulated by resveratrol in SAMP8 mice; inhibition of Wnt renders in this model an increase in active β-catenin. Resveratrol's antioxidant properties were manifested by SOD increase and changes in oxidative stress and mitochondrial function markers. In conclusion, this study corroborates the importance of redox mechanisms in the neuroprotective effect of resveratrol, supporting the theory of the crucial role of oxidative stress in the shift from normal brain aging to pathological aging; moreover results support the hypothesis that this polyphenol may have a pleiotrophic effect on cellular processes, ranging from mitochondrial functioning to Wnt modulation.

Title: The ability of concord grape juice to reverse a latent learning impairment during aging in rats depends on the duration of the supplement

Authors: *E. M. STOUFFER, P. N. MICHENER, L. C. WILSON;
Bloomsburg Univ. of PA, Bloomsburg, PA

Abstract: Two experiments were conducted to examine the ability of Concord grape juice (CGJ) to reverse the latent learning impairment that normally begins during middle age in male rats. The purpose of Experiment 1 was to determine the minimum duration of the CGJ supplement necessary to reverse the latent learning impairment normally seen in middle-aged male rats, while Experiment 2 was conducted to determine if CGJ would also be able to reverse this impairment in older male rats. In Experiment 1, 40 middle-aged (11 months old) male Sprague-Dawley rats were given 25 ml of a 50% concentration of CGJ every other day for 1, 2, 3, or 4 weeks. All rats were then trained and tested on the Latent Cue Preference (LCP) task. During training trials of the LCP task, the water-replete rats sampled water (a neutral stimulus) in 1 compartment of the 3-compartment LCP box on 1 day, and then had no water in a second compartment of the LCP box the following day (1 training trial), for a total of 4 training trials over 8 days. All rats were then water-deprived prior to a compartment preference test, during which they were allowed to move freely among the compartments with the water removed. Latent learning is demonstrated during the preference test if rats spend more time in the compartment that previously contained the water (water-paired). Results of Experiment 1 showed that the 11-month-old rats given CGJ for either 3 or 4 weeks prior to the LCP task showed a significant preference for the water-paired compartment, indicating intact latent learning abilities. However, the 11-month-old rats given CGJ for only 1 or 2 weeks showed impaired latent learning (no compartment preferences). In Experiment 2, male Sprague-Dawley rats that were 14 months old (n = 10) were given CGJ every other day for 3 weeks, and male Sprague-Dawley rats that were 20 months old were given CGJ every other day for either 3 weeks (n = 9) or 8 weeks (n = 10). All rats were then trained and tested on the LCP task as described in Experiment 1. Results of Experiment 2 showed that the 14-month-old rats given CGJ for 3 weeks and the 20-month-old rats given CGJ for 8 weeks showed a significant preference for the water-paired compartment (intact latent learning). However, the 20-month-old rats given CGJ for 3 weeks showed no compartment preferences (impaired latent learning). These results appear to indicate that the antioxidant, anti-inflammatory, and neurogenesis effects of the flavonoids in CGJ only have to be present for a short period of time during middle age to be able to reverse the functional degeneration of the brain regions necessary for latent learning, but need to be present for a much longer period of time in older rats in order to reverse the degeneration.

Title: Centella asiatica alters mitochondrial and antioxidant response pathways and improves neuronal health and cognitive function

Authors: *N. E. GRAY[1], C. J. HARRIS[1], J. A. ZWEIG[1], M. HUNTER[1], J. F. QUINN[1,2], A. SOUMYANATH[1];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Neurol. and Parkinson's Dis. Res. Educ. and Clin. Care Ctr. (PADRECC), VA Portland Hlth. Care Syst., Portland, OR

Abstract: Introduction: *Centella asiatica* is a medicinal plant traditionally used to enhance cognition. The water extract of *Centella asiatica* (CAW) reverses -amyloid (A)-induced cognitive deficits in mice and prevents A toxicity *in vitro*. CAW also affect improves mitochondrial function and induces the expression mitochondrial and antioxidant response genes *in vitro* both in the presence and absence of A suggesting potential utility beyond Alzheimer's Disease. Here we explore the cognitive enhancing, mitochondrial and antioxidant effects of CAW in healthy aged mice and neurons isolated from these animals. **Methods:** Dendritic arborization, synaptic density and mitochondrial and antioxidant gene expression were evaluation in neurons from C57J/B6 mice. Additionally 2 and 20 month old C57J/B6 mice were treated with CAW in their drinking water for two weeks prior to Morris Water Maze (MWM) assessment of learning and memory. Brain expression of synaptic markers as well antioxidant and mitochondrial genes was evaluated. **Results:** CAW increased dendritic arborization and spine density in primary neurons and induced the expression of antioxidant and mitochondrial genes. CAW improved performance in the MWM in aged mice but did not show as robust an effect in young mice. Hippocampal, cortical and cerebellar expression of mitochondrial and antioxidant response genes was induced in both young and old CAW-treated animals. We also observed an increase in synaptic gene expression in both young and old CAW-treated mice in the hippocampus and cortex but not cerebellum. **Discussion:** CAW improves neuronal health and cognitive function in models of healthy aging. Histological studies are underway to determine whether the changes in arborization and spine density observed in isolated neurons also occur in the brains of CAW-treated animals. CAW also increased expression of mitochondrial and antioxidant response genes both in primary neurons as well as in the brains of treated animals. It remains to be seen whether these gene expression changes contribute directly to the

improvement in cognitive function and neuronal health. Metabolomic analyses of the brains of treated animals are ongoing to identify other pathways that may be involved in the mechanism of action of CAW.

Title: Dietary curcumin and caloric restriction improve functional outcomes in late middle age and early senescent C57BL/6 male and female mice

Authors: ***M. SARKER**[1], S. F. FRANKS[2], N. SUMIEN[3], M. J. FORSTER[3];
[1]UNT Hlth. Sci. Ctr., Fort Worth, TX; [2]Texas Prevention Inst., [3]Pharmacol. and Neurosci., Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Dietary curcumin and caloric restriction may ameliorate age-associated functional decline based on their anti-inflammatory and/or antioxidant actions. To determine whether or not combining these two interventions would result in additive or synergistic benefits, dietary curcumin and caloric restriction were tested for functional end points, either alone or in combination, in late middle age (MAG) (15 months) and early senescent (AG) (20 months) C57BL/6J male and female mice. Mice were assigned in groups to receive: (i) base diet ad libitum (AL), (ii) weight stable caloric restriction (CR), (iii) curcumin in the base diet (7200 mg/kg diet) (CURAL) or (iv) curcumin plus CR (CURCR). After 8 weeks of treatment, mice underwent a behavioral battery that tested for cognitive and psychomotor function. Cognitive flexibility was significantly better for MAG males CURAL compared to AL, but not under CURCR, suggesting an antagonistic interaction. On the other hand, MAG females under CR, CURAL and CURCR did significantly better than AL, suggesting that a negative interaction was not present in this sex. Curcumin alone (CUR) improved reversal performance in AG females, whereas CR was ineffective in the aged mice. None of the treatments led to significant

differences in the average path length for a water maze test of spatial memory, however, MAG CURCR males performed poorly in a probe test, further suggesting a negative interaction of these treatments in MAG males. There was no apparent effect of diet on spontaneous locomotion and rearing, although mice on CURCR and CR for both sexes and ages displayed improved performance in psychomotor tests of coordinated running, bridge walking and wire suspension. These results suggest that, when implemented separately, CR and CURAL have an ameliorative effect on impaired frontal cortical function present in late middle age. These effects were similar across different behavioral tasks and were non-interactive or antagonistic, suggesting that they could involve similar mechanisms. It is noteworthy that the combination treatment has a significant antagonistic effect on cognitive performance on MAG males but not females, and that both interventions alone and combined became less effective when implemented during early senescence when compared with middle age. Overall, the results indicate that curcumin intake mimics some of the beneficial effects of CR in the absence of diminished energy intake.

Title: Electrophysiological changes underlying lapses in memory consolidation

Authors: M. CROSSLEY, F. LORENZETTI, *P. R. BENJAMIN, M. O'SHEA, I. KEMENES; Univ. Sussex, Brighton, United Kingdom

Abstract: Memory consolidation is generally conceived as a process whereby new information sequentially moves to successively longer-term stores. In invertebrates and vertebrates, including humans, there are short periods of memory lapses during consolidation. Formerly these have been regarded simply as moments of vulnerability in memory formation. Our recent work on the snail Lymnaea however suggests that they are adaptive, allowing consolidation to be regulated so that acquisition and storage are effectively modified by new information after initial learning. Previously, we found that one-trial appetitive classical conditioning using sucrose as the

unconditioned stimulus (US) and gamma-nonalactone (GNL) as the conditioned stimulus (CS), was accompanied by memory lapses at 30 min and 2 hour after training. Memory consolidation was disrupted when a disturbance is applied to the animal during one of these lapse periods but not when presented at non-lapse times. Using intracellular recording techniques in an *in vitro* training paradigm we recorded changes in electrical activity after conditioning in key interneurons previously shown to be involved in the formation of memory in Lymnaea. Using the recently developed multielectrode array (MEA) technique we analysed more global network changes recorded from entire ganglia. Using these techniques, we were able to record conditioned responses to the CS during short-term memory (10 min after training) and intermediate-term memory (1 hour after training). At the 30 min lapse point no conditioned response was observed, consistent with earlier behavioral experiments. All the important types of buccal ganglion interneurons involved in feeding network activation (CV1) and motor pattern generation (N1M) followed this temporal pattern of responses. We also recorded an interneuron (PlB) that provided inhibitory modulation of the feeding circuit. This neuron was shown to reduce its spiking activity during memory expression. Using MEA we found novel types of neurons in CNS in ganglion areas not previously known to be involved in learning. One type followed the temporal sequence seen in buccal neurons but others showed responses to the US but not to the CS after training. By recording the feeding modulatory CGC interneurons we found that a tactile sensory disturbance applied during the lapse in memory blocked depolarization of the membrane potential when recorded at 24 hour after conditioning.

Title: The role of microRNAs in memory consolidation in Lymnaea

Authors: ***G. KEMENES**[1], D. VAVOULIS[2], S. KORNEEV[1];
[1]Sussex Neuroscience, Sch. of Life Sciences, Univ. of Sussex, Brighton, United Kingdom; [2]Fac. of Engin., Univ. of Bristol, Bristol, United Kingdom

Abstract: After single-trial classical conditioning, there are well-defined time windows of activation of and requirement for key 'conventional' molecular players in the different phases of the consolidation of LTM in *Lymnaea*. Two important related discoveries we have made recently are: i) late LTM (24h post-training) requires transcription at 6h post-training, ii) at 6h post-training, there is ongoing phosphorylation of CREB1 and increased acetylation of H3, both of which can be measured in the 'learning ganglia' as well as in single identified neurons known to be involved in learning. However, the requirement for new protein synthesis for LTM only lasts for up to 1h after conditioning. Together, these findings gave rise to the testable hypothesis that newly transcribed non-coding RNAs (e.g., miRNAs) are involved in the early as well as intermediate-term phase of memory consolidation. In order to test this hypothesis we initiated studies of the temporal dynamics of the post-training expression of small non-coding RNAs (sncRNAs). sncRNA cDNA libraries were produced from the 'learning ganglia' dissected from experimental animals at 1h, 6h or 24h after a single conditioning trial, corresponding to the early, intermediate and late phases of memory consolidation. Next Generation Sequencing of the libraries and bioinformatic analysis revealed over a hundred individual sncRNAs with significant homology to miRNAs previously identified in other species, including *C. elegans, Drosophila, Aplysia*, mouse and humans. Notably, we identified individual annotated miRNAs belonging to 35 conserved miRNA families exhibiting learning-induced changes in their expression compared to naïve controls. Almost 50% of these differentially expressed miRNAs were found in all 3 experimental groups ('common' miRNAs). Interestingly, we identified 7 miRNAs that showed precisely timed changes in their expression. Among these 'phase-specific' miRNA families there are 5 that are specific for the 1h group and 2 that are specific for the 6h group. The rest of the miRNAs were differentially expressed in two phases and no miRNAs specific for the 24h group have been found. Many of the differentially expressed miRNAs are known to be involved in neuronal functions, including 14 that are also present in the human brain and 24 that are present in the *Aplysia* CNS. We have also identified potential targets for two of the differentially expressed miRNAs (*Lym-miR137* and *Lym-miR1175*) identified in our new experiments, Lym-CREB2-encoding mRNA and the long non-coding RNA *Lym-antiNOS3*. Notably, both molecules are important components of conventional mechanisms involved in memory formation.

Title: Activity of serotonergic neurons underlies choice between retrieval-induced extinction or reconsolidation of memory

Authors: *P. M. BALABAN, M. ROSHCHIN, A. ZUZINA, A. TIMOSHENKO, A. Y. MALYSHEV;
Inst. Higher Nervous Activity & Neurophysiol. RAS, Moscow, Russian Federation

Abstract: Retrieval of memory followed by reconsolidation can strengthen a memory, while retrieval followed by extinction results in a decrease of memory performance due to weakening of existing memory or formation of a competing memory. In our study we analyzed the behavior and responses of identified neurons involved in the network underlying aversive learning in terrestrial snail Helix, and made an attempt to describe the conditions in which the retrieval of memory leads either to extinction or reconsolidation. Using a specific for serotonergic neurons neurotoxin 5,7-DiHT it was shown previously that the serotonergic system is necessary for the learning, but is not necessary for maintenance and retrieval of the memory. These results suggest that serotonergic neurons that were shown to be necessary as part of reinforcement for developing the associative changes in the network may be not necessary for the retrieval of memory. The hypothesis tested in the present study is whether the activity of the "reinforcement" serotonergic neurons is the gate condition for the choice between extinction/reconsolidation triggered by the memory retrieval. It was shown in semi-intact and isolated CNS preparations that several serotonin applications effectively increased amplitude of synaptic inputs to the withdrawal interneurons, and that intracellular stimulation of a single identified giant serotonergic pedal cell #4 was effective as a reinforcement in Helix. We performed electrophysiological experiments in semi-intact preparations that allowed to deliver a drop of juice to the lip and simultaneously record intracellularly from interneurons involved in feeding and withdrawal behavior, and from the serotonergic "reinforcing" neurons. Recordings were made before and after associative training sessions in preparations. It was shown that after food-aversion training, the serotonergic cerebral interneurons involved in feeding have not changed significantly the responses to food, while the premotor interneurons (FMRFa-containing) involved in triggering the head and tentacle withdrawal started to respond with a spike discharge to previously subthreshold food stimuli. Serotonergic pedal neurons, whose intracellularly induced activity was shown to be capable to elicit associative changes in tentacle-withdrawal network, did not respond before training to the non-noxious stimuli. We examined the possibility that after associative training these neurons may start to respond during retrieval to previously ineffective stimuli, thus participating in triggering the reconsolidation.

Title: Endovanilloid-mediated synaptic potentiation contributes to behavioral sensitization

Authors: *Y. WANG, B. D. BURRELL;
Basic Biomed. Sciences, Ctr. for Brain & Behavior Res. (CBBRe), Univ. of South Dakota, Vermillion, SD

Abstract: Transient Receptor Potential Vanilloid (TRPV) channels have established roles in sensory transduction, but also have an important neuromodulatory role in the central nervous system (CNS). In the CNS, TRPV channels can be activated by endocannabinoid/endovanilloid neurotransmitters, such as 2-arachidonoyl glycerol (2-AG) and anandamide (AEA), and can elicit long-term depression or persistent synaptic potentiation (the latter as a result of disinhibition). However, the functional/behavioral relevance of these opposing forms of endovanilloid-mediated neuromodulation is poorly understood. We have examined the patterns of activity that produced endovanilloid-mediated synaptic depression vs. potentiation and the behavioral effects of both forms of neuroplasticity using the well-characterized central nervous system of the medicinal leech. Low frequency stimulation (LFS) of non-nociceptive touch-sensitive neurons or bath-application of 2-AG produced TRPV-mediated depression of nociceptive (N cell) synaptic transmission as well as a decrease in the intensity of the defensive shortening reflex (Yuan & Burrell; J Neurophsiol 110: 2607). On the other hand, high frequency stimulation (HFS) of the N cell or 2-AG treatment elicited potentiation of non-nociceptive pressure (P) cell synaptic transmission and increased defensive shortening elicited by P cell activation. Pretreatment with the TRPV1 antagonist, SB 366791, could block 2-AG- and HFS-elicited potentiation of both behavior and synaptic transmission. Furthermore, pretreatment with 2-AG synthesis inhibitor, tetrahydrolipstatin (THL), also prevent HFS-induced synaptic and behavioral potentiation indicating that this activity-induced neuromodulation required 2-AG. Studies are currently underway to confirm that this endovanilloid-dependent modulation contributes to behavioral sensitization elicited by a more physiologically/behaviorally-relevant stimuli. These results indicate that endovanilloid-mediated synaptic potentiation plays an important role in behavioral sensitization. It is speculated that this endovanilloid-dependent neuromodulation may interact with serotonin-based forms of modulation that contribute to

sensitization given that 2-AG-mediated synaptic plasticity requires activation of 5HT2-like receptors (Yuan & Burrell 2012; Brain Res 1460:1). Sensitization is a fundamental form of behavioral modulation contributing to pain signaling, anxiety, addiction and learning and memory. Therefore, these findings provide significant insights into a previously unknown role for TRPV channels in this form of neurobehavioral plasticity.

Title: Effect of sleep deprivation on crayfish olfactory thresholds

Authors: J. SALAZAR-VÁSQUEZ[1], K. MENDOZA-ANGELES[1], G. ROLDAN[1], *J. HERNANDEZ-FALCON[2];
[1]Univ. Nacional Autónoma de México, México, Mexico; [2]Univ. Natl. Autonoma Mexico, Mexico, Mexico

Abstract: Under laboratory conditions, agonistic interactions in crayfish triads result in the formation of a hierarchy with a dominant animal, a submissive 1, and a submissive 2 animals. When agonistic interactions are carried out on a daily basis, the number and the intensity of these interactions are modified in such a way that positive contacts (threats, attacks and fights) diminish, while negative contacts (retreat and escape) increase. Previous results indicate that sleep deprivation induces an increase in the number of positive contacts. Olfactory information is the main sensory input in the establishment and maintenance of the dominance order. It has been proposed that during agonistic interactions a putative substance is released in the urine stream that animals discharge from the nephropores to the antennular area of its opponent, thus identifying them as a dominant or a submissive animal. Hence, the changes found in positive contacts of interacting sleep deprived animals, could be explained by modifications in its olfactory sensitivity. Therefore, the first objective of this study was to analyze the electrophysiological olfactory response of submissive animals to urine from the dominant one. Because sleep deprivation induces an increase in the intensity of agonistic encounters, a second objective of this work was to analyze the effects of sleep deprivation in the establishment and

maintenance of the hierarchical organization of crayfish triads and its effects on the electrophysiological olfactory response. We used male crayfish, Procambarus clarkii, in intermolt, and performed two types of experiments: A) Agonistic interactions in control and sleep deprived triads, and B) Analysis of the olfactory response to dominant and submissive urine, in control and sleep deprived crayfish. Our results indicate: (a) In sleep deprived triads positive contacts increase in intensity, amount, and duration. Negative contacts also increase, which seems to indicate a decrease in the sensitivity of animals to some kind of olfactory stimulus. (b) Olfactory stimulation of submissive crayfish using the dominant animal urine produced an escape reflex, whose latency was higher in sleep deprived crayfish. The larger latencies were found in the submissive crayfish 2. (c) Sleep deprivation reduced the brain and antennular electrical response to olfactory stimuli in dominant and submissive animals. These findings implicate that crayfish seem to detect each other through the olfactory input and that sleep deprivation increases the threshold for sensory stimuli.

Title: Serotonin may convey positive and octopamine negative reinforcement signals to the learning network of Octopus vulgaris

Authors: T. SHOMRAT[1,2], *B. HOCHNER[1];
[1]Dept of Neurobiology, Hebrew Univ., Jerusalem, Israel; [2]The Ruppin Academic Center, Sch. of Marine Sci., Michmoret, Israel

Abstract: Octopuses uniquely combine vertebrate-like advanced behavior with a relatively simple invertebrate brain. This feature makes them an ideal preparation for comparative analysis of brain mechanisms evolved to mediate complex behaviors. The vertical lobe (VL), a pivotal brain region in the octopus learning system, has a robust activity-dependent long-term synaptic plasticity (LTP), analogous to suggested mechanisms for learning and memory in mammals. Serotonin (5-HT) is a facilitatory neuromodulator of synaptic transmission of the glutamatergic synaptic input to the VL, the same synaptic input that undergoes this LTP. However, differently from its related molluscan model, the *Aplysia* sensory-motor synapse, prolonged exposure to 5-HT does not lead to intermediate- or long-term potentiation. Yet, the short-term facilitatory effect of 5-HT leads to an indirect reinforcement of induction of the activity-dependent LTP. Here we show a similar short-term facilitatory effect for octopamine (OA). In contrast to 5-HT, which enhances induction of LTP by high frequency stimulation (HF-LTP), 100μM OA blocks induction of HF-LTP. Moreover, OA, when co-exposed with IBMX (increases intracellular cAMP and/or cGMP) depotentiates a previously induced HF-LTP. We therefore hypothesize that, during learning, 5-HT and OA serve as specific positive and negative reinforcement signals, respectively, allowing the octopus to associate a situation with its positive or negative consequences. Like results from mammals and insects, our research shows the universal importance of neuromodulators that, together with activity-dependent plasticity, determine the computational properties of learning and memory networks in animals with complex behavior.

Title: Short- and long-term plasticity in homologous learning and memory networks of octopus and cuttlefish are highly variable in their molecular but not computational properties or connectivity

Authors: *A. TURCHETTI-MAIA[1], N. STERN-MENTCH[1,2], N. NESHER[1,2], B. HOCHNER[1], T. SHOMRAT[1,2];
[1]Dept. Neurobiology, Silberman Inst. of Life Sciences, The Hebrew Univ., Jerusalem, Israel;
[2]The Ruppin Academic Center, Sch. of Marine Sci., Michmoret, Israel

Abstract: The vertical lobes (VL) of *Octopus vulgaris* and *Sepia officinalis* mediate the advanced learning and memory of these cephalopod mollusks. In both animals the VL network comprises three neuron types organized in a fan-out fan-in connectivity (see scheme) where ~2 million superior frontal lobe neurons (SFLn) innervate tens of millions of amacrine interneurons (AM) in the VL. These AMs then converge onto only several thousand large efferent neurons (LN). The synaptic inputs to the AM are glutamatergic, while those to the LN are cholinergic. In contrast to the similarity in connectivity, short- and long-term plasticity and neuromodulation are dichotomically different in the two species (see scheme). The activity dependent LTP of the glutamatergic SFLn-AM synapses in the octopus is absent in the cuttlefish. Instead, the cuttlefish shows LTP of the cholinergic AM-LN synapses. However, theoretical considerations suggest that the two networks have similar computational properties (Shomrat *et al*. 2011). Here we compare the mechanisms mediating LTP. In octopus, nitric oxide synthase (NOS) inhibitors blocked LTP expression without affecting LTP induction, while in cuttlefish NOS inhibitors affected neither induction nor expression. Histochemical results support the physiological differences, as the octopus VL stained for NADPH-d (indicating NOS activity), while in cuttlefish only areas outside the VL were labeled. Preliminary results suggest that LTP induction in the octopus appears to be PKC- dependent, as phorbol-ester induced LTP and chelerythrine blocked LTP induction. In contrast, in cuttlefish, phorbol-ester induced either transient facilitation or had no effect. Also, the PKC inhibitors we have so far studied had inconsistent effects in cuttlefish. These results suggest that cephalopods are an unprecedented demonstration of profound variation among homologous networks. This suggests that evolutionary convergence or self organization may select among a variety of molecular mechanisms to construct cellular properties that are universal for learning and memory networks.

Title: Inferring functional connectivity of neural circuits using information theoretic causality measures

Authors: ***Z. CAI**[1], B. AAZHANG[1], J. H. BYRNE[2];
[1]Electrical and Computer Engin., Rice Univ., Houston, TX; [2]Neurobio. and Anat., The Univ. of Texas Med. Sch. at Houston, Houston, TX

Abstract: Neural recording technologies such as voltage sensitive dyes (VSD) have enabled increasingly larger-scale simultaneous recording from neural networks, yet how signals recorded from individual neurons describe neural functions, plasticity and memory in a collective network is still poorly understood. In an attempt to tackle the aforementioned problem, we are applying and developing techniques to infer the underlying neural circuit by performing calculations of causal measures. Synthetic signals are generated by neural networks that are built using individual Hodgkin-Huxley neuronal models. Different estimation algorithms are compared and

implemented to extract the stochastic properties of the neural signals. Using these stochastic properties directed information (DI), a causal connectivity measure, is calculated between each pair of neurons. Together with the connectivity, other biophysical properties, such as the sign of a synaptic connection (i.e., excitatory or inhibitory) can also be inferred. Our initial results from using context tree weighting (CTW) estimation combined with DI show that this approach is able of detecting direct connections, eliminating indirect connections, and identifying the types of the synapses and their strength in small-scale realistic neural networks. Once the algorithm is validated using various artificial networks generated by the Hodgkin-Huxley conductance-based neural models, it will be applied to larger-scale real data. The buccal ganglion of *Aplysia* (see adjacent poster) will be used as a small brain test system. This method of combining large-scale recording techniques with signal processing tools to construct functional connectomes offers an automated tool to map a neural circuit and the ability to capture changes in synaptic strength due to learning or other behavioral modifications.

Title: Voltage-sensitive dye (VSD) recordings reveal the network dynamics that underlie fictive behaviors

Authors: *C. NEVEU, D. A. BAXTER, J. H. BYRNE;
Neurobio. and Anat., The Univ. of Texas Med. Sch. At Houston, Houston, TX

Abstract: Feeding behavior in *Aplysia* is a useful model system for investigating the neural basis of behavior. Much of neural network that mediates feeding behavior is located in the buccal ganglia. Previous studies suggest that ~100 neurons in each hemi-ganglia are involved in the genesis of feeding behaviors such as the ingestion of food and the rejection of inedible objects. In isolated buccal ganglia preparations, at least two fictive behaviors (i.e., buccal motor patterns, BMPs) are observed: one is associated with ingestion (iBMPs) and another with rejection (rBMPs) of food. Both iBMPs and rBMPs have a protraction and retraction phase that correspond to different movements of a tongue like structure. Here, we report using a

combination of extracellular nerve recordings and VSD recordings of somatic action potentials to monitor activity in relatively large numbers of neurons within the feeding circuit. Extracellular recordings were used to categorize the BMPs as either iBMP or rBMP, and the VSD recordings monitored activity in up to 30 individual neurons simultaneously. Activity was monitored continuously for 2 min using the absorbance dye RH-155. Our preliminary results indicate that changes in activity occurred in at least half of the cells monitored via VSD recordings during spontaneous switching between fictive ingestion and rejection. Moreover, the majority of the changes in neuronal activity occurred during the protraction phase of BMPs. We also measured neuronal activity during an additional 2 min recording 5 min after the application of L-DOPA. Consistent with previous findings, L-DOPA increased the overall frequency of fictive behavior and biased the network towards iBMPs. Extensive reorganization of feeding circuit was observed in the presence of L-DOPA. For example, a comparison of neural activity during control iBMPs versus L-DOPA-induced iBMPs indicated that L-DOPA induced different levels of the activity in the majority of cells monitored via VSD recordings. Moreover, the preliminary data suggest that the neural activity during L-DOPA-induced iBMPs was substantially different from control iBMPs, which may reflect a fundamentally different mechanism for behavioral switching and/or genesis of fictive ingestion. Results from this study indicate that the use of VSD recordings will help to characterize the activity patterns of individual neurons during behavior and understand the extent to which a network of neurons can be reconfigured by prior events (e.g., learning) and extrinsic factors (e.g., pharmacological manipulations).

Title: Role of p38 MAPK and ERK activation in doxorubicin mediated attenuation of 5-HT-induced long-term synaptic facilitation

Authors: ***H. LAKSHMINARASIMHAN**, Y. ZHANG, L. J. CLEARY, J. H. BYRNE; Dept. of Neurobio. and Anat., The Univ. of Texas Med. Sch. At Houston,, Houston, TX

Abstract: Doxorubicin (DOX), a common chemotherapeutic agent, is associated with chemotherapy induced memory deficits colloquially known as “chemobrain.” In *Aplysia* sensory neurons, DOX (2.5 μM, 120 min) treatment results in elevated levels of phosphorylated ERK, phosphorylated p38 MAPK and phosphorylated CREB2, leading to an attenuation of 5-HT-induced LTF and enhancement of FMRFa-mediated LTD (Liu et al., J. Neurosci. 34:13289, 2014). The LTF impairment was rescued by inhibition of p38 MAPK. Given that ERK activation is essential for LTF and p38 MAPK activation is essential for LTD (Michael et al., Proc. Natl. Acad. Sci. 95:1864, 1998; Guan et al., J. Neurosci. 23:7317, 2003), the above results suggest that DOX activated p38 MAPK is more effective than activated ERK. The dominant effects of p38 MAPK may be due to differences in time-course or magnitude of activation. We tested this hypothesis by examining the temporal profile of ERK and p38 MAPK phosphorylation using varying durations of DOX treatments (2.5 μM for 30, 60, 90 and 120 min). The duration of DOX treatment significantly affected the activation of p38 MAPK (treatment x duration; $F(3,46) = 4.75$; $p = 0.006$) with significant main effect of DOX treatment (treatment; $F(1,46) = 32.08$; $p = 0.0$) as well as duration of DOX treatment (duration; $F(3,46) = 27.3$; $p = 0.0$). Peak p38 MAPK activation was observed after at least 90 min (increase by 32.4% at 30 min, 88.1% at 60 min, 93.3% at 90 min and 64.4% at 120 min compared to Vehicle) of DOX treatment. This result suggests that levels of active p38 MAPK increase with the duration of treatment. However, the DOX-induced increase in ERK activation (treatment; $F(1,54) = 7.1$; $p = 0.01$ and duration; $F(3,54) = 4.4$; $p = 0.007$) was relatively independent of the treatment duration (treatment x duration; $F(3,54) = 0.13$; $p = 0.93$) indicating that the increase in ERK activation is rapid (increase by 34.7% at 30 min, 20.6% at 60 min, 39.6% at 90 min and 33.5% at 120 min compared to Vehicle). These results suggest that over time the magnitude of the increase in active p38 MAPK dominates over the effects of activated ERK, resulting in attenuation of LTF and enhancement of LTD. We are now examining the effects of DOX pre-treatment (30 min) on the 5-HT-mediated changes in the activation of ERK and p38 MAPK. At this early time point, we aim to explore the nature of the interaction (additive versus synergistic) between DOX and 5-HT treatments on these kinases. We are also incorporating these findings into a computational model of the molecular mechanisms underlying LTF induction (Liu et al., J. Neurosci. 33: 6944, 2013) to design a training protocol to rescue the DOX-induced deficit of LTF.

Title: The role of growth factor signaling in post-transcriptional RNA regulation during long-term memory formation in *Aplysia*

Authors: *A. M. KOPEC, A. A. MIRISIS, T. J. CAREW;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: It is widely appreciated that signaling via several different growth factor (GF) families is required for long-term memory (LTM) formation, but the roles of distinct GF families in mediating unique molecular and cellular signaling events remains to be elucidated. Previous data from our laboratory show that GF signaling via the TrkB and TGFβr-II receptors is engaged in unique spatial and temporal profiles during Two-Trial LTM formation in *Aplysia* (Kopec et al. 2015) Interestingly, these different GF families each mediate a unique phase of MAPK activation, but synergistically interact to regulate expression levels of the immediate early gene c/ebp. Specifically, Trial 1 TrkB signaling increases the expression of c/ebp, and Trial 2 TGFβr-II signaling prolongs the expression of this c/ebp message. To explore the mechanism by which Trial 2 TGFβr-II signaling prolongs the expression of c/ebp mRNA, we sought to characterize the level of c/ebp associated with the RNA binding protein ELAV, a member of the Hu family of RNA binding proteins which has been demonstrated to stabilize c/ebp transcripts in *Aplysia* (paper). Here we report that mRNA and protein levels of ELAV do not change from baseline 15 mins after Trial 2. However, RNA immunoprecipitation experiments demonstrate a positive correlation between the level of c/ebp induction after Trial 2 and the amount of c/ebp bound to ELAV. Collectively these data support the hypothesis that Trial 2 promotes the binding of ELAV and c/ebp mRNAs, and thus implicates the complex regulatory mechanisms of mRNA expression in LTM formation. In our next experiments, we will (i) test the hypothesis that ELAV-c/ebp binding induced by Trial 2 requires TGFβr-II signaling, (ii) further characterize the molecular signaling pathways that regulate ELAV-c/ebp associations, and (iii) determine the behavioral relevance of this association during memory formation in *Aplysia*, with the ultimate goal of examining post-transcriptional processing as an additional level of regulation important for plasticity and memory formation.

Title: Synaptic generation of a retrograde intracellular signal requires tyrosine kinase and mitogen-activated protein kinase activity in *Aplysia*

Authors: *S. STOUGH[1], A. KOPEC[2], T. CAREW[2];
[1]Psychology, Augustana Col., Rock Island, IL; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Cellular changes underlying memory formation can be generated in an activity-dependent manner at specific subsets of synapses. Thus an important question concerns the mechanisms by which synaptic signals communicate with the cell body in order to coordinate these cellular changes. The monosynaptic neural circuit underlying memory for sensitization in *Aplysia* is well-suited to study this question because different subcellular compartments (e.g. sensorimotor SN◊MN synapses, SN◊MN axonal connections, and SN cell bodies) can be manipulated and studied independently. We have previously shown that incubation of the SN◊MN circuit with a 5 min pulse of a high KCl (370mM) and serotonin (5HT, 50μM) , which combines depolarization with neuromodulation (activity-dependent [AD] stimulation), induces both MAPK activation in SN cell bodies and synaptic facilitation (Shobe et al., 2009). Here, we report that AD stimulation applied to the entire neural circuit activates MAPK in a temporally specific pattern in different subcellular compartments. Interestingly, we find that this temporal pattern of MAPK activation can be generated if the AD (KCl/5HT) training pulse is delivered only to the SN◊MN synapses in a split bath preparation (Sherff and Carew, 1999). Specifically, we find that (i) MAPK activation is first transiently generated at SN◊MN synapses during training, (ii) immediately after training MAPK is transiently activated in SN◊MN axonal connections and persistently activated in SN cell bodies, and finally, (iii) MAPK is activated in SN cell bodies and SN◊MN synapses 1hr after training. These data suggest there is an intracellularly transported retrograde signal generated at the synapse which is later responsible for delayed MAPK activation at SN cell bodies. This retrograde signal requires activation of a tyrosine kinase (TK) signaling cascade in the synapses at the time of training, but does not require TK signaling at SN cell bodies for 1 hr MAPK activation in SN cell bodies. An intriguing hypothesis is that MAPK, which is rapidly activated locally at the synapse in response to AD training, is itself the retrograde signal that travels to SN cell bodies. In support of this hypothesis, blocking MEK activity at the synapse disrupts subsequent persistent MAPK activation in SN cell bodies. In conclusion, we have identified a temporally and spatially coordinated profile of

MAPK activation following a synaptically-generated signal which could be a candidate mechanism that underlies communication between the synapse and cell body during memory formation.

Title: Non-nuclear ERK/MAPK signaling is temporally correlated with the opening of training windows for long-term memory formation in *Aplysia*

Authors: *A. CHEN, T. J. CAREW, G. T. PHILIPS;
New York Univ., New York, NY

Abstract: A highly conserved principle of learning and memory is that the temporal patterning of experiences regulates the acquisition and retention of long-term memory (LTM). We have previously shown that ERK/MAPK signaling plays an important role in supporting the interactions of spaced experiences during two-trial learning and LTM formation in *Aplysia* californica (Philips et al. 2013). Specifically, nuclear MAPK signaling, which was required for activation of CREB-mediated transcription, was temporally correlated with the opening of a permissive training "window" at 45min (but not at 15min or 1h) following training trial 1. Although Trial 1-induced MAPK signaling to CREB was shown to be necessary to support two-trial LTM formation, it remains unclear whether this signaling is responsible for opening permissive training "windows" for LTM formation. In the present study we show that MAPK is activated as soon as 30min after training trial 1, but no earlier (i.e. no activation is observed at 20min). Using immunohistochemistry we found that the activated MAPK is cytoplasmic (non-nuclear) at 30min, with significant nuclear translocation of MAPK occurring at 45min. Intriguingly, the CREB kinase p90rsk, which is localized to the cytoplasm and is an established target of trial 1 MAPK signaling, is significantly activated (phosphorylated at ser380) by 30min. Moreover, the non-nuclear MAPK signaling to p90rsk is temporally correlated with the opening

of the two-trial learning window: animals acquired and expressed LTM for sensitization with two-trial training at 30min, but not 20min training intervals. Thus, our data suggest that cytoplasmic ERK/MAPK activation engages the CREB kinase p90rsk to contribute to the "opening" of a permissive training window for LTM formation.

Title: Molecular and cellular mechanisms of endogenous neurotrophic factor signaling during long-term synaptic plasticity in *Aplysia* californica

Authors: *A. ALEXANDRESCU[1], T. J. CAREW[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: The molecular and cellular mechanisms of long-term memory formation are highly conserved across species. One such evolutionarily conserved mechanism is neurotrophic factor signaling. The marine mollusk *Aplysia* californica is a powerful model system for studying the molecular mechanisms of long-term synaptic plasticity underlying long-term memory for sensitization. Previous studies from our laboratory have shown that neurotrophic factor signaling critically participates in the formation of long-term synaptic facilitation and long-term memory (Purcell et al. 2003; Sharma et al. 2006; Kopec et al. 2015). Furthermore, we have identified a novel endogenous neurotrophic factor, *Aplysia* cysteine-rich neurotrophic factor (ApCRNF), which shares structural and functional characteristics with mammalian neurotrophins (Pu et al. 2014). When paired with subthreshold training for sensitization (1 tail nerve shock / 1 pulse of serotonin), exogenous application of recombinant ApCRNF induces a gain-of-function in both ERK/MAPK activation in sensory neuron somas and in long-term facilitation of sensory-motor neuron synapses. Using an immunocytochemical analysis, we find that ApCRNF protein is localized to the cytoplasm of both sensory and motor neurons. Furthermore, ApCRNF binds to

receptors on the cell surface of both sensory and motor neurons in co-cultures treated with exogenous recombinant ApCRNF. Our current studies are focused on an investigation of the molecular and cellular mechanisms engaged by ApCRNF within the sensory-motor neuron microcircuit during long-term synaptic facilitation.

Title: *Aplysia* neurotrophin acts as a presynaptic autocrine, anterograde, and retrograde signal during the transition from short-term facilitation to intermediate-term facilitation produced by 5HT at *Aplysia* sensory-motor neuron synapses

Authors: *I. JIN[1], H. UDO[2], E. R. KANDEL[1], R. D. HAWKINS[1];
[1]Dept. of Neurosci., Columbia Univ., New York, NY; [2]Dept. of Biol., Kyushu Univ., Fukuoka, Japan

Abstract: Spontaneous neurotransmitter release from the presynaptic neuron acts as an anterograde signal during the transition from short-term facilitation (STF) to intermediate-term facilitation (ITF) produced by 5HT at *Aplysia* sensory-motor neuron synapses (Jin et al., 2012a, b). It activates mGluR5 to recruits postsynaptic mechanisms of ITF, which may be an early step in a cascade leading to long-term facilitation (LTF) and synaptic growth. In addition, activation of presynaptic PKA during STF increases the release of *Aplysia* neurotrophin (ApNT) from the presynaptic neuron. The ApNT then binds to its receptor (ApTrk) on the presynaptic neuron and activates downstream signaling including PKA. This signaling cascade forms a presynaptic positive feedback loop that enhances spontaneous glutamate release and may also enhance presynaptic PKA for the transition to LTF (Jin et al., 2014). We report here that ApNT also acts as an anterograde signal in a transynaptic feedback loop. 10 min bath application of 5HT increases the release of overexpressed ApNT-pHluorin from the presynaptic neuron. Injection of antisense oligo against ApTrk into the postsynaptic motor neuron reduces the increase in mini

frequency produced by 10 min 5HT, and activation of postsynaptic ApTrk increases mini frequency. These data suggest that ApNT released from the presynaptic neuron activates postsynaptic ApTrk, which stimulates a retrograde signal that enhances presynaptic spontaneous release. Interestingly, ApNT also acts as the retrograde signal. Injection of siRNAi against ApNT into the postsynaptic neuron reduces the increase in mini frequency produced by 10 min 5HT, suggesting that postsynaptic ApNT is involved. Activation of postsynaptic ApTrk increases the release of overexpressed ApNT-pHluorin from the postsynaptic neuron. Furthermore, the increase in mini frequency produced by postsynaptic ApTrk activation is reduced by injection of antisense oligo against ApTrk into the presynaptic neuron. These results suggest that ApNT released from the postsynaptic neuron acts as a retrograde signal and enhances spontaneous transmitter release through activation of presynaptic ApTrk. In summary, ApNT plays three essential roles during the transition from STF to ITF produced by 5HT at *Aplysia* sensory-motor synapses: (1) it is part of a presynaptic positive feedback loop, which amplifies the signaling molecules required, (2) it acts as an anterograde signal to recruit postsynaptic mechanisms including ApNT itself, which then (3) acts as a retrograde signal, forming a transynaptic feedback loop that may also amplify the molecules required and coordinate the pre- and postsynaptic neurons.

Title: Role of the nitric oxide signaling cascade in the induction of the behavioral changes produced by aversive stimuli in *Aplysia*

Authors: J. FARRUGGELLA, J. A. ACEBO, *M. L. WAINWRIGHT, R. MOZZACHIODI; Texas A&M Univ. - Corpus Christi, Corpus Christi, TX

Abstract: When *Aplysia* is exposed to aversive stimuli (i.e., electric shocks to the body wall), it exhibits a learned behavioral change known as sensitization through which defensive responses (e.g., the tail-siphon withdrawal reflex; TSWR) are enhanced. Training protocols that induce sensitization also cause a concurrent suppression of a non-defensive behavior, feeding.

Specifically, long-term sensitization (LTS) training (four 10-s trains of electric shocks spaced 30 min) induces sensitization and feeding suppression lasting at least 24 h, whereas single-trial sensitization (STS) training (one 10-s train of electric shocks) induces sensitization and feeding suppression lasting for at least 2 h but less than 24 h. Although serotonin has been shown to mediate sensitization, it is not involved in the concomitant suppression of feeding, suggesting that distinct signaling cascades regulate the different behavioral changes produced by aversive stimuli. This study sought to investigate whether nitric oxide (NO) contributes to the induction of sensitization and feeding suppression. Because the NO signaling cascade may contribute selectively to specific temporal domains of the changes produced by sensitizing stimuli, both LTS and STS training protocols were used. The NO synthase inhibitor L-NAME was used to block the NO signaling cascade. In all the experiments, L-NAME was injected systemically 1 h before training. TSWR duration and feeding (i.e., number of bites in a food extract solution) were assessed prior to and 24 h after LTS training, and 15 min and 2 h after STS training. For both training protocols, four groups were included: L-NAME-injected trained, L-NAME-injected untrained, vehicle-injected trained, and vehicle-injected untrained. Following the LTS protocol, sensitization and feeding suppression were blocked at the 24-h time point in L-NAME-injected trained animals, whereas they were both observed in vehicle-injected trained animals. Similarly, following the STS protocol, feeding suppression was prevented in L-NAME-injected trained animals at both 15-min and 2-h time points, whereas it was induced in vehicle-injected trained animals. Ongoing experiments are characterizing the contribution of the NO pathway to the sensitization induced by the STS protocol. The above findings suggest that the NO signaling cascade may contribute to the induction of both short-term and long-term feeding suppression. Interestingly, this signaling cascade also appears being involved in the induction of long-term sensitization, suggesting that a complex interaction between serotonin and NO pathways underlie the long-term changes induced by LTS training.

Title: Persistent transcriptional correlates of long-term sensitization training in Aplyisa californica

Authors: J. PATEL[1], C. CONTE[1], S. HERDEGEN[1], S. KAMAL[1], I. E. CALIN-JAGEMAN[1], *R. CALIN-JAGEMAN[2];

Abstract: Sensitization is a ubiquitous form of non-associative memory. The long-term expression of sensitization memory depends in part on persistent changes in gene expression. We are using microarray and qPCR to enumerate the persistent transcriptional changes accompanying long-term sensitization of the tail-elicited siphon-withdrawal reflex in the marine mollusc *Aplysia* californica. To accomplish this, animals receive unilateral long-term sensitization training. After behavioral confirmation of long-term memory 1 day after training, pleural ganglia are harvested, and gene expression is compared from the trained to untrained ganglia. We have so far confirmed or identified 7 transcripts that are strongly up-regulated for at least 24 hours after sensitization training: BiP, Tolloid/BMP-1, sensorin, Egr, GlyT2, VPS36, and an uncharacterized protein (LOC101862095). We are now in the process of conducting microarray analysis on pleural ganglia samples harvested 1 day after training to reveal the complete transcriptional profile accompanying long-term memory expression. This work will help shed light on the transcriptional networks that help sustain the expression of a long-term memory.

Title: Classical conditioning in the *Aplysia* siphon-withdrawal preparation involves RNA synthesis and DNA methylation

Authors: *R. D. HAWKINS[1,2], I. ANTONOV[1], A. NAGARAJ[1], Q. YANG[1];
[1]Neurosci., Columbia Univ., New York, NY; [2]New York State Psychiatric Inst., New York, NY

Abstract: We have been studying mechanisms of simple forms of learning using a reduced preparation of the *Aplysia* siphon withdrawal reflex in which it is possible to record the activity and synaptic connections of identified neurons during the learning. The preparation undergoes intermediate-term habituation, dishabituation, sensitization, and classical conditioning that are similar to learning in the intact animal. Each of those forms of learning is due in part to plasticity at the synapses from LE sensory neurons to LFS motor neurons (Antonov et al., 1999, 2001, 2010). Conditioning involves pairing-specific facilitation at those synapses, which is due to two mechanisms that interact through retrograde signaling: (1) activity-dependent enhancement of the presynaptic PKA pathway and (2) Hebbian potentiation induced by activation of postsynaptic NMDA receptors (Antonov et al., 2003). The conditioning also involves NO, which comes from the L29 interneurons and acts directly in both the LE and LFS neurons (Antonov et al., 2007), where it activates HCN channels that enhance the NMDA current (Hawkins et al., 2014). We have now begun to examine mechanisms of long-term conditioning. In preliminary experiments the preparation exhibited 24 hr retention of the pairing-specific increases in siphon withdrawal and its correlates in the LE and LFS neurons, suggesting that long-term conditioning involves the same cellular mechanisms as intermediate-term conditioning. Conditioning was also accompanied by an increase in synaptophysin puncta, which may be an initial step in synaptic growth. In addition, we have begun to examine the role of gene regulation. We compared changes in the withdrawal reflex in groups that received either paired or unpaired training with a siphon tap CS and a tail shock US while the ganglion was bathed in either normal seawater or DMSO (control), the RNA synthesis inhibitors Actinomycin D or DRB, or the DNA methyl transferase inhibitor RG108. In the control group, paired training produced an increase in the response to the CS compared to either the pretest or unpaired training, demonstrating classical conditioning. Either Actinomycin D (50 μg/ml), DRB (300 μM), or RG108 (200 μM) significantly reduced conditioning during the later part of training. As controls, the drugs had no significant effects on unpaired training or the amplitude of the initial siphon withdrawal in response to either the CS or US. These results suggest that classical conditioning in this preparation involves DNA methylation and changes in transcription. An accompanying abstract (Bostwick et al, 2015) uses nRNAseq to identify transcripts preferentially expressed during the conditioning.

Title: Impact of chronic sleep deprivation on short-term and long-term associative memory in *Aplysia* californica

Authors: *H. KRISHNAN, E. NOAKES, L. C. LYONS;
Biol. Science, Program in Neurosci., Florida State Univ., Tallahassee, FL

Abstract: Sleep is an evolutionarily conserved process and plays an important role in the modulation of memory. Chronic sleep restriction, prevalent in modern society, leads to cognitive deficits and performance impairments; however, the underlying mechanisms are not clear. Given the high degree of conservation underlying memory formation across species, the marine mollusk *Aplysia californica* with its relatively simple neural circuitry provides an ideal model for studying the interactions between sleep and memory formation. Previously, we have shown that *Aplysia* sleep in consolidated bouts, have higher arousal thresholds with longer response latencies during sleep, and demonstrate rebound sleep after sleep deprivation (Vorster et al., 2014). Using an associative learning paradigm, learning that food is inedible (LFI), in which the animal associates a specific netted seaweed with the failure to swallow, we previously found that 9 hours of acute sleep deprivation was sufficient to block the induction of short-term (STM) and long-term memory (LTM). We also found that 6 h acute sleep deprivation during the last half of the night blocked induction of LTM, but had no effect on STM. In our current research, we investigated the effects of chronic sleep restriction on short-term and long-term memory. In initial studies, we found that 3 consecutive nights of sleep deprivation during the last 4 h of the night blocked the induction of STM but not LTM. We are also examining the effects of more severe chronic sleep restriction on STM and LTM. Defining the interactions between sleep and memory through behavioral studies in a relatively simple model system provides a basis for future studies delineating the underlying mechanisms through which sleep affects memory and potentially will identify novel ways to alleviate cognitive deficits incurred due to restricted sleep.

Title: The role of stimulus novelty in attention in the invertebrate *Aplysia*

Authors: K. PEARCE, M. E. KIMBROUGH, X. ZHAO, T. S. DEHGHANI, E. J. MOC, D. ENAYATI, S. S. BENTLEY, V. KONG, *T. W. ABRAMS;
Pharmacol., Univ. of Maryland Med. Sch., Baltimore, MD

Abstract: We recently explored whether the non-visual invertebrate *Aplysia* exhibits attention using a distraction paradigm. In general, distraction requires that a subject is first "paying attention" to a stimulus. We tested whether *Aplysia* could be distracted from a conditioned stimulus (CS) that animals had learned signaled the occurrence of a noxious US. Animals were first trained in a fear conditioning paradigm (Walters et al. 1981) with dilute carrot juice as the CS and tail shock as the US. The 90 s CS and the 15 s US coterminated during each of 6 pairing trials over 2 days. Sensitized animals received the same two stimuli during training, separated by 15 min. When the siphon withdrawal response (SWR) was tested in the presence of the CS on day 3, fear conditioned animals showed a substantially greater increase in the duration of the withdrawal response than sensitized animals. To test for the effect of a distractor, in posttests a very mild vibration stimulus was introduced 5 s prior to the onset of the CS. These weak distractor stimuli had no effect on the SWR of sensitized animals. In contrast, the presence of the distractor dramatically reduced or completely eliminated the enhanced SWR of fear conditioned animals. This suggests that in *Aplysia*, the fear response to the CS requires that animals "pay attention" to this stimulus. However, there are two alternative interpretations for the lack of an enhanced defensive response in the presence of the distractor: 1) The animals may be conditioned to the context, and the addition of the vibration stimulus represents a different context, which animals distinguish from the training context. 2) The CS + distractor may represent a distinct compound stimulus that was not associated with the tail shock. We reasoned that if the distractor stimulus indeed competed for the animals' attention, causing them to ignore the CS, then the efficacy of the distractor should depend on its novelty. To determine the importance of novelty for an effective distractor, we tested the effect of 5 pre-exposures to the distractor stimulus on the day of testing. Pre-exposure to the distractor largely eliminated its efficacy in reducing the enhanced defensive response to the CS ($p = 0.007$), suggesting that the novel stimulus is indeed "distracting the animals' attention." These results further suggest that in *Aplysia*, much as in humans, including infants, the ability of a stimulus to attract attention strongly depends on the novelty of the stimulus.

Title: Prolonged food deprivation alters the co-expression of sensitization and food suppression induced by aversive stimuli in *Aplysia*

Authors: K. A. MAC LEOD, M. L. WAINWRIGHT, *R. MOZZACHIODI;
Dept. of Life Sci., Texas A&M Univ. - Corpus Christi, Corpus Christi, TX

Abstract: Organisms learn to adapt their behaviors in response to environmental stimuli in order to maintain a balance of their energetic needs. Following exposure to aversive stimuli, an organism budgets its behaviors by augmenting defensive responses and reducing/suppressing non-defensive behaviors. For example, in the marine mollusk *Aplysia*, exposure to noxious stimuli concurrently enhances defensive withdrawal reflexes (i.e., sensitization) and suppresses feeding. Recent work has revealed a strong relation in the temporal dynamics of sensitization and feeding suppression, which suggests a mechanistic link between these two processes. In this study, we attempted to uncouple the co-expression of sensitization and feeding suppression by manipulating of the animal's motivational state through prolonged food deprivation. A training protocol, consisting of a single 10-s train of electric shocks to the body wall, induces concomitant sensitization of the tail-siphon withdrawal reflex (TSWR) and feeding suppression in animals food deprived for 2 days. Both behavioral changes last at least 2 h, but less than 24 h. Here, we analyzed whether extending the period of food deprivation to 14 days could alter this co-expression of sensitization and feeding suppression. Four groups of animals were included: trained/14-day food deprived (T-14), untrained/14-day food deprived (UT-14), trained/2-day food deprived (T-2) and untrained/2-day food deprived (UT-2). For each group, TSWR duration and bites in response to a food stimulus were measured prior to and 15 min and 2 h after training. Sensitization of the TSWR was not expressed either 15 min or 2 h after training in T-14 animals, whereas it was observed in T-2 animals at both time points. Notably, prolonged food deprivation did not affect baseline TSWR duration, current threshold to elicit a detectable TSWR, or sensitivity to sensitizing shocks, indicating that the lack of sensitization in T-14 animals was not due to a reduced responsiveness to external stimuli. In contrast to sensitization, feeding suppression was not affected by prolonged food deprivation as it was observed at 15 min and 2 h in both T-14 and T-2 animals. Overall, the above results indicate that prolonged food deprivation

uncouples the co-expression of sensitization and feeding suppression. The lack of sensitization might be ascribed to prolonged food deprivation interfering with biochemical pathways underlying this behavioral change. The persistence of feeding suppression in T-14 animals might represent a strategy in which reducing bites following aversive stimuli could conserve energy in the short term.

Title: Identifying neuronal dynamics of short-term associative memory in *C. elegans*

Authors: ***A. SYLVAIN**[1], M. RAHIMI[2], G. STEIN[3], C. T. MURPHY[2];
[1]Princeton Neurosci. Inst., [2]Lewis Sigler Inst. for Integrative Genomics, [3]Mol. Biol., Princeton Univ., Princeton, NJ

Abstract: All animals make decisions based on the information they learn and remember about their environment, which requires neural plasticity. *C. elegans* is able to remember an association between food and odor (butanone) for a short time (less than 2 hours), an ability that is equivalent to classical short-term associative memory (STAM). We have defined many of the molecular components of this process through genetic analyses, but the circuit dynamics of STAM are not yet known. We have found that AWC^{on} exhibits increased odor-evoked Ca^{2+} responses upon STAM training, and that the number of animals responsive to the odorant decreases with increased post-conditioning time in close parallel to that observed in population STAM assays. We developed a novel microfluidic chip to simultaneously assay AWC^{on} activity and animal behavior to test whether the enhanced neuronal response correlates with the behavioral changes, and have identified neurons required for STAM performance. Finally, we have used these tools to begin to address the mechanism underlying *daf-2*'s three-fold increased STAM duration. These studies provide the framework for comprehensively understanding molecular and neural circuit mechanisms of short-term associative memory.

Title: UNC-43T, a putative ortholog of CaMKII$_\gamma$, appears necessary for associative conditioning in *C. elegans*

Authors: *J. K. ROSE, L. K. ALFILER, M. R. PRIBIC;
Psychology, Western Washington Univ., Bellingham, WA

Abstract: Calcium/calmodulin-kinase II (CaMKII) plays a role in the neuronal plasticity mechanisms that underlie learning. Recently, it has been demonstrated that CaMKII$_\gamma$ functions as a nuclear transporter involved in initiation of gene transcription (Ma et al., 2014). In *C. elegans*, the *unc-43* gene is considered an ortholog of CaMKII. The *unc-43*(gk452) mutant strain carries a specific deletion for the UNC-43T isoform, a putative ortholog of human CaMKII$_\gamma$. Our current results indicate that *unc-43*(gk452) worms show deficits in associative chemotaxis and chemoavoidance, *C. elegans* associative conditioning assays where acquisition of stimulus pairing occurs over the course of 1+ hours. More recently, we have determined that the *unc-43*(gk452) strain also shows impairment for rapidly acquired learning using a newly developed Classical Conditioning protocol that involves delayed presentation of a light stimulus (either UV or blue wavelength light; US) following onset of a vibrational stimulus (100 Hz tone; CS). With this Classical Conditioning procedure, wild-type *C. elegans* show an increased reversal magnitude (CR) to tone alone (CS) when presented one minute after pairing ($p<0.05$). Interestingly, *unc-43*(gk452) worms show a different response pattern after pairing: smaller mean reversal magnitudes as well as decreased response probability ($p<0.05$, $p<0.05$, respectively). These results suggest that CaMKII$_\gamma$ may be a necessary component for associative conditioning in *C. elegans*. Current work includes identifying necessary coding regions as well as determining retention duration.

Title: lrn-2/scd-2 mutations dissociate sensory integration and associative learning in *C. elegans*

Authors: *G. S. WOLFE[1], V. TONG[2], D. VAN DER KOOY[2];
[1]Inst. of Med. Sci., [2]Mol. Genet., Univ. of Toronto, Toronto, ON, Canada

Abstract: The cellular and molecular mechanisms of learning and memory can be studied in detail by taking advantage of model organisms such as the nematode, Caenorhabditis elegans. With a fully mapped connectome and genetic tractability, *C. elegans* has a wide variety of behaviours controlled by comparatively few neurons. We have characterized an EMS derived mutant strain, lrn-2, which shows deficits in both sensory integration and a wide variety of associative learning paradigms. Mapping, sequencing, complementation tests and wild type gene rescue have localized this mutation to the gene scd-2. Our experiments suggest that while sensory integration and associative learning mechanisms share genes in common, these genes act within independent pathways underlying separable psychological processes. The primary test of associative learning used in this project involved learning about pathogenic bacteria. The N2 control strain learns to associate the pathogenicity of PA14, a strain of P. aeruginosa, with the odor of the bacteria after 4 hour exposure. This results in N2 worms leaving the PA14, and migrating to a safe E. coli lawn on the other side of the plate. The lrn-2 mutants do not learn this association and remain on the pathogenic bacteria. The sensory integration deficit in these same mutant worms is demonstrated by the mutant's inability to integrate two cues by crossing an aversive copper barrier to reach an attractive diacetyl odorant. Both learning and sensory integration involve the processing of multiple sensory cues leading to altered behavioral output. While sensory integration does not require these changes to persist, associative learning requires these changes to persist as memories. lrn-2/scd-2 plays a role in both sensory integration and associative learning; however, we have found that each of these psychological processes require lrn-2/scd-2 expression independently. The gene fsn-1 has been shown to have an upstream suppressive effect on scd-2 sensory integration, but we have found that in an associative learning assay, fsn-1 may act differently, downstream of scd-2. Expression of wild type scd-2 in AIA neurons rescues sensory integration, but not associative learning, indicating that the two processes use different neuronal pathways. These data suggest a dissociation of the mechanisms of sensory integration and associative learning, despite some shared genetic components.

Title: Flexibility of the learned antenna projection response to natural contexts in Periplaneta americana

Authors: *M. POMAVILLE[1], D. D. LENT[2], A. LAWLESS[2];
[2]Biol., [1]California State University, Fresno, Fresno, CA

Abstract: The American cockroach, Periplaneta americana, has demonstrable advantages when exploring neural underpinnings of sensory processing, learning and memory. It is often more efficient to experiment on animals such as cockroach, to gain a basic understanding of how form follows function in neural systems. These experiments examine the interaction of multi-modal sensory acquisition, motor control, learning and memory systems and how they are organized in the brain of the cockroach. The antennal projection response (APR) is an established paradigm to explore learning and memory in the cockroach. It has been used to explore the neural basis of associations between olfactory and visual space and how this spatial encoding is integrated with motor cues. An interesting question that has not been addressed is whether measuring APRs or correlating the APR with motor output can be done with freely moving cockroaches, which antennate vigorously most of the time. Natural behaviors in cockroaches likely require learning associations across multiple modalities in an environment enriched with visual, olfactory, and auditory spatial cues. The inclusion of freely moving behaviors, as a complementary approach, to previous studies of associative and spatial learning and memory in the cockroach are providing much needed insight into the flexibility of the APR to a natural context. Here we examine how the learned APR of semi-restricted cockroaches translates to free running choices made during foraging. A series of experiments were performed which examined the visual associative and spatial learning abilities of the cockroach. We examined the effects of full antennal function and with restricted antennal function as well as intact brain animals and animals which had a procedure done to divide the halves of the brain by lesioning the central complex. Both the antennal function and the brain lesions have been shown to have an effect on the type of information learned and the length of resulting memory. Cockroaches were first trained in a semi-restricted setup where they learn to associate visual cues and odor cues. Following training cockroaches were tested in a free moving choice paradigm. Our data suggests that the APR

analyzed in the laboratory context is highly predictive of choices made in the freely moving cockroaches. This data also revealed multiple elements underlying complex spatial learning behavior and choice in foraging, including, the role of unilateral and bilateral sensory acquisition and learning, memory localization within the brain hemispheres, memory transfer and interference, and the interaction of neural systems.

Title: Crucial evidence of the prediction error theory in a behavioral pharmacological study

Authors: ***K. TERAO**[1,3], Y. MATSUMOTO[4], M. MIZUNAMI[2];
[1]Grad. school of life science, Hokkaido Univ., Sapporo,, Japan; [2]Fac. of Sci., Hokkaido Univ., Sapporo, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan; [4]Fac. of Liberal Arts, Tokyo Med. and Dent. Univ., Ichikawa, Japan

Abstract: In associative learning in mammals, it is widely accepted that the discrepancy, or error, between actual and predicted unconditioned stimulus (US) determines whether learning occurs when a stimulus is paired with a US. Complete evidence for the prediction error theory, however, has not been obtained in any learning systems: Blocking can also be accounted for by other theories. In this study, we obtained unequivocal evidence of blocking and evidence to reject the alternative theories in classical conditioning in crickets. Prediction error theory stems from the finding of blocking by Kamin, who found that when a stimulus (X) is paired with a US in a compound with another stimulus (Y), learning of X is blocked if Y has been previously paired with the US. Kamin argued that the blocking is due to the requirement of surprise for learning, i.e., no learning occurs when the US is fully predicted. This idea was formulated into the prediction error theory. Recent research in mammals has demonstrated that activities of dopamine (DA) neurons in the midbrain mediate reward prediction error signals in classical conditioning and instrumental conditioning. Unambiguous demonstration of the prediction error

theory, however, has not been achieved in any learning systems. Blocking can also be accounted for by other theories, such as attentional theory. Here, we performed behavioral analysis of blocking and obtained evidence to reject attentional theory in crickets. Crickets are newly emerging experimental animals for learning. We previously observed that octopamine (OA) receptor antagonists impair appetitive learning but not aversive learning, whereas DA receptor antagonists impair aversive learning but not appetitive learning. To obtain further evidence supporting the prediction error theory and rejecting alternative theories, we constructed a neural model to match the prediction error theory, and tested a prediction from the model: We noticed that our model predicts that blockade of synaptic transmission from OA neurons by an OA receptor antagonist during a pairing of a stimulus (Y) with reward (Y+ training) impairs learning of Y but not formation of reward prediction by Y. Thus, subsequent Y+ training, after recovery from the synaptic blockade should produce no learning. We observed such an "auto-blocking" in appetitive learning, which could be accounted for by the prediction error theory but not by alternative theories. We also observed an auto-blocking in aversive learning in use of a DA receptor antagonist. This study demonstrates validity of the prediction error theory and providing solid basis to elucidate computational mechanisms of the prediction error.

Title: Are the neural circuits controlling the temporal structure of spontaneous actions involved in operant self-learning?

Authors: C. ROHRSEN, *B. BREMBS;
Univ. Regensburg, Regensburg, Germany

Abstract: Variability is an adaptive and ubiquitous feature of all our behaviors, which is actively regulated according to task demands. Behavioral variability explains why under identical circumstances, individuals are able to initiate different actions. The amount of behavioral variability predicts operant learning performance (e.g., 1-3), because behavioral variability is a necessary prerequisite for operant learning. Tethered *Drosophila* fruit flies exhibit random-like turning attempts in stationary flight (4), which can be operantly conditioned (5). In a first screen, we have identified neurons in the ellipsoid body of the fly brain to be involved in the temporal

structure of these spontaneous turning attempts. We have started a behavioral characterization of flies where these neurons have been genetically manipulated. In particular, we will present results of flies with compromised physiology in these ellipsoid-body neurons in operant self-learning and world-learning experiments. The behavioral experiments are complemented by anatomical characterization of the neurogenetically identified circuits using immunohistochemistry and confocal microscopy. Skinner, B. 1981. Title: Forgetting is mediated by a dopamine→Scribble→Rac signaling pathway

Authors: *I. CERVANTES-SANDOVAL, M. CHAKRABORTY, R. L. DAVIS;
Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Forgetting of continuously acquired memories is crucial for proper function of the memory system. Nevertheless, little is known about the molecular, cellular and circuit basis for forgetting memories. Here we show that Scribble, a scaffolding protein known primarily for its role as a cell polarity determinant, is required for proper forgetting of olfactory memories in *Drosophila*. Knocking down scribble in either dopaminergic or mushroom body Kenyon cells, important elements of the circuitry for learning and forgetting, impairs normal memory loss. In addition, we show that Scribble functions within Kenyon cells to regulate active forgetting in a

signaling pathway that is activated by extracellular dopaminergic inputs and upstream of the small GTPase Rac. These results place Scribble as a central scaffolding molecule in the emerging signaling system underlying active forgetting.

Title: Investigating the histone deacetylase 4 (hdac4) memory pathway: interaction with ankyrin2?

Authors: *S. SCHWARTZ, H. L. FITZSIMONS;
Massey Univ., Palmerston North, New Zealand

Abstract: A growing body of evidence shows that learning and memory are regulated by epigenetic mechanisms. We have previously shown that HDAC4 plays a critical role in memory formation in *Drosophila*, and it is similarly required for memory in mammals, however its specific functions have not yet been elucidated. In an effort to identify genes that interact in the HDAC4 memory pathway, we performed a genetic screen in *Drosophila*. Overexpression of HDAC4 in *Drosophila* photoreceptors results in a mild “rough eye” phenotype, with disorganised ommatidia and bristles. This phenotype is ideal for screening for modifiers of HDAC4 activity, as it is an *in vivo* phenotype that is easily scored and does not affect viability. A panel of 115 candidate RNAi lines were screened and 26 were found to significantly enhance the HDAC4-induced rough eye phenotype. As each individual gene did not itself induce a significant rough eye phenotype, the enhancement of the HDAC4 phenotype would suggest that the gene interacts in the same molecular pathway as HDAC4. The screen confirmed several genes known to interact with HDAC4 in other organisms or tissues, e.g. mef2, creb and 14-3-3ζ, establishing its reliability. Novel HDAC4 interactors were identified including ankyrin2 which was chosen for further investigation as it has been implicated in synaptic stability and in human intellectual disability. In addition, HDAC4 harbours a conserved ankyrin binding domain, suggesting a potential physical interaction. Immunohistochemistry analyses showed that ankyrin2 is strongly expressed in the adult brain where it co-localises with cytoskeletal components futsch and

neuroglian. Like HDAC4, ankyrin2 localises to axons of the mushroom body (MB), a key structure for memory formation in flies. Knockdown of ankyrin2 in the developing brain results in defects in mushroom body development including axon outgrowth and guidance. Further investigation will help elucidate whether an interaction between ankyrin2 and HDAC4 leads to changes in long-term memory formation in flies. In this study we have identified candidate proteins that interact with HDAC4 in neurons. This is fundamental in order to clarify the genetic pathways underlying memory processes and for the contribution to the study of cognitive disorders that disrupt memory, bringing new insights that can lead to new pharmacological treatments.

Title: Electric-Shock Sensory in *Drosophila* central brain

Authors: *W. HU, Y. PENG, F. ZHANG, L. WANG, Y. ZHONG;
Sch. of Life Sci., Tsinghua Univ., Beijing, China

Abstract: Canonical aversive learning in *Drosophila* uses electric-shock as unconditioned stimulus (US) mostly. It is found that a small group of dopamine neurons mediated electric shock input and converged with the odor signal in mushroom body, but these dopamine neurons do not affect flies sensing and avoiding shock. However, it is not clear about the electric-shock sensing in fly brain. Here we report that a subgroup of central complex neurons highly respond to electric-shock delivered to feet but not abdomen of flies. Acutely blocking these neurons leaded flies to decreased sensitivity of shock in flies, while acutely activating the same neurons could substitute US in aversive training. Our results demonstrate these neurons could be an elementary sensory center for electric-shock.

Title: A glycine receptor subunit homologue, AVR-14, alters short-term memory in an interstimulus interval-dependant manner

Authors: ***C. H. RANKIN**, T. MCDIARMID;
Univ. British Columbia, Vancouver, BC, Canada

Abstract: Habituation is a learned decrement in responding following repeated exposure to a stimulus. Despite its importance the mechanisms underlying habituation remain largely unknown. Repeated exposure to taps (non-localized mechanosensory stimulation) leads to habituation of a reversal withdrawal response in *C. elegans* that is dependent on glutamate transmission. Here we use high throughput behavioural analysis to characterize the role of AVR-14, an inhibitory glutamate gated chloride channel homologous to vertebrate glycine subunits that is expressed on the mechosensory neurons. avr-14 loss of function mutants display a larger initial reversal duration in response to tap and faster habituation to tap stimuli than wild-type animals at a 10s interstimulus interval (ISI). At long ISIs (60s), avr-14 mutants habituated significantly less than wild-type animals. The stark contrast in phenotypes at short and long ISIs necessitated analysis of habituation across ISIs (10-60s ISIs). This revealed that mutations in avr-14 result in faster habituation at short ISIs, wild-type habituation at intermediate ISIs, and slower habituation and longer ISIs. Together these studies suggest mutations in avr-14 alter habituation in an ISI-dependent manner. Experiments using cell-specific knockdown, rescue, and stimulation will localize the memory functions of AVR-14 to elucidate how it modulates the tap habituation circuit. These studies will determine how the inhibitory functions of glutamate mediate short-term habituation in *C. elegans*, furthering our understanding of the processes underlying learning and memory.

Title: Dopamine receptor activities regulate learning-dependent odor preference changes in *Drosophila*

Authors: *S. NAGANOS, M. SAITOE;
Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: Experience-dependent preference changes often happen to animals through either a good or a bad experience. Such phenomena also occur even in *Drosophila*. Olfactory conditioning is an example of such experience-dependent preference changes, and we use two aversive conditioning odors (CS) to condition flies; flies are sequentially exposed to the first CS+ odor with electrical shocks and the second CS- odor without electrical shocks. In this study, we found two classes of memory components, memory for avoiding CS+ (CS+ memory) and memory for approaching CS- (CS- memory), after single cycle olfactory conditioning. Importantly, without CS+ memory formation, flies still avoid CS- odor, suggesting that significance of CS- odor for flies is changed by previous experience. In addition whereas CS+ memory was maintained more than 3hr, CS- memory was declined within 3hr. We explored molecular mechanisms concerned with these memory formations by employing well-established olfactory memory mutants. As a result, we found that mutations in D1 type dopamine receptor (D1R) gene disrupt both CS+ and CS- memory formation. Therefore, to explore the brain regions required for CS+ and CS- memory formation, we employed GAL4/UAS binary system, which allows us to manipulate D1R expression in specific brain regions. We found that D1R function in the mushroom bodies (MBs), neural center for olfactory memory formation, is necessary for CS+ memory but not for CS- memory. Especially, D1R activity in γ lobes but not in α / β and α' / β' lobes is sufficient for CS+ memory formation. In contrast, D1R function in the projection neurons (PNs) in the antennal lobes (ALs), the primary olfactory center, is required for CS- memory but not for CS+ memory. These results suggest that although both CS+ and CS- memory require D1R activity they are formed in different brain regions.

Title: Octopamine in Sexual Behavior

Authors: *A. I. FERNANDEZ[1], J. LIM[1], J. JAMES[1], P. EVANS[2], K.-A. HAN[1];
[1]Univ. of Texas At El Paso, El Paso, TX; [2]The Inositide Lab., The Babraham Inst., Cambridge, United Kingdom

Abstract: Octopamine (OA) is a monoamine that acts as a neuromodulator in invertebrates and is homologous to norepinephrine in mammals. OA modulates numerous physiological processes such as motivation, pheromone response, olfaction, learning and memory in the fruit fly *Drosophila* melanogaster. The aim of our study is to understand the mechanism by which OA regulates various aspects of sexual behavior. *Drosophila* has four known OA receptors OAMB, Octβ1R, Octβ2R, and Octβ3R. To achieve the goal we investigated basal and high order courtship behaviors of the flies deficient in individual OA receptors or OA biosynthesis. Basal courtship analysis was performed by examining a male's behavior towards a female and measuring the latency and duration of courtship and copulation. To study the role that OA has on the learning and memory processes, a conditioned courtship test was performed. The test measures the ability of the male to learn and remember aversive courtship experience. When subjected to the assays, the OA receptor mutants oamb, octb1r and octb2r exhibited delayed courtship and copulation latency, reduced courtship index and altered copulation duration. On the other hand, oamb but not the other receptor mutants show impaired learning. Studies are in progress to identify the relevant neural sites that the OA receptors regulate the sexual behavior. This study was supported by the USDA/NIFA grant 010-65105-20625, NIMHD grant 2G12MD007592 and the RISE grant R25 GM 069621 grants.

Title: The roles of dopamine in sexual behavior

Authors: *J. LIM, J. JAMES, J. JOHNSON, K.-A. HAN;
Univ. of Texas At El Paso, El Paso, TX

Abstract: Dopamine (DA) is an important monoamine neuromodulator in the central nervous system of both invertebrates and mammals. It regulates motivation, reward, disinhibition, learning and memory and sexual behavior. However, the neural sites where individual dopamine receptors function to modulate these behaviors need to be clarified. The goal of our study is to understand the neural and cellular mechanisms that dopamine regulates sexual behavior. To address this, we have used the genetically tractable model organism *Drosophila* melanogaster and examined basal and high order courtship behaviors of the flies deficient in individual DA receptors or DA transporter (DAT). They include the D1 receptor mutants dumb1 and dumb2, D2 receptor mutant dd2r, dopamine/steroid ecdysone receptor mutant der, D5 receptor mutant damb, and DAT mutant fmn. Wild type naïve male flies usually respond to distinct incoming sensory inputs and actively court virgin females. D1 receptor mutants, however, show altered courtship activity. Studies are in progress to identify the neural sites that the D1 receptors play a role in sexual behavior. This work was supported by the National Institute of Minority Health and Health Disparity grant 2G12MD007592.

Title: Hormonal convergence in regulation of *Drosophila* courtship memory

Authors: *S.-S. LEE[1], N. KARAPETIANS[1], C. RIVERA-PEREZ[3], T. WIJESEKERA[4], F. G. NORIEGA[3], B. DAUWALDER[4], M. E. ADAMS[2];
[1]Neurosci., [2]Cell Biol. & Neurosci. and Entomology, Univ. of California, Riverside, Riverside, CA; [3]Biol. Sci., Florida Intl. Univ., Miami, FL; [4]Biol. and Biochem., Univ. of Houston, Houston, TX

Abstract: Formation and expression of memories are critical for context-dependent decision-making. In *Drosophila*, courting males that experience repeated rejection by mated females court less avidly when paired subsequently with virgin females. Both short-term and long-term memories associated with rejection have been demonstrated; here we show that hormonal state is critical for both. Ecdysis triggering hormone (ETH) appears to be essential for male courtship memories via two signaling pathways: one is indirect through promotion of juvenile hormone (JH) synthesis, while the other is direct through action on mushroom body neurons. With regard to the indirect pathway, suppression of JH levels by ETH receptor (ETHR) silencing in corpora allata of males leads to both short-term and long-term courtship memory deficiencies, both of which are rescued following treatment of JH analog methoprene. Our evidence shows that JH is essential for 1) sensing aversive male-specific chemical cues from mated females and 2) recognition of behavioral cues provided by the mated female. Conditional gene expression and age-dependent rescue experiments demonstrate a critical period for JH action in memory formation. JH-dependent long-term courtship memory requires expression of JH receptors Met and Gce in mushroom body neurons. Evidence for a direct role of ETH signaling in long-term memory formation comes from its suppression by silencing ETHR in mushroom body neurons. Block of ETH release from Inka cells also negatively affects memory performance, confirming that hormonal signaling is required for memory formation. Our findings indicate that ETH promotes convergent signaling pathways contributing to "state-dependent" learning and memory of social context.

Title: The role of beta adrenergic-like octopamine receptor Octβ1R in learning and memory

Authors: *J. B. SABANDAL[1], P. EVANS[2], K.-A. HAN[1];
[1]The Univ. of Texas At El Paso, El Paso, TX; [2]The Inositode Lab., The Babraham Inst., Cambridge, United Kingdom

Abstract: Octopamine, the invertebrate counterpart of mammalian norepinephrine, is a major monoamine in invertebrates and plays a critical role in learning and memory. Previous studies show that octopamine is crucial for appetitive memory formation, but its role in aversive learning and memory is not fully characterized. In order to identify octopamine's role in aversive learning and memory in *Drosophila* melanogaster, we employed negatively reinforced olfactory classical conditioning in which flies were presented with an odor (conditioned stimulus +) paired with an aversive stimulus, electric shock (unconditioned stimulus). They were then presented with another odor without shock. To test the capacity of the flies to learn and remember, flies were transferred into the apparatus called T-maze and presented with the two odors on opposite sides of the apparatus. This decision-making process measures whether flies were able to distinguish the odor paired with shock and avoid it. Performance indices were calculated by subtracting the number of flies that made the incorrect choice (odor with shock) from the correct choice (odor without shock), divided by the total number of flies. Wild-type Canton-S flies performed well in learning and short-term memory tests. However, the flies lacking the octopamine receptor Octβ1R exhibited poor learning but normal memory decay. This suggests that Octβ1R is essential for aversive olfactory learning but not for short-term memory. The studies are in progress to identify the critical neural site where Octβ1R regulates aversive learning.

Title: Serotonergic modulation of goal-directed habituation during exploration in *Drosophila*

Authors: *G. W. ROMAN[1], S. ZHANG[1], M. DE LA FLOR[1], L. CHEN[1], G. GUNARATNE[1], H. DIERICK[2];
[1]Univ. Houston, Houston, TX; [2]Baylor Col. of Med., Houston, TX

Abstract: Novel environments elicit exploratory behaviors in many species. These behaviors allow the animal to gather information about its environment, and are likely to have a strong adaptive value. As the animal explores, goal-directed habituation of the novelty stimulus leads to a gradual decrease in exploratory behaviors. We use the open field arena behavior of *Drosophila* to understand how goal-directed habituation can be modulated to alter the amount of exploration. When *Drosophila* are placed within a novel open field arena, the fly explores the arena's boundary. During exploration, *Drosophila* display high levels of activity and a directional persistence. As the fly visits each segment of the arena boundary, the novelty is habituated and both directional persistence and mean absolute activity decay to spontaneous activity levels. Serotonin is a bidirectional modulator of the rate of goal-directed habituation during exploration. Increasing the activity of serotonergic neurons through the targeted expression and activation of the TrpA1 channel or the ectopic expression of the NaChBac sodium channel resulted in a significant increase in novelty habituation. Moreover, increasing serotonin levels by feeding flies the serotonin precursor 5-HTP also significantly increased the rate of habituation. These effects of increasing serotonin are reverted 72 hours after feeding the flies' 5-HTP, indicating a temporary effect on habituation. Interestingly, decreasing the activity of the serotonergic neurons by hypo-polarizing with the targeted expression of the Kir2.1 channel resulted in decrease in habituation and a consequent increase in the amount of exploration. Pharmacologically reducing serotonin levels by feeding the inhibitor of serotonin biosynthesis alpha-methyl tryptophan also decreased the rate of habituation in the open field arena. Mutations in the 5HT1A and 5HT1B receptors also display reduced levels of habituation and increases in exploration, and these mutations effectively block the effect of 5-HTP feeding on the rate of habituation. The overexpression of 5HT1A and 5HT1B in subsets of the central nervous system also drives increased rates of habituation. Together, these results suggest an important role for serotonin in modulating the rate of goal-directed habituation during the exploration of novel environments.

Title: Mechanisms contributing to experience-dependent changes in the structure of hippocampal replay sequences

Authors: *T. FENG, D. SILVA, D. FOSTER;
Neurosci., Johns Hopkins Univ. SOM, Baltimore, MD

Abstract: Hippocampal replay is a phenomenon that occurs mainly during sharp-wave ripple events, in both awake and sleep states, in which place cells are active in precise sequences. These sequences represent temporally compressed depictions of movement trajectories through navigable space. However, the mechanisms by which such activity patterns are generated with increased experience remain largely unknown. Here we applied high-density electrophysiological recording techniques to examine the development of the fine temporal structure of replay between individual experiences from rats exploring on a novel linear track. As reported previously, significant replays emerged during early experience, that is, immediately after the first running lap on a novel linear track, and covered the whole length of the track. However, the pattern of early replays differed from later replays. Specifically, the speed at which hippocampal replay traversed a linear track slowed down when the animal gained familiarity with a novel environment. By contrast, hippocampal pyramidal cells maintained constant firing rates, while emitting more spikes and being more active during late replays than early replays. The dissociation between place cell firing rate and the speed of replay indicates that certain models of neuronal sequence generation, such as synfire chains, or continuous attractor models with global inhibition, may not be sufficient to represent the underlying mechanism of replay. Moreover, consistent with another on-going study in our laboratory (Pfeiffer BE & Foster DJ), in which the trajectory of replay in a familiar environment was discretized in alternating states of static representation and rapid movement, and phase-locked to the slow-gamma (25-50Hz) rhythm, replays during early exploration of a novel environment were also modulated by slow-gamma oscillations. Further, the number of discrete alternating states in replay increased with experience, accompanied by an increase of the duration of the static representation states and a decrease of the duration of the rapid movement states. In conclusion, hippocampal replay may undergo rapid plasticity with experience, and the change of propagation speed of replay involves fine structural change of the discretized represented trajectory.

Abstract: Neuronal circuits can produce self-sustaining sequences of activity patterns, but the precise mechanisms remain unknown. It has long been hypothesized that an auto-associative (self-connected) network of recurrently excitable neurons can retrieve discrete memories as attractors (networks whose activity evolves over time to a small number of stable patterns or states). However, sequence retrieval is more problematic to model computationally, since errors in the recovery of each item of information will result in poor recovery of the next item in the sequence; over multiple sequential items, such errors can amass to a catastrophic collapse of the sequence. A theoretical solution is to embed auto-association error-correction for each item within a wider hetero-associative loop for sequence propagation, thereby allowing each item to be accurately represented via attractor network dynamics before transitioning to the next item in the sequence. Information encoded by such a process would be expected to result in "jumpy" sequences that sharpen individual item representations before transitioning to successive items; however, direct evidence for such theoretical processes is lacking, due in large part to the difficulty of obtaining data from very large ensembles of neurons expressing internally-generated sequences recorded at the time resolution of neuronal dynamics. Here we provide the first direct evidence for auto-associative dynamics in sequence generation. During sharp-wave/ripple (SWR) events, hippocampal neurons are known to express sequenced reactivations, and we now show that these reactivations are composed of discrete attractors. Each attractor corresponds to a single location, the representation of which sharpens over the course of several milliseconds, as the reactivation focuses at that location. Subsequently, the reactivation transitions rapidly to a spatially discontiguous, but adjacent new location. This alternation between sharpening and transition occurs repeatedly within individual SWRs, and is locked to the slow-gamma (25-50Hz) rhythm. These findings validate long-standing theoretical notions of neural network function, as well as reveal a fundamental discretization in the retrieval of memory in the

hippocampus, together with a novel function for gamma oscillations in the control of attractor dynamics.

Title: Hippocampal area CA3 is necessary for the induction of sharp-wave ripples in area CA1

Authors: *H. DAVOUDI[1], D. J. FOSTER[2];
[1]Dept. of Biomed. Engin., [2]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Hippocampal area CA1 local field potential exhibits high frequency (100- 250 Hz) events known as Sharp-Wave Ripples (SWRs). These events that occur during slow-wave sleep and awake restfulness have been shown to be important for the consolidation of spatial memory. However, the mechanism of formation of SWRs is not yet well understood. Although it is hypothesized that projections from the highly recurrent network of the hippocampal area CA3 might be responsible for the formation of SWRs in CA1, this has not been causally demonstrated. In a study by Nakashiba et al. (2009), in which CA3's Schafer Collateral (SC) projections to CA1 were genetically silenced over the time course of a few days, the number of SWRs did not change, while the peak frequency of a fraction of SWRs decreased. However, the time course of genetic silencing in that study was sufficient to allow for the possibility of compensatory mechanisms in the development of ripple activity in CA1. We hypothesized that a more acute shutdown of CA3 input to CA1 might reveal a more significant role. Therefore, we bilaterally expressed proton pump Arch3.0 in SC of 2-3 months old Long-Evans rats. Here we report that, using multi-tetrode recording and reversible optogenetic manipulation, the silencing of SC terminals in CA1 decimates SWRs. In particular, SWRs and their associated spiking activity were abolished when light was delivered to CA3 terminals in CA1 but intact when light was off. Meanwhile, activities in other frequency bands were not affected by light. These

findings shed light on the functional interconnections between hippocampal subregions that support episodic memory.

Title: Rate of reverse, but not forward hippocampal replay increases with a relative increase in reward

Authors: *E. AMBROSE[1], B. E. AMBROSE[2], D. J. FOSTER[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Replay, the sequential activity of place cells during sharp wave ripples (SWRs) in the hippocampus, may be a mechanism by which current experience is encoded into episodic memory. Replay sequences are capable of reflecting many paths through an environment, of varying length and in the forward or reverse direction, but whether specific types of sequences play different roles in behavior and memory is unknown. Furthermore, the occurrence and content of replays has not been correlated to any particular behavior or context, although it has been shown that sequences can be biased toward a remembered goal location. Using tetrode recording to simultaneously monitor the activity of large ensembles of hippocampal CA1 pyramidal cells in behaving rats, we demonstrate that altering reward contingency in an environment is reflected by changes in SWRs, the overall production of replays, and dynamic shifts in the content of those replays. In agreement with previous studies we find that the rate of SWRs is decreased in the absence of reward and increased to a larger reward, and hippocampal replay also changes in a similar way. However, in the presence of increased reward, the behavior of forward and reverse replays diverges. The rate of reverse replay is relatively increased at that location, while the rate of forward replay is unchanged. Reward strengthens the encoding of salient behavioral episodes, and we suggest that reverse replays may serve to promote encoding

of behaviors which resulted in reward while forward replays may have a different function such as planning.

Title: Seeing the woods for the geometries: The hippocampus is necessary for configural but not elemental cue use in spatial orientation

Authors: *I. N. JOHNSTON;
Sch. of Psychology, The University of Sydney, Australia

Abstract: A custom-built Olton 8-arm radial maze was used to study free-operant spatial behaviour in the rat. On each trial, one arm of the maze was randomly designated the 'active' arm, and the rat received 10-sec access to sucrose from an automated fluid dispenser in a cup at the end of the arm. After the reinforcer had been delivered, the next trial began and another arm was randomly designated as the active arm, and this procedure was repeated for each subsequent trial. In addition to this, white curtains surrounded the maze and an overhead data projector with a wide-angled lens projected an oblique triangular array of black and white cues onto the curtains around the maze. On each trial, these cues were rotated so they remained in a consistent spatial configuration with the active arm. The results of these experiments indicate that: 1. The rats made significantly fewer errors in finding the active arm in the presence of the visuospatial cues compared to trials when they were absent; 2. The number of errors increased in probe trials when elements of the visuospatial configurations were removed. 3. When elements of the configuration were transposed but maintained the shape of the array, the rats preferred the arm indicated by the geometric shape of the array rather than the elements that would normally be closest to the goal. Moreover, temporary inactivation of the hippocampus with muscimol did not affect performance with the single elemental cues, but did impair performance with the configural cues. These studies suggest that rats can use virtual cues to orient themselves towards a goal location, and do so via the geometric properties of an array.

Title: Assessing movement similarity in the morris water task

Authors: *D. BARTO, D. HAMILTON;
UNM, Albuquerque, NM

Abstract: Performance in the Morris Water Task (MWT) is usually depicted through latency and path length to reach the hidden platform. While these latency and path length measures are useful for molar aspects of performance they fail to capture the qualitative aspects of the rat's trajectory. Examining the changing curvature of path trajectories could reveal movement patterns that emerge as a rat learns to navigate to a hidden platform in the MWT. Identifying these patterns, and to what degree they deviate from an optimal path provides detailed information about an individual rat's movement sequence. The present study plotted the rats' path trajectories and utilized a dynamic time-warping algorithm to assess similarity between path trajectories on successive trials from a single release point. Rats completed 60 trials (12 per day, 4 release points) of hidden platform MWT training. The results indicate that a similar pattern of movement emerges between the 2nd and 3rd training trial for release points located far from the platform. Additionally, path trajectories became significantly dissimilar between training days suggesting a 24-hour forgetting effect. These results illustrate how assessing similarity between path trajectories can capture the idiosyncratic movement patterns that emerge within rats as they learn goal directed navigation.

Title: The roles of the medial and lateral divisions of the entorhinal cortex in visual scene memory

Authors: *S.-W. YOO, I. LEE;
Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The medial and lateral divisions of the entorhinal cortex (the MEC and LEC, respectively) might provide functionally segregated inputs to the hippocampus; that is, the MEC might provide spatial information and the LEC might send nonspatial item information. We have previously shown that the dorsal hippocampus is critical for making scene-dependent decision making. However, it is unclear whether background visual scene information is processed predominantly in the MEC or LEC, or both. We investigated whether the MEC and LEC might play differential roles in processing scene memory in the current study. Specifically, we ran five rats (male Long-Evans) in a scene-based memory task. A T-maze was surrounded by a set of three adjacent LCD monitors and a start box was attached to the stem of the T-maze. Once a trial started, the rat exited the start box and a visual scene was displayed in the LCD monitors. The rat was required to choose one of the food wells in either the left or right arm in association with the displayed visual scene to obtain food reward. Two visual scenes (zebra and pebbles patterns) were used for initial training (40 trials). Once the rats were trained to criterion (>80% correct response per scene and response bias <15%) for two consecutive days, the rat was trained with the second pair of scenes (bamboo and mountain patterns) to criterion. Then, the rat was trained with those four scenes to criterion before surgical implantation of a custom-made 3D cannula complex for targeting both LEC and MEC bilaterally within the same animal. Once the rats (n=5) recovered from surgery (7 days), it was retrained to pre-surgical performance criterion for four scenes. Afterwards, when the rat was injected with either vehicle solution (artificial cerebrospinal fluid, or ACSF) or muscimol (MUS) before testing (0.3uL per site), the MUS injected in either LEC or MEC produced performance deficits ($p<0.01$ and $p<0.05$ for LEC and MEC, respectively), compared to ACSF-injected conditions in the same rat. In three animals, we also tested whether inactivation of the LEC or MEC impaired scene trace memory by turning off the scene stimulus when the rat passed one of the three sensors along the track. In the trace

memory task, it appears that the whole EC (MEC+LEC) inactivations produce the biggest deficits, compared to the vehicle condition, and the MEC inactivations result in bigger trace memory deficits than the LEC inactivations. These results need to be confirmed with more subjects, but our tentative conclusion is that the MEC plays bigger roles in processing visual scene memory than the LEC especially when scene information needs to be kept in working memory for some time for upcoming behavioral choice.

Title: The perirhinal cortex, but not the postrhinal cortex, is required for visual, but not tactile, object recognition memory

Authors: *J. AHN, I. LEE;
Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The rodent perirhinal cortex (PRC) and postrhinal cortex (POR) may provide functionally differential inputs to the hippocampus. PRC, but not POR, might play important roles in object recognition memory. Most prior studies, however, used a spontaneous object exploration paradigm in which animals freely explore old and new objects in an environment. In the current study, we used an explicit object memory task to compare the roles of PER and POR in the same rats. Specifically, rats (n=7) were trained in a task in which a toy object (ice cream or burger) attached to a sand-filled jar must be recognized for correct choice (pushing or digging) to be made to the jar. Only the correct response type associated with the object allowed the rat to

obtain reward. Once the animals were trained to criterion (> 75% correct for each object), they underwent surgery to receive implantation of a custom-made cannula complex targeting both PRC and POR bilaterally. Following recovery from surgery, rats were retrained to criterion, and artificial cerebrospinal fluid (ACSF) was injected in the PRC bilaterally before testing. On the next day, muscimol (MUS) was injected to inactivate the same region. The PRC inactivation yielded deficits initially, but performance improved gradually to control level in the second half of the session. The same injection protocol was repeated for the POR, but the POR inactivation only minimally affected performance. Choice latency (measured from track entrance to response initiation) did not differ between ACSF and MUS conditions. Since the MUS-induced deficit in the PRC mostly appeared in the earlier part of the session, it is possible that the rat switched between different cognitive strategies (e.g., from a visual to tactile strategy) within a session. This possibility was explored by encasing the objects in a transparent acrylic box to bias the rat to use only visual, but not tactile information. PRC inactivation produced sustained impairment through the second half of the session, whereas POR inactivation did not. When rats were tested in complete darkness, however, rats were not affected by MUS in either PRC or POR, suggesting that the performance deficits associated with PRC inactivations were specific to visual modality. The rats were subsequently trained in a simple object discrimination task and the PRC-inactivated rats performed normally, suggesting that MUS in the PRC left visual perceptual memory intact. Taken together, these results implicate that the PRC, but not the POR, is required for conditional behavioral choice based on visual, but not tactile, object memory.

Title: Synchronization between hippocampus and prefrontal cortex during social behavior

Authors: *Y. ZHAN, Y. TANG;
Chinese Acad. of Sci., Shenzhen Inst. of Advanced Technol., Guangdong, China

Abstract: Recent electrophysiological studies in rodents have implicated hippocampal-prefrontal connectivity in anxiety, spatial learning and memory-related tasks. In this study we used *in vivo*

electrophysiological recordings of local field potentials in prefrontal cortex and hippocampus, two structures implicated in the social interaction and exploration, to measure functional connectivity during social interaction behavior. LFP coherence between prefrontal cortex and hippocampus as well as between left and right hippocampus was significantly reduced in *Cx3cr1*$^{-/-}$ mice, a mouse model for microglia-dependent synaptic pruning, across a wide frequency range. Next, we used Granger causality to examine the directionality of information between hippocampus and prefrontal cortex. During social interaction persistent higher PFC driving to dorsal HPC was found. *Cx3cr1*$^{-/-}$ mice showed reduced baseline PFC driving to dorsal HPC. PFC to dorsal HPC causality could predict the actual time spent interacting with the social stimuli. To investigate the consequence of disrupting the synchronization between the hippocampus and the prefrontal cortex, we used optogenetic tools to silence nucleus reuniens, a midline thalamic structure which is thought to mediate the communications between the hippocampus and the prefrontal cortex. When the nucleus reuniens was inhibited, the mice showed reduced time spent with the social stimulus compared to the control animals when they explored a three chambered social interaction box. In the subsequent social novelty test when another novel social stimulus was introduced to the test, inhibiting the nucleus reuniens did not produced deficits in discriminating the two social stimuli. These results point to a role of nucleus reuniens in social behavior, possibly by mediating the information processing between the hippocampus and the prefrontal cortex.

Title: Dorsal hippocampus is unnecessary for the expression of either a place or response spatial strategy in the rodent submerged T-maze

Authors: ***J. S. ASEM**, P. C. HOLLAND;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: The ability to navigate in one's environment is critical to survival, be it in order to acquire positive reinforcers_ food, water, mates, shelter, sleep_ or to escape negative

consequences_predation and pain. Spatial navigation is commonly examined using the T-maze, in which experimenters are able to dissociate two distinct strategies that are exhibited by animals when acquiring the location of a goal. Previous work has shown that animals exhibit inverse behavioral patterns when appetitively and aversively motivated. In the food-rewarded (dry) T-maze, rats initially adopt a flexible, hippocampal-dependent place strategy, later switching to an automatic, striatal-dependent response strategy (Packard & McGaugh, 1996). However, in an escape-motivated (submerged) T-maze, rats exhibit the opposite pattern: initially adopting a response strategy, and later switching to a place strategy with extended training (Asem & Holland, 2013). Recent work suggests that the role of the dorsolateral striatum in the submerged T-maze is a subtle one: necessary for the early acquisition, but not expression, of the initial response strategy (Asem & Holland, 2015). However, the role of the dorsal hippocampus in the observed behavior has not yet been explicated. The hippocampus has been implicated many times over in spatial learning and navigation as well as rapid, even one-trial, learning. Critically, these results provide conflicting predictions for the submerged T-maze. If the hippocampus is critical for rapid, initial learning, the hippocampus subserves the immediate response strategy. If the hippocampus is critical for spatial and relational information, its recruitment in the submerged T-maze is a gradual one. We sought to investigate whether the role of the dorsal hippocampus is similar in the submerged T-maze as that in the dry T-maze. In Experiment 1, we examined performance of rats receiving either a lidocaine or saline infusion to the dorsal hippocampus immediately prior to probe tests. We observed no effect of drug condition on behavior exhibited during probe tests, suggesting that the dorsal hippocampus is not required for the expression of either behavior. In Experiment 2, we confirmed the effectiveness of the infusion protocol in a positive control task with the same subjects. In Experiment 3, we examined immediate early gene expression in subregions of the hippocampus in subjects expressing a response or place strategy after early or late training.

Title: Role of visual cues in idiothetic and allocentric strategies for spatial position coding in hippocampus

Authors: *J. KOENIG, M. NOUGUIER, G. MARTI, F.-X. MICHON, J. EPSZTEIN; INMED/INSERM, U901, Marseille, France

Abstract: Hippocampal place cells can use two strategies to generate their typical space modulated firing patterns: idiothetic and allothetic coding. Idiothetic coding relies on internal cues generated by self-motion (proprioceptive cues, vestibular cues, optic flow) while allothetic coding relies on cues from the external world (visual, tactile and olfactory cues). Both strategies can be used to calculate an animal's location in an environment. We are interested in understanding the environmental attributes that determine the use of one spatial coding strategy over the other by hippocampal place cells and notably the role of proximal visual cues. To address this question we used virtual reality which enables the selective modification of proximal visual cues without altering inputs from other sensory modalities. Head-fixed C57 BL6 mice were trained to run on a polystyrene ball surrounded by screens on which a virtual linear track was displayed. Ball movements were used to update the position of the mice's avatar in the virtual linear track. Mice were trained to go back and forth for liquid rewards in one of four virtual linear tracks (275 cm long) which differed in the availability of proximal, proximo-distal or distal visual cues. Once a stable performance was reached (~ 3 rewards per minute), acute silicon probe recordings were performed to determine the coding strategy used by place cells in area CA1 and CA3 of the hippocampus. The influence of experience on coding strategy was also investigated.

Title: Ventral hippocampus inactivation impairs goal-directed spatial navigation in obstacle-laden environments

Authors: M. CONTRERAS[1], T. PELC[1], M. LLOFRIU[2], A. WEITZENFELD[2], *J.-M. FELLOUS[1];
[1]Psychology, Univ. of Arizona, Tucson, AZ; [2]Computer Sci. and Engin., Univ. of South Florida, Tampa, FL

Abstract: Most lesions studies that show a dorso-ventral double dissociation find that ventral but not dorsal hippocampus lesions affect emotional behavior, while dorsal but not ventral hippocampus lesions impair spatial memory and navigation. Electrophysiology studies have also shown that ventral hippocampal cells have lower spatial selectivity and larger place fields than dorsal cells. However, most of the experiments performed to assess the dorsal and ventral contributions to spatial navigation have employed relatively simple tasks that may not have required a strong coordination along the dorso-ventral hippocampal axis. In this study, we tested the hypothesis that the ventral hippocampus may be critical for goal-directed navigation in rich, obstacle laden environments. We trained rats to get rewards from feeders positioned at the periphery of an open-field. After the animals learned a specific set of feeders, we placed small or large obstacles on the maze before the memory recall phase. We report that bilateral ventral hippocampal inactivation (2.5% Bupivacaine or 0.9% saline solution; 1μl per side) impaired spatial navigation in both large and small obstacle conditions. This effect was larger when small objects where present compared to the large objects configurations. Importantly, this impairment did not result from a deficit in the spatial memory for the set of feeders (i.e. recognition of the goal locations) because ventral hippocampus inactivation did not affect recall performance when there were no obstacles on the maze. Furthermore, inactivation of the dorsal hippocampus produced only a minor deficit in large, but not in small obstacle configurations. These results show that, the ventral hippocampus supports spatial navigation when obstacles are present in the environment suggesting that this portion of the structure is necessary to compute effective trajectories when faced with multiple routes to obtain rewards. We used a computational model to test the informational advantage of the multi-scale representation. A reinforcement learning model involving the hippocampus, entorhinal cortex and striatum learned idiothetic actions based solely on firing rates of multi-scale place and head direction cells. We found that, in a simpler Morris-like maze, the combination of scales is a better source of information for navigational purposes than when taken in isolation. Additionally, larger fields improved learning more than smaller ones when the inactivation experiments were simulated. Results were obtained using computer simulations as well as a mobile robotic platform.

Title: Prefrontal-hippocampal theta coherence, sharp wave ripples, and bursts of cortical unit activity underlie choices and encoding in the radial arm maze

Authors: *M. V. MYROSHNYCHENKO[1], C. LAPISH[2];
[1]Indiana Univ., Indianapolis, IN; [2]Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: The radial arm maze (RAM) is a foraging task that is often used to assess executive function guided decision-making. Optimal foraging strategies on this task require the integration of executive and memory systems, which include retrospective and prospective codes. To explore the neural basis of decision-making during RAM performance, the current study acquired multielectrode single-unit and local field potential (LFP) recordings simultaneously in hippocampus (HC) and anterior cingulate (ACC). Initially, rats were presented with four of the eight total maze arms open at once ("training phase"), and the rest of the arms were opened up after the subjects collected the rewards and a one-minute delay was completed ("test phase"). Any arm re-entries were counted as errors, and only trials with one test phase error or less were used in the analysis. ACC unit firing was elevated at choice points and reduced at reward points. Moreover, both ACC and the HC showed elevated theta power shortly prior to the reward point and sharp wave ripples shortly after reward acquisition on correct choices only, which is consistent with findings in other choice tasks. These observations held during test phase and were disrupted during the training phase in ACC, but not the HC. It has been suggested that HC sharp wave ripples contain episodes of replay of visited locations and theta of locations ahead of the animal - information necessary for decision-making using both prospective and retrospective codes. Theta and ripples are present in the HC during both training and test phases, consistent with lesion evidence that hippocampus is necessary for both prospective and retrospective strategies. In ACC, theta and ripples are only present during test phase and not during training phase, which is in line the evidence showing that prefrontal cortex is only necessary for prospective coding. These task phase-dependent observations may help explain how HC and ACC networks integrate information related to prospective and retrospective codes.

Title: Egocentric learning deficits in rats produced by developmental manganese overexposure or adulthood 6-hydroxydopamine toxicity are exacerbated in combination

Authors: *R. A. BAILEY, A. GUTIERREZ, R. M. AMOS-KROOHS, C. V. VORHEES, M. T. WILLIAMS;
Neurol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: While manganese (Mn) is an essential nutrient in the human diet, it causes neurotoxicity in excessive doses. In adult humans, manganese overexposure (MnOE) produces gait disturbance, rigidity, bradykinesia, and cognitive deficits. A number of genes involved in Mn homeostasis are also affected in some types of familial Parkinson's disease (PD), however the relationship between these two conditions is poorly understood. In an initial study, Mn (100 mg/kg) was galvaged to Sprague-Dawley rats from postnatal day (P)4 to P28 every other day, and the MnOE animals were studied in a variety of learning and memory tasks. In the Cincinnati Water Maze (CWM), the MnOE animals had longer latencies and more errors than controls, indicating deficits in egocentric learning. These animals also have deficits in spatial learning in the Morris water maze (MWM). Sprague-Dawley rats given 6-hydroxydopamine (6-OHDA) dopaminergic lesions of the neostriatum at a subthreshold dose that is used to model PD also had deficits in egocentric learning. This finding is similar to PD patients, who often have trouble with egocentric navigation. In this study, we combined MnOE with 6-OHDA to investigate if MnOE exacerbates the effects of dopamine lesions. Sprague-Dawley rats were treated with Mn or saline from P4-28 and on P60, were administered 6-OHDA or vehicle into the neostriatum. In a preliminary analysis, animals with Mn and 6-OHDA had longer latencies and more errors than Mn or lesions alone in the CWM. These animals were also tested in the Morris water maze and conditioned fear test, and these data are currently being analyzed to determine if there is an interaction of MnOE and dopamine depletions. The data suggest that Mn may play a role in exacerbating the cognitive symptoms following dopaminergic depletions by sensitizing the animals to a "second hit." Mn may be an environmental factor predisposing to earlier or more severe PD.

Abstract: Background: For many years, researchers have sought to characterize the homology between the hippocampal formation (HF) of birds and mammals, based on the functional conservation of these structures. The mammalian hippocampus creates representations of the surrounding environment by recruiting neuronal ensembles, resulting in the transcription of immediate early genes (IEGs) such as *zif268*. **Method:** We used fluorescent *in-situ* hybridization and confocal microscopy to measure IEG *zenk* (avian orthologue of *zif268*) expression in the HF of male brown-headed cowbirds following exposure either to two different contexts or the same context twice. **Results:** The proportion of cells repeatedly expressing *zenk* was significantly higher in birds that explored the same context twice compared to birds that visited different contexts. **Conclusions:** This suggests that the pattern of *zenk* expression in the avian HF is spatially selective and that cells are recruited to form contextual maps in a similar manner to the mammalian hippocampus. These data are also consistent with findings demonstrating that HF cells in the pigeon show place cell-like patterns of activity.

Title: Neural representations of others' place-related information

Authors: *T. DANJO, S. FUJISAWA;
Lab. for Systems Neurophysiol., Riken Brain Sci. Inst., Wako, Japan

Abstract: Observing and understanding others' behavior are critical for animals' survival and social interaction. It has been well demonstrated that mirror neurons that are activated both for particular actions of one's own and other animals play important roles in learning new skills. However, even though some species of animals are capable of understanding others' behavior as a whole and making decisions accordingly, how the overall recognition of others' behavior is represented and processed to make one's decisions has not been well identified. Here, we focus on how the complex information regarding to others' behavior, decisions and positions is represented in the rodent brain. As for the information of the position, it has been well established that pyramidal neurons in the hippocampus represent the place of its own. In contrast, little is known about how animals represent other animals' place and how the cognitive spatial map is related with the representation of others' place. To examine these questions, we designed a behavioral task with a T-maze apparatus for a pair of rats in which one rat has to observe the behavior of the other and decide its choices depending on the observation. We show behavioral results in this task and the electrophysiological data from the hippocampus and prefrontal cortex during the task.

Title: Functional reorganization of the medial temporal lobe memory system following neonatal hippocampal damage in monkeys

Authors: *P. LAVENEX[1], L. CHAREYRON[2], L. STICKLEY[2], P. BANTA LAVENEX[1], D. G. AMARAL[3];

Abstract: In humans, the hippocampus is essential for the processing of semantic and episodic memories; damage to this structure in adulthood results in amnesia. However, semantic memory is preserved in subjects who sustained hippocampal damage early in life, suggesting that the medial temporal lobe memory system might undergo structural and functional reorganization after neonatal hippocampal lesion. Similarly, we have previously shown that spatial relational learning is impaired in monkeys who sustained hippocampal lesion during adulthood, whereas spatial relational learning persists in monkeys who sustained hippocampal lesion shortly after birth. Here, we aimed to characterize the structural and functional reorganization of the medial temporal lobe memory system in rhesus macaques following neonatal hippocampal lesion. Shortly before death, animals explored a novel open-field environment in order to activate brain structures involved in spatial learning and memory. We performed quantitative analyses of expression of the immediate-early gene c-fos, a marker of neuronal activation, to determine the brain structures that might enable spatial learning following early hippocampal lesions. The cortical regions known to contribute to spatial memory processing, and which originate most of the afferent inputs to the hippocampal formation, were differentially affected by early hippocampal lesions. In early hippocampal lesioned monkeys, the exploration of a novel environment induced an activation of the parahippocampal and caudal perirhinal cortices, as in control monkeys. In contrast, in lesioned monkeys exploration did not lead to significant activation of the entorhinal, retrosplenial and posterior cingulate cortices, as in control monkeys. Analyses of retrograde tracer injections did not reveal a major structural reorganization of the medial temporal lobe memory system following early hippocampal lesions. We hypothesize that spatial information can be transferred and processed via the perirhinal and parahippocampal cortices, in absence of functional hippocampal circuits. In contrast, the absence of activation of the entorhinal, retrosplenial and cingulate cortices suggests that spatial information processing in these cortical areas might be dependent on proper hippocampal function and output. These results suggest that the functional reorganization that contributes to the preservation of memory function following early hippocampal damage might be characterized by subtle changes in

functional connectivity between cortical areas, which could be sufficient to support allocentric spatial memory formation over repeated trials.

Title: Validation of the clockmaze as a robust task for hippocampus-related spatial cognition in mice

Authors: ***P. T. HUERTA**, R. SANKOWSKI, E. GIBSON, C. REY, K. J. CLUNE, T. S. HUERTA, S. ROBBIATI;
Mol. Med., The Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: Cognitive impairment (CI) is a major risk factor for disability in a variety of clinical conditions. The recent years have shown a tremendous gain in understanding the molecular mechanisms of CI, but the impact of these findings on improving CI remains marginal. This lack of basic-to-clinical translation is puzzling, and it substantially hinders preclinical drug development. Given that mice are highly used in preclinical CI studies, we hypothesize that the intrinsic limitations of the behavioral paradigms applied to mice are a contributing factor to the current status. For example, the Morris watermaze (MWM) remains the most widely used task for hippocampus-related learning although it is notorious for strain bias in mice. Also, hippocampal dysfunction can be masked in MWM if mice apply mixed (spatial, nonspatial) solving strategies. The objective quantification of such strategies is complex and further confounds the interpretation of results. Deacon & Rawlings (Behav. Neurosci. 116, 472-478, 2002) introduced a task in which mice learned to escape from shallow water in a paddling pool. Here we present a large-scale validation of this task, which we have dubbed the clockmaze, as a highly reliable tool to test spatial cognition. The clockmaze is a circular arena equipped with 12 potential exits that are located in the wall of the arena like the numbers on the face of a clock. All

exits are blocked (black plugs) except for one that leads to a small tunnel. Mice learn to escape from the arena, which is filled with 2 cm of water, by using distal cues. We tested 3 strains: C57BL/6 (55 males, 58 females), Balb/Cj (55 males, 50 females) and Swiss (25 males, 25 females). We found that C57BL/6 and Balb/Cj mice learned with similar ease several versions of the task (reference memory, working memory, trials to criterion). We developed a robust algorithm to assess the strategies (spatial, nonspatial, futile) with easily quantifiable readouts. Using pharmacological approaches (n = 37) and genetic disruption of NMDA receptor function (n = 53), we show that the clockmaze relies on the integrity of the hippocampus. We conclude that the task provides a robust assessment of cognitive performance, which will facilitate hypothesis testing and contribute to the global effort to combat CI.

Title: The vestibular contribution to self-motion perception in the behaving mouse

Authors: ***E. BRACEY**[1,2,3], B. PICHLER[3], C. V. ROUSSEAU[3,2], T. MARGRIE[3,2];
[1]The Francis Crick Inst., Neurophysiol., London, United Kingdom; [2]Sainsbury Wellcome Ctr., London, United Kingdom; [3]Natl. Inst. for Med. Res., London, United Kingdom

Abstract: Vestibular signals are thought to be critical for the neuronal representation of heading direction and distance travelled. How accurately the vestibular system allows rodents to perceive and discern self-motion information has, however not been quantified. To address this, we designed a go/no-go discrimination paradigm in head-fixed mice that measures perceptual responses to precisely delivered rotational stimuli. Mice were positioned on a rotating platform in a dark, sound-attenuated chamber with their semicircular canals positioned around the rotation axis, then trained to discriminate two 45° horizontal rotations with different peak angular velocities, moving in the same direction with the same stimulus onset and offset times. All mice surpassed 80% accuracy for 100 consecutive trials (criterion) within 3000 repetitions, typically performing 100 - 300 trials per day. Mice were next trained on a go/no-go olfactory task and

achieved high discrimination accuracy for both rotation and odor stimuli (final 200 trials: rotation; 85 ± 1.42 %; odor; 90 ± 1.29 %, n = 6; mean ± SEM). After reaching criterion on both tasks, the left and right posterior and horizontal semicircular canals of three mice were exposed and injected with 5ul kanamycin (500 mg/g b.w.). After recovery, kanamycin-treated mice performed significantly worse on rotation discrimination than sham-treated animals (first 200 rotation trials after treatment: sham; 79.33 ± 1.99%, n = 3 mice vs kanamycin; 64.83 ± 2.61%, n = 3 mice, MWU p value 0.3). Discrimination deficits were not due to loss of licking motor-function, reduced motivation or impaired memory because odor discrimination was unaffected in kanamycin and sham-treated mice (first 200 odor trials post treatment: sham; 82.0 ± 2.75%, n = 3 mice vs kanamycin; 91.67 ± 1.56%). These experiments indicate mice can accurately discriminate horizontal rotations with different velocity profiles - to our knowledge the first direct evidence of a behavioral correlate of egocentric motion-perception in rodents. Reduced discrimination scores after kanamycin treatment suggest this ability relies critically on signals generated in the vestibular apparatus rather than proprioceptive or somatosensory cues. Ongoing work is investigating discrimination limens and detection thresholds for rotational stimuli that will be combined with neuronal recording and opto-genetic manipulation of underlying brain regions involved.

Title: Expanded firing patterns of grid cells in rats climbing on a wall

Authors: *G. CASALI, K. J. JEFFERY;
Exptl. Psychology, UCL, Inst. of Behavioural Neuroscience, UCL, London, United Kingdom

Abstract: Place cells (PCs) are hippocampal neurons whose firing increases when an animal is in one particular region of the environment, producing a focus of activity known as place field. Grid cells (GCs), found one synapse upstream in entorhinal cortex, display multiple evenly spaced place fields. Therefore, in contrast to PCs encoding the animal's current location, GCs process metric information by integrating travelled distances and directions, information likely to be used by the PCs to support navigation. A question of interest is whether GCs and PCs encode vertical space in the same way as horizontal. In a previous study on a pegboard maze(1), we found that GCs did not encode distance in the vertical dimension, producing vertical stripes instead of circular firing fields. However in that experiment, the animals remained horizontally oriented while climbing on the pegs, leading us to propose that GCs might use the plane of locomotion as the reference frame for encoding. In the present experiment we tested this by recording as animals climbed on a wall covered with chicken wire, where their bodies were now oriented vertically. We found that GCs now produced circular firing fields on the wall; however there was an increase in both field size and inter-field distances. PCs had fewer firing fields on the wall than on the floor but their size was unchanged. We then analysed theta, a 7-11 Hz local field potential oscillation that may be important for distance calculations. We found that theta frequency correlated with animal's speed on the wall as well as on the floor but there was a decrease in both the slope and intercept of the regression line, possibly suggesting an altered computation of movement speed on the wall. In conclusion, these results support the hypothesis that body orientation determines the GC and PC frame of reference; additionally, GCs' processing of distances is radically altered in the vertical plane and PCs also show firing changes. The speed/theta-frequency relationship is also affected. Collectively our findings suggest that the plane of locomotion relative to Earth-horizontal affects spatial encoding in three ways: (i) it determines the GC frame of reference, and (ii) it affects the spatial scale of GC firing, and (iii) it affects the relationship between locomotor speed and local field potential oscillations. These findings support the hypothesis that mammalian encoding of space is planar, and also that encoding of the vertical plane has different metric properties from that of the horizontal.

Title: Selective silencing of medial prefrontal parvalbumin interneurons induces cognitive schizophrenia-like symptoms in mice

Authors: *G. RIEDEL[1], M. WOLOSZYNOWSKA-FRASER[2], B. PLATT[1], B. CROUCH[1]; [1]Univ. Aberdeen, Aberdeen, United Kingdom; [2]Sch. of Med. Sci., Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Cognitive impairment is widely recognized as a core component of schizophrenia (SZ) alongside the positive and negative symptoms which form the basis of diagnosis. Despite this recognition very little progress has been made toward cognitive restoration in SZ patients. As cognitive function is considered a prime determinant of quality of life in SZ there is an incentive to understand the neural correlates of cognitive symptoms. Multiple lines of evidence point to dysfunction of parvalbumin positive interneurons (PVIs) in the dorsolateral prefrontal cortex (DLPFC) in SZ patients. As the DLPFC is a key regulator of working memory (WM), the emergent hypothesis therefore is that dorsolateral PVI dysfunction underlies the cognitive symptoms of SZ. To evaluate this hypothesis we generated a prospective mouse model of SZ via selective cell silencing of PVIs in the rodent medial prefrontal cortex (mPFC), the rodent analogue of the human DLPFC. This was achieved by a bilateral intracerebral injection of a novel cre dependent adeno-associated virus (AAV) into the mPFC of mice expressing cre recombinase under the parvalbumin promoter. AAV payload consisted of either green fluorescent protein (GFP) only (control) or in combination with tetanus toxin light chain (TeLC). Cognitive function was assessed using a Barnes maze paradigm incorporating both acquisition and reversal learning with concurrent bilateral recording of local field potentials (LFPs) from the mPFC and the hippocampal CA1. Results demonstrate no significant difference between groups during acquisition learning ($p>0.05$, virus effect, 2-way ANOVA) or in acquisition probe trials ($p>0.05$, 2-tailed t-test). During reversal learning TeLC transfected animals displayed a significantly faster reduction in mean path length ($p<0.001$) and escape latency ($p<0.0001$) than GFP controls (virus effect, 2-way ANOVA). TeLC animals also displayed poor reversal probe performance paradoxically indicating poor reversal learning. An analysis of visuo-spatial search strategies indicated that this difference is entirely explained by a lack of persistent preference for a previously learned target and a greatly reduced use of spatially precise search strategies in TeLC mice. Analysis of LFP recordings during training indicated that this deficit stems from inappropriate modulation of theta range oscillatory activity in the mPFC of TeLC animals. Cumulatively the results indicate that a selective silencing of *only* PVIs in the rodent mPFC alone is sufficient to induce a schizophrenia-like working memory impairment mirroring that observed in the human condition.

Title: Flexible spatial learning in rats requires intact hippocampal-prefrontal circuits

Authors: *P. AVIGAN, K. SEIP-CAMMACK, M. L. SHAPIRO;
Neurosci., Mount Sinai Sch. of Med., New York, NY

Abstract: Adaptive behavior is guided by reward history and updated when contingencies change. Bidirectional interactions between the hippocampus (HIPP) and medial prefrontal cortex (PFC) may contribute to adaptive behavior by integrating new experiences with long-term memory. The present study investigates whether intact PFC/HIPP circuits are required to adapt spatial responses to changing reward contingencies in a constant environment. Rats trained on a serial spatial reversal task were implanted with four cannulae: two bilaterally aimed at PFC (prelimbic/infralimbic regions) and two bilaterally aimed at either dorsal (dHIPP) or ventral (vHIPP) hippocampus. Spatial learning was tested in a plus-shaped maze with two start arms (North, South) and two goal arms (East, West). In each trial, a rat was placed on a pseudorandomized start arm and could find food reward at the end of one of the goal arms. The same goal arm was rewarded on subsequent trials until a rat achieved criterion performance (10 correct trials out of the previous 12 trials). Then, the other goal arm was rewarded until the rat achieved criterion performance. These spatial reversals continued for a total of 64 trials. Microinfusions of the GABAA agonist muscimol were used to transiently inactivate (a) contralateral PFC/HIPP, (b) bilateral PFC, (c) bilateral HIPP or (d) ipsilateral PFC/HIPP. If projections between PFC/HIPP are primarily ipsilateral, and if PFC/HIPP circuits must be intact in order for rats to respond adaptively to changing contingencies in a given environment, then contralateral and bilateral (but not ipsilateral) inactivations should impair rats' ability to learn serial spatial reversals. Bilateral dHIPP and vHIPP inactivation each impaired rats' ability to learn the initial contingency, and different patterns of errors followed inactivation of the two regions. Bilateral PFC inactivation selectively impaired reversal learning but not learning of the initial contingency; rats continued to visit the previously rewarded goal after the first contingency change. Contralateral inactivation of PFC and vHIPP impaired rats' ability to learn the initial contingency whereas contralateral inactivation of PFC and dHIPP had no effect. Thus, learning initial spatial contingencies requires both the dorsal and ventral hippocampus, whereas

adapting to changing contingencies in familiar circumstances requires the PFC and its interactions with vHIPP.

Title: Neural representation of space and objects in rat anterior claustrum

Authors: ***M. M. JANKOWSKI**, S. M. O'MARA;
Trinity Col. Inst. of Neuroscience, Trinity Col. Dublin, Dublin, Ireland

Abstract: The claustrum of the mammalian brain is an anatomically-substantial but largely unexplored and uninvestigated structure. The claustrum has been the subject of a limited degree of speculation regarding its potential functions, however, its physiological role still remains unknown. Among widespread connections with cortical and subcortical areas, claustrum is connected with medial and lateral entorhinal cortices and hippocampus, structures well known for coding of space and its content. In the present study, we investigated the spatial and temporal properties of neurons located in the anterior claustrum in freely-moving rats. Extracellular recordings were performed using 32-channel drivable microelectrode arrays. The spiking activity of neurons was simultaneously coupled with the animal's position in the environment and direction of the head in horizontal plane. Recordings were performed in different environmental conditions including presentation of objects. Our data suggest, unexpectedly, the presence of cells in anterior claustrum that are responsive to the position in space of the animal, to boundaries enclosing the environment and finally to the presence of objects in the environment. This novel claustral signal potentially directly modulates a wide variety of anterior cortical regions. We hypothesise that one of the key functions of the claustrum is to provide dynamic information about body position, boundaries and landmark information, enabling dynamic control of behaviour.

Title: Effects of environmental enrichment on anxiety, sensory gating, sociability, and spatial learning in mice

Authors: T. R. HENDERSHOTT, S. LANGELLA, P. S. MCGUINNESS, *A. C. BASU; Psychology, Col. of the Holy Cross, Worcester, MA

Abstract: In 1942 Donald Hebb compared the spatial problem solving ability of rats raised in his home as pets to rats raised in standard laboratory conditions. He found that the pet group showed superior learning ability to the laboratory group. Not only did the pet group initially show better spatial problem solving ability, but the rats in this group also improved more from trial to trial than the laboratory group. This led Hebb to hypothesize that "the richer experience of the pet group during development made them better able to profit from new experiences at maturity." Many researchers have attempted to replicate Hebb's results using laboratory-based environmental enrichment protocols in rodents, however there are three common challenges to interpreting data from these studies: (i) a running wheel is included in the enriched environment, (ii) control animals are raised in isolation rather than standard group housing conditions, (iii) the effects of enriched housing are measured only in mutant animals without wild-type control groups that would allow assessment of enrichment effects alone. We have not included a running wheel as an aspect of our enrichment protocol, and used wild-type animals reared in standard laboratory conditions with cagemates as our control group. In this experiment we compared male and female wild-type C57BL/6J mice reared from weaning age in a standard laboratory environment (SE) to those reared in an enriched environment (EE), using measures of anxiety-like behavior, sensory gating, sociability, and spatial learning and memory. Enriched animals displayed significantly less anxiety-like behaviors and reduced prepulse inhibition. To evaluate spatial learning and memory, we analyzed the latency to escape, path lengths, and search strategies used by the mice in a Morris Water Maze. The search strategies were grouped into either spatially precise (SP) or imprecise (SI). We found that enriched mice displayed enhanced spatial learning.

Title: Effects of different levels of environmental enrichment on reversing cholinergic deficits in rats

Authors: ***E. P. WIERTELAK**[1], D. PALMER[2], J. MEYERS-MANOR[2];
[1]Neurosci. Studies, Macalester Col., Saint Paul, MN; [2]Neurosci. Studies, Macalester Col., SAINT PAUL, MN

Abstract: Previous research has found environmental enrichment (EE) to ameliorate the effects of anti-cholinergic drugs seen to mimic the inhibition of ACh activity found in Alzheimer's patients, as well as positively influence the physical growth of specific neuroanatomical structures in the brain. This study illuminates the importance of different levels of EE in reversing the effects of the anti-cholinergic drug, scopolamine, on a rat's ability to acquire and retain information in the Morris water maze. Rats (10 months old) were housed in groups of two or four (dependent on experimental condition) in three different levels of enrichment: rats in the Standard Enriched Environment (SE) were housed in groups of two in standard, clear, plastic laboratory cages (46cm x 24cm x 21cm); rats in the Moderate Enriched Environment (ME) were housed in the same cages as the SE animals; however, a transparent plastic tube was placed in the cage and corn chips were added daily; rats in the Heavy Enriched Environment (HE) were housed in groups of four in identical larger, wire and plastic cages (64cm x 15.75cm x 32.5cm), with a transparent plastic tube, corn chips, a running wheel, and a ladder to a second level. After being housed under one EE condition for one month, rats were trained to navigate to a hidden platform in the Morris water maze for two days, at twelve trials per day. Half of the rats in each housing condition were given a subcutaneous injection of scopolamine (.6mg/kg), while the remainder received saline (vehicle) solution. The time taken to reach the platform in the Morris water maze was recorded for each rat during each trial. Final analysis examined rat latencies to reach the platform in the last learning trial of the second day. Overall, these data suggest that spatial memory in rats is significantly affected as enrichment increases - where rats in heavier enriched environments learn and process information at a more effective rate than standard

enriched rats in relation to their recorded latencies to reach the platform. Analysis suggests that heavy enriched, scopolamine, rats have lower latencies than standard enriched, scopolamine, rats; furthermore, heavy enriched, scopolamine, rats showed similar latencies to standard enriched, saline, rats. Environmental enrichment may play both a treatment and prevention role by targeting some of the neurological symptoms seen in AD, memory and spatial awareness.

Title: Neural correlates within nucleus prepositus and paragigantocellularis during active and passive movement

Authors: *J. R. DUMONT, S. S. WINTER, K. B. FARNES, J. S. TAUBE;
Psychological Brain Sci., Dartmouth Col., Hanover, NH

Abstract: An animal's perceived sense of orientation depends upon the head direction (HD) system, involving structures primarily along Papez' circuit. However, how the HD signal is generated and maintained remains unclear. Damage to the vestibular system disrupts neural firing within the HD system. Several brainstem nuclei including the nucleus prepositus hypoglossi (NPH) and dorsal paragigantocellularis reticular nuclei (PGRNd) form part of an ascending vestibular pathway to the HD circuit, and may contribute critical neural information utilized for navigation and orientation. Indeed lesions to the NPH severely disrupt HD cells within the anterodorsal thalamic nuclei. To further understand how the NPH and PGRNd may contribute to the HD system, extracellular recordings were made in these areas while rats either freely foraged in a cylindrical environment or were restrained (head-fixed) and passively rotated. During active movement in the cylinder, both of these nuclei contained cells that correlated with changes in the rat's angular head velocity (AHV). Two types of AHV cells were observed: 1) symmetrical AHV cells that increased neural firing with increases in velocity to both clockwise and counterclockwise head rotations; 2) asymmetrical AHV cells, which responded differentially to clockwise and counterclockwise head rotations (e.g., increased responding to increases in velocity in clockwise direction while decreasing in the counterclockwise direction). When rats

were passively rotated, cells in NPH and PGRNd maintained their sensitivity to changes in AHV. In addition to AHV cells, some neurons within PGRNd encoded the position of the rat's head in the pitch plane, similar to those seen before in the lateral mammillary nucleus, where firing increase as the rat pitched its head vertically. These cells perhaps allow the rat to maintain its orientation while traveling along vertical surfaces. These results indicate that spatially modulated neurons exist within brainstem nuclei forming part of an ascending vestibular pathway to the HD circuit, and provide critical information about rotational movement of the rat's head in both the pitch and yaw plane. In addition, the AHV signal is maintained during passive rotation, most likely by vestibular inputs as opposed to proprioceptive/motor efference cues.

Abstract: Hippocampal theta oscillations were proposed to play a key role in multiple cognitive functions, including memory and navigation, as well as in forming the hexagonal firing patterns of grid cells. Previous findings from bats have questioned these proposals, by reporting absence of theta rhythmicity in hippocampal place cells and entorhinal grid cells. However, recent *in-vitro* experiments suggested possible low-frequency (below-theta) subthreshold oscillations in the entorhinal cortex of bats, which could possibly support the same functions. Here we tested this proposal by recording *in-vivo* from interneurons, place-cells and grid-cells, in both crawling and flying bats. We found that none of these cell types exhibited movement-related rhythmic oscillations, neither at theta nor at any frequency - below or above theta. Surprisingly, although the local field potential (LFP) was highly variable in the bat (unlike the periodic theta-rhythmic LFP in rats), many neurons did exhibit locking to the up-swings or down-swings of the LFP. This neural locking to LFP modulations could potentially serve to synchronize hippocampal-entorhinal cell assemblies. These findings support the notion that, across species, normal hippocampal-entorhinal function may require synchronization of cell-assemblies - and this

synchronization could be non-rhythmic as in bats, or rhythmic as in rodents. Finally, we are now examining whether bat neurons exhibit phase precession relative to the phase of the irregular LFP fluctuations; initial analyses indicate that some cells indeed phase-precess - suggesting the possible existence of phase coding without oscillations.

Title: 3D grid cells and border cells in flying bats

Authors: ***G. GINOSAR**, A. FINKELSTEIN, A. RUBIN, L. LAS, N. ULANOVSKY; Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Grid cells and border cells are neurons found in the mammalian medial entorhinal cortex and nearby regions. Both of these cell types are thought to be important for navigation and spatial orientation in mammals by encoding animal position and distance as well as environmental geometry in a 2D space. However, although many animals navigate daily through 3D space - including squirrels, bats, dolphins, and monkeys - no studies to date have attempted to characterize the 3D volumetric firing of grid cells or border cells, in any species. To address this, we used Egyptian fruit bats to investigate whether 3D grid cells and 3D border cells exist, and what their firing patterns look like. We have previously found 2D grid cells in bats crawling on a 2D surface, as well as volumetric 3D place cells in freely-flying bats. Here, bats were trained to fly in a large flight room (~6 x 5 x 3 m) in search of randomly-positioned food, while we wirelessly recorded single-neuron activity in several brain regions where 2D grid cells and border cells are known to exist. Results revealed grid-like structures in recorded 3D firing-rate maps, consisting of repetitive blobby firing-fields. The spacing between firing-fields was more variable than in simulated perfect grids, but was substantially less variable than for randomly-distributed fields - suggesting that 3D firing fields of bat entorhinal neurons are repetitively spaced with a specific spatial scale. We also found 3D border cells that fired along the walls or floor of the environment. Taken together, these preliminary results reveal a complex 3D spatial representation in the bat entorhinal cortex.

Title: Vectorial representation of goals in the hippocampus of bats

Authors: ***A. SAREL**, A. FINKELSTEIN, L. LAS, N. ULANOVSKY;
Dept. of Neurobio., Weizmann Inst. of Sceince, Rehovot, Israel

Abstract: Navigation, the ability to reach a desired destination, requires knowledge of one's own location as well as the position and direction to the goal. Decades of research have revealed several types of spatially-tuned neurons in the mammalian hippocampal formation - such as place cells, grid cells and head-direction cells - that encode the position and orientation of the animal. However, very little is known about how neural circuits represent the location or direction of goals - which is essential for goal-directed navigation. To investigate how goal-related information is represented in the brain, we trained Egyptian fruit bats to fly towards elevated platforms (defined as 'goals') in search of food reward, while the activity of single neurons from hippocampal area CA1 was recorded. We found a subpopulation of hippocampal neurons that exhibited rather narrow angular tuning to goal-direction. Additionally, some neurons increased their firing-rate when the bat was approaching the goal, reminiscent of approach cells reported in rodents. Taken together, our preliminary results suggest the existence of goal-direction and goal-proximity signals in the bat hippocampus - a vectorial representation that could support goal-directed navigation.

Title: Positional firing properties of the dorsal subiculum in the navigating rat

Authors: *J. M. OLSON, J. K. LI, E. L. TAO, K. TONGPRASEARTH, D. A. NITZ;
Dept. of Cognitive Sci., UCSD, La Jolla, CA

Abstract: By virtue of its ability to encode environmental positions, the hippocampal formation plays a major role in spatial cognition, navigation, and the generation of episodic memories. The dorsal subiculum serves as perhaps the major efferent pathway leaving the hippocampal formation. Yet, the positional firing properties of subicular neurons have not been examined to nearly the same extent as other hippocampal sub-regions. Therefore, to reveal the role of different spatial frames of reference on the discharge of subicular subpopulations, we recorded ensembles of rat subicular neurons during a simple self-guided navigational task. Individual task trials entailed movement through a sequence of three left or right 90-degree turns to one of four potential reward sites. Completion of trials always yielded reward provided that the current path/action sequence was not that of the previous trial. All four paths were of the same length. Two additional 'return' paths along the maze perimeter led the animals back to the starting point for a new trial. Utilizing only uninterrupted path traversals, linearized positional firing rate vectors were constructed for each of the six possible paths (4 main, 2 return) by fitting tracking and spiking data to custom, path-specific templates. With the addition of 90-degree track rotations in some recordings, it was possible to examine subicular activity with respect to movement actions (left versus right turning) and several external/allocentric reference frames (environment, position in specific paths, position in any path). We find that many neurons differentiate the ongoing path being traversed even across segments of the maze common to multiple paths. However, another subset neurons encode analogous portions of two or more pathways, effectively mapping allocentrically different positions according to their commonality in terms of route progression. In addition, a few neurons exhibited activity specific to single positions in the environment, reminiscent of 'place cells' of the CA1 sub-region, while some neurons exhibited orientation-specific tuning. Overall, our results indicate the dorsal subiculum as a region sensitive to position but more closely tied to behavior than the subfields of hippocampus proper.

Title: Route versus environment centered properties in the spatial firing patterns of retrosplenial cortex neurons

Authors: *A. S. ALEXANDER, D. A. NITZ;
UCSD, San Diego, CA

Abstract: Recent work from our laboratory examined the potential role of retrosplenial cortex (RSC) in encoding conjunctions of spatial information of qualitatively different types. RSC neuron ensembles effectively encoded the left versus right turning behavior of rats traversing three-turn sequences along paths through an environment indicating a mapping of spatial information in one or more egocentric frames of reference. The same ensembles contained neurons whose positional rate vectors distinguished positions across the same paths, thereby providing spatial information in a route-based frame of reference above and beyond what could be accounted for by firing correlates to specific actions (e.g., left or right turns). Nevertheless, largely distinct route-position-encoding ensembles were observed when the path occupied different locations within the larger environment. Thus, RSC maps position within complex routes and the position of routes within an environment. In the present work, we further examine the positional firing properties of RSC neurons as animals traversed part or all of the perimeter of a plus shaped track having views to the surrounding recording environment. Full track traversals returned the animal to its starting location after executing a R-L-R-R-L-R-R-L-R-R-L-R turn sequence with 25 cm inter-turn intervals. Half track traversals required the animal to spontaneously stop after completing a R-L-R-R-L-R turn sequence. Half versus full track traversal was dictated by the experimenter's placement of the animal at one of two randomly selected positions on the track at the beginning of each trial. The task design permits assessment of several aspects of RSC: 1) the extent to which RSC ensembles discriminate common portions of two paths having complete overlap in environmental space; 2) the extent to which RSC, as for neighboring posterior parietal cortex, maps recurrence in the shape of path segments; and 3) whether rate vectors for 1/2-path traversals match the first, middle, or last 1/2 of the rate vectors observed across the full path. The latter question further addresses the manner in which RSC ensemble patterns mapping position in routes is related to the larger environmental/allocentric space. Overall, RSC neuronal ensembles did not discriminate portions of the half and full

traversals that overlapped in allocentric space. RSC neurons, did however, discriminate similarly shaped route segments that occurred in distinct allocentric locations. The results indicate that RSC route-referenced activation is dependent upon the allocentric position of the route within the broader environment.

Title: A subset of CA1 and subiculum neurons selectively encode rewarded locations

Authors: *J. L. GAUTHIER, D. W. TANK;
Princeton Univ., Princeton, NJ

Abstract: Lesion studies have demonstrated that the hippocampus is critical for the retention of spatial memories, such as the location of an escape platform in a water maze, as well as transferring those memories to other brain areas. However it remains unclear which features of hippocampal physiology convey the memory. Previous studies have shown that when rewards are presented at fixed locations, a higher density of place fields in CA1 develop near the rewards. We set out to distinguish whether this reflects a generally increased density of place fields, or whether the activity of some cells is specifically related to reward. Mice were trained to run on two virtual linear tracks with rewards at several possible locations, and simultaneous optical recordings were made from two major hippocampal output structures, CA1 and the subiculum. Consistent with previous studies, an increased density of place cells was found near rewarded locations. Interestingly, when environmental changes were made that induced either global remapping or rate remapping, the same subset of neurons maintained firing fields near the reward. These observations reveal a previously undescribed feature of hippocampal remapping: a distinct neural population that shifts its firing fields to consistently predict a rewarded location, despite unrelated restructuring of simultaneously recorded place fields. A further trial-by-trial analysis revealed that activity of reward-predicting cells correlated with behavioral anticipation

of reward, raising the possibility that these cells transmit memory of the rewarded location to other brain areas.

Title: Landmark-control over place cells varies within the CA1 pyramidal layer

Authors: ***T. GEILLER**[1], J.-S. CHOI[2], S. ROYER[1];
[1]KIST, Seoul, Korea, Republic of; [2]Korea Univ., Seoul, Korea, Republic of

Abstract: Whether the range of spatial and non-spatial factors controlling hippocampal place cells involves functionally and/or anatomically distinct circuits is largely unknown. A difficulty when examining the impact of particular landmarks on place cell activity in typical recording environments is the abundance and simultaneity of local/distal cues. To circumvent this difficulty, we used a treadmill apparatus, to have mice run multiple times through a series of small objects, while monitoring neuronal activity in CA1 and CA3. Head-restrained mice moved themselves the treadmill belt, onto which objects were fixed. This setting was previously shown to elicit hippocampal firing patterns similar to place fields, and allows a fine control over spatial cues, which are reduced to the few landmarks on the belt. We found a diversity of pyramidal cell types, contrasting in their firing responses to the distinct landmarks, their remapping dynamics, and their localizations along the radial axis of the pyramidal cell layer. We found that a large fraction of cells had their place fields tightly controlled by specific landmarks, mapping positions before and within landmarks, repeating identically for duplicated positions of the same landmarks, and instantly emerging/disappearing when landmarks were added/removed from the belt. Other cells were separable by their distinct remapping dynamics: ‘switching’ cells, initially silent, developed single fields several trials after landmark additions, while ‘drifting’ cells, located in relatively more superficial parts of the CA1 pyramidal layer, exhibited fields that drifted backwards by tens of centimeters. While place cells are often regarded as a single phenomenon, our findings suggest a variety of mechanisms, with specific anatomical organization across CA regions, and within the CA1 pyramidal layer. The existence of OSLV

cells fits quite well the landmark vector hypothesis, where representation of space is achieved via an encoding of distances to discrete landmarks. In return, cells with looser tie to specific landmarks might provide the flexibility for encoding combinations of cues, or representations less dependent on cues, such as prospective cells and episode cells

Title: Impact of cues on optogenetically identified Mossy cells of the dentate gyrus

Authors: ***S. KIM**[1], D. JUNG[1,2], S. ROYER[1];
[1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of;
[2]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: While the dentate gyrus (DG) is believed critical for discriminating the contexts, not much is known about its neural correlate. It has been shown that DG neurons activity is more sensitive than CA1 and CA3 to small environmental changes, consistent with its hypothesized role in pattern separation. The dentate gyrus network is composed of several cell types. In particular, excitatory Mossy cells and inhibitory interneurons, located in the hilus, are reciprocally connected with the granule cells, forming a recurrent network whose operations are largely unknown. To investigate the neuronal correlate of different DG cell types, we trained mice to run for water rewards on a treadmill equipped with the long belt (~2 m) enriched with visual-tactile cues. Typically 4 types of objects with contrasting color and texture were used: 1) a 'forest' of ~3 cm high spines made with hot glue, 2) a field of scattered shrink tubes, 3) a field of scattered pieces of Velcro, and 4) a single ~0.8 cm diameter shrink tube. A ~5µl sweet water reward was delivered through a lick port at a specific belt position on every trial. In order to express halorhodopsin in Mossy cells, we injected cre-dependent halorhodopsin expressing virus in DRD2-cre mice. To simultaneously record and deliver light stimuli, we equipped 3 shanks of a 6-shanks silicon probe (Buzsaki64sp) with optical fibers of 15µm diameters, which connect to a yellow laser (561nm). The laser was turned ON in a given portion of the belt, on alternate trials. Among a total of 880 recorded neurons over 11 sessions, we could identify 35 cells with

activity significantly suppressed by the light stimulation and 55 neurons with activity significantly enhanced. Light-suppressed neurons had spike auto-correlogram shapes characteristic of Mossy cells, as previously described (Henze & Buzsaki 2007). On the other hand, light-excited cells discharged more in bursts and had shorter inter-spike intervals. A large fraction of DG neurons exhibited either single or multiple sharp and stable firing fields associated with the objects of the belt. Light-suppressed cells exhibited a larger fraction of multiple firing fields (23%) relative to the light-excited cells (12%). Our results suggest that mossy cells have distinct neuronal properties and exert an overall inhibitory effect on other cell types in DG.

Title: How generalizable is rodent hippocampal function across other species? Preliminary hippocampal recordings in the ferret (Mustela putorius)

Authors: S. L. S. DUNN[1], J. BIZLEY[1], *D. A. BENDOR[2];
[1]Ear Inst., [2]Univ. Col. London, London, United Kingdom

Abstract: In rodents, the hippocampus plays a fundamental role in spatial navigation. Lesions to the hippocampus disrupt spatial memory, while hippocampal neurons (place cells) are tuned to an animal's location in its environment. Furthermore, theta oscillations, a 5-12 Hz rhythmic component in the local field potential, are linked to locomotion and play a critical role in numerous hippocampal models of spatial navigation. However, neural coding principles of the hippocampus are based almost exclusively on rodent studies, and it remains an open question which principles can be generalized to other species. Rodents primarily rely on the proximal sensing strategies of sniffing and whisking. Therefore, their sensory world is tied very closely to their current location. In species where distal sensing is more dominant, activity in the hippocampus is not always consistent with the rodent data. For example, 'spatial-view cells'

have been observed in non-human primates, and theta activity is more closely coupled with echolocation rather than locomotion in bats. To further investigate inter-species differences we have started to record hippocampal activity from the ferret (Mustela putorius): a predatory carnivore, which relies predominantly on the distal senses of audition and vision. Here we present a 3D reconstruction of the ferret hippocampus, which was used to guide electrode implantation, and preliminary data recorded from the ferret hippocampus during various behavioural paradigms.

Title: Inter-spike intervals reveal functionally distinct cell populations in the medial entorhinal cortex

Authors: *P. LATUSKE[1], O. TOADER[2], K. ALLEN[2];
[1]Dept. of Clin. Neurobio. at the Med. Fac. of Heidelberg Univ., Dept. of Clin. Neurobio. At the Med. Facu, Heidelberg, Germany; [2]Dept. of Clin. Neurobiology, Med. Fac. of Heidelberg Univ. and German Cancer Res. Ctr. (DKFZ), Heidelberg, Germany

Abstract: The superficial layers of the medial entorhinal cortex (MEC) contain spatially selective neurons that are crucial for spatial navigation and memory. These highly specialized neurons include grid cells, border cells, head direction cells and irregular spatially selective cells. In addition, MEC neurons display a large variability in their spike patterns at a millisecond time scale. In this study, we analyzed spike trains of neurons in the MEC superficial layers and found that these cells can be classified in two groups based on their propensity to fire spike doublets at 125-250 Hz. The two groups, labeled ”bursty” and ”non-bursty” neurons, differed in their spike waveforms and interspike interval adaptation but displayed a similar mean firing rate. Grid cell spatial periodicity was more commonly observed in bursty than in non-bursty neurons. In contrast, most neurons with head direction selectivity or that were firing at the border of the

environment were non-bursty neurons. During theta oscillations, both bursty and non-bursty neurons fired preferentially near the end of the descending phase of the cycle, but the spikes of bursty neurons occurred at an earlier phase than those of non-bursty neurons. Finally, analysis of spike-time crosscorrelations between simultaneously recorded neurons suggested that the two cell classes are differentially coupled to fast spiking interneurons: bursty neurons were twice as likely to have excitatory interactions with putative interneurons as non-bursty neurons. These results demonstrate that bursty and non-bursty neurons are differentially integrated in the MEC network and preferentially encode distinct spatial signals.

Title: Transgenic activation of MEC LII results in similar changes in the firing properties of CA1 place cells across distinct environments

Authors: *C. LYKKEN[1], N. ESTRADA[1], B. KANTER[1], C. KENTROS[2];
[1]Univ. of Oregon, Eugene, OR; [2]Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: The hippocampus is critical for episodic memory. The spatial component of episodic memory is thought to be encoded by place cells, which fire in specific locations of the environment. Environmental novelty causes place cells to change their firing rate and/or firing location, a process called remapping. Remarkably, there is no discernible relationship between the firing fields of a particular cell in two distinct environments. The medial entorhinal cortex (MEC), the major input to the hippocampus, contains several cell types with spatial receptive fields, including grid, head direction, and border cells. The relationship between upstream MEC neurons and remapping of downstream hippocampal neurons is still unclear. In order to address this question, we used the tTA-tetO system to express an hM3Dq DREADD (Designer Receptors Exclusively Activated by Designer Drugs) in MEC layer II. The hM3Dq is a modified muscarinic G-protein coupled receptor exclusively activated by an otherwise inert ligand, clozapine-N-oxide (CNO). Previous electrophysiological recordings in our lab demonstrated that systemic injection of CNO increases the firing rate of neurons in layer II of the MEC and causes

grid fields to expand without changing the grid vertices. However, CNO-induced activation of MEC LII neurons produces drastic changes in CA1 place fields ("artificial remapping") in downstream CA1 pyramidal neurons. Multiple transgenic activations of the same entorhinal inputs via multiple CNO injections leads to the same hippocampal network response, suggesting that artificial remapping may be a hard-wired network response. To investigate whether transgenic activation of the same set of MEC LII neurons has a similar effect on two distinct receptive fields of the same CA1 place cell, we recorded activity in CA1 while mice explored two distinct environments before and after the administration of CNO. Since place cells remap between environments, any similarities between two artificial remappings of the same place cell reveal the effects of the same network manipulation on two distinct CA1 receptive fields. In contrast to remapping induced by changes in the animal's experience, our preliminary results suggest that there is a discernible relationship between firing rate changes in distinct environments following transgenic activation of MEC LII. These results not only provide further support for the idea that artificial remapping in response to transgenic activation of MEC LII is a hard-wired network response, but also raise the question of how known changes in input are interpreted by the hippocampal-entorhinal network.

Title: Transgenic activation of medial entorhinal cortex similarly alters spatial firing properties of CA3 and CA1 place cells

Authors: *B. R. KANTER[1], T.-T. P. NGUYEN[1], C. G. KENTROS[2];
[1]Univ. of Oregon, Eugene, OR; [2]Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: The hippocampus is required for the encoding of episodic memory, the recollection of "what" happened, "when" it happened, and "where" it happened. Hippocampal place cells are preferentially active as an animal passes through specific locations (i.e. place fields) of a particular environment. When introduced to a novel environment, the firing rate and/or location of place fields drastically change, a process called remapping. Exactly how place cells remap

remains one of the most elusive questions in our field. Our laboratory uses a transgenic mouse line expressing a mutated human muscarinic glutamate receptor (the hM3Dq DREADD) primarily in medial entorhinal cortex layer II (MECII), one of the main inputs to the hippocampus. Systemic injection of clozapine N-oxide (CNO), which only binds to hM3Dq receptors, depolarizes a subset of MECII neurons. We have previously shown that this leads to "artificial remapping" of CA1 place cells, where cells remap though the animal remains in a stable environment. Here, we show that artificial remapping is also induced in CA3 place cells. CA3 has unique recurrent connectivity and responds differently than CA1 to environmental change. Therefore, it has been proposed that CA3 may nonlinearly transform sensory input to support the complementary functions of pattern completion and pattern separation (Guzowski et al., 2004). The authors predict that relative to those of CA1, the firing properties of CA3 will change less with small changes to the environment, but will change more with large changes to the environment. We therefore hypothesized that dose-response curves measuring changes in spatial firing properties at different doses of CNO would differ between CA3 and CA1. To test this hypothesis, we injected a range of doses of CNO to simulate varying amounts of contextual change while recording from CA3 and CA1 place cells. We computed spatial correlations between rate maps of a given cell before and after CNO injection to assess the degree of remapping. Surprisingly, the dose-response curves for the two regions are quite similar. Rather than disproving the model, our results may highlight the mechanistic differences between artificial and traditional remapping. By altering the firing rate of entorhinal inputs in a stable environment, we dissociate an animal's sensory experience and the evoked neural activity to address what truly causes a place cell to remap.

Title: Long-term refinement of CA1 ensemble representations of associations between reward and spatial location

Authors: *E. OTTO HAMEL, M. C. LARKIN, L. J. KITCH, M. J. SCHNITZER;
Stanford Univ., Stanford, CA

Abstract: Memories of rewarding episodes generally last longer than memories of neutral events. The mammalian hippocampus is essential for the formation of episodic memory, but how it preferentially retains memory of rewarding events is poorly understood. In hippocampal area CA1, pyramidal cells exhibit place fields at a higher prevalence around reward and goal locations. However, it has been unknown how CA1 representations of rewarding experiences evolve over the course of learning and whether place fields encoding rewarded locations are more stable than others over the long term. To examine these issues, we used a head-mounted miniature fluorescence microscope to track the calcium dynamics of >10,000 CA1 pyramidal cells (10 mice) expressing the calcium indicator GCaMP6m as the mice learned to perform a reward-motivated spatial task over 9 days. As the mice learned the association between place and reward, there was a progressive refinement of the CA1 neurons' place fields that gradually resulted in a greater preponderance of place fields at rewarded locations. When we altered the spatial profile of reward contingencies, the CA1 representation of space shifted to reflect the new reward sites. The bulk of these changes in the ensemble code arose from cells that had previously been silent or non-coding. Even after the mice learned the new contingencies, the refinement of the neural code continued for multiple days. However, once cells participated in the ensemble representation of space, those encoding a rewarded location were no more likely to persist, re-map, or exit the coding population than other coding cells. Overall, our study reveals key aspects of how CA1 hippocampal codes evolve over days to reflect rewarding experiences and emphasizes the role of cells that are initially silent or non-participants in the coding ensemble.

Title: Presence of significant directional modulation in rodent hippocampus, in real and virtual environments

Authors: *Z. M. AGHAJAN[1,2,3,4], L. ACHARYA[1,2,3,5], J. MOORE[1,2,3,6], C. VUONG[1,2,3,4], M. R. MEHTA[1,2,3,4,7];

Abstract: Place cells in the hippocampus provide a cognitive map of space in that they fire in a spatially localized manner. These spatial firing properties have been extensively studied and shown to be modulated by multisensory inputs. However, the existence of and mechanisms underlying directional selectivity of place cells have been largely debated[1]. While it is widely accepted that directionality exists on linear paths, the reports on its presence during random foraging have reached conflicting conclusions. Further, the observed directional selectivity has been attributed to vestibular-based self-motion signal in some studies and to distal visual cues in others. These contradictions can arise in part because the traditional analysis methods cannot account for spiking activity modulated by multiple covariates, as is the case for place cells. Additionally, the sources of angular information, namely vestibular and visual cues, are always in register in real word (RW) environments under normal conditions and hence their contributions to directional selectivity are confounded. To address these issues, we first used a generalized linear model (GLM) framework to obtain the underlying directional modulation of hippocampal neurons in RW during a random foraging task. This estimate was independent of the neurons' spatial modulation and unaffected by the behavioral biases within the place fields. Moreover, we used a virtual reality (VR) setup that allowed us to isolate the contribution of visual cues to directional selectivity while keeping the vestibular signal minimal. By utilizing the GLM method, we found that 25% of neurons exhibited significant directional modulation in RW. Surprisingly, a similar level of directional modulation was found in VR demonstrating that visual cues alone are sufficient to elicit directional tuning and that vestibular cues are not necessary[2]. Taken together, these results challenge the commonly held beliefs about rodent hippocampal directional responses. The presence of intact directional selectivity despite impaired spatial selectivity in VR[3] suggests a dissociation between the mechanisms of the two and is reminiscent of the results observed in human and non-human primates. 1. Title: Causal role of visual cues in determining hippocampal directional responses at single neuron and ensemble level

Authors: *L. ACHARYA[1,2,3], Z. M. AGHAJAN[1,2,4], C. VUONG[1,2,4], J. J. MOORE[1,2,5], M. MEHTA[1,2,4,5,6];

Abstract: Hippocampal pyramidal neurons encode both position and direction. In rodents the latter has so far been observed only on linear tracks and it is thought the firing properties of place cells are not influenced by the animal's head direction in two-dimensional environments. However, there have been a few, albeit conflicting, reports of directional selectivity in two-dimensional arenas in rats, bats and monkeys. In addition to the inconsistency between one- and two-dimensional tasks, the sensory mechanisms behind this activity remain ambiguous. We recorded CA1 neuronal activity from rats performing a random foraging task in both real world (RW) and virtual reality (VR) two-dimensional arenas with visually distinct walls[1]. About a quarter of neurons in both worlds exhibited significant head-directional modulation, which is comparable to the fraction observed in the head direction system. Since in VR, visual cues are the only reliable spatially and directionally informative cues, and vestibular cues are diminished, this result suggested visual inputs can directly modulate hippocampal activity. To test this hypothesis, we ran rats in four different VR arenas, each with a different amount of angular information. In two, visual cues provided no angular information and had either angularly symmetric visual cues or no walls. Under these conditions no significant directional tuning was

observed. Directional tuning was revived in the second set of arenas that had a single polarizing visual cue that either occupied 90° or 10° of the visual field. Here, the fraction of neurons exhibiting significant directional modulation increased with polarization of the visual cue. These stark differences were not only observed at the individual neuronal level, but also at the level of the ensemble. While there was no directional bias of the ensemble of neurons with significant directional tuning in the rich RW and VR environments, there was a significant ensemble bias towards the sole visual cue in the environments with polarizing cues. Moreover, the magnitude of bias also increased with polarization of the cue[2]. These results show that visual cues are not only sufficient to generate directional modulation of rodent hippocampal neurons but also play a causal role in driving activity at both the neuronal and population levels. They also bridge the gap between rodent and primate studies where hippocampal neurons are responsive to visual scenes. 1.Aghajan, Z. Title: Hippocampal neural dynamics in a virtual Morris water maze navigation task

Authors: *J. J. MOORE[1,2,3,4], L. ACHARYA[1,2,3,5], J. D. CUSHMAN[6,3], C. VUONG[1,2,3,7], Z. M. AGHAJAN[1,2,3,7], B. POPENEY[8], M. R. MEHTA[1,2,3,7,9];

Abstract: It is commonly believed that a stable cognitive map of space is necessary for the successful execution of any navigation task. Indeed, removal of the hippocampus, which contains place cells thought to underlie the cognitive map, impairs performance in the Morris Water Maze task, suggesting a crucial role of hippocampal activity in this task. However, it is unclear if this also means that hippocampal *spatial selectivity* is required for successful execution of this landmark-based spatial navigation task. Recent results from rodents exploring environments in virtual reality (VR) raise questions about this requirement. We recently demonstrated that while rat hippocampal neurons show robust spatial selectivity during random foraging in the real world, spatial selectivity is impaired when body-fixed rats perform the same task in a two-dimensional virtual reality environment (1). Instead, neural responses showed selectivity to distance traveled along systematic paths (1,2). The impaired spatial selectivity could possibly stem from the rats not paying attention to the visual cues during random foraging. Interestingly, rats are able to quickly learn to solve a virtual Morris Water Maze task, where they must pay attention to the visual cues, using the exact same apparatus (3). What, then, is the nature of hippocampal neuronal dynamics during this virtual navigation task? To address this question, we measured neural responses from the dorsal hippocampus while the rats executed the virtual navigation task. Eats were placed on a 2m diameter virtual platform within a 3x3m virtual room with distinct visual cues on the walls. The rats had to find a predetermined, unmarked location on the virtual platform to receive liquid rewards. Rats quickly learned this task. Upon successful learning of the task rats were implanted with multi-tetrode hyperdrives and single unit responses were measured from the dorsal hippocampus. Here we quantify the properties of neural responses in this task and their relation to behavioral performance in this navigational task. This is the first measurement of hippocampal neural responses during a navigation task in a purely visual virtual reality, which can lead to a substantial advance in our understanding of the neural mechanisms underlying navigation. 1. Title: Motivation and validation of an EEG-based estimate of hippocampal replay content

Authors: *C. M. ALTIMUS[1], R. E. AMBROSE[2], B. E. PFEIFFER[3], J. B. HARROLD[2], D. J. FOSTER[2];

Abstract: Pyramidal cells in the hippocampus, known as place cells, fire robustly in a location specific manner, but also fire in temporally compressed sequences known as replay that can reflect remembered past or planned future behavioral trajectories through the environment. Previously we have introduced a novel and rapid assay using only the local hippocampal electroencephalogram (EEG) that can infer properties of replay sequences without the technically challenging requirement of simultaneously recording large numbers of single units. Here we addressed the question of how the new assay compares to direct measurement of replay sequences, in animals for which both kinds of measurement were taken. We recorded from large numbers of hippocampal place cells simultaneously in freely moving rats, together with local hippocampal EEG. First, we investigated the dependence of accurate replay sequence estimation on the numbers of simultaneously recorded single units, by subsampling cells from the original recorded population. Whereas the position of an animal during spatial exploration can be estimated with high accuracy from as few as 25 cells, the accuracy of replay sequences degraded rapidly as the cell count dropped below 100. At 50 cells, decoded replay sequences showed dramatic changes compared to the original sequences, often with erroneous estimation of the trajectory path. Thus, we find strong motivation for an EEG assay of replay for use in smaller recording preparations such as freely moving mice. Second, in order to validate our novel EEG measure, we compared it directly to replay sequences. We find that as hypothesized the duration of sharp-wave ripple (SWR) events correlates positively with the decoded trajectory length of replay events. Thus replay, that has been reported previously based on a subsampling of the hippocampal cell population and a subset of population spiking events, was found to correlate with a global measure of hippocampal neural activity, the duration of hippocampal SWRs.

Title: Local and distant input controlling excitation in layer II of the medial entorhinal cortex

Authors: *R. PINNA[1], E. C. FUCHS[2], A. NEITZ[2], S. MELZER[2,3], O. TOADER[2], A. CAPUTI[2], H. MONYER[2];

Abstract: Layer II (LII) of the medial entorhinal cortex (MEC) comprises grid cells that support spatial navigation. The unique firing pattern of grid cells might be explained by attractor dynamics in a network, which requires either direct excitatory connectivity between phase-specific grid cells or indirect coupling via spatially tuned interneurons. However, neither scenario has strong experimental support. Based on electrophysiological and morphological criteria, we identified in LII MEC four types of excitatory neurons that exhibit a cell type-specific local connectivity. Using retrograde and anterograde labeling technique and optogenetic stimulation, we provide evidence that LIII pyramidal cells excite both ipsilateral and contralateral LII neurons. We injected the adeno-associated virus CaMKIIa-ChR2-mCherry in the MEC and stimulated the projecting axons with blue laser light in the contralateral MEC. Employing the same techniques, we demonstrate that the medial septum controls excitation via long-range GABAergic neurons that target preferentially fast-spiking interneurons in LII thereby disinhibiting local circuits. We thus identified local excitatory recurrent connections that could support attractor dynamics and external inputs that likely govern local excitation in LII. The functions of the different cell types *in vivo* remain to be established.

Title: Intact allocentric spatial memory during virtual navigation in rhesus monkeys with bilateral hippocampal lesions

Authors: *B. M. STEEMERS[1], R. SAUNDERS[1], M. MISHKIN[1], C. DOELLER[2], S. GUDERIAN[1];

Abstract: The hippocampus has been implicated in allocentric spatial memory in rodents, non-human primates, and humans. However, the majority of rodent studies employed tasks that involve a navigational component in a three dimensional environment, whereas the majority of studies in primates did not require navigation, thus rendering the translation of findings from rodents to primates difficult. In the present experiment, we investigated the effect of hippocampal lesions on allocentric spatial navigational memory in rhesus monkeys using a virtual environment. The task, a variant of the Morris Water Maze, which has been used extensively to test navigational spatial memory in rodents, required monkeys to use a joystick to navigate to a rewarded location within a circular arena. This circular arena resided in a larger hexagonal room, with six unique images on the walls of the room providing cues for orientation. No navigational cues were present within the circular arena. The orientation cues, as well as the rewarded location within the arena, were different on each testing day, thus providing a different allocentric spatial memory problem in each session. On each trial, monkeys started navigating from a random location within the circular arena. Performance was assessed as the ratio between the distance traveled (DT) and the optimal distance (OD), given each trial's starting location (perfect performance thus being 1). Preoperatively, monkeys were able to reliably reach a DT/OD ratio of around 1.5 and learned to locate the reward within 20-30 trials. Critically, neither learning rate early in the session nor ceiling performance was significantly reduced after bilateral neurotoxic lesions of the hippocampus. Furthermore, neither performance as a function of proximity of the reward location to the arena wall nor performance as a function of proximity of the starting location to the reward location was decreased after hippocampal lesions. The results

suggest that, in rhesus monkeys, the integrity of the hippocampus is not critical for memory-based allocentric spatial navigation in a virtual reality environment.

Title: Quantifying and exploring the emergence of the late members of the active set of hippocampal place cells in novel environments

Authors: *S. E. FOX[1], J. BARRY[2], K. BOLDING[3];
[1]Dept Physiol & Pharmacol, Downstate Med. Ctr., Brooklyn, NY; [2]Dept. of Neurolog. Sci., Univ. of Vermont Col. of Med., Burlington, VT; [3]Dept. of Neurobio., Duke Univ. Sch. of Med., Durham, NC

Abstract: Hill (1978) reported that for 2 of 12 place cells recorded on a novel T-maze, the place field required up to 10 min to develop. Frank, et al. (2004) showed that such late-onset place fields, absent for minutes, develop abruptly (within < 15 s) on novel arms of T-mazes. Monaco, et al. (2014) identified a relationship between head-scanning and the sudden onset of late-developing place fields in double cue-rotation and novel closed-loop tracks. Temporal Categories. We recorded place cells in environments where rats foraged for pellets on 2-D surfaces and separated the cells into 3 groups by field onset time. We defined “early cells” as those that had a place field (9 edge-contiguous pixels with firing rate > 0) in the first 2 min of a recording session. The onset times of late-developing place fields were bimodally distributed. Place cells that developed a field 2-8 min (3.2 ± 0.3) into a session were defined as “common late cells”; these occurred in both familiar and novel environments and comprised about 15%-20% of the total population of place cells. “Novel late cells” developed a place field between 8 and 16 min (9.3 ± 0.4) and appeared only in environments sufficiently novel to trigger global remapping, where they then comprised 20-30% of the total stabilized place cell population. Disinhibition. For locations outside the fully developed place field of both common and novel late cells, the firing rates before and after onset of rapid in-field firing were similar, so disinhibition seems an unlikely cause for the late-onset firing. Theta Rhythm. After septal injections of gabazine that nearly eliminated theta, 8 late place cells were recorded and all

developed fields in 10 min or less (4.5 ± 1.0). The distribution of these field onset times did not differ from that of common late cells (p_{log} = .23), suggesting that theta oscillations may contribute to the development of firing in novel late cells. Edge Fields. Among early cells, 8 of 50 (16%) had concave place fields at the edge of a novel circular chamber, suggesting they are driven by border cell inputs. A similar fraction (3 of 23, 13%) of such fields occurred among common late cells, but no novel late cells had concave edge fields (0 of 20, binom p = .03 re: early cells). NMDA. Re-analysis of recordings in novel environments after systemic CPP (Kentros, et al., 1998) showed only common late cells, no novel late cells. That may have occurred because place field development in novel late cells requires NMDA, but it also may have occurred because after CPP, thigmotaxis was so pronounced that all cells with late-developing fields were concave edge cells. The CPP-treated rats rarely visited the regions where the fields of novel late cells develop.

Title: Visual cue-related activity of MEC cells during navigation in virtual reality

Authors: *A. A. KINKHABWALA[1,2], D. ARONOV[1,2], D. W. TANK[1,2];
[1]Princeton Univ., Princeton, NJ; [2]Princeton Neurosci. Inst., Princeton, NJ

Abstract: Previous studies have found distinguishing features for the spatial and orientation tuning of cells in MEC (Medial Entorhinal Cortex), such as the triangular lattice of firing fields of grid cells, the orientation tuning of head direction cells, and the boundary-related activity patterns of border cells. These features were initially revealed by analysis of chronic electrode recordings performed in rodents while they foraged in an open arena. We complemented real arena recordings with navigation along virtual tracks containing a set of landmarks. In this setup, allocentric information experienced by the subject could be more precisely quantified to better understand the type of information represented by the spiking of cells in MEC. Tetrode recordings were obtained in the MEC of mice navigating in both real and virtual environments. We found a striking spatial firing pattern for a subset of recorded cells: firing fields were present

only near the set of cue locations in the virtual environment. To quantify this feature of the spatial firing rate, a cue score was developed. We first defined a ‘cue template’ (1 at cue locations; 0 otherwise) to identify where visual cues were located along the virtual track. We then calculated the maximal cross correlation between the cue template and the firing rate for different spatial offsets of firing field and template. Cells were defined as cue cells if their cue score exceeded a threshold calculated by a bootstrapping procedure using spike shuffled data. We next asked how cue cells respond when cues are removed and found that firing fields were no longer present in the regions where cues were missing. Using activity recorded during foraging in a real arena, the grid, border, and head direction scores for all units were calculated. A large fraction of cue cells had spatially stable firing patterns in the real environment. Some cue cells were conjunctive with border (17%) or grid (11%) cell types, and many of these cells had a significant head direction score during foraging in real arenas (60%). We conjecture that cue cells may play a role in error correction of grid cell spatial firing patterns.

Title: Direct input from MECIII to hippocampal CA1 is crucial for long-range "active" replay during wake but not during sleep

Authors: *J. YAMAMOTO, J. SUH, S. TONEGAWA;
PILM, MIT, Cambridge, MA

Abstract: Hippocampal replay has been suggested to play an important role in spatial navigation, learning an environment, and future path planning. The major input from CA3 to CA1 is considered to be providing mnemonic information for CA1 to re-express temporally structured sequences of recent spatial experiences. However, the functional role of the direct inputs from MEC layer III to CA1 with regard to hippocampal replay remains unknown. In this study, we recorded a large number of CA1 units in MECIII-TeTX transgenic mice with blocked transmission from MECIII to CA1, and their control littermates. We applied a Bayesian Poisson position reconstruction method to decode CA1 unit activities while animals traversed a linear

track. As has been previously reported, we found no major differences in place cell quality, including sharp-wave ripples between these genotypes. However, we found that spatial coverage of replays during quiet wakefulness was significantly shorter (15-30% of 1.5 m linear track) in mutants than in controls (70-90%) during quiet-awake replays; Individual place cells tended to fire longer in mutants to result in comparable sharp-wave ripple duration between groups (50-150 ms). Both impaired and normal replay events mostly started from the animal's current location. We then examined replay events during subsequent sleep. Surprisingly, we found no differences in the coverage of replays during sleep in both genotypes. CA1 units in mutants could re-express a comparable length of the track (70-90%) suggesting that replay during quiet awake versus sleep may be governed by different hippocampal circuits. Quiet awake replays during spatial navigation tasks have been suggested to reflect an animal's "active" future path planning; Our results support the idea that the direct input from MECIII to CA1 may play a crucial role in "active" memory retrieval rather than "passive" memory replay.

(KNAW), Amsterdam, Netherlands

Abstract: Several plasticity sites have been described in the cerebellar cortex, among which the Parallel Fiber-Purkinje Cell synapse, displaying both Long Term Depression (LTD) and Long Term Potentiation (LTP), has received most interest. We previously showed that a lack of PF-PC LTD altered self-motion processing and subsequent dependent hippocampal processes, i.e. maintaining a cognitive representation of space using self-motion information and using it for optimal goal-directed behavior. However, it remains unclear if these navigation processes specifically depend on cerebellar LTD per se or ensue from a general disruption of cerebellar circuitry. To test this we investigated the functional consequences of a deficit of LTP at PF-PC synapses using L7-PP2B mice model. Hippocampal place cell properties of L7-PP2B mice were characterized during free exploration of a circular arena. In contrast to mice lacking cerebellar LTD, place cell properties of L7-PP2B mice were not impaired when mice had to rely on self-motion cues. Surprisingly, L7-PP2B place cells displayed instability in the absence of any proximal cue manipulation in 20 % of the recording sessions, characterized by a coherent angular rotation of the whole set of recorded place cells. During these events, in which the spatial relationships between the object and the mouse spatial representation are changed, mice displayed an increased exploration of the object, suggesting that for the mouse the object was located at a new position. These data suggest that, in the absence of cerebellar LTP, hippocampal spatial representation cannot be reliably anchored to the prominent external cue. These results along with those from L7-PKCI mice, indicate that the cerebellum might be involved in multiple sensory processing required to navigate properly.

Abstract: The Probabilistic Selection Task (PST) is a paradigm that evaluates whether subjects learn better from positive or negative outcomes of probability-related choice behavior mediated through cortical-striatal dopaminergic pathways. The PST has been utilized to evaluate several neuropsychiatric and neurodegenerative disorders, and has revealed reward-related learning impairments in selected patient populations (e.g, schizophrenia, autism). The intent of our studies was to assess probabilistic reward learning in non-human primates (NHPs) for evaluating potential novel therapeutics in a species with close homology to humans. Eight adult male Cynomolgus macaques were trained initially on a 1- and then 3-pair concurrent discrimination (CD) task in which selection of one stimulus in a pair resulted in delivery of a food reward 100% of the time (100 trials/session). The animals had to identify which stimulus in the pair was associated with the reward and reliably select it with ≥ 80% accuracy for ≥ 2 test sessions before moving to the next level of training. Stimulus pairs were novel in each test session and presented first as blocked then randomized trials. Animals acquired the rules of the CD task quickly and reached proficiency at each level within 5 test sessions. Following CD training, animals began PST training, modeled after the work of Waltz et al., 2007 (Biol Psych 62;756-64). For this task, animals were presented with 3 unique stimulus pairs (A/B; C/D; E/F) in each session, each rewarded with a different probability (A-80%/B-20%; C-70%/D-30%; E-60%/F-40%). On each trial, the NHPs made a two-alternative forced choice and learned to choose the most frequently rewarded stimulus from each set based on the identified probabilities. Animals received blocks of 60 trials of pseudo-randomized presentations of the pairs until 1) they met the criterion of selecting ‘A’ 65% of the time, ‘C’ 60% of the time, and ‘E’ 50% of the time, or 2) they had completed 6 blocks of trials (360 trials, 120 of each pair). Once animals reliably met the performance criterion, the transfer test, consisting of novel combinations of stimuli, was introduced to test whether NHPs learn better from positive (rewarded, i.e., A/C; A/D; A/E; A/F) or negative (non-rewarded, i.e., B/C; B/D; B/E; B/F) events. Our early results indicate macaques readily learn the PST through a combination of positive and negative events, with evidence of learning being driven more consistently through positive feedback, in line with the observed behavior in healthy subjects. The PST in macaques may serve as a translatable animal paradigm to assess probabilistic reward learning in a preclinical species.

Title: Sign-tracking to a lever-CS in autoshaping is due to instrumental learning

Authors: *M. NAEEM[1], N. WHITE[2];
[2]Psychology, [1]McGill Univ., Montreal, QC, Canada

Abstract: In autoshaping with rats a CS (lever insertion) is repeatedly followed by a US (food) regardless of what the rat does, a Pavlovian paradigm (Boakes, 1977, in H. Davis & H. M. B. Hurwitz (Eds.), *Operant-Pavlovian Interactions,* 67). Some rats (sign trackers) learn to press the lever, a response that is thought to be due to acquisition of a Pavlovian association (CS-US, or stimulus-outcome). However, lesions of the amygdala, a structure known to be critical for Pavlovian learning have limited effects on this form of sign-tracking (Chang, et al, 2012, *Brain Research*, 1450, 49; 2012, *Neurobiology of Learning and Memory*, 97, 441), raising questions about whether the learning underlying the lever press response is in fact Pavlovian. An alternative is based on the fact that every lever-press response made by a sign-tracker is reinforced after the end of the CS (Williams & Williams, 1969, *Journal of the Experimental Analysis of Behavior*, 12, 511), on what amounts to an interval schedule, suggesting that the response could be due to instrumental learning. To test this hypothesis rats with lesions of structures known to be critical for instrumental learning were trained in an autoshaping

paradigm. Thirty six per cent (7/19) of the rats in the sham-lesioned control group were sign-trackers (lever press before food magazine entry on most trials); no rats with lesions of either dorsolateral (DLS, n=8) or dorsomedial (DMS, n=9) striatum were sign-trackers. Rats with DMS, but not DLS, lesions increased their frequency of magazine entries. These findings are consistent with the hypothesis that sign-tracking with a lever press response is primarily due to (non-Pavlovian) instrumental learning, probably some combination of action-outcome and S-R associations. However, amygdala lesions do impair sign-tracking measured as simple approach to the CS with no additional response (e.g., Hatfield, et al, 1996, *Journal of Neuroscience*, *16*, 5256; Parkinson, et al, 2000, *European Journal of Neuroscience*, 12, 405), suggesting that behavior may be due to Pavlovian learning.

Title: Behavioral flexibility in reversal learning of “what” vs “where”: a Bayesian approach

Authors: ***R. BARTOLO**, L. KENNERLY, V. D. COSTA, B. B. AVERBECK; NIMH/NIH, Bethesda, MD

Abstract: Learning comes in many forms and separable circuits may underlie learning stimulus-reward vs. location-reward associations. To begin to examine this hypothesis, we have trained two macaques on a stochastic, two-armed bandit oculomotor reversal learning task. In the task, animals have to learn to associate either locations or objects with rewards in randomly interleaved blocks of 80 trials. In each block one of two stimuli (circle or square - stimulus blocks, n=226) or one of two locations (left or right - location blocks, n=223) had a higher reward probability with respect to the other according to one of three possible reward schedules (0.6/0.4, 0.7/0.3, and 0.8/0.2). The block types were not cued and animals had to infer whether locations or objects were relevant in each block. For both block types, at a random trial between the 30th and 50th, reward mappings were inverted across the two targets (stimuli or locations), and the animals had to reverse their choice preference. Behavior was analyzed by fitting a Bayesian model to the data. The model was based on our previously published model (Costa et

al., 2015, J. Neurosci. 35(6):2407-2416). However, it was extended to account for the two different block types (stimulus or location learning). The model allowed us to estimate posterior distributions over block type (stimulus or location) and reversal trial. Furthermore, two versions of the model were used to estimate 1) the trial at which the animals reversed their choices (behavioral model) and 2) the trial at which an ideal observer would reverse its choices, based on the previous outcomes. The absolute value of the difference between estimates from the two models, an index of the animal's reversal sensitivity, decreased for easier schedules for both location and stimulus blocks. However, a 2-way ANOVA revealed a significant schedule×block-type interaction effect ($F_{368,2}=7.04$, $p=0.001$). To assess if switching from one block type to another had an effect on choice behavior, we analyzed choices by plotting the choice rate for the initially more rewarded target. Data were split according to the previous and current block types to assess if switching block type had an impact on the choices. After the first trial, choice-rates increased quickly for the most rewarded target, independently of the previous block's type. Bayesian estimates of block-type posterior probabilities across trials quantified this, and were affected only by the reward ratio. In summary, acquisition was similar between stimulus and location blocks, but reversal performance showed differences.

Title: Measuring and manipulating corticostriatal functional neural circuitry in the socially monogamous prairie vole

Authors: *E. A. AMADEI[1], Z. V. JOHNSON[2], J. KWON[2], A. C. SHPINER[3], V. SARAVANAN[2], W. D. MAYS[4], L. J. YOUNG[5,6,7], R. C. LIU[4,7];

Abstract: The ability to form positive social relationships is key to mental health, and yet the underlying functional neural circuitry remains poorly understood. The socially monogamous prairie vole is a canonical animal model for social bonding. Previous anatomical, genetic, and pharmacological studies have implicated two corticostriatal nodes – the medial prefrontal cortex (mPFC) and nucleus accumbens (NAcc) – in vole social bond formation. However, these approaches do not provide a dynamic view of the functional neural activity and connectivity of these regions during social interactions leading to a bond. To address this, we measured and manipulated neural activity within this circuit in socially-behaving female voles. We found an enhancement in low-frequency mPFC-to-NAcc connectivity during mating, a behavior that accelerates vole bond formation, compared to the control, non-social behavior of self-grooming. Further, optogenetically stimulating mPFC afferents to the NAcc at low frequencies in the absence of mating shifts later behavioral preference towards a partner, suggesting that low-frequency activation of this circuit is functionally relevant for bond formation. Finally, phase-amplitude coupling from mPFC to NAcc is enhanced during mating, suggesting that mPFC activation during social bonding drives NAcc by rhythmically modulating its excitability. Together, these results reveal a dynamic picture of corticostriatal activation during bond formation, with exciting implications for how affiliative social interactions can recruit reward and reinforcement systems to drive changes in behavior. A key ongoing direction is to determine the role of neurochemicals (e.g. oxytocin) in modulating this system.

Title: Post-extinction inactivation of the dorsolateral striatum blocks extinction of egocentric response learning, but not place learning, in the plus-maze

Authors: *J. GOODMAN, M. G. PACKARD;
Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: In the response learning version of the plus-maze task, animals acquire an egocentric turning response that may serve as an exemplar of the stimulus-response/habit memory system. Whereas extensive research has investigated the neural substrates supporting initial acquisition, little research has examined the neural substrates supporting extinction of response learning. The present study examines whether the dorsolateral striatum (DLS), which is critical for initial acquisition, might also be required for extinction of response learning. In addition the present study examines whether the role of the DLS in extinction is selective to response learning or whether it might also be implicated in extinction of place learning. In the response learning task, adult male Long-Evans rats were released from varying start points (North, South) and were reinforced to make the same egocentric turning response (e.g. turn left) at the choice point to receive a palatable food reward at the end of a separate goal arm (East or West). In the place learning task, animals were released from varying start points and were reinforced to go to a consistent goal arm (e.g. the West arm) to receive the food reward. Following initial acquisition in both tasks, animals were given two days of extinction training, which was conducted in a manner identical to initial acquisition except without the food reward. Immediately after the first day of extinction, animals received bilateral intra-DLS infusions of bupivacaine (0.75%) or physiological saline, and effects of drug were examined on the second extinction day. In the response learning task, post-training administration of bupivacaine blocked consolidation of extinction, whereas in the place learning task bupivacaine was ineffective. These results suggest that the DLS is selectively required for the consolidation of extinction in a DLS-dependent response learning task, but not in a place learning task. In view of evidence that the DLS-dependent habit memory system may underlie some symptoms of human psychopathologies (e.g. drug addiction), the present findings may be useful in determining the neurobiological mechanisms that support the suppression of habit-like symptoms in these disorders.

Title: The contribution of dorsomedial and dorsolateral striatum during different phases of Morris water maze training

Authors: *T. POOTERS[1], I. GANTOIS[2,1], B. VERMAERCKE[1], R. D'HOOGE[1];
[1]Lab. of Biol. Psychology, Leuven, Belgium; [2]Sonenberg Lab., Montreal, QC, Canada

Abstract: Impairments in cognitive and executive functioning occur in different basal ganglia disorders (e.g. schizophrenia and Parkinson's disease), and remain largely intractable with available treatments. The striatum, the largest area of the basal ganglia, has been suggested to contribute significantly to these cognitive deficits, but the specific role and time-dependent involvement of striatal subregions in cognitive (dys)functioning remain unclear. Therefore, we studied spatial learning and memory in mice with lesions in dorsomedial (DMS) and dorsolateral striatum (DLS). Animals were trained for 15 days in the hidden-platform version of the Morris water maze. To determine the time-dependent involvement of DMS and DLS, lesions were applied during different phases of MWM training (before training or after 5 or 10 days of acquisition training). Compared to sham controls, animals that received DMS damage before training were severely impaired during acquisition training, whereas animals with DLS lesions did not show any impairment at all. DMS-damaged mice displayed delayed acquisition, increased thigmotaxis and increased distance to the platform during the entire course of training, but when lesions were applied after 5 or 10 days of training, performance was similar to controls. Search strategy analysis indicated that the deficits due to DMS damage coincided with decreased ability to switch flexibly between spatial, non-spatial and repetitive search strategies. In conclusion, these data suggest that DMS (but not DLS) is crucial during the initial phase of acquisition, and that DMS controls goal-directed behaviours.

Title: Context-dependent action selection mediated by specific temporal coordination between prefrontal cortex and striatum

Authors: *S. ARDID, J. SHERFEY, M. M. MCCARTHY, N. KOPELL;
Ctr. for Computat. Neurosci. & Neural Technology. Dept. of Mathematics, Boston Univ., Boston, MA

Abstract: In rule-based decision tasks, the proper response to a stimulus varies depending on context or "rule". The behavioral performance may also differ; for instance in response to color vs. orientation of a bar, responses are faster for orientation. Rule selective neurons have been identified in prefrontal cortex (PFC). However, the underlying dynamics are not fully understood. Recently, Buschman et al. have shown that the activity of rule selective cells is temporally coordinated. Around stimulus onset, high β rhythmic activity emerges in the frontal cortex simultaneously in neurons encoding alternative rules (color and orientation). However, (1) the magnitude of this synchrony is higher for the neurons encoding the active rule, and (2) the increase in synchrony is significantly larger when the dominant rule is active (orientation trials), compared to when the subordinate rule is active (color trials). Rhythmic activity at α frequencies, on the other hand, appears before stimulation, but specifically under the subordinate condition (color trials), and only for those PFC neurons encoding the dominant dimension (orientation selective cells). These observations suggest specific functional roles for the two types of rhythmic activity. First, high β rhythmic inputs may stimulate downstream striatal neurons to activate the associated motor response. Second, α rhythm inputs to downstream striatal neurons may trigger inhibitory control of salient information that is behaviorally irrelevant. Here we show in a modeling framework that the rhythmic activity in PFC may activate alternative pathways of the basal ganglia, mechanistically via local interactions with distinct intrinsic resonances within the striatal circuit. We have built a model of the striatum composed of D1 and D2 receptor medium spiny neurons (D1 and D2 MSNs), which represent the input stage of the direct and indirect pathways of the basal ganglia, respectively. PFC inputs in the model do not show any bias with respect to D1 vs. D2 MSNs. The frequency at which D1 and D2 MSNs cells resonate depends on the excitability of each cell type in the circuit, so the higher the excitability, the higher the frequency at which the cells oscillate in the model. Our model is based on a regime of higher excitability for D1 MSNs compared to D2 MSNs. Results from the model demonstrate that when D2 MSNs resonate at β1 (low β) frequencies and D1 MSNs resonate at β2 (high β) frequencies, a rhythmic input from PFC at either α vs. high β frequencies is capable of enforcing a β1 vs. β2 rhythm in the local circuit. Hence, inputs from PFC at different frequencies are capable of activating respectively the indirect vs. direct pathway of the basal ganglia.

Title: Modeling neuronal diversity and fast network oscillations in rat anterior cingulate cortex (ACC)

Authors: *J. S. SHERFEY[1], N. E. ADAMS[2,3], F. E. N. LEBEAU[3], N. KOPELL[1,2];
[1]Computat. Neurosci. and Neural Technol., Boston University, Sch. of Med., Boston, MA; [2]Mathematics, Boston Univ., Boston, MA; [3]Neurosci., Newcastle University, Med. Sch., Newcastle-upon-Tyne, United Kingdom

Abstract: Fast network oscillations (gamma: 30-80Hz, beta: 15-30Hz) and flexible population activity are thought to underlie many of the cognitive functions associated with the ACC. We recently demonstrated that activation of the glutamatergic system evokes robust beta and/or gamma-frequency network oscillations in rat ACC (analogous to primate ACC/PFC) *in vitro* and that ACC neurons exhibit a wide diversity of response properties. We used cluster analysis to further investigate the organization of ACC cell diversity and then computational modeling to study its mechanistic origins and relation to fast network oscillations. First, the intracellular recordings from ACC neurons were analyzed to extract 10 intrinsic response properties (IPs) for each neuron. Cluster analysis grouped the ACC neurons into 5 classes with 4 IPs explaining >80% of the variance: after-hyperpolarization duration, spike width, spike rate at threshold, and resting membrane potential. However, neuron classes were broad and partially overlapping, suggesting they may represent physiological regimes between which ACC neurons could transition depending on their biophysical state. The mechanistic basis of ACC cell diversity was explored using conductance-based models with 10 ion currents known to exist in ACC/PFC. A set of models capturing the observed diversity was obtained by varying maximal conductances and fitting IPs to the 5 most explanatory distributions. Across the resulting cell models, each intrinsic property was regulated by a distinct set of currents suggesting how coordinated changes in potassium, sodium, and calcium channels could switch a given cell from one class to another. Next, the heterogeneous model population was coupled to inhibitory interneurons with time constants of inhibition based on IPSPs observed experimentally in cells rhythmic with the network beta or gamma-frequency oscillation. The resulting ACC network model replicated the different frequencies observed experimentally and demonstrated that cell diversity spreads out network frequencies without disrupting the underlying oscillation. These results suggest distinct interneuron populations in ACC pace beta and gamma-frequency network oscillations capable of temporally grouping diverse cell activities into flexible assemblies for task-relevant processing.

Title: Balancing consistency with flexibility in anterior cingulate cortex (ACC) action representations

Authors: ***J. K. SEAMANS**[1], L. MA[2], D. DURSTEWITZ[3], J. HYMAN[4];
[1]Psychiatry, UBC, Vancouver, BC, Canada; [2]Dept. of Physiol. and Pharmacol., Western Univ., London, ON, Canada; [3]Bernstein Ctr. for Computat. Neurosci., Central Inst. of Mental Health, Heidelberg Univ., Mannheim, Germany; [4]Dept. of Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Efficient, flexible behavior involves detecting the differences as well as similarities in the actions required to deal with new situations. The anterior cingulate cortex (ACC) has been implicated in action planning or action monitoring/control and while it does not directly generate actions, it may alter the way they are represented across different situations. The present study quantified the flexibility of ACC action representations by recording from neurons as rats performed 3 different operant actions (a nose-poke, lever press and wheel turn) in two different sequences or contexts. Consistent with past studies, ACC ensembles exhibited unique activity state patterns during the performance of each action and the action-specific patterns were shifted by a switch in the context or sequence. Importantly, the magnitude of the context or sequence dependent shift was well equalized across the 3 actions and as a result the separation between the 3 action representations was the same before and after the switch. The equalized movement was a result of highly balanced increases versus decreases in firing across the population. When neurons were sorted according to their selectivity for actions (versus the baseline period), a well-defined selectivity curve was observed. Remarkably the same selectivity curve appeared after the sequence or context switch but the sorting order was now completely different. This indicated a high degree of remapping and accordingly only the top 10% most action selective neurons maintained the same degree of selectivity before/after the switch. Using leave-one-out variant of

Support-Vector-Machine (SVM) decoding, we found that individual neurons varied in their selectivity for the 3 actions on a trial by trial basis. PCA was then run on the SVM scores of all neurons but separately for each action. PC1 and PC2 were virtually identical across the 3 actions: PC1 always exhibited stable values before/after the switch and likely reflected the consistent encoding of the actual actions themselves. PC2 attained high values in sequence 1 but dropped precipitously at the sequence 1 to 2 transition point and this drop was synchronous across the 3 actions. The similarity of PC1 and PC2 across the 3 actions was only present at the ensemble level as single neurons could exhibit a PC1- or PC2-like pattern on any combination of the 3 actions. Collectively these results suggest that individual ACC neurons track subtle differences in actions across different situations but by balancing all these changes across the population, ensemble representations maintain a high degree of consistency.

Title: Coding of emotional valence in the rodent Anterior Cingulate Cortex (ACC)

Authors: *B. CARACHEO[1], J. GREWAL[2], J. SEAMANS[3];
[1]UBC Brain Res. Ctr., Vancouver, BC, Canada; [2]Brain Res. Ctr., [3]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The vast majority of basic research on the Anterior Cingulate Cortex (ACC) has focused on it role in cognition. Yet the ACC is classically 'emotional' cortex and the results from human imaging experiments as well as lesions (anterior cingulotomies) indicate that the coding of emotional valence may be an equally or even more important function. Here we investigated how ACC neurons in rats represent periods of varying emotional valence. The task was simple and straightforward. The first stage consisted of 3 blocks and in each block a unique auditory tone (conditioned stimulus, CS) was paired with one of 3 unconditioned stimuli (US), a shock (negative valance US), the delivery of food (positive valance US) or nothing (neutral US). Each

CS was presented for 5 seconds before the US, and the pair was presented at 20-60 second intervals. In the second stage of the task, the CS-US pairs were interleaved within one task block. Sixteen tetrodes implanted in the ACC recorded neural activity over at least four sessions from four rats. Neural activity was recorded and characterized using single unit activity selectivity indices, principal component analysis (PCA), probabilistic states through Hidden Markov Models (HMM) and measures of entropy and complexity. At the ensemble level, HMM and PCA identified unique neural states that emerged during the presentation of each CS-US pair, as well a baseline state. Analyses of single unit selectivity revealed neurons that responded to the CSs, the USs, or some combination of both. Single neurons could also respond to various combinations of 2 CSs but none were found that responded to all 3. Surprisingly, using these traditional measures we have yet to find clear evidence that the neutral CS was encoded any differently from the valanced CSs. These results are therefore consistent with the conclusions of our studies of ACC activity during cognitive tasks. Namely that ACC neurons represent whatever the animal is currently experiencing or doing. We are now considering different coding schemes that could represent 'emotional states' as distinct from discrete events.

Title: Unilateral naris occlusion effectively abolishes gamma oscillations in the rat ventral striatum

Authors: ***J. E. CARMICHAEL**[1,2], J. M. GMAZ[2], M. A. A. VAN DER MEER[1,2];
[1]Psychology and Brain Sci., Dartmouth Col., Hanover, NH; [2]Biol., Univ. of Waterloo, Waterloo, ON, Canada

Abstract: The ventral striatum (vStr), an anatomically heterogeneous region, receives a convergence of anatomical connections from structures in the cortico-striatal-thalamic loop, as well as from the hippocampal formation and amygdala. Prominent gamma-band oscillations can be recorded from the vStr local field potential (LFP), to which fast-spiking interneurons in particular can show strong phase locking. Furthermore, vStr gamma oscillations can cohere with

anatomically related areas, raising the possibility that these oscillations may reflect a dynamic routing mechanism. However, what combination of underlying sources is responsible for generating gamma oscillations recorded in the vStr remains unknown. In Experiment 1, we used high-density silicon probes with regular site spacing to reveal the phase and amplitude distributions of LFP oscillations across a region of the vStr (1.4mm2). Rats (n = 4) were recorded while they rested on a pedestal or engaged in a foraging task. Neither condition yielded evidence of sources or sinks in the power of the gamma oscillations across the vStr, for either low-gamma, high-gamma, or indeed any other frequency band. Instead, we found a consistent linear gradient of gamma power which increased in the ventrolateral direction, suggested that the source of these gamma oscillations may lie outside of the vStr. The adjacent piriform cortex has been suggested as a possible source of gamma oscillations in vStr (Berke, 2009). To test this possibility directly, Experiment 2 used a reversible unilateral naris occlusion procedure, known to abolish piriform gamma oscillations ipsilateral to the occlusion (Zibrowski & Vanderwolf, 1997). In rats (n = 3) with unilateral electrodes implanted into the vStr, gamma power was effectively abolished during ipsilateral naris closure, while contralateral occlusion and controls showed no effect on gamma power. This suggests that the gamma signal reported in previous literature is likely not locally generated within the vStr. Taken together, these results demonstrate that although strong gamma oscillations can be found in the vStr LFP, these oscillations are in fact volume-conducted from the piriform cortex. Phase-locking to this rhythm within the vStr may be the result of inputs from piriform cortex pyramidal cells onto vStr neurons. This updated view of vStr oscillations has important implications for studies of “functional” or “effective” connectivity involving the vStr and associated regions. Strong coherence between vStr and its in- and outputs may be due to common input from piriform cortex, rather than a local or pairwise implementation of a gain modulation or routing mechanism.

Title: Environmental enrichment and striatal perineuronal net dissolution exert opposing behavioural effects in the puzzle-box task

Authors: *A. M. O'CONNOR, C. A. LEAMEY, A. SAWATARI;
Bosch Inst., University of Sydney, Australia

Abstract: Environmental enrichment (EE) provides animals with increased sensory, motor and social stimuli. Previous work has demonstrated that EE from birth can improve performance in cognitive behavioural tasks and accelerate the maturation of Perineuronal nets (PNNs) within the striatum, an important component of basal ganglia circuitry. Although both EE and the enzymatic removal of PNNs can adjust levels of plasticity in established neural circuits, the manner in which these processes remain related is unclear. As a first step, we examined the impact and interaction of both EE and striatal PNN removal upon behaviours of animals within the Puzzle-Box task, a test of goal-orientated learning and problem solving. C57BL6J mice were raised within standard (S) and enriched (E) housing conditions until 12 weeks old. Performance of untreated animals (S, n=18; E, n=21), mice receiving striatal Chondroitinase ABC (ChABC) injection (SC, n=8; EC, n=13), and animals receiving striatal vehicle injection (SV, n=7; EV, n=13) within the Puzzle-Box was assessed by the time taken to solve obstruction puzzles. Video recordings were taken and assessed using TopScan software, with the Puzzle-Box arena divided into various zones to analyse behavioural patterns. There was a significant effect of treatment group upon time taken to solve the Puzzle-Box ($P<0.001$), with E animals taking less time and SC animals taking more time than other treatment groups. E animals travelled less distance than all other treatment groups ($P=0.001$), spent a lesser proportion of time directly next to the walls of the arena ($P=0.012$) and a greater proportion of time engaged with obstruction puzzles ($P=0.001$). SC animals spent a greater proportion of time directly next to the walls of the arena than S mice ($P=0.033$). EE animals exhibited shorter latencies to solve puzzles within the apparatus, as well as decreased locomotor hyperactivity, altered thigmotactic behavioural patterns, and increased engagement with novel obstruction puzzle objects. Striatal ChABC treatment had an opposite effect in both standard and enriched animals, increasing the time taken to solve Puzzle-Box tasks, increasing thigmotactic behavioural patterns, and decreasing interaction with novel obstruction puzzle objects. Our results demonstrate that EE and striatal PNN dissolution exert opposing behavioural effects, suggesting that there may be levels of plasticity within the striatum worked upon by these treatments.

Title: Incidental learning in the ventral striatum elicits context-specific inhibition in a visual discrimination task supported by the dorsolateral striatum

Authors: *D. C. GIDYK, C. M. BYE, K. M. NIEDERMEIER, R. J. MCDONALD; Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Multiple memory systems theory states that in the mammalian brain, mnemonic function is organized into multiple neural systems. These systems are complex, operate in parallel, and support different forms of learning and memory through dynamic cooperative and competitive interactions. Our previous work has provided empirical support for multiple memory systems theory through the dissociation of learning and memory function in the rat during different behavioural tasks. In cases where one neural system is necessary for learning and memory on a given behavioural task, other systems may acquire incidental information that can be uncovered under certain testing conditions. A demonstration of this can be seen in a series of studies in our lab that discovered that an incidentally acquired context-specific inhibitory representation is acquired by the ventral hippocampus (vHPC) during a striatal-dependent stimulus-response (S-R) visual discrimination task. We hypothesize that the ventral striatum (VS) is a key part of the circuit mediating context-specific inhibition due to it's connectivity with the vHPC and medial prefrontal cortex (mPFC). It is our view that the VS is part of a system that suppresses or invigorates actions for goal-directed and habitual behaviours which are dependent on the dorsomedial striatum (DMS) and dorsolateral striatum (DLS) respectively. The present study was designed to asses the hypothesis that the VS is a key part of the circuit mediating the context-specific inhibition effect described in our previous work. Sixteen male Long-Evans rats were trained on an S-R visual discrimination task (8-arm radial arm maze; RAM) in either context A or context B under a reward contingency of either lit arms or dark arms predicting the presence of a food reward (L+ D- and L- D+ respectively) in a counterbalanced manner. After reaching a set performance criterion, rats were then trained in the new context with the reward contingency reversed and again trained to criterion. All rats received chronic bilateral cannula implants into the VS allowed to recover, then given a single competition test after Ropivacaine or Saline infusion into VS. The results of this study will contribute to the understanding of multiple memory systems and which neural substrates are critical for the formation and expression of context-specific inhibition.

Title: Role of the dorsolateral and dorsomedial striatum in reward learning

Authors: *A. LIPKIN, H. BERGSTROM, C. PICKENS, C. PINARD, A. HOLMES;
Lab. of Behavioral and Genomic Neurosci., Natl. Inst. On Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: Brain processes of reward learning are essential for shaping and guiding decision-making. Dysfunctions of reward learning can lead to maladaptive behaviors such as addiction. The dorsal striatum is required for mediating various forms of reward learning. The dorsal striatum is functionally subdivided into lateral (DLS) and medial (DMS) zones, based on differences in patterns of cortical innervation and contributions to various forms of reward learning. However, the exact contribution of the DLS and DMS to reward learning, and the specific components of reward learning these regions mediate are not understood. To test reward learning, we used an operant task in which mice must first visually discriminate objects presented on a touchscreen display and then physically touch the one that predicts an appetitive reward. Prior to visual discrimination learning, an adeno-associated viral construct (rAAV8/CAG-ArchT-GFP) was bilaterally expressed in a population of DLS neurons in C57BL/6J mice. Silencing DLS neurons when mice made a “choice” on the touchscreen facilitated discrimination learning, as compared to controls expressing an inactive virus (rAAV8/CAG-GFP). Facilitated learning was accompanied by reduced errors rates, shorter strings of incorrect responses, and increased win-stay and lost-shift probabilities in the earliest stages of learning. By contrast, silencing DLS neurons during reward collection did not affect performance. To dissect the relative contribution of the DLS-Direct and Indirect pathways in reward learning we used D1-Cre and A2A-Cre mutant mice, respectively. We found that silencing the D1-direct pathway (rAAV5/EF1a-DIO-eArch3.0-eYFP) largely recapitulated the results of DLS-ArchT-CAG inhibition, with a greater percentage of correct responses, shorter strings of incorrect responses, and increased win-stay and lose-shift probability in the earliest stages of learning. Silencing the (A2) “indirect” pathway resulted in a reduction in errors at the early stages, but no change in correct responses. In contrast to DLS inhibition, silencing DMS neurons attenuated discrimination learning, increased total errors and decreased win-stay probabilities. Overall, these results support a model whereby the DLS and DMS compete for

control over performance over reward learning. Further, these results provide support for the view that the direct and indirect pathways work do not necessarily work in opposition in the acquisition of reward learning. This series of experiments provide new insight into how the DLS direct and indirect pathways functionally contribute to visual discrimination learning.

Title: Optogenetic stimulation of striatum during an active visual change detection task in mice

Authors: *L. WANG, K. RANGARAJAN, R. J. KRAUZLIS;
NIH, Natl. Eye Inst., Bethesda, MD

Abstract: The role of the striatum in associating relevant sensory information with rewarded motor actions is well established. The striatum is also implicated in sensory discrimination, but because most studies measure behavior with orienting movements, it can be difficult to dissociate motor bias from sensory discrimination *per se*. To address this issue, we trained mice to report changes in the orientation of drifting gratings by licking or not licking a central spout (yes/no task), and used transgenic mice to optogenetically stimulate specific types of neurons in the striatum. Mice were head-fixed and ran on a styrofoam wheel within a sound-attenuating chamber during presentation of the visual stimuli, displayed on two flat panels. The visual stimuli consisted of two (left and right) vertically oriented Gabor patches superimposed on a pink noise background. Mice initiated each trial by running or walking, and the distance traveled on the wheel controlled the visual stimuli. During individual trials, the drift speed of the two vertical gratings was determined by the running speed of the mice, and after a randomized distance was traversed, one of the two gratings changed its orientation. The task of the mice was to lick the spout if an orientation change happened on either side of the display, and to withhold from licking before the change occurred. Correct responses were rewarded by a drop of soymilk, and premature licks prompted auditory feedback and a timeout penalty. We used *Drd1a-Cre* and *A2a-Cre* mice to target the direct and indirect pathway medium spiny neurons (MSNs) in the

striatum. Cre-dependent virus AAV2-DIO-ChR2 was unilaterally injected into the dorsal striatum of these mice. During optogenetic stimulation experiments, brief low intensity (0.05-0.2mW) 465nm continuous light was delivered to the striatum through an implanted optic fiber at the onset of the orientation change in a randomized subset of trials. Our preliminary data show that: 1) with optogenetic stimulation in both Drd1a and A2a-Cre mice, there was a significant increase of hit rate when the orientation change occurred contralateral to the stimulation side, but not when the visual changes was on the ipsilateral side; 2) there was a reduction of mouse running speed during the stimulation epoch compared to no-stimulation controls. These results show that MSNs in both the direct and indirect pathways in the striatum contribute to the performance of the visual change detection task. Our preliminary finding that the effects were selective for visual changes on the contralateral side suggests that the optogenetic stimulation affected sensory discrimination *per se* rather than simply introducing a motor bias.

Title: Representation of learned action sequences in the dorsolateral corticostriatal circuit

Authors: *N. MARTIROS[1,2], A. M. GRAYBIEL[1,2];
[1]Brain and Cognitive Sci., [2]McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: Well-ingrained behaviors often consist of a series of actions “chunked” together and executed in an automated manner. The dorsolateral striatal circuit is known to be important for the execution of such behaviors, but how neural activity in this region subserves this functional role is not understood. To test how neurons in this region of striatum represent such learned

action sequences, we designed a self-paced task in which each rat learned to perform a unique sequence of three lever presses in order to obtain a reward. After performing a clustering procedure on the task response profiles of single neurons, we found that the phasic responses of the striatal projection neurons recorded from rats that learned six possible 3-step lever press sequences occurred at four distinct trial periods: around the time of the first lever press, the time of the last lever press, at reward delivery, and during an extended period during reward consumption. Together with previous finding in our laboratory that a similar pattern of responses occurs during the performance of a T-maze task, we conclude that in a variety of reinforced behaviors requiring movements of different nature and timing, projection neurons in the dorsolateral striatum universally represent the initiation/termination or transitions between behaviors rather than having only simple motor responses. To explore how these patterns of activity are influenced by the corticostriatal link in this circuit, we recorded simultaneously from the region of motor cortex with dense projections to the targeted striatal region. Contrasts between the activity in the motor cortex and dorsolateral striatum were notable, including with respect to the occurrence of the beginning-and-end accentuation patterns. Whereas the beginning-and-end patterning was conspicuous in many striatal neurons, it was less evident in the motor cortical populations recorded. Ongoing optogenetic experiments exploring this corticostriatal circuit are addressing the role of the motor cortical input in the task-related neuronal firing of striatal projection neurons.

Title: Devascularization of sensorimotor cortex produces persistent deficits in a string pulling task

Authors: ***A. BLACKWELL**[1], W. L. WIDDICK[1], J. L. CHEATWOOD[2], D. G. WALLACE[1]; [1]Northern Illinois Univ., Dekalb, IL; [2]Southern Illinois Univ., DeKalb, IL

Abstract: Previous work investigating fine motor control and unilateral sensorimotor cortex lesions typically utilized behavioral assessments that require extensive training. The spontaneous string pulling behavior observed in rats may provide a novel technique to characterize the fine motor control deficits associated with rodent models of neurological disorders. The current study

assessed the ability of movement organization observed during string pulling behavior to dissociate persistent motor deficits from compensatory mechanisms associated with permanent sensorimotor cortex devascularization. Twelve male Long-Evans rats were given eight trials a day for three days to retrieve a cashew by pulling a string of increasing length. Subsequent to training, rats received either sensorimotor devascularization (n=7) or sham (n=5) surgeries and string pulling behavior was assessed one day, three days, and once per week to 70 days. Following behavioral testing, brains were extracted, sliced in coronal sections, and stained with Cresyl Violet for histological analyses of lesion extent. Initially rats with sensorimotor devascularization took longer to retrieve the cashew relative to sham rats; however this deficit abated across testing days. In contrast, a persistent difference was observed in the number of misses observed between rats with sensorimotor devascularization and sham surgery rats. This persistent deficit was most pronounced in the contra-lesion forelimb. These results demonstrate the potential of string pulling behavior as a robust assessment of fine motor control that involves bimanual coordination and depends on relatively few training trials.

Title: Neglecting to protect: Unilateral DCS lesions disrupt food protection behavior organization

Authors: *P. A. BLANKENSHIP[1], C. N. WOLF[1], J. L. CHEATWOOD[2], D. G. WALLACE[1]; [1]Psychology, Northern Illinois Univ., Dekalb, IL; [2]Anat., Southern Illinois Univ., Carbondale, IL

Abstract: Multimodal neglect is a spatial impairment characterized by an inability to detect stimuli or direct movement to one side of the body. The dorsocentral striatum (DCS) has been shown to be an important component of a corticostriatal network responsible for egocentric processing. The current study evaluated the role of the DCS in food protection behavior. Both egocentric and temporal information processing have been shown to contribute to the organization of food protection behavior. Egocentric processing has been shown to influence the ability to detect an incoming conspecific and successfully protect a food item. Temporal processing has been shown to influence the transition between dodging (large lateral movements)

and bracing (pivoting about the hind limbs). Female Long-Evans rats received unilateral infusions of NMDA or saline into the DCS and subsequently served as dodgers tasked with protecting a food item from a robber conspecific. Analysis of food protection behaviors yielded significant group differences. DCS lesion animals accrued more thefts than sham operated animals. Examining this effect revealed that thefts were lateralized to the side contralateral to the lesion. Additionally, significant group differences were observed in the transition between food protection behaviors. DCS animals transitioned from dodges to braces much later than sham operated animals. Observed disruption of food protection behavior in DCS animals is consistent with deficits in egocentric and temporal processing. This work demonstrates the potential of using organized spontaneous behavior to investigate an animal model of neurological disorders such as multimodal neglect.

Title: Frontal cortical circuits for the control of consummatory behavior

Authors: *L. M. AMARANTE[1], M. S. CAETANO[2], M. M. CLASEN[1], K. SWANSON[1], B. WETZELL[1], M. LAUBACH[1];
[1]American Univ., Washington, DC; [2]UFABC, Sao Paulo, Brazil

Abstract: The medial prefrontal cortex (mPFC) is a crucial structure for processing reward values and exerting control over action. Neuronal ensembles in the mPFC exhibit changes in activity when animals initiate consummatory behavior (Horst and Laubach, 2013). These changes in firing rates are accompanied by phase-locking in cortical theta rhythms (Horst and Laubach, 2013). These neural signals are concentrated in the rostral part of the prelimbic cortex, an area that may be homologous to the ventromedial/orbitomedial frontal cortex in primates. Reversible inactivations of this region eliminate the expression of incentive contrast for liquid

sucrose rewards and temporally fragment licking (Parent et al., 2015). In the present study, we examined functional circuits linking the rostral mPFC with subcortical brain regions associated with homeostatic and reward related processing. In addition, we compared functional connections between the rostral mPFC and the laterally adjacent agranular cortex, which contains the putative oral motor cortex in rodents. Electrical and optogenetic stimulation methods were combined with immediate early gene (IEG) mapping (c-Fos and Npas4) and anatomical tract-tracing. Stimulation of both cortical areas led to an immediate cessation of ongoing licking in rats tested in a sucrose consumption procedure. Similar results were obtained in rats tested in a delayed response task. Stimulation of both cortical areas revealed IEG expression in agranular insular cortex, paraventricular thalamic nucleus, globus pallidus, lateral hypothalamus, and medial septum. IEG expression in dorsal striatum was also evident following stimulation of the oral motor cortex, but not the rostral mPFC. These findings suggest that a common set of brain regions associated with homeostatic and reward processing are linked to frontal areas that control consummatory behavior.

Title: Modulation of cellular activity by effort and reward in Anterior Cingulate Cortex

Authors: *S. HASHEMNIAYETORSHIZI[1], K. D. SESSFORD[2], A. J. GRUBER[1], D. R. EUSTON[1];
[1]Neuroscience, CCBN, Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Med., Univ. of Calgary, Calgary, AB, Canada

Abstract: Lesions in anterior cingulate cortex (ACC) of rats have been shown to induce deficits in decisions about whether to exert a certain amount of effort to achieve a reward (Walton et al.,

2002 JNS 22(24):10996-11003). However, exactly how the ACC contributes to such decisions remains unclear. To address this question, this study investigated how neurons in the ACC of rats encode costs and benefits in effort-reward decisions. We trained four rats individually on a maze which involved a choice between two effort-reward combinations. Effort was indexed by the height of a wire-mesh ramp which the rat had to climb to achieve reward. Reward consisted of varying amounts of high-calorie liquid. Both ramp height and reward amount were varied dynamically during each experimental session in a partial factorial design with three levels of effort and two levels of reward on both left and right arms of the maze. Electrophysiological recordings of spike rates were acquired from a population of cells in ACC via an array of implanted four-channel electrodes ("tetrodes"). Analysis of the recorded data demonstrated that a significant fraction of ACC cells were discriminative for effort, reward and the chosen path (left/right). As has been reported by others, the discriminative activity for reward and effort was strongest just before the climb and weak during the period before paths diverged. Of the cells selective for reward, many exhibited ramping activity leading up to the reward. Roughly one third of the recorded cells show activity discriminative of ramp height in the period immediately before climbing, while one fourth of cells encoded ramp height when climbing down the ramp after receiving reward (which, based on our observations seemed to be effortful). Hence, the ACC encodes both the anticipation of effort as well as effort as it is being exerted. The results show that the ACC has access to both the costs and benefits of a decision and therefore could guide decisions by weighing these two factors and sending the appropriate outputs to motor-related regions.

Title: Neuronal signals related to self-agency in forontopolar cortex

Authors: *K. TODA[1], B. N. AFRICK[2], G. K. ADAMS[3], J.-F. GARIEPY[2], M. L. PLATT[2]; [1]Neurobio., [2]Dept. of Neurobio., Duke Univ., Durham, NC; [3]Ctr. for Translational Social Neurosci., Yerkes Primate Res. Center, Emory Univ., Atlanta, GA

Abstract: Self-agency is defined as the sense of oneself as the cause of one's own actions. This cognitive function allows oneself to feel distinct from others, and contributes to the subjective phenomenon of consciousness (Gallagher, 2000). Despite the importance of this faculty, the neural mechanisms mediating self-agency remain poorly understood. We previously reported findings from a novel self-agency task appropriate for neurophysiological studies in primates (Toda et al., 2014, SfN abstract). Here we report that neuronal activity in frontopolar cortex, an area greatly expanded during primate evolution and long-associated with the sense of self, carries signals related to self-agency in monkeys performing this task. First, we demonstrate that rhesus monkeys show evidence of self-agency in a two-stage joystick-movement task. Each trial consisted of a manipulation stage and a subsequent decision stage. In the manipulation stage, two dots and a target were presented on the display. Movement of one dot was correlated with the monkey's manipulation of a joystick (avatar), while the movement of the other dot (decoy) replayed the manipulation from the previous trial. Monkeys were required to move the avatar to the target. In the subsequent decision stage, monkeys were required to choose the color of the target they operated in the manipulation stage by moving a dot to one of two targets. To uncover the sense of agency, we compared internal and external cue conditions. In the internal cue condition, monkeys were required to detect the avatar by comparing proprioceptive and efference copy information about their movements with visual feedback. In the external cue condition, dot color directly indicated the appropriate avatar for the monkey to select. Monkeys successfully performed the manipulation stage and reported the color of the avatar during the decision stage, indicating they have a sense of their own agency and can report this information to an observer. These findings demonstrate the utility of our task for direct investigation of the neural basis of self-agency. We next asked whether and how the neurons in frontopolar cortex signal information during performance of our self-agency task. Many neurons showed task-related activity closely synched to task events. Further, some neurons appeared to signal agency-detection and/or agency-based decisions. Nevertheless, differential activity in the internal and external cue condition was rare. We also observed robust feedback-related activity in this area. Future studies of the impact of pharmacological inactivation of this area may reveal the functional contributions of these signals to the sense of agency.

Title: Neural dynamics between the basal forebrain and the dorsolateral prefrontal cortex during wakefulness, sleep and anesthesia

Authors: *Y. ISHIZAWA[1], C. MARTINEZ-RUBIO[2], A. PAULK[2], J.-B. EICHENLAUB[3], S. S. CASH[3], E. ESKANDAR[2];
[1]Anesthesia, Critical Care & Pain Med., [2]Neurosurg., [3]Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Neuroimaging and EEG studies suggest similarities between the sleeping brain and the anesthetized brain. Suppression of the cholinergic pathway of the ascending arousal system has been implicated in the regulation of states of consciousness during normal sleep-wake cycles as well as general anesthesia. Here we explore neuronal dynamics during dexmedetomidine (DEX) induced loss of consciousness versus natural sleep in the nucleus basalis of Meynert (NBM) and the dorsolateral prefrontal cortex (DLPFC). We performed simultaneous neural recordings from the NBM and the DLPFC in non-task performing primates. During each recording session, an IM dose of DEX was given to the animal after awake baseline data was collected. In addition, sleep recording experiments were performed at night (from 7pm) in order to acquire good natural sleep. While simultaneously acquiring extracellular data from the NBM and DLPFC, we performed standard EEG using non-invasive EEG electrodes on the scalp to identify sleep-wake cycles. Our preliminary results demonstrate a decrease in gamma and an increase in delta waves during natural sleep (NREM sleep) in both DLPFC and NBM. Interestingly, we found a more pronounced slow-wave delta in DLPFC when compared to the NBM. Coherence between DLPFC and NBM was significantly increased in the slow frequency, but decreased in the high frequency. During DEX-induced unconsciousness, there was a clear increase in coherence between NBM and DLPFC in the low frequency bands. In conclusion, our results demonstrate that neuronal dynamics changes in DLPFC and NBM are similar during sleep and DEX anesthesia. This may suggest overlying mechanisms of these different states of unconsciousness through the ascending cholinergic pathway to the neocortex.

Title: Alteration of NREM Sleep in mice with increased low-threshold burst firing in thalamocortical neurons

Authors: *J. HONG[1], J. LEE[2], G. HA[1], H.-S. SHIN[2], E. CHEONG[1];
[1]Yonsei Univ., Seoul, Korea, Republic of; [2]Inst. for Basic Sci., Daejeon, Korea, Republic of

Abstract: Sleep is composed of multiple states including non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep which have characteristic electroencephalogram (EEG), respectively. REM sleep displays low amplitude brain rhythms in theta frequency range (6-9Hz) and NREM sleep brain rhythms show high amplitude and multiple EEG patterns composed of slow wave (<0.5 Hz), delta wave (1-4 Hz) and spindle (7-14 Hz) by the frequency. The transition from wake to NREM sleep at the onset of sleep accompanies the dramatic change in brain rhythms in EEG from irregular and low amplitude pattern to relatively regular oscillatory and large amplitude pattern reflecting the synchronized thalamocortical oscillatory activity. Thalamocortical oscillations have been described to initiate from the intra-thalamic circuit composed of GABAergic thalamic reticular nucleus (TRN) neurons and glutamatergic thalamic cortical (TC) neurons and then to be transmitted to cortical neurons. Low-threshold burst firing of TC neurons mediated by T-type Ca2+ channels has been attributed in this phenomenon. However, the extents to which TC burst firing contribute to sleep architecture or sleep brain rhythms are not fully understood yet. Here we investigated the alteration of sleep patterns in mice with increased burst firing in TC neurons. Thalamic-restricted gene knockdown also displayed the alteration in NREM sleep confirming the role of TC burst firing in NREM sleep. We expect that this study could suggest the potential role of TC burst firing in the regulation of NREM sleep.

Abstract: Innate fear, induced by a threat such as the odor of a predator, plays a critical role in survival. Unlike conditioned fear, the neuronal circuitry underlying innate fear is largely unknown. Here, we discovered that the laterodorsal tegmentum (LDT) and lateral habenula (LHb) were specifically activated by the mouse predator odorant trimethylthiazoline (TMT). Using optogenetics to selectively stimulate GABAergic neurons in the LDT immediately produced fear-like responses (freezing, accelerated heart rate, and increased serum corticosterone), whereas prolonged stimulation caused anxiety-like behaviors. Interestingly, while selective stimulation of parvalbumin (PV)-positive interneurons similarly induced fear-like responses, stimulation of somatostatin-positive interneurons or inhibition of PV neurons in the LDT suppressed TMT-induced fear-like responses without affecting conditioned fear. Finally, activation of LHb glutamatergic inputs to LDT interneurons was sufficient to generate fear-like responses. Thus, the LDT plays an essential role in regulating innate fear and provides a potential target for therapeutic intervention for anxiety disorders.

Title: Voluntary movement gates vestibular sensory coding in the ventral posterior lateral thalamus

Authors: *A. DALE, K. E. CULLEN;
Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Successful navigation of the world around us is accomplished through precise coordination of our actions, and accurate perception of the motion we experience as a result of our own movements as well as occurrences in our environment. Vestibular system responses to self-motion are relayed through the thalamus to cortex where they contribute to higher-order processing. To date, the responses of neurons in the vestibular thalamus, specifically the ventral posterior lateral nucleus (VPL), have not been characterized during voluntary, natural movements in rhesus monkeys. Accordingly, here, we recorded from individual non-eye movement responsive VPL neurons during yaw rotations that were either passively applied or self-produced. In addition, we characterized responses to neck proprioceptive inputs to elucidate how this neuronal population integrates signals from multiple modalities. We found that neurons fell into two separate groups: approximately half encoded head-in-space (vestibular) motion while the other half were sensitive to both vestibular and neck proprioceptive signals, thereby providing an estimate of relative head and body motion. Moreover, all neurons showed dramatically reduced (nearly 90%) firing rate modulation in response to self-generated head motion relative to passive motion. Furthermore, during combined passive and active stimulation, the observed attenuation persisted such that neurons reliably encoded only the externally-generated component of the motion. Notably, VPL neurons encoded unexpected motion even more selectively than neurons in earlier stages of vestibular processing (vestibular nuclei: Roy and Cullen 2001; deep cerebellar nuclei: Brooks and Cullen 2013). Thus, our results demonstrate that ascending vestibular pathways through the thalamus carry a robust representation of unexpected self-motion, which is critical for ensuring perceptual stability during everyday behaviors.

Title: Loss of prefrontal control of a brainstem defensive behavior circuit following social defeat

Authors: *L. MARRONE, T. FRANKLIN, B. SILVA, C. GROSS;
EMBL, Monterotondo (RM), Italy

Abstract: The prefrontal cortex (PFC) is a brain area critical for behavioural flexibility and decision making in response to a changing environment and plays an important role in regulating emotions and moderating social behavior. It is known that the PFC exerts its functions through extensive connections with cortical and subcortical structures. Some of these structures are part of a network of brain regions associated with sociability, but the contribution of specific cortical-subcortical projections to social behavior has not yet been established. Using a model of repeated social defeat in mice, we investigated how projections from medial PFC (mPFC) to dorsal periaqueductal grey (dPAG), a structure involved in defensive behavior, play a role in behavioural adaptation to social threat. Using cholera toxin retrograde tracers and transgenic cell-type markers we showed that dPAG receives afferents exclusively from layer V mPFC excitatory neurons. Using *in vivo* local field potential recordings we found a decrease in functional connectivity between mPFC and dPAG in defeated mice and selective pharmacogenetic inhibition of mPFC-dPAG projections mimicked the behavioural adaptation to social defeat. These data suggest that mPFC projections exert inhibitory control over brainstem defensive circuits and are weakened during social defeat to adapt social behavior to the environment. To pinpoint the plasticity underlying this remodeling, we identified brain regions showing altered levels of several plasticity-associated molecules following social defeat. Immunostaining for pS6, a ribosomal protein whose phosphorylation reflects translational regulation, was decreased in the mPFC of defeated mice, suggesting that plasticity in mPFC may be involved in the behavioral remodeling. Currently, we are investigating changes in gene expression, cell morphology, and AMPA receptor subunit composition in mPFC-dPAG projecting neurons to identify the molecular mechanisms underlying the behavioral adaptation to social defeat.

Title: Glutamatergic lateral hypothalamic inputs to VTA produce avoidance and suppress dopamine release in the nucleus accumbens

Authors: *E. NIEH, C. M. VANDER WEELE, K. N. PRESBREY, K. M. TYE;
Brain and Cognitive Sci., Picower Inst. For Learning and Memory, MIT, Cambridge, MA

Abstract: Recently we have shown that LH neurons sending projections to the VTA encode the learned action of seeking a reward, while LH neurons receiving projections from the VTA encode the conditioned and/or unconditioned stimuli. Activating the LH-VTA projection increases the willingness of mice to cross a shock floor to obtain sucrose rewards, while inhibiting the projection decreases this drive. After revealing that the LH sends both excitatory and inhibitory monosynaptic inputs onto both dopamine and GABA neurons in the VTA, we show that the inhibitory components are likely mediating the reward-seeking behavior while the excitatory components play a more modulatory role. Here, we show that activating the GABAergic component of the LH-VTA projection supports real-time place preference (n=6 ChR2, n=8 eYFP, **p=0.0025) and intracranial self-stimulation (***p=0.0009). In contrast, activating the glutamatergic component causes real-time place aversion (n=7 ChR2, n=6 eYFP, **p=0.0031). These data are contrary to the previous conceptualization of glutamatergic inputs from LH to VTA mediating positive reinforcement. In fact, it is quite surprising that inhibiting a projection to the VTA would be rewarding, while exciting it would be aversive, given the nature of dopamine neurons in the VTA. However, we used fast-scan cyclic voltammetry (FSCV) to measure the effects of activating the GABAergic LH component on dopamine release in the nucleus accumbens (NAc) and find that it increases dopamine release (n=2 mice, 20 trials each;

***p<0.0001). Meanwhile, activating the glutamatergic component of the LH-VTA projection decreases dopamine release (n=3 mice, 20 trials each; ***p<0.0001). Together these data suggest that the LH promotes and suppresses the release of dopamine in the NAc via the disinhibition of dopamine neurons in the VTA.

Title: Observing and controlling projection-defined medial prefrontal cortex subpopulations in reward and aversion

Authors: *C. M. VANDER WEELE[1], R. WICHMANN[1], I. C. ESPINEL[1], E. H. S. SCHUT[2], E. IZADMEHR[1], C. E. WILDES[1], K. M. TYE[1];
[1]Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Donders Inst., Radboud Univ., Nijmegen, Netherlands

Abstract: The medial prefrontal cortex (mPFC) has been implicated in higher order cognitive functions and coordinates the execution of motivated behaviors though its projections to downstream targets. However, how mPFC neurons that project to different downstream targets represent and coordinate motivated behaviors is unclear. Our goal is to understand how mPFC

neuronal subpopulations encode stimulus valence and where this information is communicated downstream to instigate adaptive behavioral responses, such as approach or avoidance. Using *in vivo* freely-moving calcium imaging enabled by a genetically-encodable calcium indicator (GCaMP6m), we explored the real-time neural dynamics in the mPFC during exposure to innately appetitive and aversive olfactory stimuli. We have found that the mPFC neurons have diverse response profiles. Approximately 50% of neurons (n = 273) responded similarly, perhaps encoding general salience. ~26% showed selective responding to only one of the stimuli. Another subset of mPFC neurons (~19%) showed opposing responses, characterized by increased activity to one stimulus and decreased activity to the other. mPFC neurons encoding positive or negative valence likely have distinct downstream targets. The periaqueductal gray (PAG) is has been linked to aversive behaviors and we have found that optogenetic activation of mPFC terminals in the PAG produces avoidance (n = 6 ChR2, p = 0.01) and anxiety-related behaviors (p = 0.04). Further, stimulation of this pathway evokes defensive (p = 0.03) and escape (p = 0.01) behaviors in the marble burying assay, suggesting that stimulation of the mPFC:PAG circuit triggers active avoidance behaviors. These effects were not observed in control animals (n = 6 eYFP; p > 0.05). The paraventricular nucleus of the thalamus (PVT) has been implicated in reward, and receives dense input from the mPFC. To selectively manipulate mPFC neurons terminating in PVT, we used an anterogradely traveling viral vector carrying ChR2 in a double inverted open reading frame in the mPFC and a retrogradely traveling viral vector carrying cre-recombinase in the PVT. In animals expressing ChR2 only in neurons originating in the mPFC and terminating in the PVT, we show that activation of the PVT-projecting mPFC neurons is positively reinforcing (n = 3 ChR2, p = 0.04); an effect not observed in controls (n = 3 eYFP; p > 0.05). Together, these data suggest that the mPFC controls avoidance and approach behaviors through its projections to the PAG and PVT, respectively. Our results advance us towards a circuit-level explanation for how the mPFC can exert control over valence-defined motivated behaviors.

Title: Retrieval of positive and negative associations produces opposite responses in BLA neurons projecting to NAc and CeM

Authors: *A. BEYELER, P. NAMBURI, C. SIMONNET, G. F. GLOBER, G. F. CONYERS, R. LUCK, C. P. WILDES, K. M. TYE;
Brain and Cognitive Sci., Picower Insitute for Learning and Memory, MIT, Cambridge, MA

Abstract: The ability to process positive and negative emotional valence guides our daily life, allowing us to produce adaptive behaviors in order to ensure our survival and well-being. The basolateral amygdala (BLA) is necessary for processing associative memories of both positive and negative valence. However, the natural encoding dynamics of BLA neurons with specific downstream targets has not been explored. By combining optogenetic photo-identification of BLA neurons with a specific projection target and large-scale electrophysiological recordings in behaving mice, we tested whether BLA neurons projecting to different downstream targets encode valence differently. After mice learned to associate an auditory cue with a rewarding outcome (sucrose delivery), and a second tone with an aversive outcome (quinine delivery), we recorded BLA neurons while the animals were performing the task. Of the 993 single units we recorded in the BLA, 53% responded to cues of positive and/or negative valence. Units photo-identified as projecting to the nucleus accumbens (25 NAc projectors, n=5 mice) were either 1) excited by cues of positive valence or 2) inhibited by cues of negative valence. Conversely, BLA neurons projecting to the medial division of the central amygdala (35 CeM projectors, n=3 mice) were either 1) excited by cues of negative valence or 2) inhibited by cues of positive valence. Both NAc- and CeM-projecting BLA neuron populations also had some cells that responded to both cues. In contrast to the conditioned valence-specific encoding properties of BLA-NAc and BLA-CeM populations, BLA units photo-identified as projecting to the ventral hippocampus (33 vHPC projectors, n=3 mice) showed a similar distribution of responses compared to the entire BLA population. These results support a model where NAc and CeM projectors provide valence-specific excitation to their downstream target during cues of positive and negative valence, respectively, and provide inhibition during cues of opposite valence. The mutually exclusive pattern of coding of the NAc and CeM projectors also suggests that these two populations may engage in reciprocal inhibition.

Title: Amygdala-prefrontal interactions during the competition of fear- and reward-related memories

Authors: *A. BURGOS-ROBLES, M. ANAHTAR, K. M. TYE;
Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: In nature, environmental stimuli signaling positive or negative outcomes may be presented simultaneously, forcing animals to choose behavioral responses that may be in competition with each other. However, the neural mechanisms underlying the competition, coordination or selection of opposing motivated behaviors (reward-seeking and freezing) are not well understood. In this study, we use multichannel single-unit recordings and optogenetic manipulations in freely-moving rats to examine functional interactions between the basolateral amygdala (BLA) and the prelimbic cortex (PL), which are two highly interconnected structures that have been widely implicated in various fear and reward conditioning tasks. We have detected in both structures populations of neurons that exhibit phasic changes in firing to cues that predict either footshocks (BLA: 11/110, 10%; PL: 12/76, 16%) or sucrose (BLA: 9/110, 8%; PL: 14/76, 18%). We also observe cells that exhibit the same response (BLA: 15/110, 14%; PL:

22/76, 30%) or opposite responses (BLA: 13/110, 12%; PL: 7/76, 9%) to the fear and reward cues. Cross-correlation analysis shows strong correlated activity between the BLA and PL during the presentation of both fear and reward cues. We are using optogenetic-mediated stimulation or inhibition to determine whether BLA-PL interactions play a functional role in the modulation of cue-evoked fear and reward-seeking. Photostimulation reduces the latency to conditioned freezing when rats are challenged by the simultaneous presentation of the fear and reward cues ("competition trials"; Laser-OFF: 7.7 s, Laser-ON: 2.8 s, $p = 0.0043$). Despite shorter latency to freezing, the total percentage of time that rats spend freezing during the cue presentation is unaffected by BLA-PL stimulation ("fear trials", OFF: 59%, ON: 58%, $p = 0.74$; "competition trials", OFF: 8%, ON: 11%, $p = 0.52$). Meanwhile, stimulation of BLA terminals in PL does not significantly affect the latency for sucrose-port entry ("reward trials", OFF: 3.8 s, ON: 3.1 s, $p = 0.46$; "competition trials", OFF: 3.6 s, ON: 4.1 s, $p = 0.76$), nor does it affect the total time that rats spend in the port collecting sucrose ("reward trials", OFF: 62%, ON: 63%, $p = 0.69$; "competition trials", OFF: 60%, ON: 57%, $p = 0.75$). Together these preliminary results suggest that BLA projections to PL promote faster expression of conditioned fear when environmental stimuli of opposite valence are competing to drive behavioral responses.

Title: Subregions of the thalamic paraventricular nucleus make distinct contributions to emotional behavior

Authors: *J. R. BARSON[1,2], S. F. LEIBOWITZ[2];
[1]Behavioral Neurobio., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Lab. of Behavioral Neurobio., The Rockefeller Univ., New York, NY

Abstract: Background: The paraventricular nucleus of the thalamus (PVT) is a limbic region thought to play a role in emotional behavior. With recent studies showing the anterior (aPVT)

and posterior (pPVT) areas of this nucleus to have different roles in consummatory behavior, the present study investigated whether these subregions also make different contributions to emotional behaviors. Methods: Adult male Long-Evans rats with cannulas aimed at the aPVT or pPVT were microinjected in a between-subject design with the GABA(B)+GABA(A) agonists baclofen+muscimol (0.3+0.03 nmol) or saline vehicle (0.3 ul) (n=7-8/injection/area) and tested 5 minutes post-injection. On separate days, they were tested in a novel open field (15 min); then after three additional daily exposures in a familiar open field (15 min); and then one week later in an elevated plus maze (5 min). The order of injections was counterbalanced for each subject. Results: In the novel open field, inactivation with GABA agonists of the aPVT and pPVT significantly reduced locomotor activity (as measured by ambulatory distance, time, counts, and episodes, average and total velocity, and vertical counts), with this effect somewhat stronger after pPVT inactivation. In the familiar open field, inactivation of these subregions also caused a significant reduction in locomotor activity, which was similar in magnitude for both the aPVT and pPVT. This is in contrast to anxiety-like behavior in the elevated plus maze, which was significantly increased (as measured by reduced open arm time and entries) by inactivation only of the pPVT, with locomotor activity in the plus maze (closed arm entries) otherwise unaffected. Conclusions: These results suggest that, while both PVT subregions are necessary for locomotor activity in a familiar environment, the pPVT has an additional function in novelty-induced locomotor activity and is necessary for the expression of anxiety-like behavior, indicating that this subregion plays a greater role in reacting to aversive stimuli. These changes in emotional behaviors induced by inhibitory GABA agonists in the pPVT were somewhat unexpected, in light of other evidence showing an excitatory neurochemical, orexin/hypocretin, to have the same effects in the pPVT. With prior studies also showing GABA and orexin/hypocretin in the pPVT to be similar in promoting food intake, the present results suggest that different neurochemical pathways from the pPVT can impact a specific behavior in similar ways. Taken together, these findings support a role for the PVT in the expression of emotional behavior and show for the first time that its subregions make distinct contributions to this activity.

Title: Differential activity in afferents to the paraventricular nucleus of the thalamus in response to incentive and predictive stimuli

Authors: *J. L. HAIGHT[1,2], S. B. FLAGEL[1,3];
[1]Psychiatry, [2]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI; [3]Mol. and Behavioral Neurosci. Inst., Ann Arbor, MI

Abstract: Cues that are repeatedly paired with rewards can acquire predictive value, guiding behavior towards valuable resources in the environment (e.g. food, water, etc.). However, reward-paired cues can also acquire incentive value (i.e. incentive salience), and can come to control behavior, often to the point that it becomes maladaptive. Until recently, it was difficult to study the neural circuitry underlying the attribution of incentive salience to reward-paired cues, since it was assumed that the incentive and predictive values of cues were acquired simultaneously. However, using an animal model that captures individual variation in response to discrete reward-paired cues, we are now able to parse these properties of stimulus-reward learning. When rats are exposed to a Pavlovian conditioning paradigm, wherein a discrete cue predicts food reward, some rats, termed sign-trackers (STs), attribute both predictive and incentive value to the cue. Other rats, termed goal-trackers (GTs), treat the cue exclusively as a predictor of impending reward delivery. Previous studies from our laboratory have highlighted the paraventricular nucleus of the thalamus (PVT) as a critical component of the neural circuitry mediating these behaviors. Here, we sought to explore the engagement of PVT circuitry in sign- and goal-tracking behaviors. The retrograde tracer Fluoro-Gold (FG) was injected into the PVT and levels of cue-induced neuronal activity were assessed by quantifying the amount of c-fos in FG-expressing cells. This technique allows us to assess differences in activation between STs and GTs specifically in afferents to the PVT. We were especially interested in examining activity in the medial prefrontal cortex, since previous studies from our lab have suggested that prelimbic cortical afferents to the PVT are involved in mediating goal-tracking behavior. As predicted, results show that, relative to STs, GTs have increased cue-induced cortical activation, specifically in prelimbic and infralimbic neurons that project to the PVT. There we no significant ST/GT differences in neuronal activation in hypothalamic brain areas that project to the PVT, including the dorsomedial nucleus and lateral hypothalamic nucleus. These results demonstrate that sign- and goal-tracking behaviors engage distinct neural circuits projecting to the PVT in response to cue presentation, and support the hypothesis that GTs have greater cortical-control of their behavior. Ongoing analyses will further explore activity in different afferent projections to the PVT, including the insular cortex and central amygdala, as well as PVT efferents to the nucleus accumbens and extended amygdala.

Title: Chemogenetic manipulations of prelimbic inputs to the paraventricular nucleus of the thalamus alter sign- and goal-tracking behavior

Authors: *I. RIVERO-COVELO[1], J. L. HAIGHT[1], K. M. FRASER[1], B. N. KUHN[1], S. M. FERGUSON[2], S. B. FLAGEL[1];
[1]The Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [2]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA

Abstract: Environmental cues that predict the presence of natural rewards (e.g. food or sex) can acquire incentive motivational value in addition to predictive value. Notably, cues that acquire incentive motivational value can gain inordinate control over behavior, often leading to maladaptive tendencies such as overeating or drug addiction. When rats are exposed to a Pavlovian conditioned approach task, in which the presentation of a lever precedes the presentation of a food reward, some rats, termed sign-trackers (STs), approach the lever; while other rats, termed goal-trackers (GTs), approach the food cup. Thus, for STs, the cue becomes an incentive stimulus; whereas for GTs it is just a predictor. Recently, we have shown that the paraventricular nucleus of the thalamus (PVT) is involved in the regulation of sign- vs. goal-tracking behavior. Selective lesions of the PVT enhance sign-tracking behavior in both STs and GTs, but may serve distinct functions in these two phenotypes. Relative to GTs, STs show enhanced c-fos expression in the PVT in response to a discrete cue that has been previously paired with food- or drug-reward. Further, for STs, cue-induced c-fos levels in the PVT correlate with cue-induced c-fos in subcortical regions; whereas for GTs, cue-induced c-fos in the PVT correlates with the prelimbic cortex (PrL). Thus, we postulate that the PVT may act as a node for the attribution of incentive motivational value to reward cues in STs, and that inputs to the PVT from the PrL may serve to inhibit this process in GTs. Here, we interrogated the role of this circuit in sign- and goal-tracking behaviors using a dual viral vector approach to selectively express Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) in projection neurons from the PrL to the PVT. A Cre-dependent flip-excision AAV viral vector expressing inhibitory Gi/o- or stimulatory Gq-coupled DREADDs was infused into the PrL of GTs and STs, respectively, while a CAV-Cre viral vector was injected into the PVT. This resulted in Gi/o-

DREADD expression in PrL-PVT neurons in GTs, and Gq-DREADD expression in STs. Activation of Gi/o-DREADDs via systemic administration of clozapine N-oxide (CNO) inhibited the PrL-PVT circuit in GTs, and resulted in an increase in sign-tracking behavior. Conversely, in STs, CNO-induced stimulation of Gq signaling in PrL-PVT neurons increased goal-tracking behavior. Thus, "turning off" the PrL-PVT circuit leads to sign-tracking behavior in GTs, while "turning on" the PrL-PVT circuit induces goal-tracking behavior in STs. Top-down processes from the PrL to the PVT may therefore be a critical component of the circuitry that goes awry in addiction and related disorders.

Title: A population of parvalbumin-expressing (pv+) neurons in the lateral habenula promotes anxiety

Authors: *L. POZZI, I. PALLUCCHI, I. LAZARIDIS, I. POLLAK DOROCIC, K. MELETIS; Karolinska Institutet, Stockholm, Sweden

Abstract: Dysfunction in GABAergic parvalbumin-expressing (PV) interneurons has been implicated in the pathogenesis of various neuropsychiatric disorders including anxiety. Neurons in lateral habenula (LHb) respond to punishment and aversive stimuli, and this circuit has been implicated in mood disorders. The neuron subtypes present in LHb and how they contribute to discrete aspects of emotional behavior has not been determined. We have identified a population of PV-expressing neurons in the LHb that promotes anxiety-like behaviors. Genetic targeting (AAV DIO GFP) of the LHb in Vglut2-Cre and Vgat-Cre mice revealed that LHb PV+ neurons express both glutamatergic (30% Vglut2) and GABAergic (20% Vgat) markers. We further used optogenetics in PV-Cre mice to selectively activate PV+ neurons in the LHb (AAV DIO ChR2-mCherry) and to investigate their functional role in modulation of anxiety-like behaviors in the open field and the elevated plus maze. We found that photoactivation of LHb PV+ neurons induced anxiety-like behavior. In the open field, optogenetic stimulation resulted in a significant

decreased in the time spent in the center. Similarly, in the elevated plus maze optogenetic stimulation of LHb PV+ neurons resulted in a significant decrease the time spent in the open arms. These findings expand our understanding of the diversity of neuronal populations in the LHb and provide a foundation for investigating the role of LHb PV+ neurons in anxiety.

Abstract: Maladaptive aggressive behavior is associated with a number of neuropsychiatric disorders and is thought to result, in part, from inappropriate activation of brain reward systems in response to aggressive or violent social stimuli. A series of nuclei within the ventromedial hypothalamus, extended amygdalar and limbic circuits are known to encode the initiation of aggression; however, little is known about the neural circuit mechanisms that directly modulate the motivational or rewarding component of aggressive behavior11. To address this question, we established a mouse behavioral model to measure the valence of aggressive inter-male social interaction with a smaller 6-8 week old subordinate intruder as reinforcement for the development of conditioned place preference (CPP). In this model, aggressors (AGG) develop a CPP, while non-aggressors (NON) develop a conditioned place aversion (CPA), to the intruder-paired context. Further, we identify a dopamine receptor 2-containing GABAergic medium spiny neuron projection from the ventral striatum (vStr) to the lateral habenula (lHb) that bi-directionally controls the valence of intruder interactions. Circuit-specific optogenetic silencing of inhibitory GABAergic vStr-lHb terminals of AGG with halorhodopsin (NpHR3.0) increases lHb neuronal firing and abolishes CPP to the intruder-paired side. Conversely, activation of

GABAergic vStr-lHb terminals of NON with channelrhodopsin (ChR2) decreases lHb neuronal firing and promotes CPP to the intruder-paired side. Lastly, we show that inhibitory transmission at vStr-lHb terminals do not control the initiation of aggressive behavior in NON, but rather modulates the intensity of aggression in AGG. These results demonstrate that the vStr-lHb circuit plays a critical role in regulating the valence of inter-male aggressive behavior, and provide novel mechanistic insight into the neural circuits modulating aggression reward processing.

Title: Pyramidal cells-OLMα2 interneurons network underlies theta activity and anxiety related behavior in the ventral hippocampus

Authors: S. MIKULOVIC[1], *C. RESTREPO[1], S. PUPE[2], A. TORT[4], K. KULLANDER[3], R. LEÃO[3];

Abstract: Theta oscillations in the dorsal hippocampus are described as one of the most prominent rhythms of the brain. This 4-12 Hz have been associated with multiple behaviors, especially with movement. Differentially, theta activity in the ventral hippocampus has been implicated in emotions related behavior. It was suggested that specific GABAergic interneuron subtypes play differential roles in driving hippocampal oscillations. Although different populations of hippocampal interneurons fire preferentially to specific phases of theta, phase-locking firing itself does not prove a causal role in theta generation. We found a specific subtype of oriens lacunosum-moleculare (OLM) interneurons expressing Chrna2 receptor differentially distributed along the dorso-ventral hippocampal axis. Using optogenetic tools in anesthetized and

freely moving animals, we found that activation of this population induce prominent theta activity in the ventral but not in the dorsal hippocampus. This circuit includes pyramidal cells activity. Interestingly, the induced theta rhythm was not correlated with animals' movements. In addition, we found that this induced theta activity regulates anxiety related behavior. Taken together, our results provide the first evidence of a single morphologically defined cell population which in a network including pyramidal cells causally drives ventral hippocampal theta oscillations.

Title: Dissection of social neurocircuitry using chemogenetics and pharmaco-MRI

Authors: ***M. BENEKAREDDY**, M. SAXE, M. VON KIENLIN, B. KUENNECKE, A. GHOSH;
Neurosci. Discovery and Biomarkers, Roche Innovation Ctr. Basel, F. Hoffmann-La Roche, Basel, Switzerland

Abstract: Neurodevelopmental disorders like autism spectrum disorders and schizophrenia are often characterized by marked impairments in social function. The brain regions responsible for generating social behavior are currently not well understood. The prefrontal cortex (PFC) has been highlighted as an important node in the 'social brain' network. In this study, we used a combination of chemogenetics and rodent social behavior tasks, to assess the consequences of altered neural activity in the PFC on social behavior in rats and mice. Further, using pharmacological magnetic resonance imaging (phMRI) methods, we identify a network of brain regions associated with socially-directed behavior. Acute activation of the PFC using hM3D (a Gq-protein-coupled chemogenetic neural activator) in excitatory neurons led to a reversible decrease in sociability in both rats and mice. Chronic perturbation of PFC activity with expression of either hM3D in excitatory neurons or with hM4D (a Gi-protein-coupled chemogenetic neural inhibitor) in parvalbumin or somatostatin inhibitory neuronal subtypes altered social function in a time-dependent and cell-type-dependent manner. In a further effort to investigate the brain-wide consequences of activating the PFC, animals were subjected to MRI

during chemogenetic activation. Activation of the PFC using hM3D led to a significant increase in blood perfusion in the PFC and in other brain regions including nucleus accumbens, and the dorsal raphe nucleus. Our results suggest that reciprocal connections between PFC and several key subcortical regions provide a circuit level framework for altered cortical and sub-cortical function to modify social behavior.

Title: Characterizing behavior-suppressing circuits: optogenetic stimulation of basal amygdala terminals in nucleus accumbens shell suppresses cue-evoked seeking and drinking

Authors: *Z. MILLAN, P. H. JANAK;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: The nucleus accumbens shell strongly inhibits feeding during satiety, reward seeking in the presence of an unrewarded cue, and drug seeking following its extinction. Understanding the mechanisms that promote suppressive control over motivated behavior has important implications for pathologies such as drug addiction and binge-eating disorders, which are characterized by a significant loss of control over seeking and consumption. Here we used an optogenetic approach to examine basal amygdala (BA) projections that target the accumbens shell [NAc(shell)] and whether stimulation of a BA-to-NAc(shell) pathway might be sufficient to suppress conditioned behavior evoked by either alcohol- or sucrose-predictive cues. Rats in the alcohol study received intermittent homecage access to EtOH (15%v/v) followed by Pavlovian conditioning of a 10s auditory cue paired with delivery of EtOH (15% v/v). Rats in the sucrose study received Pavlovian conditioning as above, reinforced with sucrose (10%v/v). On test, rats were assessed for cue-evoked seeking in the presence of both non-reinforced and reinforced

reward cues. We found that stimulation of BA terminals in NAc(shell) during reward cue presentations impaired conditioned port entries under non-reinforced or reinforced test conditions. Importantly, when cue-associated EtOH or sucrose was delivered at the offset of optical stimulation, rats maintained their ability to port entry. This latter finding suggests that the suppressing effect of stimulation on conditioned behavior is well-timed to the duration of stimulation. Finally, we examined whether the inhibitory effect of BA-to-NAc(shell) stimulation could also accutely interrupt licking during bouts of alcohol or sucrose drinking. Rats were placed on a 10 min homecage access regime prior to stimulation test. We confirmed the ability of this pathway to suppress drinking behavior. Together, these findings suggest that optogenetic stimulation of a BA-to-NAc(shell) pathway is sufficient to disrupt both conditioned and unconditioned reward-motivated behaviors.

Title: Are the auditory pathways converging in the Lateral Amygdala required for the expression of Pavlovian defense reactions?

Authors: *L. DIAZ-MATAIX[1], N. BENABDALLAH[1], S. A. SERKA[1], V. DOYERE[2,1], J. E. LEDOUX[1,3];

Abstract: In Pavlovian auditory threat conditioning the conditioned stimulus (CS) arrives to the Lateral Nucleus of the Amygdala (LA) through two main brain pathways: a direct thalamo-amygdala, and an indirect thalamo-cortico-amygdala connection. The acoustic stimulus arrives to the medial areas of the auditory thalamus composed by the Medial Geniculate Nucleus (MGm) and the Post Intralaminar Nucleus (PIL), and from these nuclei projections is sent to the LA. The CS can also reach the LA through a pathway from the auditory thalamus to the primary auditory cortex (Temporal Associatin Cortex area TE1) which in the rat projects to TE3, and from there to the LA. Either of these two pathways (thalamo- and cortico-amygdala) is sufficient to mediate threat conditioning (Romanski & LeDoux., 1992; LeDoux., 1995). Electrophysiological studies show that threat learning induces persistent enhanced synaptic plasticity in both cortico and

thalamo-amygdala pathways (Tsvetkov et al., 2002; Rogan et al., 1997). Although the contribution of these auditory pathways to threat learning has been extensively studied, little is known about their role in the expression of threat memories. By using chemogenetics we examined the contribution of these auditory pathways to the expression of learned defense responses to a pure tone. MGm/PIL or TE3 was infected with virus carrying inhibitory Designer Receptors Exclusively Activated by Designer Drugs (DREADDs). After 6 weeks cannulae were implanted bilaterally into LA with a stainless steel recording electrode attached to the left cannula. Rats were habituated to the CS and context before conditioning them by presenting 3 tone (CS)-shock (US) pairings. Long-term memory tests were performed by presenting 5 unreinforced CSs after intra-LA infusion of the DREADD agonist CNO (Clozapine-N-oxide) or vehicle in the same animals in a counterbalanced manner to allow within animal comparison. The inactivation of the thalamic terminals in the LA by the infusion of CNO impairs freezing in parallel with a decrease in the amplitude of the LA auditory field evoked potential. Ongoing experiments are being conducted to elucidate the role of auditory cortex on threat memory expression. So far, the results suggest the necessity of an intact and functional thalamo-amygdala circuit for the expression of previously learned defense responses.

Title: An extended amygdala to ventral tegmental area circuit underlies ethanol-seeking behavior in mice

Authors: *M. M. PINA[1], C. L. CUNNINGHAM[2];
[1]Behavioral Neurosci., [2]OHSU, Portland, OR

Abstract: Associations between external stimuli and abused drugs contribute to relapse to use by eliciting craving and driving subsequent drug seeking. The bed nucleus of the stria terminalis (BNST) is an extended amygdala structure that appears to underlie drug-seeking behavior. Anatomically, the BNST send a dense set of projections to the ventral tegmental area (VTA), a region critically involved in motivated behavior. Behaviorally, BNST inhibition disrupts stress- and cue-induced drug seeking. Importantly, BNST disconnection from the VTA has been shown to significantly attenuate cue-induced cocaine seeking, as measured by conditioned place preference (CPP). Though indirect, this evidence indicates that a projection from the BNST to the VTA may underlie cue-induced drug seeking. In the present experiments, we used selective manipulations to directly establish a role for the BNST and its VTA projections in cue-induced ethanol seeking behavior in adult male DBA/2J mice. An unbiased CPP procedure was used, where ethanol (2 g/kg, IP) was given immediately before exposure to a distinct tactile cue and an expression (seeking) test was given 24 h after the final conditioning session. In experiment 1, we gauged the BNST's ability to regulate ethanol CPP expression using virally-expressed inhibitory designer receptors (i.e., Gi-DREADDs). Stimulation of Gi-DREADDs by injection of clozapine-N-oxide (CNO; 10 mg/kg, IP) 30 min before the expression test significantly disrupted ethanol CPP. In experiment 2, an intersectional approach was used to selectively express Gi-DREADDs in BNST-VTA projection neurons. Silencing of BNST-VTA neurons by CNO (as in exp. 1) abolished ethanol CPP entirely. Control studies show that these results were not due to a direct effect of CNO, as CNO (10-20 mg/kg) did not affect ethanol CPP expression or test activity in the absence of Gi-DREADDs. Our findings suggest that a BNST-VTA circuit is required for the expression of ethanol-seeking behavior, as indexed by CPP. Moreover, our work complements and expands upon previous findings and provides novel evidence for a direct BNST input to VTA in cue-induced ethanol seeking. Taken together with the existing literature, these studies indicate that the BNST and its projections to VTA are promising neural targets for treatments directed at reducing craving and relapse.

Title: Mesointerpeduncular circuitry and dopaminergic control of affective state

Authors: *S. R. DEGROOT, R. ZHAO-SHEA, P. GARDNER, A. TAPPER;
UMASS Med. Sch., Worcester, MA

Abstract: Anxiety disorders are the most common class of mental disorders. Anxiety is an affective state classically governed by the prefrontal cortex, hippocampus, and the extended amygdala, which includes the bed nucleus of the stria terminalis (BNST). Previous studies suggest that stimulation of glutamatergic BNST efferents in the ventral tegmental area (VTA) is anxiogenic. Further, the VTA can exhibit control of affective state by heterogeneous efferent terminal activation in certain brain regions. Recently, we showed that the mesointerpeduncular circuit, which consists of VTA dopaminergic (DAergic) neurons that innervate the interpeduncular nucleus (IPN), is an important component in nicotine withdrawal-induced anxiety. The current study further explores the mesointerpeduncular circuitry, specifically DAergic control of the IPN in drug naïve mice. Using cell-attached patch-clamp electrophysiology in acute mouse brain slices, we defined two neuronal populations of the ventral IPN by input resistance and response to exogenous application of DA. Type A neurons have low input resistance and respond to DA with an increase in spontaneous action potential frequency (sAPF), while Type B neurons exhibit a higher input resistance and respond to DA with a decrease in sAPF. DA only affected sAPF in the ventral half of the IPN and the dorsal lateral subnucleus with little effect in the rostral IPN. Using viral mediated gene delivery and CRE-Lox technology, we expressed channelrhodopsin-2 (ChR2) specifically in putative DAergic VTA neurons of tyrosine hydroxylase (TH)-CRE mice. Fluorescence microscopy revealed VTA terminals located specifically in regions of the IPN where DA modulated sAPF. Light stimulation of VTA IPN afferents resulted in modulation of sAPF consistent with exogenous DA application. D1-family DA receptor antagonists blocked the main effect of ChR2 stimulation and DA-induced changes in sAPF. Whole-cell patch clamp recordings revealed changes in excitatory postsynaptic current frequency, but not amplitude in IPN neurons during VTA terminal stimulation suggesting that DA acts presynaptically to modulate IPN inputs. Our study further characterizes the mesointerpeduncular circuit, which may play a critical role in affective behavior.

Title: Structure and function of circuits that provide input to dopaminergic and serotonergic neurons

Authors: *I. POLLAK DOROCIC, D. FÜRTH, Y. XUAN, K. MELETIS;
Dept. Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: New genetically-restricted transsynaptic tracing strategies allow us to dissect neural circuits in unprecedented detail. Our aim is to define circuits that provide direct inputs to dopaminergic, serotonergic and GABAergic neurons, focusing on striatum-projecting cells, and to probe those circuits functionally. Here, we employ a genetically modified rabies virus in transgenic mice to selectively map monosynaptic inputs to striatum-projecting dopaminergic and GABAergic cells in the ventral tegmental area (VTA) and substantia nigra (SN) region as well as striatum-projecting serotonergic and GABAergic cells in the dorsal raphe nucleus (DR) region. To obtain selective targeting of specific cell types, we first injected a Cre-dependent adeno-associated virus containing TVA receptor and rabies glycoprotein into the VTA/SN region of TH-Cre and Vgat-Cre animals, and into the DR region of SERT-Cre and Vgat-Cre animals, respectively. Subsequently, Rabies-EGFP was injected into the striatum and is taken up only by the TVA-expressing axons of the projection neurons. Rabies-EGFP retrogradely crosses one synapse into the presynaptic partners of the projection neurons. Using this strategy we were able to localize and characterize the specific brain-wide input neurons to only striatum-projecting dopaminergic, serotonergic and GABAergic cells. One region found to have prominent input to dopaminergic cells of the VTA and serotonergic cells of the DR is the lateral habenula (LHb), a region involved in negative reinforcement. In order to functionally probe this input population, we used a variant of the transgenic rabies virus, which contains the excitatory opsin channelrhodopsin (Rabies-ChR2). By monosynapic tracing using Rabies-ChR2 from dopaminergic cells of the VTA and serotonergic cells of the DR, we were able to optogenetically stimulate these presynaptic LHb populations to directly investigate their distinct roles in shaping motivated behaviors.

Title: Different outputs of lateral hypothalamus GABAergic neurons control appetitive and consummatory behaviors

Authors: C. ZHU, *S. SONG, Y. XIONG, W. SHI;
Tsinghua Univ., Beijing, China

Abstract: The GABAergic neuron in lateral hypothalamus (LH) has been found playing an important role in feeding behavior. Activation of LH GABAergic neuron produces appetitive and consummatory behaviors, and these two behaviors are encoded in distinct neurons (Stuber ,2015). We think the two kinds of GABAergic neurons may have different inputs and outputs, especially the outputs. We first do anterograde tracing in LH in wild type (WT) and VGAT-ires-cre mice to get the projection profile. Compared with the overall neurons, GABAergic neurons sends more projection to midbrain and pons, less to cortex and spetum. By using optogenetic tools, we find that activation of GABAergic projections mainly increase feeding behavior and show a preference to high fat food than normal food. Interestingly, the behavior of these projections has a little different. Activating LH->midbrain GABAergic projections such as LH->VTA GABAergic projection increases feeding and induces unusual appetitive motor sequences such as licking and gnawing the floor or empty space as shown in another paper(Edward H.Nieh,2015), while activating LH->pons GABAergic projections shows a mixed behavior including seeking and feeding. At the beginning of stimulation, the mice show more seeking behavior than feeding behavior, as the experiment processing, seeking behavior component decreases and feeding behavior component increases.

Title: Activation of D2-expressing neurons in the nucleus accumbens enhances motivation

Authors: *C. SOARES-CUNHA[1,2], B. COIMBRA[1,2], A. DAVID-PEREIRA[1,2], S. BORGES[1,2], L. PINTO[1,2], A. J. RODRIGUES[1,2], N. SOUSA[1];
[1]Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal; [2]ICVS/3B's - PT Government Associate Lab., Braga/Guimarães, Portugal

Abstract: Natural rewards, such as food or sex, exhibit reinforcing properties by activating the mesolimbic system, which comprises dopaminergic projections arising from the ventral tegmental area to the medium spiny neurons (MSNs) of the nucleus accumbens (NAc). These GABAergic MSNs comprise up to 95% of all NAc neurons and are typically segregated into two distinct subtypes - those expressing dopamine D1-type receptors (direct pathway) and those expressing dopamine D2-type receptors (indirect pathway). Whereas D1-MSN activation is canonically related to positive valence and induces persistent reinforcement, D2-MSN signalling is thought to mediate aversion. However, this functional/behavioural bias of both types of MSNs has been questioned by some pharmacological and genetic studies. In this perspective, we decided to use novel optogenetic tools to selectively stimulate accumbal D2 neurons and evaluate its modulatory effects in different motivation-related behaviours. In the present report, we first show that the pattern of activation of NAc neurons predicts motivational drive. Also, we found a positive correlation between the number of activated D2-expressing neurons and behavioural performance in a motivation-dependent task. We subsequently show that optogenetic modulation of D2 neurons enhances motivation in different behavioural paradigms and is able to induce behavioral conditioning. To complement these findings, we show that specific D2-neuronal activation in the NAc normalized motivational deficits in an animal model of stress-induced anhedonia. Altogether these results demonstrate that activation of D2 neurons in the NAc is necessary to modulate motivated behaviours.

Title: A mesoaccumbal glutamatergic population that induces aversion when stimulated optogenetically

Authors: *S. PUPE, J. PEDERSEN, T. VIERECKEL, C. J. A. SMITH-ANTILLA, M. LAGERSTRÖM, Å. WALLÉN-MACKENZIE;
Uppsala Univ., Uppsala, Sweden

Abstract: The ventral tegmental area (VTA) is traditionally recognized as a hub for processing reward-related stimuli, particularly via its projections to the nucleus accumbens (NAcc). In the past few years, a more detailed picture of the mechanisms through which the VTA mediates reward and aversion has emerged, mainly through an understanding of how the different cell types in this structure and their projections interact to produce behavior. In this work, we characterize the anatomy and function of a population of cells defined by the expression of a specific promoter (further referred as VTA1), located mostly in the anterior part of the VTA. Through *in situ* hybridization, we have verified that a sizable majority of these cells express the vesicular glutamate transporter type 2 (VGLUT2), a characteristic that suggests they release glutamate. After injection of Channelrhodopsin-2 in VTA1-Cre mice, they preferred to avoid the optogenetic stimulation of VTA1+ cells in the VTA in a real-time place preference test. This aversive response was even stronger when the stimulation was directed towards the NAcc medial shell, a target of dense projections from the VTA1 population. We were able to establish that approximately half of postsynaptic cells in the NAcc medial shell display EPSPs when these projections are stimulated optogenetically, and that these EPSPs can be blocked by AMPA receptors, suggesting glutamate is being released in these synapses. To establish whether glutamate was the neurotransmitter mediating the behavioral response that we saw, we crossed VTA1-Cre mice with a Vglut2-Lox line, generating conditional knockouts in which glutamate was not released by these cells anymore. When the real-time place preference test was performed again, no aversion was found either by stimulating in the VTA or in the NAcc. In conclusion, we believe that the neuronal population characterized by expression of VTA1 in the midbrain is mostly glutamatergic, and the excitation produced in the NAcc by its stimulation induces aversion.

Title: Selective activation of glutamatergic inputs from the pedunculopontine tegmental nucleus to the ventral tegmental area is reinforcing

Authors: *H.-L. WANG[1], A. CHAKRABORTI[1], S. ZHANG[1], J. QI[1], S. STEIDL[2], M. MORALES[1];
[1]IRP/NIDA/NIH, Baltimore, MD; [2]Dept. of Psychology, Loyola Univ. Chicago, Chicago, IL

Abstract: The pedunculopontine tegmental nucleus (PPTg) has been implicated in reward function. The PPTg is composed of cholinergic (expressing choline acetyltransferase; ChAT), GABAergic (expressing glutamic acid decarboxylase; GAD), and glutamatergic (expressing vesicular glutamate transporter 2; VGluT2) neurons (Wang & Morales, 2009). While these neurons are know to provide inputs to the ventral tegmental area (VTA), the relative proportions with which they innervate the VTA are not known. To identify and quantify PPTg neurons projecting to the VTA, we injected the retrograde tracer Fluoro-Gold (FG) into VTA, and phenotyped FG-labeled PPTg neurons by *in situ* hybridization. We found that among PPTg FG-neurons nearly 67% expressed VGluT2 mRNA, 17% expressed ChAT mRNA, and nearly 16% expressed GADs mRNA. Thus the major projection from the PPTg to the VTA is glutamatergic, with minor projections arising from cholinergic or GABAergic neurons. To determine PPTg glutamatergic postsynaptic targets in the VTA, PPTg glutamate neurons were selectively tagged with channelrhodopsin 2 (ChR2) tethered to mCherry in VGluT2::Cre mice. Axon terminals from tagged PPTg-VGluT2 neurons established asymmetric synapses mainly on dopamine neurons. We next tested whether optical stimulation of PPTg glutamate inputs to the VTA established instrumental responding. In these behavioral studies, PPTg VGluT2 neurons were transfected with either yellow fluorescent protein (VGluT2-eYFP) alone or eYFP tethered to ChR2 (VGluT2-ChR2-eYFP). Mice were implanted with optic probes aimed at the VTA and were allowed to earn VTA optical stimulation by rotating one of two response wheels. VGluT2-ChR2-eYFP mice, but not VGluT2-eYFP mice, rotated the reinforced (‘active’) wheel

significantly more often than the non-reinforced ('inactive') wheel. To confirm that wheel-turning was goal-directed, we switched the contingencies between the wheels for 4 days of reversal testing following 8 days of training. VGluT2-ChR2-eYFP mice switched to the newly reinforced wheel during the first reversal session and continued responding on this wheel for three subsequent reversal testing sessions. Together, the data suggest that (1) the majority of inputs from the PPTg to the VTA are glutamatergic; (2) within the VTA, the PPTg provides glutamatergic inputs mainly to dopamine neurons; (3) VTA selective excitation of PPTg glutamatergic inputs elicits reliable intracranial self-stimulation in VGluT2::Cre mice.

Title: Monosynatic inputs to ventral tegmental area glutamate neurons

Authors: *C. MEJIAS-APONTE[1], B. B. GARCIA IGLESIAS[2], D. J. BARKER[2], S. ZHANG[2], M. MORALES[2];

Abstract: Glutamate neurons are one of the three major cell types of the ventral tegmental area (VTA). These neurons express vesicular glutamate transporter 2 (VGluT2), a marker of glutamate neurotransmitting neurons. Like VTA dopamine and GABA, glutamate neurons send forebrain afferents to brain networks involved in psychiatry disorders including schizophrenia and addiction. To better understand the function of VTA glutamate neurons, we set to investigate their afferents. Using a transgenic mouse line that expresses Cre under the regulation of the VGluT2 promoter, we targeted VGluT2-expressing VTA neurons for monosynaptic tract-tracing using the modified pseudorabies technique. Specifically, VGluT2::Cre mice were injected with adenoviral vectors into the VTA to selectively express an avian cognate receptor, TVA, a mammalian rabies glycoprotein (RG), and the fluorescent reporter mCherry in VTA VGluT2 neurons. Three weeks after, a rabies vector modified with an avian glycoprotein and the

fluorescent reporter green fluorescent protein was injected into the VTA. The initial "starter" neurons from which afferents were identified from were delineated by co-expression of green fluorescent protein and mCherry. The neurons monosynaptically projecting to VTA VGluT2 neurons were delineated by expression of green fluorescent protein alone. Approximately one week after the rabies vector was delivered, brains were collected. Retrogradely-labeled neurons were mapped throughout the brain. Because of the ubiquitous expression of VGluT2 neurons in area surrounding the VTA, control injections were also made in a number of proximal regions including the suprammamillary, red nucleus, and interpeducular nucleus. Ongoing experiments are aimed to verify major inputs to VGluT2-VTA neurons using anterograde tracing.

Title: Brain mapping of neurons with a dual glutamatergic-GABAergic phenotype

Authors: *D. H. ROOT, H.-L. WANG, M. MORALES;
Neuronal Networks Section, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Glutamate is both a metabolic amino acid and an excitatory neurotransmitter. As a metabolic amino acid, glutamate is a substrate for protein synthesis and a substrate for the enzyme glutamic acid decarboxylase (GAD) to produce the inhibitory neurotransmitter GABA. As a neurotransmitter, glutamate is accumulated in synaptic vesicles by one of three known vesicular glutamate transporters (VGluT1, 2, and 3), while GABA is accumulated in synaptic vesicles by the vesicular GABA transporter (VGaT). The VGluTs and VGaT are incorporated into the membranes of synaptic vesicles that get concentrated in axon terminals. Upon neuronal depolarization and presynaptic calcium entry, each of these vesicles release either glutamate or GABA. Accumulating evidence indicates that VGluTs are in different neurons from those containing GAD and VGaT. Thus glutamate is largely used as signaling molecule by a set of neurons different from other neurons that use GABA as signaling molecule. However, we had identified in the ventral tegmental area a group of neurons that co-express transcripts encoding

VGluT2 and GAD. These neurons target the lateral habenula and co-release from the same axon terminal glutamate and GABA (Root et al., 2014; Nat Neurosci). In order to determine if $VGluT2^+$ GAD^+ neurons exist in other brain regions, we used a combination of double *in situ* hybridization to map neurons co-expressing VGluT2 mRNA and GAD mRNA across the rat brain. Major populations of $VGluT2^+$ GAD^+ neurons were observed in a select group of subcortical regions: the entopeduncular nucleus, lateral subregion of the supramammillary nucleus, anterior and medial subregions of the ventral tegmental area, and the posterodorsal tegmental nucleus. As all four regions in which $VGluT2^+$ GAD^+ neurons were identified have well-established projections to limbic structures, we hypothesize that $VGluT2^+$ GAD^+ neurons play unique roles in learning, memory, motivation, and emotionality. To test this hypothesis we are currently mapping the distinct circuits involving $VGluT2^+$ GAD^+ neurons. This research was supported by the intramural research program at NIDA/NIH.

Title: The lateral habenula receives an unexpected glutamatergic input from the lateral preoptic area

Authors: *D. J. BARKER[1], D. H. ROOT[2], H.-L. WANG[2], S. ZHANG[2], M. MORALES[2]; [1]Natl. Inst. On Drug Abuse- Intramural Resea, Baltimore, MD; [2]Neuronal Networks Section, Natl. Inst. on Drug Abuse, Intramural Res. Program, Baltimore, MD

Abstract: The Lateral Habenula (LHb) has been identified as a brain region that plays important roles in drug abuse, psychiatric illnesses and motivated behavior. Convergent evidence has established that the LHb receives a major input from the Lateral Preoptic Area (LPO). Although the nature of this LPO-LHb pathway hasn't bee determined, it has been prosed to be inhibitory, presumably from LPO GABAergic neurons. Here, we characterized the anatomical and functional network between the LPO and the LHb. To identify specific LPO neurons targeting the LHb, the retrograde tracer fluorogold was injected into the LHb (1% via iontophoresis). Next, we established the phenotype of the fluorogold-tagged neurons by *in situ* hybridization

detection of transcripts encoding either glutamic acid decarboxylase 65/67 mRNA (GAD, a marker of GABAergic neurons) or vesicular glutamate transporter 2 mRNA (VGluT2, a marker of glutamate neurons). Surprisingly, we found that within the total population of fluorogold-positive neurons only 15.9 ± 3.2% expressed GAD mRNA, and as many as 74.7 ± 3.2% expressed VGluT2 mRNA. These neuroanatomical findings indicate that the major projection from the LPO to the LHb is from excitatory glutamatergic neurons rather that from inhibitory GABAergic neurons, as has been previously proposed. Based on our current understanding of the habenula, this suggests that the LPO-LHb glutamatergic pathway may be important for numerous psychopathologies including depression or the aversive effects of psychostimulants. Future work will focus on the participation of the LPO-LHb glutamatergic pathway in ongoing behavior in order to specifically investigate its participation in psychiatric illness.

Title: Feeding behavior and reward are differentially induced by optogenetically activating GABAergic lateral hypothalamic projections to VTA at different stimulation frequencies

Authors: *M. F. BARBANO[1], H. WANG[2], R. WISE[2], M. MORALES[2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Neuronal networks section, NIDA/NIH, Baltimore, MD

Abstract: The lateral hypothalamus (LH) is a heterogeneous brain structure that has been classically involved in feeding, motivation and reward. Optogenetic approaches have recently confirmed that GABAergic LH neurons induce feeding and reward. It has also been shown that GABAergic projections from the LH to the ventral tegmental area (VTA) modulate feeding and compulsive sucrose seeking. However, it is still unclear if the same population of GABAergic lateral hypothalamic neurons that projects to the VTA promotes both feeding and reward. In the present study, we addressed this question by using a combination of optogenetic, behavioral, and pharmacological techniques in transgenic male mice expressing Cre recombinase under the regulation of the vesicular GABA transporter (VGaT::Cre mice). We found that VTA

photoactivation of GABAergic LH projections using low frequencies (5 Hz but not 40 Hz) promoted feeding in food sated mice. This effect was decreased by the intra-VTA administration of a mix of GABA A and B antagonists. Conversely, photostimulation of the same pathway was highly rewarding and reinforced instrumental behavior when high frequencies were used (40 but not 5Hz). The best operant performance was achieved using high frequencies of stimulation (40 Hz). The motivated operant responses were also reduced by the administration of GABA antagonists. To further characterize the reinforcing properties of low and high frequencies of stimulation on reward, we conducted a place conditioning study. Different groups of mice received continuous photostimulation with frequencies either low (5 Hz) or high (40 Hz) after entering a light-paired chamber on a three chamber apparatus. Only mice conditioned with the high frequency showed a significant preference for the light-paired chamber during training and also during subsequent testing, when the light was no longer available. These and similar findings confirm that activation of GABA fibers originating from the lateral hypothalamus and projecting to the ventral tegmental area can contribute to the rewarding and feeding-inducing effects long established by electrical stimulation studies. It is unclear if the differential effectiveness of low and high frequency stimulation reflects the activation of different subsets of GABA neurons or difference levels of responses by the same group of GABA neurons.

Title: Glutamatergic neurons from the ventral tegmental area establish multiple synapses on single parvalbumin-GABAergic interneurons in the nucleus accumbens

Authors: ***S. ZHANG**, J. QI, M. MORALES;
Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD

Abstract: The ventral tegmental area (VTA) is thought to play a role in goal directed behavior and in the reward processing of natural rewards and on several drugs of abuse (Schultz, 2002; Wise, 2004). Two populations of VTA neurons (dopaminergic neurons and GABAergic neurons) have been extensively characterized. However, recent findings indicate that the VTA has neurons

that express the vesicular glutamate transporter 2 (VGluT2). VGluT2 is integrated into membranes of synaptic vesicles for the accumulation of glutamate. The VTA-VGluT2 neurons are diverse in their biochemical composition and connectivity (Morales and Root, 2014). We recently found that nucleus accumbens (nAcc) optical stimulation of fibers from VTA-VGluT2 neurons evokes conditioned place aversion mediated by local release of GABA, which is accompanied by expression of c-Fos in parvalbumin-GABAergic interneurons (Qi et al., 2015 SfN). To determine the synaptic connectivity established by VTA-VGluT2 neurons in the nAcc, we used a combination of cell specific viral vector tracing and immunoelectron microscopy. In these studies, axons from VTA glutamatergic neurons were tagged by the *in vivo* expression of channelrhodopsin-2 [(ChR2) tethered to mCherry] in the VTA-VGluT2 neurons of VGluT2::Cre mice. By double immunolabeling and electron microscopy, we detected in the nAcc medial shell axon terminals containing immunoreactivity (IR) for both VGluT2 and mCherry, indicating that these VGluT2-IR/mCherry-IR-terminals were originated from VTA glutamatergic neurons. Further analysis of these VGluT2-IR/mCherry-IR-terminals showed that they made asymmetric (excitatory type) synapses on dendrites. Next, by triple immunoelectron microscopy, we found the VTA VGluT2 neurons established multiple synapses on a single parvalbumin-GABAergic interneuron. The mesoaccumbens glutamatergic pathway shown here to form multiple asymmetric synapses on parvalbumin-GABAergic interneuron is the first anatomically identified glutamatergic pathway to nAcc GABAergic interneurons.

Title: Glutamatergic inputs from the ventral tegmental area to nucleus accumbens drive aversion by acting on GABAergic interneurons

Authors: ***J. QI**, H.-L. WANG, S. ZHANG, D. J. BARKER, M. MORALES;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: The ventral tegmental area (VTA) is best known by its dopamine neurons, some of which project to the nucleus accumbens (nAcc). However, the VTA also has glutamatergic

neurons that innervate the nAcc. The role of this mesoaccumbens glutamatergic pathway remains unknown. Here, we report that within the nAcc, fibers from mesoaccumbens-glutamate neurons, which mostly innervate the nAcc shell, form local asymmetric synapses (Zhang et al., 2015 SfN). Photoactivation of mesoaccumbens glutamatergic fibers promotes conditioned place aversion, and establishes escape-avoidance responding in both a negative-reinforcement task and a positive-reinforcement task. Although the mesoaccumbens glutamatergic fibers lack GABAergic markers, the aversion evoked by these fibers depends on glutamate and GABA receptors, but not on dopamine receptors. The mesoaccumbens glutamatergic fibers make multiple asymmetric synapses on parvalbumin interneurons in the nAcc, and photoactivation of these mesoaccumbens glutamatergic fibers elicits activation of parvalbumin interneurons. Moreover, photoactivation of nAcc parvalbumin interneurons also promotes aversion. We conclude that mesoaccumbens glutamatergic neurons play a role in controlling inhibitory neurotransmission within the nAcc shell. The mesoaccumbens glutamatergic pathway is the first glutamatergic input to nAcc shown to mediate aversion, rather than reward.

Title: Connectivity of neural microcircuitry in frontal cortex revealed by large-scale network imaging

Authors: *J. T. TRACHTENBERG, P. GARCIA-JUNCO CLEMENTE, D. RINGACH, E. TRING;
UCLA, Los Angeles, CA

Abstract: We present a novel approach to microcircuit analysis based on resonant-scanning 2-photon imaging of large populations of identified cortical neurons in frontal cortex of behaving mice. Gcamp6-slow was used to image inhibitory neurons, using cell type-specific cre-driver lines that also expressed a red-fluorescent protein, and excitatory neurons were imaged, simultaneously, using Gcamp6-fast. Interneurons expressing vasointestinal peptide (VIP) are strongly activated during alertness, as measured by monitoring pupil diameter and running, whereas the activity of interneurons expressing somatostatin (SOM) was strongly suppressed.

Notably, fast spiking, parvalbuming (PV)-expressing interneurons and excitatory pyramidal (PYR) neurons responded heterogeneously to alertness, with half the population strongly activated in alert states and the other half strongly suppressed. When mice stopped running, these populations reversed their activities, with the formerly suppressed neurons now strongly active and the formerly active now strongly suppressed. Hereafter we refer to these cells as PV-up and PV-down, and PYR-up and PYR-down. Correlation coefficients across cell groups and across mice identify a novel and very specific microcircuit in which VIP interneurons and PYR-up neurons receive a common feedback, neuromodulatory input, possibly from adrenergic neurons in the locus coerruleus. Once activated in the alert state, VIP neurons strongly suppress PYR-down neurons. Thus, VIP interneurons appear to target a specific population of PYR neurons. In a second microcircuit revealed by our approach, presumptive thalamic input drives the activity of PV-down, PYR-down, and SOM interneurons, and not other cell types. These findings reveal a novel and specific microcircuitry in frontal cortex that is readily testable. Significantly, we find that cell populations once thought to be fairly homogeneous are in fact bistable and that this bistability underlies brain states associated with alertness and quiescence.

Title: Epigenetics of social anxiety disorder: Oxytocin receptor gene (OXTR) hypomethylation as a risk marker?

Authors: *C. ZIEGLER[1], I. LAEGER[2], S. STEVENS[3], K.-P. LESCH[4], V. AROLT[2], A. GERLACH[3], J. DECKERT[1], P. ZWANZGER[2], K. DOMSCHKE[1];
[1]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Universityclinic Würzburg, Wuerzburg, Germany; [2]Dept. of Psychiatry and Psychosomatics, Muenster, Germany; [3]Dept. of Clin. Psychology and Psychotherapy, Cologne, Germany; [4]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Div. of Mol. Psychiatry, Lab. of Translational Neurosci., Wuerzburg, Germany

Abstract: Social anxiety disorder (SAD) is an anxiety disorder affecting 6.8% of the US population. Oxytocin (OXT) is a neuropeptide produced in the hypothalamic paraventricular and supraoptic nucleus. It binds to a G protein-coupled receptor (OXTR) widely expressed in the central nervous system. The oxytocin peptide has been suggested as a promising anxiolytic pharmacotherapeutic agent in disorders related to social dysfunction. The oxytocin receptor gene (OXTR) located on chromosome 3p25.3 has been implicated in social cognition and behavior. The A allele of the 6930G>A (rs53576) variant was associated with non-beneficial social traits in humans. Recently, epigenetic modifications have been suggested as dynamic regulatory mechanisms of gene expression. The present study for the first time investigates the role of OXTR methylation in SAD on a categorical as well as a dimensional phenotype level. One-hundred and ten patients with SAD (f=76; age: 33.0+1.0) and 110 age- and sex-matched healthy controls were analyzed for OXTR methylation at 12 CpG sites located in the protein-coding region of the gene by direct sequencing of sodium bisulfite converted DNA extracted from whole blood. Dimensional measures of social anxiety severity were ascertained in both patients and controls using the Social Phobia Scale (SPS) and the Social Interaction Anxiety Scale (SIAS). Furthermore, patients and controls were genotyped for the 6930G>A (rs53576) variant located in the third intron of the OXTR gene. Patients with social anxiety disorder showed significantly decreased overall OXTR methylation as compared to healthy controls, particularly conferred by methylation at a single CpG dinucleotide CpG 3 ($F=8.111$; $p<0.001$). Furthermore, methylation at this CpG site negatively correlated with SPS scores ($r=-0.393$; $p<0.001$) and SIAS scores ($r=-0.399$; $p<0.001$) across patients and controls. A-allele carriers of the 6930G>A variant showed significant decreased overall OXTR methylation across patients and controls ($F=5.045$; $p=0.007$). The present results provide multi-level evidence for a role of OXTR hypomethylation in social anxiety disorder. A hypomethylation of the OXTR gene potentially leads to an up-regulation of the gene expression which could serve as a compensatory mechanism for lower overall oxytocin levels found in patients with social anxiety disorder. Anyway, given robust replication, OXTR hypomethylation could serve as a peripheral biomarker of disease risk and/or severity and might finally allow for indicated preventive interventions as well as more personalized treatment options targeting the oxytocin system.

Title: Effect of a single episode of footshock on anxiety and neuropeptide precursors in the striatum and extended amygdala

Authors: *H. WANG[1], S. LI[1], G. J. KIROUAC[1,2];
[1]Oral Biol., [2]Psychiatry, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Corticotropin releasing factor (CRF) and dynorphin are neuropeptides that have been associated with negative emotional states. Experimental evidence indicates that dynorphin neurons located in the nucleus accumbens (NAc) and CRF neurons in the bed nucleus of the stria terminalis (BST) and the amygdala mediate the behavioral effects produced 24-48 hrs after exposure to a stressful episode. The present study was done to evaluate if changes in the levels of the mRNA for these peptides in the striatum, BST, and amygdala were associated with the long-lasting anxiety induced in a subset of rats exposed to moderately intense footshocks. On day 1, shocked rats were exposed to footshocks (5 × 2 s of 1.5 mA presented randomly over 3 min), whereas nonshocked (NS) rats were placed in the shock chamber for 5 min. On day 2, rats were tested in a novel chamber and according to the amount of time spent immobile, shocked rats were grouped as high responders (HR; immobility > 60%) or low responders (LR; immobility < 40%). On day 3, fear to the shock context was assessed by measuring immobility to the shock chamber for 5 min. On days 10 & 11, the elevated T-maze (ETM) was used to assess avoidance (a measure of anxiety) and escape (a measure of helplessness). On day 14, the rats were anesthetized and the amygdala, BST, NAc and caudate putamen were removed for analysis using real-time RT-PCR. HR displayed long-lasting anxiety in the elevated T-maze whereas LR had low levels of anxiety similar to NS rats. An enhanced level of CRF mRNA was detected in the amygdala of the HR compared to LR and NS rats. In contrast, CRF, prodynorphin and proenkephalin mRNA levels in the striatum, BST and amygdala were not different between HR, LR and NS rats. This study provides evidence that CRF neurons in the amygdala play a role in the long-lasting anxiety produced in a subset of rats exposed to footshocks.

Title: Effect of progesterone withdrawal on experimental anxiety and hypothalamus - pituitary-adrenal axis in Wistar and Wistar Kyoto in intact female rats

Authors: *D. M. ISLAS[1], P. DE GORTARI[1], N. VEGA-RIVERA[1], C. LÓPEZ-RUBALCAVA[2], G. UGALDE-FUENTES[1], E. ESTRADA-CAMARENA[1];
[1]Inst. Nacional De Psiquiatria, México, Mexico; [2]Ctr. de Investigación y Estudios Avanzados del IPN, México, D.F., Mexico

Abstract: Women with Premenstrual Dysphoric Disorder (PMDD) showed high levels of anxiety and a blunted response to stress of serum corticosterone (CORT) and Allopregnanole (ALLO) levels during the luteal phase of the menstrual cycle (Girdler et al., 2007). Here, Wistar Kyoto (WKY) rats were used to evaluate the effect of progesterone withdrawal (PW), as an animal model of PMDD, on the Hypothalamus-Pituitary-Adrenal axis (HPA) response through CRH, GR mRNA expression in PVN and Hippocampus as well as CORT serum levels. Also, the mRNA expression of the 5α-reductase type 2 (5αRED2) enzyme in hippocampus and PVN and ALLO serum levels was determined. WKY strain present HPA axis hyper-reactivity toward stressful stimuli in relation to Wistar (W) strain and show high levels of anxiety- and depression-like behaviors, two traits of PMDD. Intact female Wistar (as a control strain) and WKY rats (250-300g) were randomly assigned to independent groups: one treated with vehicle (corn-oil) and other with progesterone (0.5 mg/kg, s.c., daily for 5 days) per strain. Twenty-four hours after a last administration of hormonal treatment, animals were tested in the Burying Behavior Test (BBT) and euthanized by decapitation 60 min later. Brain and blood were immediately collected and stored at -70 ◦C for posterior analysis of CRH, GR, 5αRED2 mRNA expression by RT-PCR and CORT and ALLO by commercial ELISA kits. Results showed that anxiety like behavior was augmented in both strains as a consequence of PW. In vehicle treated groups higher levels of serum CORT, CRH and GR mRNA expression and lower levels of ALLO were observed in WKY respect to W ($p<0.05$); no differences in 5αRED2 expression were noted. In response to PW, hippocampal CRH expression was augmented in WKY when compare against its proper control ($p<0.05$) and no changes were observed in GR and 5αRED2 expression. On the contrary, in PVN of WKY both CRH and GR expression decrease in PW ($p<0.05$) while no changes in W were observed. 5αRED2 mRNA enzyme expression was increased in W but not in WKY ($p<0.05$). Finally CORT and ALLO levels were similar to the vehicle control group in both strains, suggesting a no response to PW. The fact that 5αRED2 mRNA expression and CORT and ALLO did not change in response to PW in WKY rats suggests that this strain might be useful to establish neurobiological correlates that contribute to PMDD study.

Title: Role of arginine vasopressin on the amygdaloid modulation of fear and anxiety in the rat

Authors: *O. R. HERNANDEZ PEREZ[1], E. PALOMARES[2], M. CRESPO RAMIREZ[2], M. PÉREZ DE LA MORA[2], K. FUXE[3];
[1]Univ. Nacionalautonoma De México, México, Mexico; [2]Neurociencias Cognitivas, Inst. de Fisiología Celular, Mexico City, Mexico; [3]Div. of Cell. and Mol. Neurochemistry, Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: The amygdala plays a central role in fear and anxiety. Vasopressinergic fibers project from the hypothalamus and strongly innervate medial amygdala (MeA) and bed nucleus of the stria terminalis (BNST). Three different receptors have been so far identified for vasopressin effects (V1a, V1b and V2 receptors). V1b receptor has been identified within the central amygdaloid nucleus and its participation in the amygdaloid modulation of anxiety has been suggested. Behaviorally, the intra-amygdaloid infusion of arginine vasopressin agonists and antagonists elicits anxiogenic and anxiolytic effects respectively on conditioned models of anxiety. However, the role of arginine vasopressin in unconditioned anxiety is less known and even contradictory. The aim of this study was to evaluate the behavior of rats in the elevated plus-maze and the shock-probe burying test following vasopressin administration (1 an 10 ng/side) within the central amygdaloid nucleus. The effects of the simultaneous administration of arginine vasopressin (1 ng/side) and SSR149415 (1 and 10 ng/side), a specific V1b vassopresin receptor antagonist, were also tested in the same paradigms and dark light box. The results showed that the bilateral microinjection of arginine vasopressin at lower (1ng /side) but not at higher (10 ng/side) doses significantly increased the time spent by the rats in the open arms of the elevated plus-maze as compared with their saline-treated controls. No effects of this treatment were observed on the total number of entries into open + closed arms of the maze. In

contrast, the infusion of arginine vasopressin (1ng/side) increased the burying behavior in the shock-probe burying test. Interestingly, this last behavior was not observed when SSR149415 was administered simultaneously with vasopressin. Our results suggest, that the bilateral administration of arginine vasopressin is dependent effects of the test used to assess anxiety and seems to have effects on higher aversion paradigms while those that are less aversive its after effects seem to be low or absence of such.

Title: Cannabinoid receptor 2 activation and anxiety after repeated social defeat stress

Authors: *H. J. STRATTON[1], D. ALLEN[3], J. WU[2];
[1]Neurol. Res., [2]Barrow Neurolog. Inst., Phoenix, AZ; [3]Arizona State Univ., Tempe, AZ

Abstract: The United States population has a 12-month incidence for anxiety-related disorders of 18.1% and affects more than 40 million individuals nationwide. Components of the behavioral response to stressful stimuli are mediated by G-Protein Coupled Receptors (GPCR's) of the endogenous cannabinoid system (ECS). These receptors have been demonstrated to act as primary regulators of behavioral and cellular alterations following exposure to stressful stimuli. Recent evidence has localized cannabinoid receptor 2 (CB2) to the CNS where it has been found on neurons and glial cells. This receptor is of particular interest because it has been shown to alter the activity of DA neurons within the VTA, which is a primary regulatory nucleus in the expression of anxiety behavior (Figure 1). Increased DA neuron firing originating in the VTA is strongly associated with exposure to social defeat stress and preliminary data shows mice lacking the CB2 receptor demonstrate an enhanced to response to social defeat (Figure 2). This effect is potentially driven by CB2 activation altering DA neuron output, which indicates a potential role for this receptor in modulating VTA DA neuronal output to reduce expression of pathological levels of anxiety. Behavioral evidence suggests CB2 over-expression produces an anxiety-resistant phenotype and that application of CB2 specific agonist JWH133 results in reduced expression of anxiety behavior in non-stressed mice. Additionally, data obtained from dissociated single DA neurons from the VTA demonstrated that application of the JWH-133

decreased the firing rate of spontaneous action potentials from these neurons. This study sought to determine the effects of CB2 activation on the expression of anxiety behavior as well as the activity of VTA DA neurons in socially stressed mice. The open field test was used to determine the effects of systemic application of JWH133 on the expression of anxiety behavior in C57BL/6J mice following repeated submaximal social defeat stress. Multi-electrode field recording of VTA slices in the same mice were employed to determine the effects of JWH133 on this social defeat stress-induced altered activity. CB2-/- mice underwent the same experimental conditions with a saline vehicle to compare the expression of anxiety behavior and alteration in VTA DA firing to wild type littermates following social stress. Results indicate a possible role for CB2 receptor activation in the reduction of anxiety behavior and the restoration of normal firing patterns in the VTA following social stress.

Title: Sex difference in anxiety-like effects of the THC agonist CP55,940

Authors: *H. T. FRENCH[1], A. KLAMBATSEN[2], S. JENAB[1], V. QUINONES-JENAB[2]; [2]Psychology, [1]Hunter Col., New York, NY

Abstract: Aim: Sexual dimorphism exists at different levels of the cannabinoid system and THC induced responses, including receptor distribution, metabolic processing of THC, and analgesic responses. Anxiety responses in both human and animal males are dose dependent: low acute doses of cannabinoids are anxiolytic while high and/or chronic doses are anxiogenic. In this study we aimed to examine if the biphasic behavioral effects of cannabinoids that have been demonstrated in males are also present in females. Methods: Male and female Wistar rats (8 weeks old) received 0, 0.001, 0.01, 0.075 or 0.125 mg/kg i.p. of the THC agonist CP55,940_n=10-11 per group. Thirty minutes later, animals were placed in the elevated plus maze (EPM) for 10 minutes, and their behavior analyzed by Med Associates tracking software. Results: A significant main effect of CP55,940 doses was observed [$F(4, 92) = 6.863$, $p < 0.01$]; 0.075 mg/kg showed a significant reduction in percent time in open arms compared to vehicle ($p = 0.05$). Furthermore, 0.001mg/kg showed significantly more time in open arms than: 0.01 ($p = 0.045$), 0.075 ($p < 0.01$) and 0.125 ($p < 0.01$). Conclusion: Sex differences were observed in the

effect of CP55,940 on anxiogenic and anxiolytic responses. Although males showed biphasic dose dependent responses to this THC agonist, female rats showed only an anxiogenic response to CP55,940. Our study is in agreement with previous studies suggesting sex-dependent behavioral effects of cannabinoids. Further research is needed to understand the underlying mechanisms responsible for these differences.

Title: Loss of forebrain 5-HT1A receptors results in a depression but not anxiety-like phenotype

Authors: *A. GARCIA[1], S. CANETTA[1], B. P. GUIARD[2], A. GARDIER[2], C. KELLENDONK[1], A. DRANOVSKY[1], E. D. LEONARDO[1];
[1]Integrative neuroscience, Columbia University, New York Psychiatry Inst., New York, NY;
[2]Faculté Pharmacie, Univ. Paris Sud, Chatenay-Malabry, F-92296, France., Paris, France

Abstract: Despite significant evidence linking 5-HT_{1A} receptor function to depression in humans, to date rodent models of 5-HT_{1A} function have primarily focused on anxiety. This focus may be due to the fact that early studies with the 5-HT_{1A} receptor KO mouse described a significant anxiety phenotype with no clear depressive phenotype. Interestingly, the anxiety phenotype is developmentally mediated as normal expression of 5-HT_{1A} receptors is required during the 2nd and 3rd week of life for the emergence of normal anxiety, with mice lacking functional 5-HT_{1A} receptors during this time developing pathological levels of anxiety. Recently, studies from our lab have recapitulated the anxiety phenotype of the whole-brain KO mice in 5-HT_{1A} autoreceptor KO mice. Conversely, we have previously found that whole life suppression of 5-HT_{1A} heteroreceptors affect responses to forced swim stress, without effects on anxiety-like behavior. These results coupled with the absence of a phenotype when heteroreceptors are

repressed in adult animals strongly suggested that variation in 5-HT_{1A} heteroreceptor function during development would have lasting effects on an animals baseline behavior in a manner that was distinct from that observed with autoreceptor manipulations Here, we use a genetic mouse system to independently manipulate 5-HT_{1A} heteroreceptors with temporal and spatial specificity to understand their function within raphe-forebrain circuitry. We demonstrate that mice lacking 5-HT_{1A} heteroreceptors display increased behavioral despair and anhedonia while maintaining normal anxiety levels. This behavioral phenotype was accompanied by changes in the response of prefrontal cortex neurons to stress and changes in raphe firing rates. We further found that suppression of 5-HT_{1A} heteroreceptors during adolescence was sufficient to confer these long-lasting behavioral and physiological effects. Our results demonstrate a developmentally mediated depression related phenotype that results from altered 5-HT_{1A} signaling in the forebrain. We also provide evidence to support the idea that, 5-HT_{1A} heteroreceptors in the prefrontal cortex might be responsible for this phenotype.

Title: L. reuteri decreases baseline anxiety, alters fear-related memory, and buffers stress-induced anxiety in C57/BL6 mice

Authors: *R. J. PENDRY[1], R. P. MADIGAN[2], M. D. ERIKSSON[2], J. D. WHITE[2], M. J. EIMERBRINK[2], M. J. CHUMLEY[3], G. W. BOEHM[2];
[2]Psychology, [3]Biol., [1]Texas Christian Univ., Fort Worth, TX

Abstract: This research explored how chronic ingestion of *L. reuteri* altered baseline anxiety, fear-related memory, and whether or not *L. reuteri* could protect against stress induced anxiety. All animals were weaned between 21 and 28 days of age, and were taught to self-administer 0.5 mL of a 10% sucrose MRS broth solution within approximately 20 minutes. Once trained, animals were randomly assigned to either the probiotic or vehicle treatment condition. Animals in the probiotic condition received 0.5 mL of the sucrose solution that contained the 10^9 cfu of *L. reuteri,* while vehicle-treated animals received sucrose solution only. Treatment was maintained until all animals in the cohort were at least 70 days of age, after which we began behavioral

testing. To assess anxiety behaviors, animals were first tested in an elevated zero maze, followed by two days of open field testing. Separate batches of animals were tested in both a contextual and delay conditioning paradigm. Finally, a third batch of animals was tested using a 2x2 design (treatment x stressor), during which animals from each respective treatment group was either exposed to an environmental stressor in a conditioning chamber or placed in the chamber for a comparable duration, without the stressor. To assess potential biological differences mediating behavioral changes, we evaluated peripheral corticosterone and specific neurotransmitter receptor expression in the hippocampus and amygdala. Results indicate that treatment with *L. reuteri* has the ability to decrease expression of baseline anxiety behaviors, alter fear related memory, and protect against stress-induced exaggerations of anxiety behaviors. Additionally, these behavioral changes corresponded to differential gene/protein expression. Overall, results from these studies indicate that repeated ingestion of *L. reuteri* can alter behavioral and physiological measures associated with anxiety and fear-related memory.

Title: Dissociated linkage between serotonin related gene polymorphisms, fearful voice and face processing, amygdala activity and trait anxiety: a combined fmri and erp study

Authors: *Y.-C. CHEN[1], C. CHEN[1], C.-H. HU[1], Y. CHENG[1,2];
[1]Inst. of neuroscience, Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Dept. of Rehabil., Natl. Yang-Ming Univ., Yilan, Taiwan

Abstract: Serotonin transporter polymorphism (5-HTTLPR) usually links anxiety and amygdala reactivity. However, their relations seem to be mixed. Here, we enrolled 95 adults, who varied n threat sensitivity (Spielberger trait anxiety scale), and examining the amygdala reactivity in response to the conscious and nonconscious (backwardly masked) perception of fearful and angry faces and also recording the mismatch negativity (MMN) to emotionally spoken syllables *dada*. There were 12 participants (6 males) in the ll group, 48 participants (20 males) in the ls group and 35 participants (23 males) in the ss group. When the fearful MMN were treated as a latent variable, genotype was treated as independent variable, and errors were assumed to be

uncorrelated, we performed path analysis to test whether the influence of the 5-HTTLPR polymorphism on trait anxiety was dependent on its influence on the amygdala, and to find the best-fitting model from three possible candidates: (1) TPH23 amygdala 3 CGI-I; (2) TPH2 3 CGI-I 3 amygdala; (3) TPH23 amygdala, TPH2 3 CGI-I (Figure 1).

Title: Conditional knockout of ASIC1a in ASIC4-positive neurons reverses innate fear and anxiety phenotypes in ASIC4 KO

Authors: *Y.-C. CHIEN[1,2], S.-H. LIN[1], C.-C. CHEN[1,3];
[1]Inst. of Biomed. Sci., Academia Sinica/Institute of Biomed. Sci., Taipei, Taiwan; [2]Program in Mol. Medicine, Natl. Yang-Ming Univ. and Academia Sinica, Taipei Taiwan, Taiwan; [3]Natl. Comprehesive Mouse Phenotyping and Drug Testing Ctr., Taiwan Mouse Clin., Taipei, Taiwan

Abstract: ASIC4 is expressed in many nuclei in the CNS, however, its physiological function is still unclear. To probe the role of ASIC4, we generated an ASIC4-knockout/Cre-ERT2-knockin mouse line. Compared with wild-type littermates, ASIC4 knockouts showed higher levels of fear response (freezing) to the presence of 2,4,5-trimethylthiazoline (TMT), a synthetic analog of red fox feces; ASIC4 knockouts also demonstrated higher levels of anxiety-like behaviors in the OF and EPM task. These phenotypes were opposite to the ASIC1a knockout mice, which showed lower levels of TMT-induced fear and less anxiety-like behaviors in these two mouse anxiety tasks. Based on genetic mapping results, we hypothesized that ASIC4 in the CR/VIP-positive cortical interneurons (or the NG2-positive glia) might modulate innate fear and anxiety state by counteracting the membrane expression and thus the activity of ASIC1a. To test this working hypothesis, we first generated ASIC1a-/-::ASIC4-/- double knockouts and screened the phenotypes in the TMT, OF and EPM task. Results indicated that ASIC1a-/-::ASIC4-/- double knockouts showed ASIC1a-like phenotypes in the innate fear and anxiety tests. Further, we tested the hypothesis by breeding an ASIC4Cre-ERT2/+::ASIC1afloxed/floxed mouse line. After 14 days tamoxifen treatment, we screened the innate fear and anxiety phenotypes between ASIC4Cre-ERT2/+::ASIC1afloxed/floxed and ASIC4Cre-ERT2/+::ASIC1a+/+ mice. ASIC4Cre-ERT2/+::ASIC1afloxed/floxed mice demonstrated the same phenotypes as ASIC1a

conventional knockouts. Our conditional knockout results supported that ASIC1a in ASIC4-positive neurons is responsible for the fear/anxiety phenotypes.

Title: Corticotropin-releasing factor modulates ultrasonic calling behavior and anxiety in rats

Authors: *J. O. TAYLOR, V. GJINI, A. LEMKE, B. G. COOPER;
TCU, Fort Worth, TX

Abstract: In a given year, 18% of the adult population in the United States will suffer from an anxiety disorder, and the rate increases to 29% over a person's lifetime. This prevalence rate illustrates the need to develop and improve therapeutic treatments for anxiety disorders. Toward that end, we seek to refine behavioral measures of anxiety in laboratory animals by determining whether specific vocalizations occur when animals are in an elevated state of anxiety. Rat ultrasonic vocalizations (USVs) broadly signal affective state. They can be categorized into one of two frequency ranges, 22 kHz or 50 kHz. The 22 kHz calls are more closely associated with negative affect states, whereas the 50 kHz range is associated with positive affective states. The 50 kHz range consists of calls that can be categorized into multiple subtypes; one USV subtype, flat calls, which are constant frequency 50 kHz (CF 50 kHz) calls, are not viewed as signaling a particular emotional state. We have been testing the novel hypothesis that these calls are promoted by anxiogenic situations. We tested this hypothesis using a behavioral paradigm where animals are introduced to a novel environment and then exposed to a series of six, temporally predictable, unsignalled footshocks (UFS). Exposure to the novel environment and initial footshocks is the anxiogenic component of the test, and the repeated footshocks should generate fear-related behaviors. In the UFS paradigm, rats initially produce CF 50 kHz calls (baseline and shocks 1-3) and then increase the production of 22 kHz calls following shocks 3-6. In the current experiment, rats were given intraventricular administration of corticotropin-releasing factor (CRF) or vehicle control 30 min prior to UFS testing. We hypothesized that CRF would increase CF 50 kHz USV production during the baseline and initial footshocks. Consistent with our hypothesis, during the UFS behavioral test, pretreatment with CRF increased CF 50 kHz USV production during the baseline and initial footshocks. During the testing, CRF administration

reduced rearing behaviors but not change freezing. Animals were subsequently tested on the elevated plus maze. CRF pretreatment decreased time spent in open arms compared to vehicle control infusion. These preliminary results provide further support for the hypothesis that CF 50 kHz USVs are produced when animals are in an elevated state of anxiety, and suggest that this USV classification provides a valuable behavioral measure for animal models of anxiety disorders.

Title: Effects of acute pharmacogenetic activation of excitatory cortical neurons on anxiety and depressive-like behavior

Authors: *S. PATI, V. SINGH, V. VAIDYA;
Tata Inst. of Fundamental Res., Mumbai, India

Abstract: A balance between excitatory and inhibitory neurotransmission in local cortical microcircuits has been hypothesized to play a key role in adaptive stress responses. Such a balance of inhibition-excitation may also be important in the maintenance of a normal affective state. Recent results suggest that altering this balance within cortical microcircuits by acute pharmacogenetic inhibition of cortical inhibitory interneurons results in increased anxiety-like behavior (Soumier and Sibille, 2014). However, effects of direct activation of cortical excitatory neurons on anxiety and depressive-like behavior remain currently unknown. In the present study, we examined the effects of acute activation of neurotransmission within CamKIIα-positive excitatory neurons on anxiety and depressive-like behavior. We used a genetic strategy in mice to express the Gq coupled designer receptor exclusively activated by designer drugs (DREADD-hM3Dq) in cortical excitatory neurons of the forebrain using a Ca2+/ Calmodulin-dependent protein kinase II (CamKIIα) driver. Our results suggest that acute administration of the DREADD agonist clozapine-N-oxide (0.5 mg/ Kg) leads to decreased anxiety like behavior in the open field test, elevated plus maze and light-dark avoidance test. However, no apparent change in depressive-like behavior was observed in the tail-suspension test and forced swim test.

Future studies are aimed at investigating the role of increased excitatory neurotransmission through CamKIIα-positive neurons in mediating adaptive stress response.

Title: Tau pathology induced anxiety symptoms through impairing vGAT-GABA system in mice hippocampus CA3

Authors: *X. LI[1], J. WANG[2];
[1]Key Lab. of Ministry of Educ. of Neurolo, HUBEI, China; [2]Pathophysiology Dept., Key Lab. of Ministry of Educ. of Neurolog. Dis., HUBEI, China

Abstract: Whether human tau pathology played a role in anxiety disorder in AD was unknown. Mice which were overexpressed with tau40-GFP on hippocampus CA3 showed significantly anxiety disorder. Abnormal neuronal network and impaired inhibitory tones were observed on CA3 regions. Extracellular GABA in CA3 decreased significantly in tau40 group on free-moving microdialysis test. We applied vGAT-ChR2 tg mice, optogenetically excited vGAT positive neurons impaired by tau in CA3 appeared obvious anxiolytic effect. In our study impaired GABA is related to the decline protein level of vGAT on tau infected mice. We used overexpression vGAT-RFP AAV, artificially restored vGAT level in CA3 could rescue tau induced anxiety behaviors. Collectively, these data reveal that tau pathology induced anxiety symptoms through impairing vGAT-GABA system in mice hippocampus CA3.

Title: Chronic administration of exogenous ketone supplementation reduces anxiety in Sprague-Dawley rats

Authors: ***C. ARI**, A. POFF, S. KESL, C. GOLDHAGEN, C. MURDUN, D. D`AGOSTINO; Mol. Pharmacol. and Physiol., Hyperbaric Biomed. Res. Laboratory, Univ. of South Florida, Tampa, FL

Abstract: Nutritional ketosis has proven effective for seizure disorders and other neurological disorders. Anecdotal reports suggest that nutritional ketosis can promote a reduction in anxiety. The focus of this study was to determine the effects of ketone supplementation on anxiety. We tested three exogenous ketone supplements fed chronically to Sprague-Dawley rats prior to assessment of anxiety measures. A total of 47 male Sprague-Dawley rats were fed for 83 days with either standard rodent chow (SD) or SD + ketone supplementation. Four treatment groups included low-dose ketone ester (1,3-butanediol-acetoacetate diester, 10g/kg/day, LKE), high dose ketone ester (25g/kg/day, HKE), beta-hydroxybutyrate-mineral salt (BHB-S), and BHB-S +medium chain triglyceride (BHB-S+MCT). Elevated plus maze (Coulbourn Instruments) was used to assess anxiety-related behavior of the rats. Behavioral data collection was conducted manually by a blinded observer and a video-tracking system (SMART V3.0 PLATFORM, Harvard Apparatus). Time spent (p=0.017;0.021, respectively) and distance traveled (p=0.03; 0.02, respectively) in open arms were significantly more in BHB-S and BHB-S+MCT groups, while time spent (p=0.011; 0.005, respectively) and distance traveled (p=0.002 in BHB-S group) in closed arms were significantly less in these groups, compared to control (SD). Latency to first entrance to closed arms was significantly higher in HKE, BHB-S and BHB-S+MCT groups (p=0.037; 0.035; 0.015, respectively). Blood ketone levels were elevated in all ketone supplement treatment groups similar to levels reported previously with a ketogenic diet. We conclude that chronic administration of exogenous ketone supplementation reduced anxiety in Sprague-Dawley rats.

Title: Local administration of serotonin in the thalamic reticular nucleus induces anxiety in rat via 5HT1A receptor

Authors: *M. GARCIA-RAMIREZ, G. AVILA, B. DEL RIO;
ENCB-IPN, DF, Mexico, Mexico

Abstract: The Reticular Thalamic nucleus (RTn), a thin sheet of GABAergic neurons located between the external medullary lamina and the internal capsule of the thalamus, has been shown has a role to regulate flow of information between thalamus and cortex and serves a direct role in process of attention, arousal and sleep control (McCormick and Wang, 1991; Rodrigo-Angulo et al., 2008). RTn receive serotonergic projections from supralemniscal nucleus and express two major postsynaptic 5-HT receptors, 5-HT1A and 5-HT2A receptors, 5HT1A receptor being the most abundant (Rodriguez J et al., 2011). The local application of serotonin (5HT) at RTn suppress the burst firing of RTn neurons, resulting in single fire spike seen during arousal and attentive state. The first purpose of this study was to known the effect of 5HT application at RTn on anxiety behavior, the second purpose is explore if 5HT1A is related with these response. Rats were implanted unilaterally with a cannula in the RTn and infused with 5HT at different doses (1.17-117 nM). Anxiety was tested by the Shock Burying electrode Test (SBT), Elevated Plus Maze (EPM) and Social Interaction (SI). Motor activity was measured in automated activity counters after the end of SBT, EPM or SI. All doses of serotonin consistently produced anxiety, viewed as decreased in time in open arms and increased in time of frozen behavior in SBT and decreased time in SI. Motor activity was not affected with any dose. Anxiety induced by 5HT was reverted by previous administration of WAY 100635 (an antagonist 5HT1A). In conclusion these findings suggest a serotonergic involvement in anxiety via 5HT1A receptor. García-Ramirez M is fellow of COFAA

Title: Nucleus accumbens shell, but not core, regulates the expression of discriminative conditioned

Authors: *P. T. PIANTADOSI, D. C. M. YEATES, S. B. FLORESCO;
Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Motivated behavior can be interrupted by the presentation of a previously conditioned, fear-inducing stimulus, a phenomenon known as conditioned suppression. The contribution of amygdala and prefrontal cortical circuitries to various aspects of conditioned fear and suppression has been well defined. The nucleus accumbens (NAc) is a major projection target of both of these regions, yet considerably less is known about the functional role of different accumbens subregions to aversive learning generally, and conditioned suppression specifically. Here we investigated whether two subregions of the NAc, the core (NAcC) and the shell (NAcS), are necessary for the appropriate discriminative expression of conditioned suppression. Male Long Evans rats were trained to lever press for sucrose reward on a VI-60 reinforcement schedule. They were then subjected to discriminative fear conditioning entailing eight, 30s presentations each of a CS+ (9kHz tone and flashing houselight terminating with 0.5mA/0.5s footshock) and a CS- (1kHz tone and continuous cue lights, no shock), without access to sucrose. Two days later, rats underwent an expression test session during which each CS was presented four times during VI-60 lever pressing for sucrose. The suppression of lever pressing during each CS served as the index of conditioned fear. Rats received inactivation (baclofen/muscimol; 75ng each/0.3µl saline per side) or saline infusion prior to the expression test phase of the task. Control rats in each condition (NAcC or NAcS) displayed appropriate discrimination, suppressing lever pressing during the CS+ exclusively. Inactivation of NAcS dramatically reduced conditioned suppression during CS+ presentation, but did not induce a non-specific disinhibition of lever pressing. In comparison, inactivation of NAcC had no impact on the ability to appropriately suppress appetitive responding in the face of an aversive stimulus, but did reduce food-seeking behavior as measured by a reduction in lever pressing. These results are in keeping with the particular role for NAcS, but not NAcC, in response inhibition and suggest that, in addition to facilitating certain aspects of reward-related behavior, the NAcS also plays a key role in reorganizing behavior in response to aversive stimuli. Given that we and others have reported a similar effect following prelimbic (PL) medial prefrontal cortex inactivation, future experiments will attempt to dissect this potential circuit level interaction.

Title: Blocking of orexin receptors in the paraventricular thalamus has no effect on conditioned fear but has anxiolytic effects

Authors: X. DONG[1], S. LI[1], Y. LI[2], *G. J. KIROUAC[1];
[1]Oral Biol. and Psychiatry, Col. of Dent., Winnipeg, MB, Canada; [2]Key Lab. of Mental Hlth., Inst. of Psychology, Beijing, China

Abstract: Fear is an emotional response to an imminent danger whereas anxiety is a response to an unknown threat. The paraventricular nucleus of the thalamus (PVT) projects strongly to the central nucleus of the amygdala that contains the neurons that produce the coordinated fear response and recent experimental evidence indicates a role for the PVT in conditioned fear. Furthermore, the PVT receives a dense orexin input, a neuropeptide that regulates arousal, and injections of orexin antagonists in the PVT have anxiolytic effects. The present study was done to determine if administration of a dual orexin receptor antagonist (DORA) in the region of the PVT interferes with the expression of fear in rats conditioned using cued or contextual paradigms. In the cued conditioning experiment, rats were exposed to six 0.65 mA 0.5 s footshocks co-terminating with tones (70 dB at 5 kHz for 30 s). Twenty four hours later, fear expression (freezing) to the tone alone was measured after the infusion of different doses of the DORA in the PVT. In the contextual conditioning experiment, rats were exposed to five 1.5 mA 5 s footshocks over 10 min. Twenty four hours later, fear expression to the shock context was assessed in rats that received infusion of the DORA in the PVT. Two weeks later, the contextual conditioned rats were used to determine if the DORA has anxiolytic effects in the social interaction and open field tests. Infusion of 0.5 µl of a DORA named N-biphenyl-2-yl-1-{[(1-methyl-1H-benzimidazol-2yl)sulfanyl] acetyl}-L-prolinamide at a concentration of 0.1, 1.0, and 10 nmol had no effect on the freezing produced by the auditory cue or the context previously associated with footshocks. In contrast, the 1.0 and 10 nmol doses were anxiolytic in the social interaction test but not in the open field test. The results of the present study do not support a role for orexin receptors in the PVT in the expression of cued or contextual learned fear. The finding that blocking of orexin receptors in the PVT region reduces anxiety is consistent with other studies indicating a role for orexins in the PVT in anxiety-like behaviors.

Title: A neuropeptidergic trace of acute stress in a central fear circuit switches active to passive coping strategies

Authors: *P. PLIOTA[1], F. GRÖSSL[1], V. BÖHM[1], J. GRIESSNER[1,2], W. HAUBENSAK[1]; [1]Res. Inst. of Mol. Pathology (IMP), Vienna, Austria; [2]Med. Univ. of Vienna, Vienna, Austria

Abstract: Survival critically depends on optimizing behavioral strategies for avoiding threats. Animals learn from aversive experiences that specific cues predict danger and best be avoided. In the absence of such discrete cues, however, the threat remains unpredictable. In these cases the animal adapts by switching from active to more passive behaviors. Here, we developed a behavioral paradigm to study these behavioral effects of acute stress on subsequent environmental challenges on mice. We used molecular, pharmaco-, optogenetic and electrophysiological methods to dissect the underlying mechanisms in central amygdala (CE) - a key structure for fear behaviors. Quantitative cholera toxin B retrograde tracing identified the paraventricular thalamus (PVT) - a structure being implicated in stress - as one of the major inputs to the CE. Site-specific lesions and projection-specific optogenetic manipulation indicated that the PVT-CE connection is involved in behavioral effects of acute stress. Combining electrophysiology with optogenetics, we observed that PVT asymmetrically innervates two antagonistic circuits in CE. Our data support the notion, that acute stress experience activates PVT-CE projections and releases a local neuropeptidergic signal, that modulates circuit dynamics in a synergistic manner, leading to a switch from active to passive coping behaviors.

Title: Effects of CB1 receptor agonism and antagonism on fear and stress responses in adult intact, ovariectomized, and estradiol-treated female rats

Authors: *J. J. SIMONE[1], B. L. MALIVOIRE[2], C. M. MCCORMICK[3];
[1]Biol. Sci., Brock Univ., St Catharines, ON, Canada; [2]Psychology, Biol., [3]Psychology, Brock Univ., St. Catharines, ON, Canada

Abstract: We have previously reported differential effects of CB1 agonism on unconditioned (innate) and conditioned fear in adult male rats (Simone et al., 2015). How CB1 regulates fear in females, however, is largely unknown. **In experiment 1**, we investigated the effects of the highly selective CB1 agonist ACEA (0.1 mg/kg and 0.01 mg/kg) and antagonist AM251 (1 mg/kg) on fear and stress responses in adult intact female rats (N = 60). AM251 increased anxiety-like behaviour in the elevated plus maze (decreased time on the open arm relative to ACEA and vehicle, all $p < 0.05$). ACEA was without effect. In the open field test, 0.01 mg/kg ACEA decreased anxiety-like behaviour (increased time in the centre) compared to all other groups (all $p < 0.04$). AM251 impaired locomotor activity (decreased distance travelled) compared to 0.01 mg/kg ACEA ($p = 0.013$) and vehicle ($p = 0.036$). When tested 24 hours after fear conditioning (3 tone-shock pairings, 1 minute ITI), neither ACEA nor AM251 affected generalized fear to a novel context or recall of the conditioned fear. AM251 and 0.1 mg/kg ACEA impaired, and 0.01 mg/kg ACEA enhanced, fear extinction. AM251 increased plasma corticosterone after fear extinction compared to 0.1 ($p = 0.02$) and 0.01 ($p = 0.005$) mg/kg ACEA and vehicle ($p = 0.06$). **In experiment 2**, adult ovariectomized rats (N = 108) were treated with sesame oil or 17β-Estradiol either 6 or 48 hours before behavioural testing. Irrespective of hormone treatment, AM251 decreased time spent on the open arms of the EPM relative to 0.01 mg/kg ACEA ($p = 0.03$) and vehicle ($p = 0.001$). Neither hormone nor drug had an effect on anxiety-like behaviours in the open field. There was an effect of hormone and drug on locomotor activity; estradiol increased distance travelled compared to oil ($p = 0.005$), and AM251 decreased distance travelled compared to vehicle ($p = 0.03$) and ACEA ($p = 0.002$). When tested 24 hours after fear conditioning, AM251 decreased generalized fear to a novel context compared with vehicle ($p = 0.01$) and ACEA ($p = 0.06$). Neither hormone nor drug had any effect on recall or extinction of the previously conditioned fear, however, both ACEA and AM251 increased fear-induced corticosterone concentrations compared to vehicle (all $p < 0.02$). These results provide evidence for sex-differences in CB1 regulation of fear and stress. ACEA had no effect in females at a dose effective in male rats, and only modest effects at a lower dose. Despite no evidence of estradiol modulating the effects of ACEA or AM251, gonadal status appears to be a contributing factor given the differences between intact and ovariectomized females.

Title: Endocannabinoid receptor CB_2 gene expression in hippocampus reflects modulation of anxious behavior

Authors: *J. ROBERTSON[1,2], J. K. ACHUA[1,2], J. P. SMITH[1,2,4,6,7], M. A. PRINCE[1], T. R. SUMMERS[1], P. J. RONAN[5,8,2,3], C. H. SUMMERS[1,2];
[1]Biol., Univ. of South Dakota, Vermillion, SD; [2]Neurosci. Group, [3]Dept. of Psychiatry, Sanford Sch. of Med., Vermillion, SD; [4]Sioux Valls VA Hlth. Care Syst., [5]Sioux Falls VA Hlth. Care Syst., Veterans Affairs Res. Service, Sioux Falls, SD; [6]Inst. of Possibility, Sioux Falls, SD; [7]Sanford Hlth., Sioux Falls, SD; [8]Avera Res. Ctr., Sioux Falls, SD

Abstract: Anxiety is expressed across a continuum of stressful and/or fearful intensity, with varying impacts on decision-making successfully measured in the Stress Alternatives Model (SAM). Recent legislation in many states and countries has led to the widespread availability of cannabinoids for use by people suffering from anxiety-spectrum disorders, but research on their actions and efficacy in such therapies is lacking. It has become apparent that the hippocampus plays a role in more than just certain forms of memory, but also in affective behavior, emotion, and anxiety regulation. Research suggests this may occur through endocannabinoid mediation of long-term depression (LTD) in hippocampal pyramidal cells. Hippocampal lesions cause behavioral disinhibition and anxiolysis. The specific location of CB_1/CB_2 receptor action could be important in determining emotional valence, as the ventral and dorsal hippocampal subregions project to different brain areas and have different functions. Whereas the dorsal hippocampus is involved in spatial memory and cognition, the ventral hippocampus, with projections to the PFC, BNST, amygdala, and HPA axis, is important for the emotional response to stress. However, the expression of CB_1 and CB_2 receptors in the hippocampus following anxiogenic and anxiolytic activities remain unknown. During repeated social defeat in a Stress-Alternatives Model arena

(SAM; an oval open field with escape portals only large enough for smaller animals), smaller C57BL6/N mice are subject to fear conditioning (tone = CS), and attacked by novel larger aggressive CD1 mice (US) over four daily (5 min) trials. Each SAM trial presents an opportunity for escape or submission, with stable behavioral responses established by the second day of interaction. Additional groups had ad-libitum access to a running wheel for the duration of the experiment. Gene expression of CB_1 and CB_2 were measured in conditioned animals which escaped social aggression, submitted to social aggression, and no-aggression controls. Anxiogenic activity, such as social aggression, stimulates CB_2 gene expression in the dorsal CA_1, dorsal and ventral dentate gyrus subregions in animals displaying a submissive behavioral phenotype. Escape behavior is anxiolytic, and reduces CB_2 expression in the dorsal CA_1 region. Exercising mice subjected to social aggression demonstrate an increase in CB_2 mRNA in dorsal DG/CA_1 in both escaping and submitting animals. These results suggest that the CB_2 receptor system is upregulated during anxiogenic social interactions, but also by exercise; both responses may prove to be prophylactically adaptive.

Title: Understanding the role of serotonin receptor subtypes 7 and 2C (5-HT7/2C) in comorbid pain and depression using novel compounds derived from marine cyanobacteria

Authors: ***N. C. LAX**, C. M. IGNATZ, E. J. HILTON, T. AHMED, K. J. TIDGEWELL, B. J. KOLBER;
Duquesne Univ., Pittsburgh, PA

Abstract: Chronic pain and major depressive disorder are widespread conditions in the United States. Interestingly, these conditions often occur comorbidly, with each individual disease amplifying the symptoms of the other. Many medications available on the market today for treating pain or depression target G-protein coupled receptors (GPCRs), implying that this class of receptors may be involved in the treatment of the comorbidity of these conditions. Our efforts

have sought to characterize two poorly understood GPCRs, the serotonin receptor subtypes 7 and 2C (5-HT7/2C), and the role that they play in comorbid pain and depression. Our approach for targeting these receptors uses compounds isolated from filamentous marine cyanobacteria collected from the Las Perlas Archipelago off of the coast of Panama in the Pacific Ocean. Compounds from this cyanobacterial collection show strong affinity for the 5-HT7 and 2C receptors. These compounds were screened for *in vivo* activity using a series of pain and depression behavioral assays. Compounds were delivered into male C57Bl/6J mice via intra-cerebroventricular (ICV) cannulas or injections into regions of the brain with high expression of these receptors. Compounds were tested in naïve mice or in mice subjected to a model of comorbid pain and depression, the Spared Nerve Injury (SNI) surgery. SNI surgery involves ligating two of the three branches of the sciatic nerve, the tibial and common peroneal branches, while leaving the third branch, the sural branch, intact. SNI surgery induces mechanical hypersensitivity in the ipsilateral paw (modeling pain) and also induces depression-like behavior. We have found that administration of compounds isolated from marine cyanobacteria induce effects in several standard behavioral assays. Our results suggest that cyanobacteria produce compounds with neural effects that may be useful in understanding pain and depression.

Title: Differential contribution of amygdala GABAA receptors in benzodiazepine-induced anxiolysis

Authors: *Y. GAO, S. HELDT;
Anat. and Neurobio., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Over the past decade significant advances were made in understanding the differential roles GABAA receptor (GABAAR) subtypes play in various behaviors, including anxiety. At present, it is generally believed that α2-subunit containing GABAARs (α2-subtypes) are responsible for benzodiazepine (BZ) -induced anxiolysis. However, there is some evidence

suggesting that α1- and α3-subtypes might also mediate anxiolysis. To help clarify this issue, we have examined the anxiolytic-like effects of various subtype-selective and non-selective GABAAR agonists/antagonists given to wildtype C57BL/6J (WT) mice and point-mutation mice expressing BZ-insensitive GABAARs. In these experiments, drugs were administered either systemically or via microinfusion in the basal lateral amygdala (BLA), a brain region which putatively mediates BZ-induced anxiolysis. After administration, mice are tested on the elevated-plus maze (EPM) where various behavioral markers of anxiety are obtained. Here we report some of our initial findings. In line with previous findings, systemic injections of the non-selective BZ chlordiazepoxide (CDP) induced robust anxiolytic-like effects in WT mice. These effects were potentiated in α1(H101R) mice, reduced in α3(H126R) mice, and ablated in α2(H101R) mice. Similarly, preliminary results showed intra-BLA microinfusion of CDP produced anxiolytic-like effects in α1(H101R) and α3(H126R) mice, but not α2(H101R) mice. Systemic injections and intra-BLA microinfusion of a α1-selective agonist (zolpidem) in WT mice produced slight anxiolytic-like effects at lower doses. Systemic injection and intra-BLA microinfusion of a reportedly putative α3-selective agonist TP003 produced marked anxiolytic-like effects in WT mice. Taken all together, these initial results suggest that both α2- and, to a certain degree, α3-GABAAR subtypes contribute to the BZ-induced anxiolysis and that the BLA is a major brain region mediating these effects. On the other hand, α1-subtypes are less involved in anxiolysis. The potentiated effects of CDP in α1(H101R) mice may be due to the increase availability of CDP to α2- and α3- subtypes in the absence of BZ binding to α1-GABAAR subtypes. We are currently in the process of 1) investigating whether selective antagonism of α1-subtypes can rescue the blunted anxiolytic-like effects of BZ in α2(H101R) mice; 2) investigating the effects of TP003 in α2(H101R) and α3(H126R) mice; and 3) utilizing multivariate analysis and computational methods to generate a quantitative model of each subtype's contribution to BZ-induced anxiolytic-like effects.

Title: Induction of compulsive checking with quinpirole and 8-OH-DPAT as a perturbation of security motivation: dose-response profiles

Authors: *H. SZECHTMAN, A. DVORKIN-GHEVA, A. H. ALKHATIB, M. C. TUCCI; McMaster Univ., Hamilton, ON, Canada

Abstract: A prior report showed that both the dopamine D2/D3 receptor agonist quinpirole and the serotonin 5-HT_{1A} receptor agonist 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT) can induce compulsive checking in rats, with 8-OH-DPAT producing a seemingly stronger effect than quinpirole. However, the report was a single dose study, and hence the obtained findings may reflect a dose-effect rather than indicating that "8-OH-DPAT and quinpirole produce compulsive behavior by acting on different parts of a security motivation circuit underlying OCD" [1]. Here, we used a range of doses for quinpirole and 8-OH-DPAT to induce compulsive checking and generate full dose-response profiles. Male Long-Evans rats (n=167) received twice per week for 5 weeks either 8-OH-DPAT (0, 0.03, 0.125, 0.25, 1 mg/kg) or quinpirole (0, 0.03125, 0.0625, 0.125, 0.25, 0.5 mg/kg) and after each injection introduced into a large open field (160 x 160 cm) for 55 min where their behavior was video recorded. Spatial coordinates of the rat's location in the open field were extracted at a rate of 30 fps by EthoVision software and used to derive measures of compulsive checking with custom software. Results indicated that induction of compulsive checking was faster with 8-OH-DPAT than quinpirole and that for some measures of performance the function describing the relationship between drug dose and response had different parameters for quinpirole and 8-OH-DPAT. Findings are consistent with the suggestion that quinpirole may induce compulsive checking behavior by directly driving dopaminergic activity mediating the motivational drive to check. Conversely, 8-OH-DPAT may perpetuate the activated motivational state by inhibiting the serotonergic negative feedback signals that normally deactivates security motivation and the OCD circuit. [1]. Alkhatib, A. H., Dvorkin-Gheva, A., & Szechtman, H. (2013). Quinpirole and 8-OH-DPAT induce compulsive checking behavior in male rats by acting on different functional parts of an OCD neurocircuit. *Behavioural Pharmacology, 24*(1), 65-73. doi:10.1097/FBP.0b013e32835d5b7a

Title: Blunted HPA-axis response is not sufficient to predict a complex PTSD-like behavioral phenotype

Authors: *A. I. VAZDARJANOVA[1,2], D. CRETHERS[4], K. BUNTING[2], R. NALLOOR[4], A. OHRI[4], T. PATTON[3];
[1]Charlie Norwood VA Med. Ctr., Augusta, GA; [2]Pharmacol. & Toxicology, [3]Psychology, Georgia Regents Univ., Augusta, GA; [4]Augusta Biomed. Res. Corp., Augusta, GA

Abstract: Post-Traumatic Stress Disorder (PTSD) may occur after a person is exposed to one or more highly traumatic events. Some of its hallmark characteristics are hyperarousal and anxiety, and many sufferers have impaired learning of safety (fear extinction). These maladaptive responses can lead to impaired social and cognitive functioning. Not all individuals who have experienced a traumatic event will develop PTSD; this is evidence that individual susceptibility to PTSD exists. The predictive factors, however, are poorly understood. To address this gap in knowledge, we previously reported a unique behavioral model to identify rats susceptible to PTSD-like behaviors prior to emotional trauma. In our model Susceptibility is assessed as elevated acoustic startle response (ASR) AND anxiety-like behavior in the elevated plus maze (EPM) 4 days following brief exposure to a mild stressor (cat hair). Measured PTSD-like behaviors are fear extinction after contextual fear conditioning and a second ASR three weeks after the initial ASR. Comparing Lewis and Sprague-Dawley (SD) rats in our model we tested the hypothesis that a disregulated HPA axis is sufficient to predict a PTSD-like behavioral phenotype. Lewis rats are known to have blunted corticosterone release in response to predator stress, compared to SD rats. Therefore, we hypothesized that a higher percentage of Lewis rats will be preclassified as susceptible to impaired fear extinction and in long-lasting elevated ASR. Contrary to our hypothesis, a similar percentage of Lewis and SD rats were classified as susceptible, although all Lewis rats had fewer contacts with the mild stressor. Although the ASR was comparable between the two strains, Lewis rats were more likely to enter the open arms of the EPM. Importantly, Lewis rats were twice as likely to show impaired extinction compared to SD rats (66% vs. 33%). Also, Lewis rats showed no evidence for lasting elevated ASR. There were no significant strain differences in performance on the spatial probe test and reversal probe test in the Morris water maze. These data suggest that a disregulated HPA axis is not sufficient to predict a complex PTSD phenotype and is not likely to be a useful predictive factor for susceptibility. Together with previous work with humans and with animal models of PTSD showing that high levels of corticosteroids immediately before or shortly after trauma decrease the probability of developing PTSD, the current findings make an important contribution in dissociating predictive vs contributing factors for developing PTSD.

Title: Proteomic profile changes in SAPAP3-deficient mice

Authors: ***N. S. CHEREPANOVA**[1], E. VÁZQUEZ-ROSA[2], L. N. MCDANIEL[2], A. A. PIEPER[2];
[2]Psychiatry, [1]Univ. of Iowa, Iowa City, IA

Abstract: SAP90/PSD95-associated protein 3 (SAPAP3), a postsynaptic density scaffolding protein enriched in glutamatergic synapses in the striatum, is thought to play a role in regulating synaptic function and plasticity. Rare variants in the gene encoding SAPAP3 have been implicated in obsessive-compulsive disorder (OCD), Tourette syndrome, and trichotillomania. These disorders are thought to involve dysregulated cortico-striatal circuits, and dysfunction of these circuits is evident in SAPAP3-deficient mice. SAPAP3-deficient mice display compulsive grooming behavior, as well as increased anxiety-like behavior. These mice have altered composition of striatal postsynaptic glutamatergic receptors, but the mechanism by which this occurs is not well understood. To further characterize how SAPAP3 deficiency affects behavior, we compared the striatal proteome of a SAPAP3 deficient mouse to its wild type littermate. Using two-dimensional gel electrophoresis and mass spectrometry we identified candidate proteins, including cytoskeletal-associated proteins and proteins involved in cell guidance, myelination, and vesicle endocytosis. From this list we hope to identify targets and pathways involved in the pathological grooming and anxiety-like behavior of SAPAP3-deficient mice.

Campus and Ctr. for Trophoblast Research, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The adult central nervous system (CNS) is endowed with considerable regenerative and neuroplastic potential. Neuroplasticity, in its different forms, is dynamically modulated by intrinsic genetic factors in conjugation with environmentally imposed factors of our everyday life. Nowadays, stress-exposure is a common environmental etiological factor leading to various pathological marks in neurochemical and neuroplastic phenomena, many of them underlying the so-called stress-related disorders. Moreover, several studies have shed light on how epigenetic mechanisms serve as mediators of the pathological effects of stress on brain homeostasis. Here, we aimed to study the effects of stress on the epigenetic landscapes of the dorsal and ventral hippocampal dentate gyrus (DG). Furthermore, we aimed to explore how chronic exposure to stress impacts on the DG epigenome and its repercussions to fundamental emotional and cognitive modalities. We have exposed young-adult Wistar-Han rats to a pre-validated unpredictable chronic mild stress (uCMS) protocol during 6 weeks and performed a battery of behavioral tests to analyze emotional and cognitive dimensions. After sacrifice, we have analyzed citogenesis and dendritic morphological rearrengements. In addition, we have conducted genome-wide analysis of methylation and hydroxymethylation in these areas. So far, results demonstrate that stress exposure compromises different neuroplastic processes, affecting different behavioral dimensions. Moreover, hydroxymethylation pathways are likely to be

involved in the pathological effects of stress exposure, as they are differentially regulated in control and stress-exposed animals.

Title: Increased amygdalar glutamate efflux in response to predator stress is modulated by mu opioid receptors

Authors: *A. C. SHARKO, J. PARILLA-CARRERO, K. F. KAIGLER, D. LEE, G. HARTSHORN, J. R. FADEL, M. A. WILSON;
Univ. of South Carolina-School of Med., Columbia, SC

Abstract: Exposure to predator cues is a form of traumatic stress used as a rodent model of PTSD-like changes in behavior. The central nucleus of the amygdala (CeA) plays an important role in aversive and fear behavioral responses, including responses induced by predator exposure in rats. Previous studies in our lab demonstrated that predator stress activates distinct neuronal populations in the amygdala (Butler et al., 2011) and pharmacological alteration of mu opioid receptor (MOR) activity in the CeA shaped the behavioral responses induced by ferret odor (Wilson & Junor 2008). The present study investigated endocrine and amygdalar responses to predator stress, and if pharmacological manipulation of MOR in the CeA changed glutamate and GABA released *in vivo* in response to ferret odor using *in vivo* microdialysis. Ferret odor exposure increased glutamate, but not GABA, efflux in the CeA in a manner that was dependent upon presynaptic release, since it was blocked by tetrodotoxin. Further, the increases in CeA glutamate release were positively correlated with freezing behavior, and negatively correlated with grooming behavior during the initial period (15 min) of ferret odor exposure. Interestingly,

we found that glutamate efflux elicited by ferret odor exposure was blocked by infusion of the MOR antagonist CTAP into the CeA. Infusion of the MOR agonist DAMGO into the CeA did not alter glutamate efflux in response to ferret odor, but DAMGO-treated rats showed exaggerated fear responses to ferret odor. Ferret odor exposure combined with DAMGO infusion also induced significant neuronal activation in the bed nucleus of the stria terminalis (BNST) as assessed by cFos immunoreactivity. In the vehicle treated groups, there were correlations between neuronal activation in the BNST and ventrolateral septum with fear defensive responses. These results suggest that glutamate efflux in the CeA and activation of the CeA-BNST circuit plays a modulatory role in determining the magnitude of behavioral responses predator threat, and that activation of MOR in the central amygdala may help shape behavioral responses to predator stress. Additional studies using indwelling jugular catheters also showed ferret odor exposure increased circulating levels of corticosterone, but not NPY. Completion of these studies will allow correlations between the observed endocrine changes and behavioral responses to ferret odor (freezing).

Title: Mid-insula activity to food vs non-food images is positively correlated with hunger susceptibility

Authors: *J. E. INGEHOLM[1], K. BURROWS[2], A. MARTIN[1], K. D. HALL[3], W. K. SIMMONS[2,4];

Abstract: Individuals differ in their interoceptive sensitivity to hunger sensations. To date, however, relatively little is known about which brain regions underlie the relationship between hunger susceptibility and appetitive responses to food cues. We thus assessed subjects' self-reported hunger susceptibility, and then subsequently asked the subjects to undergo an fMRI scan during which they viewed food and non-food photographs. We then examined the relationship between activity during the food/non-food picture task and hunger susceptibility. Thirty-two right-handed healthy adults completed the Three Factor Eating Questionnaire (TFEQ), a self-report measure that includes a so-called 'Hunger' subscale measuring susceptibility to sensations of hunger. Later, subjects underwent fMRI while performing a task in which they viewed food and non-food objects while making repetition detection judgments. There was a wide distribution of body mass indices across subjects, and all were screened to exclude the presence of metabolic diseases. Additionally, at the time of scanning subjects were in a eucaloric state, and had eaten two hours prior to scan session. Echoplanar imaging was collected with a 3T MRI scanner and a 16-channel head coil. A random effects paired sample t-test revealed that viewing foods relative to non-foods was associated with bilateral activity throughout regions implicated in appetitive responses to food, including the anterior and mid-insula, orbitofrontal cortex, amygdala, as well as the ventral striatum. Of critical importance to the present study, random effects group analyses of the imaging data also indicated that subjects' ratings on the TFEQ hunger subscale were positively correlated with activity bilaterally in the dorsal mid-insula cortex ($p < .05$ corrected for multiple comparisons). Individuals who report high hunger susceptibility also exhibit greater activity in the dorsal mid-insula to food images, relative to non-food images. This is significant as this region is thought to serve as a conduit for integrating appetitive and affective information with interoceptive signals about the state of the body. For example, responses in this region of the insula to food pictures are sensitive to interoceptive cues of peripheral energy availability (e.g., circulating glucose) and activity within this region has been shown to underlie interoceptive attention to visceral sensations.

Title: Effects of increasing adult hippocampal neurogenesis in mice during exposure to chronic stress

Authors: L. CULIG[1,2], S. LEGENDRE[1,2], F. MINIER[1,2], *G. GRIEBEL[3], A. SAHAY[4,5], R. HEN[6], C. BELZUNG[1,2];

Abstract: Local changes in the hippocampal network (addition of new neurons in the dentate gyrus) might change the activity of neural circuitry in the areas to which the hippocampus projects. Among those structures are the mPFC (medial prefrontal cortex), amygdala and nucleus accumbens (NAc). For example the NAc, which has a crucial role in reward and motivation, receives an input from the CA1 and ventral subiculum of the hippocampus that depolarizes the cells in the NAc, making them more excitable. Interestingly, the size of the hippocampus and more specifically the number of adult newborn granule cells, are decreased by unpredictable chronic mild stress (UCMS). Further, one of the notable effects of chronic stress is the induction of ΔFosB in the NAc, an unusually stable transcription factor which belongs to the Fos family of proteins, but unlike other members of the family, accumulates over time after repeated stress exposure. This accumulation has been observed in many animal models of depression, including UCMS, and it could be the basis of certain behavioral consequences of exposure to chronic stress. This ΔFosB induction could have a protective role against stress, but no studies so far have explored how a specific increase in neurogenesis regulates the induction. We investigated the role of increasing adult hippocampal neurogenesis on stress-related behavior (with a focus on behaviors where NAc is implicated) and the functional brain circuitry involved, in mice exposed to UCMS. We used iBax mice, in which the pro-apoptotic gene Bax was selectively ablated in neural stem cells, therefore inducibly enhancing survival and functional integration of newborn neurons in the adult brain after tamoxifen administration. In order to investigate the role of adult neurogenesis in remission after UCMS, the animals were exposed to UCMS for 8 weeks, and treated with tamoxifen 3 weeks after the beginning of the UCMS to induce increased neurogenesis. In week 8, they were submitted to a battery of behavioral tests to assess depressive-like and anxiety-like behavior, with a specific focus on tests assessing anhedonia, which is related to the NAc. In week 9, blood was collected to assess basal corticosterone levels, and the animals were sacrificed and their brain either collected for ΔFosB and c-Fos immunohistochemistry or used for dissection of brain areas of interest (NAc, mPFC and Amy).

Title: Role of inhibitory signaling in the nucleus accumbens during reward-seeking behavior

Authors: *S. E. MORRISON[1], V. B. MCGINTY[1,2], J. DU HOFFMANN[1,3], S. M. NICOLA[1]; [1]Psychiatry, Albert Einstein Col. of Med., Bronx, NY; [2]Neurobio., Stanford Univ., Palo Alto, CA; [3]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The nucleus accumbens (NAc) contains many neurons that respond with phasic increases or decreases in activity to a reward-predictive cue. Cue-evoked excitations have been shown to encode motivational significance, locomotor properties such as latency to approach a reward-associated target, and, more recently, spatial location with respect to the target. However, little is known regarding the functional significance of cue-evoked inhibitions in reward-seeking behavior. We have recently shown that these inhibitions - unlike cue-evoked excitations - are not modulated by dopamine, suggesting that they may play a distinct role in subjects' decision to approach a reward-related object. In order to determine what information is encoded by cue-evoked inhibitions during reward-seeking behavior, we analyzed the activity of individual NAc neurons recorded during two tasks: 1) a discriminative stimulus (DS) task in which rats responded to an auditory cue with a lever press in order to obtain sucrose reward and 2) a decision-making task in which the auditory cue signaled the availability of a choice between levers, while the reward size, effort requirement, and target locations associated with the levers were systematically varied. Importantly, both tasks involve flexible approach to the reward-

associated target, ensuring that NAc activity is required for task performance. Consistent with prior studies, many neurons had activity that was modulated by cue presentation, including 127 neurons (21%) with significant cue-evoked inhibitory responses (out of 607 cells recorded in 30 rats). We found that these inhibitions, similar to cue-evoked excitations, encode expectation of reward: they respond more strongly (i.e., are more inhibited) to a cue that predicts reward than an unrewarded cue. Unlike excitations, however, cue-evoked inhibitions consistently encode reward size: they respond more strongly to a cue that predicts large reward than one that predicts small reward. In contrast, cue-evoked inhibitions rarely encode expected effort, despite the frequently hypothesized role of the NAc in promoting effort exertion to obtain reward. Finally, we found that inhibitions, like excitations, are strongly modulated by spatial proximity to a rewarded target, indicating that they could play a role in gating or promoting approach to nearby reward-associated objects.

Title: Dopamine and Pavlovian conditioning: studies using a new behavioral procedure to investigate conditioned responding elicited by discrete appetitive cues

Authors: *M. D. VALYEAR[1], F. LACROIX[2], M.-P. COSSETTE[2], I. TRUJILLO-PISANTY[2], J.-M. MADDUX[2], P. SHIZGAL[2], N. CHAUDHRI[2];
[1]Psychology/Center for Studies in Behavioural Neurobio., [2]Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Discrete and contextual Pavlovian cues that predict appetitive reinforcers influence the vigour with which those reinforcers are pursued. We assessed the role of dopamine in responding to discrete appetitive cues for sucrose and alcohol in isolation from contextual cues that predict the same unconditioned stimulus. Male, Long-Evans rats received 15% ethanol

(EtOH) in the home-cage, followed by Pavlovian conditioning sessions where a 10 s auditory conditioned stimulus (CS+; white noise or clicker; 15 trials/session) was paired with EtOH (0.2 ml/CS+, 3 ml/session). Conditioning sessions occurred on alternate days in a distinct Alcohol context where EtOH was dispensed into a fluid port during each CS+ trial. Entries into the port during the CS+ and 10 s preceding the CS+ (PreCS+) intervals were recorded. On intervening days rats were exposed to a different NonAlcohol context where a neutral and distinct auditory stimulus was played (15 trials/session) but EtOH was never delivered. After an equal number of sessions in both contexts, the CS+ was presented without EtOH in the Alcohol and NonAlcohol contexts to test alcohol-seeking behaviour elicited by the CS+. At test, rats made more port entries during the CS+ in the Alcohol context than in the NonAlcohol context. This contextually invigorated CS+ responding persisted across several subsequent EtOH-free test sessions. In addition, we found that dopamine D2 (Eticlopride, 10 µg/kg sc), but not D1 (SCH23390, 10 µg/kg sc), receptor antagonism attenuated CS+ responding in the NonAlcohol context. In a subsequent experiment we used this same conditioning paradigm with 10% sucrose to test the necessity of VTA dopamine neurons in responding to a discrete sucrose cue. Male transgenic TH::Cre rats received intra-VTA infusions of a cre-dependent viral vector encoding the Gi-Coupled (hM4Di) designer receptor. The hM4Di receptor induces neuronal silencing when bound by clozapine-n-oxide (CNO). After training the CS+ was played in the NonSucrose context following a systemic injection of vehicle or CNO (10 mg/kg ip). Results suggest that silencing VTA dopamine neurons dampens CS+ responding. Currently, chemogenetic inactivation of VTA dopamine neurons during alcohol seeking is being investigated. The studies herein demonstrate that the combination of discrete and contextual cues can robustly and persistently invigorate reward-seeking behaviour and that responding to discrete cues requires dopamine D2 receptors. Moreover, chemogenetics shows promise for uncovering the neural substrates of contextually-invigorated and context-independent reward seeking behaviour.

Title: Social reward valuation in primate midbrain dopamine cells

Authors: *A. NORITAKE[1], M. ISODA[2];
[2]Physiol., [1]Kansai Med. Univ., Hirakata, Osaka, Japan

Abstract: The ecological constrains inevitably lead living organisms to competition against others for a given resource (e.g., food, water, territory). Thus, one would devalue a context in which others acquire a reward more often, even though one's own chances of getting a reward may eventually be unchanged. It remains unclear what neural mechanisms underlie such subjective reward valuation via taking others' reward into account. To address this issue, we devised a social Pavlovian conditioning procedure using two monkeys (M1 and M2) facing each other. In the procedure, a visual conditioned stimulus (CS) differently signaled each monkey's reward probability and the monkeys were alternately conditioned in two contextually different trial blocks. In one block, the probability of a reward for M1 was the same, while that for M2 was variable. In the other block, the probability of M2's reward was constant, while the probability of M1's reward was variable. We previously demonstrated that the monkeys lowered the value of their own reward as their opponent's reward probability increased (SfN2014; 364.09). We also showed that distinct cell groups in the dorsomedial prefrontal cortex (DMPFC), a critical node in social brain networks, coded self-reward probability only, other-reward probability only, and subjective reward value in response to the CS (SfN2014; 364.10). However, what brain regions can provide neural substrates for such behavior and a variety of reward signals in the DMPFC remains elusive. A good candidate is the substantia nigra pars compacta and ventral tegmental area in which dopamine (DA) cells are located. While DA cells play a crucial role in self-reward processing and reward-based learning, it is still unexplored how they may code other-reward information. We recorded single-unit activity of 125 putative DA cells and analyzed their phasic responses to CSs (151 - 450 ms). The great majority of the cells (n=90) showed monotonically increasing activity as self-reward probability increased ($P < 0.01$). Among them, one-third (n = 35) also showed monotonically decreasing activity with increasing other-reward probability ($P < 0.01$), suggesting that they encoded subjective reward value. However, we did not find DA cells that selectively coded other-reward probability or those cells that coded reward saliency regardless of which monkey was to be rewarded. These results point to an integral role for DA cells in signaling subjective value on the basis of other-reward information and self-reward information in a manner consistent with reward prediction error coding. The DA cells may constitute a neuronal network for processing multiple reward signals in social contexts.

Title: Reward amplifies Simon effect by increasing the automatic activation of spatial code

Authors: *L. WANG, K. JIANG, S. LI, X. ZHOU;
Peking Univ., Beijing, China

Abstract: Previous studies have shown that reward modulates conflict processing. However, it remains unclear whether and how reward modulates conflict processing at the response level. In the current study, we addressed this issue by investigating the neural mechanism of how reward affects the Simon effect, where response to a target in space is slowed down when the task-irrelevant stimulus location does not correspond to the response location. According to the well accepted dual-process model, the Simon effect arises from the conflict between the automatic activation of the stimulus location and the location of the response hand. In this study, we associated high or low reward with odd or even digits, which corresponded to left or right hand response, and we presented these digits at the location either congruent or incongruent with the location of response hand. We also recorded the event-related potential (ERP) components of lateral readiness potential (LRP) and N2pc. Behavioral results showed that the magnitude of Simon effect was larger for the high-reward digit than for the low-reward digit. ERP results showed that reward modulated the onset of the stimulus-locked LRP (sLRP), which reflects the automatic activation of the spatial code, but not the response-locked LRP (rLRP), which reflects the response execution process. Specifically, the difference in sLRP onset between the congruent and incongruent conditions was reduced for the high-reward digits as compared with the difference for the low-reward digits. Moreover, relative to the low-reward digits, the high-reward digits had enhanced amplitude of N2pc only in the congruent condition, not in the incongruent condition. The latency of N2pc was not modulated by reward, demonstrating more attention to but not earlier attentional processing of the reward-associated stimuli. Taken together, these results suggest that reward amplifies response conflict in Simon task by increasing the automatic activation of spatial code.

Title: Neural correlates of touch reward

Authors: *C. TRISCOLI[1], G. HÄGGBLAD[2], H. OLAUSSON[4], I. CROY[5], U. SAILER[3]; [1]Dept. of Clin. Neurophysiology, Inst. of Neurosci. and Physiol., [2]Dept. of Pedagogical, Curricular and Professional studies, [3]Dept. of Psychology, Univ. of Gothenburg, Gothenburg, Sweden; [4]Dept. of Clin. and Exptl. Med., Univ. of Linköping, Linköping, Sweden; [5]Clin. for Psychosomatic Med., Tech. Univ. of Dresden, Dresden, Germany

Abstract: Introduction. Pleasant touch plays an important role in individuals´ subjective well-being and is assumed to form the basis for affiliative behaviour and social bonding. However, how long-lasting touch is processed by the brain's reward system is not understood yet. The aim of this study was to investigate how pleasant touch evolves over a long period of time and to determine neural activation in response to it. Methods. 25 subjects were scanned during 18 blocks of 2 minutes duration each. The first and the last block constituted a baseline. During the remaining 16 blocks in-between the subjects' left dorsal forearm was continuously stroked by a custom-built MR-compatible robotic device at a velocity of 3 cm/s for an average duration of 39 minutes. Subjective ratings of pleasantness were collected in-between the stroking blocks. Regions of interest in tactile areas (S1, S2 and posterior insula) and reward areas (orbitofrontal cortex, nucleus accumbens, putamen and caudate) were defined for the subsequent analysis. Results. Touch across all 16 stroking blocks compared to baseline showed activation in all tactile and reward ROIs. Enhanced activation in reward areas occurred in the last compared to the first stroking blocks. Conversely, enhanced tactile activation in the contralateral somatosensory cortices was shown at the first compared to the last stroking block. Activation in posterior insula remained constant. This was in parallel with increased functional connectivity of posterior insula with cingulate and striatal regions. Subjective ratings of pleasantness were related to activation in the orbitofrontal region. Discussion. Increased activation in reward areas was opposed by decreased activation in somatosensory tactile areas over time, with the influence of the posterior insula as mediator between these areas. Underlying mechanisms for increased activation in reward areas may involve a compensatory sensory habituation, potentially resulting while

experiencing a relevant and pleasant long-lasting stroking stimulation. This may promote seeking of long-term stroking and, consequently, social bonding.

Title: Inhibition of adult hippocampal neurogenesis impairs motivation to obtain sucrose, but not food, reward using a progressive ratio responding paradigm

Authors: R.-M. KARLSSON, *H. A. CAMERON;
NIMH, NIH, Bethesda, MD

Abstract: Inability to experience pleasure in normally pleasurable acts, anhedonia, is a characteristic seen in many psychiatric disorders including major depression, but is poorly understood. Previously our laboratory has shown that mice lacking neurogenesis show a depression-like phenotype including a decreased sucrose preference, which is a standard measure for studying anhedonia in rodents. The aim of the present study was to further investigate the role of adult hippocampal neurogenesis in motivation to obtain either sucrose or a food reward. We inhibited adult neurogenesis using valganciclovir in transgenic mice and rats that express herpes simplex virus thymidine kinase (TK) under the control of the GFAP promoter. Mildly food restricted TK and wild-type (WT) littermate controls were trained to lever press for either chocolate flavored sucrose tablets or regular food tablets on fixed ratio (FR) and exponentially progressive ratio (PR) tasks. Both TK mice and TK rats showed normal acquisition of lever press on a FR schedule and minimal pressing of inactive lever, suggesting normal learning of lever-reward association. When switched to a PR schedule, both mice and rats lacking adult neurogenesis showed significantly reduced responding compared to their WT controls when working for sucrose rewards. However, when working for food tablets, there was no difference between WT and TK in either acquisition or PR responding suggesting normal motivation to obtain a novel food reward. This study indicates that adult hippocampal neurogenesis affects motivation for some pleasurable/hedonic reward that is distinct from motivation for non-sweet

reward. Future studies will be needed to understand how new neurons in the hippocampus differentially affect motivation to consume sweet and non-sweet rewards.

Title: Persistence of the effects of binge eating induction with corn oil in rats

Authors: *W. ZEPEDA-RUIZ[1], C. Y. RAMOS-LAZZARI[2], D. N. VELAZQUEZ-MARTINEZ[2];
[1]Univ. Nacional Autonoma De Mexico, Mexico, Mexico; [2]Psicofisiología, Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Binge eating is characterized by overconsumption of food in brief periods in absence of an energy deficit. There are different animal models to study this disorder, one of them is the Limited Access which reproduces the overconsumption of palatable food in brief periods of time. It has been described that binge eating behavior induced with vegetable shortening or sucrose can persist for several months. We also found that binge eating can be induced with a 30% corn oil concentration; here, we describe the persistence of binge eating behavior induced with this palatable food. Twenty-four rats were divided in two groups: a) Control group and b) Experimental group; both groups had ad libitum access to food and water, control group had access to corn oil 24 hours seven days a week and experimental group had access for two hours on Tuesday, Thursday and Saturday. After one month of binge eating establishment, corn oil consumption was determined in both groups under the binge protocol. Test sessions were carried out in two different food conditions (ad libitum and deprivation). Corn oil consumption of the binge group remained at the same level for at least two months. Access to corn oil in the control group was allowed only on the test days and we found that their consumption increased; this increase may be related to the deprivation of corn oil during the days preceding the test. When both groups were chow deprived, differences in oil consumption vanished since the formerly control group increased their oil intake indicating that after experiencing high caloric food, they chose such food to replenish caloric content.

Title: Motivational state but not reward value or Pavlovian cues affect forelimb motor skill learning in rats

Authors: ***A. C. MOSBERGER**, L. DE CLAUSER, H. KASPER, M. WIECKHORST, M. E. SCHWAB;
Brain Res. Institute, Univ. of Zurich, D-HEST ETH Zurich, Zurich, Switzerland

Abstract: Motor skill learning as well as the recovery of skilled movements after central nervous system (CNS) injuries is widely studied in rodents with the skilled grasping task. By using direct food reward in the form of sugar pellets, this task contains an inherent motivational component. The role of motivation in motor learning is often studied in human subjects and its role in rehabilitation success is a well-known phenomenon amongst physiotherapists. However, a connection to the most commonly used animal model and task is still missing. In the current study, we evaluate the role of motivation in learning and plateau performance of an instrumental skilled grasping task in rats. In this task, animals have to perform a chain of actions to retrieve a sugar pellet from a pedestal. To initiate a trial, the animal activates a nose poke sensor (action 1, distal to reward) to open a motorized door, giving access to the pedestal. The animal then approaches the pedestal and uses its forelimb to reach for and grasp the sugar pellet reward (action 2, proximal to reward). Completion of this movement ends the trial and the motorized door closes again. In the first experiment, we used food rewards of differentially preferred flavors (reward value) and found no effect on skilled grasping learning and performance (action 2), or on nose poke response behavior (action 1). In the second experiment, Pavlovian incentive learning was used to motivate the performance of the instrumental skilled grasping task.

Although we found a strong effect on approach behavior towards the reward, there was no effect of the Pavlovian cue on skilled grasping learning and performance (action 2), or on nose poke response behavior (action 1). In the third experiment, we changed the animals' motivational state by using different levels of food deprivation and found a strong effect on both, the distal nose poke response (action 1) and the skilled grasping learning and performance (action 2). These experiments suggest that motivational manipulations can have differential effects on specific components of an instrumental skilled motor task. These findings have implications for the design and use of such a task in the study of motor learning and recovery after CNS injury.

Title: Resting-state functional connectivity between interoceptive cortex and reward circuitry modulates ratings of inferred food pleasantness

Authors: *K. BURROWS[1], J. A. AVERY[1], K. L. KERR[1,2], C. MULLINS[1], J. BODURKA[1,4], W. K. SIMMONS[1,3];
[1]Laureate Inst. For Brain Res., Tulsa, OK; [2]Dept. of Psychology, [3]Fac. of Community Med., The Univ. of Tulsa, Tulsa, OK; [4]Col. of Engin., The Univ. of Oklahoma, Tulsa, OK

Abstract: Although increased or decreased appetite are common symptoms during acute episodes of major depressive disorder (MDD), the neural bases for these MDD-associated appetite changes remain poorly understood. Two recent fMRI findings have revealed interesting insights. First, appetite increase in MDD is associated with increased brain activity in putative reward neurocircuitry to the sight of food, while MDD-related appetite loss is associated with decreased activity in a region of the dorsal mid-insula known to underlie interoceptive signaling. Second, those depressed individuals with appetite increases who rate visually perceived foods as being most appealing also exhibit the weakest activity in interoceptive cortex during food

perception. These findings suggest that food value decisions arise from interactions between interoceptive and reward circuitry. If so, we hypothesize that food value judgments should be related to the intrinsic functional connectivity between interoceptive and reward neurocircuitry. To test this hypothesis, we recruited two groups of participants with MDD, one with increased appetite and one with decreased appetite, as well as non-depressed adults. Participants completed an 8-minute resting-state fMRI scan, followed by a food pleasantness task in which they made hedonic inferences about appetizing foods depicted in photographs. To assess functional connectivity, a region of the right dorsal mid-insula was selected as a seed region. Notably this region of the insula has been previously identified as responsive in healthy subjects to pictures of foods and interoceptive awareness of visceral signals. At the group level, the average ratings from the food pleasantness task were regressed on to the subjects' insula resting-state functional connectivity maps, and the resulting statistical images were corrected for multiple comparisons at $p<0.05$. We found that subjects' food pleasantness ratings were positively correlated with the resting-state functional connectivity between the dorsal mid-insula (interoceptive cortex) and reward-related regions of the brain, including the accumbens area and a region of the ventromedial prefrontal cortex associated with food value estimation. Interestingly individuals who exhibited the strongest functional connectivity between interoceptive and reward brain regions later expected foods to be more pleasant. This finding reveals important insight into how the brain predicts food hedonic value through the synchronization of reward and interoceptive neurocircuitry.

Title: Examination of the addictive properities of the anandamide transport inhibitor SBFI26

Authors: *P. K. THANOS[1], B. CLAVIN[1], J. HAMILTON[1], J. O'ROURKE[1], T. MAHER[1], C. KOUMAS[1], E. MIAO[1], A. ELHAGE[1], G. TENG[2], M. KACZOCHA[3], D. DEUTCH[4]; [1]Psychology, [2]Chem., [3]Anesthesiol., [4]Biochem., Stony Brook Univ., Stony Brook, NY

Abstract: The therapeutic properties of cannabinoids have been well demonstrated but are overshadowed by such adverse effects as cognitive and motor dysfunction as well as their potential for addiction. Recent research on the natural lipid ligands of CB1 receptors, also known as endocannabinoids, have shed light on the mechanisms of intracellular transport of the endocannabinoid anandamide by fatty acid binding proteins (FABPs) and subsequent catabolism by fatty acid amide hydrolase (FAAH). These findings facilitated the development of SBFI26 (Berger et al. 2012), a pharmacological inhibitor of brain-specific FABP5 and FABP7, which effectively elevates extracellular concentrations of anandamide. The goal of this study was to examine this compound for any possible effects on reward and addictive properties as well as locomotor effects given its recently reported anti-inflammatory and analgesic properties. Mice were separated into one of four treatment groups [vehicle or SBFI26 (5, 20, 40 mg/kg)]. After a habituation session, mice underwent an 8-day conditioning phase before testing. Treatment was given 1 hour prior to being placed in a conditioned place preference (CPP) apparatus. Preference was determined based on percentage of total time spent in each chamber. In addition, mice were also tested for locomotor activity as measured in an open field arena. Results showed that mice treated with SBFI26 did not show conditioned placed preference (CPP), nor conditioned place aversion. In addition, SBFI26 did not show any effect on locomotor activity during CPP or following acute treatment in an open field activity. In conclusion, these findings suggest that SBFI26 did not show addictive properties - as measured by CPP, nor did it produce any effects on locomotor activity. Therefore, FABP inhibition may provide therapeutic potential for analgesia and inflammation without the risk of dependence or motor impairment.

Title: Representation of social hierarchy and fluid value in the primate amygdala

Authors: *J. MUNUERA[1], D. C. SALZMAN[1,2,3];
[1]Neurosci., [2]Psychiatry, Columbia Univ., New York, NY; [3]New York State Psychiatric Inst., New York, NY

Abstract: Primates are social animals, and they live in groups. Group living can help individuals defend against predators and acquire nutrition, among other functions. Within a group of primates, however, conflicts between group members can arise (food sharing, mating, etc.), requiring individuals to know the status (i.e. the social position) of each group member to promote survival. Presumably monkeys learn the social status of group members through experience, just like they learn the rewarding or aversive nature of sensory stimuli that predict different types of reinforcement. Group members may thereby be viewed as differing in value. We sought to understand how the brain represents the status of each member within a social hierarchy. We hypothesized that neural representations of social hierarchy emerge in the same neuronal populations engaged in reinforcement learning and the assignment of motivational significance to previously neutral stimuli. Our initial target for study was the primate amygdala, since it has been implicated in the processing of social stimuli and of stimuli associated with rewarding and aversive events. Actor monkeys performed two types of blocks of a trace conditioning task. In one type, monkeys viewed a fractal image (conditioned stimulus, CS) that could be associated with 3 different rewards (2, 1 or 0 drops of juice delivered after a trace epoch). In the second block type, CSs were pictures of monkeys belonging to the actor monkey's group ; all completed trials resulted in delivery of one drop of juice. We computed a social index based on the trial completion rate, the type of error made, and the viewing times of different features of the images. The computed social index was similar to the social hierarchy observed between the members of the group by independent observers (e.g. the Alpha monkey of the group was the one with the highest index). We computed an analogous index for the fractal image blocks, and found a similar trend as for the social blocks: high, medium and small index values for large, medium and no reward CSs respectively, raising the possibility that the social and fluid index values reflect actor monkey preferences. Preliminary neurophysiological data reveal that the same population of neurons in the amygdala can be used to decode the reward value of CSs and the social hierarchy of the group. These results suggest a common neural substrate for processing motivationally significant social and non-social stimuli. The acquisition of neural representations of social hierarchy may therefore arise in the same neural circuits that link representations of non-social sensory stimuli with innately rewarding or aversive reinforcement.

Title: Linking neural patterns and behavioral models of outcome anticipation through representational similarity analysis

Authors: D. B. EHRLICH[1,2], Z. ZHANG[1,2], *I. LEVY[1,3,2];
[1]Section of Comparative Med., Yale Sch. of Med., New Haven, CT; [2]Interdepartmental Neurosci. Program, [3]Dept. of Neurobio., Yale Univ., New Haven, CT

Abstract: Imaging studies of reward anticipation have in the past found it difficult to adequately differentiate signals representing value and salience due to their partially confounding relationship. In combination with careful experimental design, one way to begin to examine these competing representations is through multivariate analysis methods, which are capable of deciphering more complex representational patterns in the brain compared to univariate techniques. While such multivariate methods, most notably Multi-Voxel Pattern Analysis (MVPA), have made strides in identifying subtle spatiotemporal encoding patterns, they often deliver results that are impenetrable to further interpretation. Representational Similarity Analysis (RSA; Nili et al, 2014), a novel and less widely utilized multivariate method, enables complex non-linear pattern recognition, while presenting results in an intuitive form directly comparable to computational models and behavioral data. RSA relies on mapping condition-by-condition similarities in neural data, which can then be compared to competing models of stimuli or behavioral similarity across the same set of conditions. In our study, RSA was used to compare similarity in prefrontal cortex (PFC) activation patterns, as we systematically varied saliency and value between conditions. 18 healthy subjects were scanned as they participated in a reward and punishment task. On each trial, participants were presented with probabilistic reward and punishment cues, drawn from 4 categories (money gains, money losses, pleasant pictures and shocks) each with 4 intensity levels. RSA demonstrated that neither a model drawn from subject pleasantness ratings, nor one based on inferred saliency strongly predicted the observed neural conditional similarity. A model integrating the two signals, however, in which saliency played a modulatory role in representational consistency both strongly matched the observed PFC activity as well as far outperformed the two other behavioral models. By modeling the full set of experimental conditions, while accounting for consistent patterns in voxel-by-voxel information, RSA provides a powerful method for exploring the underlying representation in

complex activation patterns. In further analysis we will use RSA to examine theories of common value and uncertainty representations across domains as well as begin to isolate theories of subjective value construction, integration, normalization and comparison that maximize biological and representational plausibility.

Title: Propranolol interferes with the reconsolidation of a sign-tracking, but not a goal-tracking conditioned response

Authors: *E. S. COGAN, N. C. TRONSON, T. E. ROBINSON;
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: In Pavlovian conditioning, individuals vary in the extent to which they approach and interact with the cues in their environment. Upon presentation of a lever conditioned stimulus (CS), some animals will vigorously interact with it and approach it (sign-trackers-ST), while others will approach the location of the reward delivery (goal-trackers-GT). However, when using a tone CS, animals cannot interact with it or approach it, thus forcing all animals to exhibit a goal-tracking conditioned response. Previous studies have examined the neurobiological mechanisms required for the expression of these phenotypes using both a lever and tone CS; however, the mechanisms underlying reconsolidation of lever and tone CS-US memories in STs and GTs have not yet been studied. In the present study, we utilize these individual differences in autoshaping to examine the effect of systemic injections of beta adrenergic receptor antagonist, propranolol on ST and GT behavior to a lever and tone CS. In experiment 1, animals were first classified as STs or GTs in a lever autoshaping task previously described followed by two successive days of autoshaping sessions in which rats were administered a post-session intraperitoneal injection of either propranolol (20 mg/kg) or saline. Animals underwent autoshaping for an additional day to assess behavior following the second injection day. We found that propranolol decreased ST behavior in STs, but not GT behavior in GTs, relative to saline controls. In experiment 2, the procedure was identical with the exception that a tone CS

was used. Under these conditions, GT behavior was again unaffected by propranolol. Propranolol has been previously reported to disrupt the reconsolidation of emotional memories in both appetitive and aversive learning. The present study suggests norepinephrine (NE) is required for reconsolidating ST memories. Additionally, it suggests that the psychological processes of ST and GT behavior may be fundamentally different in that ST is an emotional process, while GT is not.

Title: Oxytocin and playfulness in juvenile Fischer 344 and Lewis rats

Authors: *S. M. SIVIY, C. C. GARLISS, L. S. MCDOWELL, S. R. ECK, J. A. SOROKA; Dept Psychol, Gettysburg Col., Gettysburg, PA

Abstract: Oxytocin (OT) modulates a wide range of mammalian social behaviors, yet relatively little is known about the role of this neuropeptide in the control of playfulness. Previous work from our laboratory has shown that the Fischer 344 (F344) rat is consistently less playful than other inbred and outbred strains and we have been investigating (1) whether some of the strain differences in playfulness may be associated with systematic differences in OT functioning and (2) whether OT may have a modulatory influence over playfulness in juvenile rats, including the relatively non-playful F344 rat. We have previously observed a modest strain difference in hypothalamic OT, with F344 rats having fewer OT-positive neurons in the paraventricular nucleus of the hypothalamus (PVN) than male SD rats. We expanded on this earlier study to include males and females, as well as the inbred Lewis rat. Slices were taken through the hypothalamus of juvenile male and female F344, SD, and Lewis rats and processed immunohistochemically for OT-positive neurons in the PVN. No differences were found between SD and F344 rats for total number of OT-positive neurons, while male and female Lewis rats had significantly fewer OT-positive neurons than either SD ($p = .01$) or F344 ($p = .05$) rats. When adjusted for PVN volume of the sampled sections, Lewis females continued to show fewer OT-positive neurons than all other groups. While these data reinforce strain differences in

the number of OT neurons in the PVN, the observed differences were not as predicted and cannot readily account for strain differences in playfulness. We have also begun to assess the effects of intracranial infusions of OT into limbic structures thought to be involved in play and that have abundant OT receptors. Bilateral infusions of OT (1 μg/0.5 μl) or saline were made into the central amygdala of male and female F344 and Lewis rats immediately before being paired with an un-treated SD rat for 10 minutes. Play was quantified primarily by the frequency of pounces directed towards the SD partner. OT significantly increased pouncing in both male F344 and Lewis rats, while having minimal effects on females. OT has been shown by others to result in excessive grooming when infused into the central amygdala and we also observed substantial OT-induced self-grooming (> 600% over saline). The magnitude of grooming was strongly correlated with increased pouncing ($r = 0.79$, $p = .004$), suggesting a shared substrate for both effects. These data suggest that while compromised OT functioning may not contribute to the dysfunctional play of F344 rats, OT acting within the central amygdala may be an important modulator of playfulness in juvenile rats.

Title: Behavioral responding in the discriminative stimulus task is habitual

Authors: *J. MEFFRE[1,2], H. FIELDS[2], F. AMBROGGI[1,2];
[1]Lab. De Neurosciences Cognitives, Marseille Cedex 3, France; [2]Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: The nucleus accumbens core (NAc) is essential in cue-controlled reward-seeking such as in the discriminative stimulus (DS) task. In this task, NAc inactivation reduces operant responding to the DS. We previously showed which input signals are necessary for the NAc to drive behavioral responding. However, these studies did not allow to determine which

underlying cognitive process was used in the DS task. In particular, it is essential to determine whether rats use a representation of the outcome to guide reward-seeking. If the animal uses a representation of the outcome, the behavior is said goal-directed and can be adapted flexibly according to the motivational state. Habitual responding on the other hand does not depend on such representation and is driven systematically by the presentation of the stimulus. To test whether the DS task is goal-directed or habitual, we used a standard lithium chloride devaluation procedure. In the DS task, one of two distinct auditory cues, a DS and a neutral stimulus (NS) is presented every of 30 sec to food-restricted rats. The DS predicts a liquid sucrose reward if the animal presses a lever within 10 sec. Responding to the NS has no consequence. After being trained to the task, rats were split in two groups. The devaluated group received 5 LiCl injections every other day immediately after a 20 minute-free access to the sucrose reward. The non-devaluated group received free access to sucrose and LiCl injections on alternate days. When instrumental performance in the DS task was then tested in extinction, both groups continued to press the lever associated with the DS at the same rate than during training. When rats were tested in the rewarded DS task the following day, performance was also equivalent between devaluated and non-devaluated groups. These results suggest that sucrose seeking in the DS task is a habit rather than a goal-directed behavior and therefore implicate the NAc as a locus of control of stimulus-response behaviors.

Title: The neural correlates of dynamic goal pursuit

Authors: ***K. M. ANDERSON**, L. M. PATRICK, J. REINEN, A. J. HOLMES;
Psychology, Yale Univ., New Haven, CT

Abstract: The ability to pursue goals through an ever shifting and uncertain environment is core to human survival. To accomplish this, the brain must integrate internal and external stimuli

across multiple time scales. Prior work based on descriptions of discrete moments during reward anticipation and consumption has greatly advanced understanding of the cortico-striatal circuits that support motivated behavior. Yet relatively little is known about the dynamic neural mechanisms that underlie sustained goal pursuit in humans. Recent work in rodents identifies a 'ramping' of ventral striatal neural activity and dopamine release linked to the spatial proximity of an expected reward (Howe et al., 2013; van der Meer and Redish, 2011). However, the dynamic ramping of ventral striatal activity in response to the spatial proximity of anticipated outcomes has yet to be established in humans. Further, the potential links between this signal and the function of large-scale cortical networks remain an open question. In the present ongoing study, participants underwent functional MRI (fMRI) while navigating through a virtual reality T-maze. At the onset of each trial, a cue was presented predicting the value and probabilistic location of a monetary reward. Participants utilized the cue to predict reward location. Participants then manually navigated through the maze to their selected arm, where they were provided feedback. Although the current design is more complex than traditional tasks, analyses reveal canonical neural activity in the ventral striatum and medial prefrontal cortex in response to reward cues and outcomes. Ongoing timecourse analyses aim to identify neural signals that associate with reward proximity. fMRI data will be analyzed for ramp-like signals that are modulated by reward level (i.e. $0, $1, or $5) and by maze length (i.e. short or long T-maze). By revealing how dynamic goal monitoring is instantiated in the brain, the current study can inform how motivated behavior is directed and maintained over time.

Title: Glutamate released into the basolateral amygdala tracks the encoding of reward value and the use of this information to guide reward seeking

Authors: *M. MALVAEZ[1], S. STOLL[1], A. M. YORITA[2], L. FENG[2], H. G. MONBOUQUETTE[2], K. M. WASSUM[1];
[1]Psychology, [2]Chem. & Biomolecular Engin., UCLA, Los Angeles, CA

Abstract: Reward-seeking decisions are heavily controlled by the incentive value (i.e., desirability) of the specific reward they attain. This value is acquired and updated through the process of instrumental incentive learning, during direct experience of the specific reward in a relevant motivational state. Although the basolateral amygdala (BLA) has been generally implicated in the encoding and use of reward value information to guide decisions, almost nothing is known about the neurotransmitter processes within this structure mediating these effects. The BLA is densely innervated by both cortical and thalamic glutamatergic projections, so we hypothesized that glutamate released into the BLA would track changes in reward value important for value-guided decisions. To test this we used electroenzymatic biosensors to make near-real time measurements of BLA glutamate concentration changes during an incentive learning experience and during the subsequent use of this updated reward representation to guide reward-seeking decisions. Rats were trained mildly food-deprived to lever press for a food reward. When rats were then allowed to experience the food reward hungry for the first time, we found that BLA glutamate concentration was transiently elevated and that this signal tracked the incentive learning process. Glutamate elevations were not detected in a control group of subjects when they experienced the food reward in the familiar, mildly food-deprived control state. The next day all rats were tested hungry for their reward-seeking activity. Excitingly, we detected transient fluctuations in BLA glutamate concentration immediately preceding reward-seeking actions, but only in those rats who had been given the opportunity to learn the food reward's higher value when hungry. These data suggest transient BLA glutamate release tracks the reward evaluation process that drives value-based reward seeking decisions and perhaps also the use of this value information to guide reward-seeking decisions.

Program, Sch. of Life Sciences, Peking Univ., Beijing, China; [5]Britton Chance Ctr. for Biomed. Photonics, Wuhan Natl. Lab. for Optoelectronics-Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: The dorsal raphe nucleus (DRN) appears to process signals that concern reward and punishment; however, it remains unclear how 5-HT neurons and GABA neurons in the DRN respond when freely behaving animals perform reward-associated behaviors. Here, we addressed this question using fiber photometry and single-unit recording from genetically defined neurons in the mouse DRN. Natural rewards (sucrose and food) strongly activated 5-HT neurons, but aversive stimuli (quinine and footshock) did not. After a mouse learned to wait for delayed sucrose delivery, most 5-HT neurons fired tonically during waiting and then phasically upon reward acquisition, although a minority of 5-HT neurons showed different response profiles. Finally, the activity of GABA neurons was suppressed during animal reward seeking. Thus, DRN 5-HT neurons and GABA neurons encode reward signals via excitation and inhibition, respectively, suggesting their roles in mediating both anticipatory and consummatory responses to rewards.

Title: Pupil dynamics represent human task performance prior to the execution

Authors: *N. WATANABE[1,2,3,4], H. OHIRA[1];
[1]Nagoya university, Nagoya, Aichi, Japan; [2]Japan Society for Promotion of Sci., Tokyo, Tokyo, Japan; [3]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Suita, Osaka, Japan; [4]Dept. of Psychology, Rutgers Univ., Newark, NJ

Abstract: Avoiding negative outcomes and maximizing rewards are goals common to most individuals. However in reality, we sometimes fail to achieve these goals because of difficulty in regulating emotions caused by external stress or internal spontaneous state. It suggests that human brain modulates his/her inner arousal level to successfully complete challenging task. In this study, we monitored subjective arousal levels with pupil dynamics of eyes when the participants engaged in the challenging task (Stop watch task: n = 24). They were required to stop the watch at exactly five seconds without seeing the counting display. If they could stop the watch prescribed duration (e.g. 4.8~5.2 sec.), they could earn some monetary rewards which represented as the cue timing (10~990 yen for each trial) before the execution. As results, step-wised multiple regression analysis showed that the pupil dynamics at the ready timing (in 5.5 sec.) prior to the counting the numbers in their head significantly represented the interaction (performance & reward size) (Mean $\beta = -0.0531 \pm 0.0001$, $ps < 0.05$) as well as main effect of reward size (Mean $\beta = 0.1121 \pm 0.0002$, $ps < 0.05$) from approximately 1.5 to 5.5 sec. Further analyses in this interval showed that although the pupil dynamics were strongly affected by the reward size in the case of lowest performances, they showed stable waveforms regardless of monetary size in the case of highest performances (Individual data fittings with linear functions; gradients: $F(2.399, 52.784) = 4.180$, $p = 0.015$). These data do not only indicate that the pupil dynamics represent the arousal level objectively, there is also a possibility that the performance for each trial could be predicted prior to the execution.

Abstract: The magnetic field of the earth is a source of constant and reliable directional information for a vast number of organisms able to detect it. While some animals such as turtles and birds use the magnetic field to engage in horizontal migrations, other organisms like magnetotactic bacteria use it to guide their migrations vertically. The nematode *C. elegans* readily orients to artificial magnetic fields of earth strength. We found that worms appear to use the geomagnetic field to guide vertical migrations via an identified a pair of sensory neurons. Because the orientation of the geomagnetic field differs across the globe, we tested the magnetotactic ability and migratory preference of the standard lab strain (N2), and of wild-type strains isolated from different locations across the planet. We found that different populations displayed an innate preference to migrate at an angle to magnetic fields of earth-strength that would optimize their UP or DOWN direction when burrowing in their native global location. For instance, in England the geomagnetic field pierces the earth at +66 degrees (north points down). We found that well-fed British N2 worms prefer to migrate 120 degrees to an earth-strength artificial magnetic field. This seemingly arbitrary angle corresponds to the optimal angle to orient them upward when burrowing in England. By contrast, starved N2 worms migrated in the opposite direction (i.e. 300 degrees to the field), which would orient them downward in England. Consistent with natural populations adapting to local magnetic fields, we next found that worms isolated from Australia, where the geomagnetic field emanates out of the earth at -66 degrees (north points up), displayed an opposite innate pattern of migratory preference. Similar results were found for wild-type worms from Hawaii. This pattern of optimal natural variation in magnetic orientation in *C. elegans* serves as an excellent example to relate spatiotemporal genetic variation with a behavioral trait. The breath in number and distribution of wild-type *C. elegans* populations makes this a promising model for studying the effects of natural and artificial magnetic field variation on the behavior of a genetically tractable animal.

Title: Investigating the neural basis of color-based mate choice preferences in Heliconius butterflies

Authors: *N. P. BUERKLE[1,2], E. WESTERMAN[3], M. R. KRONFORST[3], S. E. PALMER[1,2]; [1]Committee on Neurobio., [2]Dept. of Organismal Biol. and Anat., [3]Dept. of Ecology and Evolution, Univ. of Chicago, Chicago, IL

Abstract: Color based mate choice in an adaptive radiation of Heliconius butterflies is an attractive system for studying how nervous systems evolve to produce novel behaviors. Here, we focus on Heliconius cydno alithea and H.c. galanthus, a group of species where wing coloration is controlled by a single Mendelian locus, with white coloration dominant over yellow. Prior behavioral work has shown that male homozygotes preferentially court females of the same color independent of species identity, while heterozygotes show no preference. To differentiate between a change in peripheral sensory reception and a difference in central brain processing, we are characterizing the eyes of homozygote butterflies using intracellular photoreceptor recordings to construct tuning curves, eyeshine microscopy and histology to identify colored screening pigments that act as pre-neural light filters, and antibody staining to examine patterns of fruitless expression, a well-known marker of cells important for courtship. Preliminary results using electroretinogram recordings suggest that spectral tuning between the two species are not significantly different from each other or from the closely related red H. melpomene. Eyeshine data indicates that these butterflies have at least two types of screening pigments, which are mostly red with some yellow. Additionally, RNA-Seq data from the eye indicates fruitless transcripts are present in male eyes one day after eclosion. The results of this study will begin to

explain how genes affect behavior at the level of neural circuits and lead to a greater understanding of how neural computation can change within the constraints of evolution.

Title: Local structure of subcellular input retinotopy in an identified visual interneuron

Authors: ***Y. ZHU**, F. GABBIANI;
Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The Lobula Giant Movement Detector (LGMD) is an identified visual interneuron in the locust that responds preferentially to objects approaching on a collision course. The LGMD receives excitatory input from the entire visual hemifield sampled by one eye that appears to preserve retinotopy down to the level of single facets on the compound eye. Because single photon imaging with CCD sensors has a relatively low penetration and exhibits considerable scattering, previous work could not directly investigate this retinotopic mapping at the level of individual thin dendritic branches. Our current work employs a custom-built two-photon microscope with sub-micron resolution in conjunction with an OLED (Organic Light-Emitting Diode) microdisplay that provides visual stimuli to the locust compound eye adequate to explore this retinotopy at the finest level. We find that the adjacent facets on the compound eye have overlapped dendritic mappings on the LGMD excitatory dendritic branch. Furthermore, the centers of mass of the dendritic branches activated by individual single facets build a retinotopic map, consistent with earlier results obtained through CCD imaging. Different facets seem to make independent synaptic contacts onto the LGMD. The separation of center-of-masses along the dorsal-ventral axis is larger than along the anterior-posterior axis. Simultaneously stimulating 2 facets results in responses similar to the sum of responses from 2 single-facet stimuli. Flashed stimuli covering three concentric facet layers generate larger responses than stimuli expanding over the same area. Translational stimuli moving from anterior to posterior generate stronger responses than similar stimuli moving from posterior to anterior. Our work reveals several new

properties of the local structure of subcellular input retinotopy that will allow more detailed modeling of the LGMD in the future.

Title: Direction-specific adaptation in neuronal and behavioral responses of cercal sensory system in the cricket

Authors: ***H. OGAWA**[1], R. MITANI[2], K. OKA[3];
[1]Dept. of Biol. Sciences, Fac. of Sci., [2]Biosystem Sci. Course, Grad. Sch. of Life Sci., Hokkaido Univ., Sapporo, Japan; [3]Dept. of Biosci. and Informatics, Fac. of Sci. and Technol., Keio Univ., Yokohama, Japan

Abstract: Stimulus-specific adaptation (SSA) is considered as the neural underpinning of habituation to frequent stimuli and novelty detection. However, neither the cellular mechanism underlying SSA nor the link between SSA-like neuronal plasticity and behavioral modulation is well understood. Cricket wind-detection system is one of the most suited models for investigating the neural basis of SSA. We found that crickets exhibit stimulus direction-specific adaptation in wind-elicited avoidance behavior. Repetitive air currents inducing this behavioral adaptation reduced firing responses to the stimulus and amplitude of excitatory synaptic potentials (EPSPs) but did not modulate paired-pulse ratio of EPSPs in wind-sensitive giant interneurons (GIs) related to the avoidance behavior. Injection of Ca^{2+} chelator, BAPTA into GIs diminished both response attenuation and synaptic depression induced by the repetitive stimulation, suggesting that adaptation of GIs induced by the repetitive stimulation is Ca^{2+}-mediated short-term depression at sensory afferent-to-GI synapses. Some types of GIs showed adaptation specific to direction of repetitive stimuli, resulting in alternation of directional tuning curve. Optical imaging of dendritic Ca^{2+} responses revealed that a transient rise in Ca^{2+} was

restricted to the specific area of dendrites in the types of GIs of which directional tuning was altered. In contrast, other type of GIs with constant directionality exhibited global Ca^{2+} elevation throughout the dendritic arbor. These results suggest that depression induced by local Ca^{2+} accumulation at continually activated synapses of key neurons underlies direction-specific behavioral adaptation. This input-selective depression mediated by heterogeneous Ca^{2+} dynamics could confer animals with the ability to detect novelty at the earliest stages of sensory processing.

Title: Preceding auditory inputs modulate responsiveness and orientation in wind-elicited walking behavior in the cricket

Authors: ***M. FUKUTOMI**[1], H. OGAWA[2];
[1]Grad. Sch. of Life Sci., [2]Dept. of Biol. Sci., Fac. of Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Animals flexibly alter their movements depending on their environmental context or experiences even if they receive identical stimulus that trigger stereotypical behavior. The context-dependent changes in locomotion are also observed in escape behavior (Domenici, 2010). For example, the goldfish against the wall alters escape direction in response to auditory stimulus to avoid collision with wall (Eaton and Emberley, 1991). This means that additional sensory inputs in different modality affect on the neuronal circuitry directing the avoidance behavior. However, relationships between characteristics of the modulating stimulus and behavioral change remain unknown. To address this question, we adopted wind-elicited walking in the crickets as experimental model. Crickets exhibits the oriented escape walking response to short airflow stimulus (Oe and Ogawa, 2013), which is mediated by wind-sensitive organ called 'cerci' at the rear of the abdomen. The auditory stimulus detected by tympanal organ at frontal legs also elicites distinct oriented behaviors. Female crickets exhibit positive phonotaxis in

response to conspecific male's calling songs (Hedwig, 2006). In contrast, ultrasound produced by approaching bats induces negative phonotaxis in flying cricket (Moiseff et al., 1978). We have been reported that tone sound preceding air puff by 800 ms biased the walking direction backward and increased response threshold of the wind-elicited escape behavior (Fukutomi et al., 2014, SfN meeting). This auditory modulation was independent from on the coincidence in stimulus directions between tone and air puff. In this study, we examined these effects of the acoustic stimulus with various temporal characteristics on the wind-elicited walking. Simultaneous exposure of tone and air puff with no delay had no effect, but preceding tone but non-overlapped with air-puff stimulus also altered the walking direction. Furthermore, and tone preceding air puff by 200 ms increased turn angle in addition to modulation in direction and threshold. These results suggest that preceding auditory inputs produce different context for the cricket and modulate the cercal-mediated escape behavior.

Title: The effect of calling songs with multiple frequencies in the phonotactic response of female cricket Acheta domesticus

Authors: *J. MENDONCA, B. NAVIA, J. STOUT;
Andrews Univ., Berrien Springs, MI

Abstract: Female cricket Acheta domesticus exhibits selective phonotaxis in response to model calling songs with intensities above 75 dB and a carrier frequency of 4 - 5 kHz. When the animal is exposed to calling songs with varying syllable periods (30 to 90 ms), it is more likely to perform phonotaxis to calls with syllable periods that approach the most attractive range (50 - 70 ms), hence demonstrating its selectivity. On the contrary, it is less likely to respond phonotactically to calling songs with syllable periods that deviate from the most attractive range. Higher frequency sounds (16 kHz), have been reported to produce an aversive effect on the animal, reducing its likelihood of responding phonotactically to such calls. We hypothesized that an attractive calling song can become unattractive by adding a 16 kHz component to an already

existing 5 kHz call. In this experiment, young females (8 - 13 days old) were behaviorally tested to auditory stimuli consisting of single and dual frequencies: i) 5 kHz, 85 dB calling songs (30 - 90 ms), ii) 5 kHz, 85 dB + 16 kHz 45 dB and iii) 5 kHz 85 dB + 16 kHz 85 dB. The intensity of the 5 kHz component remained unchanged. Preliminary results suggest that in response to a dual frequency auditory stimuli, the animal is more likely to exhibit negative phonotaxis.

Title: Crickets employ different escape strategies for different aversive stimuli

Authors: *C. L. CLELAND, A. M. CHILDS, K. L. REIMAN, R. L. GAITA, A. A. SIEBELS, A. M. SILVA, S. C. HEITSCH, C. R. EBEL, G. P. HOPKINS, J. C. SORIAGALVARRO; Biol., James Madison Univ., Harrisonburg, VA

Abstract: Animals respond to aversive stimuli with escape or withdrawal responses. In crickets, wind, which might normally be produced by an approaching predator, has been shown to evoke an escape response in which the cricket turns 180 degrees from the wind and then runs or jumps away. Similarly, looming stimuli that mimic the approach of a spider evoke similar turn and run responses. However, these results raise the question whether crickets utilize the same or a different strategy for noxious stimuli delivered directly to the cricket's leg. The goal of our research was to determine if crickets (Acheta domesticus) use the same or different strategies to escape from looming or heat stimuli delivered from different directions. Our results show that while crickets use a turning strategy for looming stimuli, they use a translational strategy for localized heat stimuli. Looming stimuli were created by attaching a 3" black polyurethane ball to the end of a 12" air cylinder (45 degrees to vertical) driven by compressed air. The direction of "attack" was varied in 45 degree increments around the cricket. In separate crickets, heat stimuli were delivered to each of the six tarsi with an infrared laser. The cricket's (n=60 crickets) response was recorded by a high-speed video camera (650 fps) from overhead. The top of the head, thoracic-abdominal junction and the tip of the abdomen were tracked over time to provide the two dimensional locations and orientation of the abdomen and the head/thorax. Further, the

initial locations of the tip of tarsi just prior to movement were recorded. Movement of the cricket was quantified in terms of turning and translation. In response to looming stimuli, crickets typically turned directly (180 degrees) away from the stimulus. Further, the response direction varied with the laterality of the stimulus. In contrast, crickets used a different strategy to escape from heat stimuli. Although they turned away from the side of the animal stimulated, the turn was small (~20 degrees) and did not depend on the laterality of the tarsi. In contrast, translation of the entire animal was directly away from the stimulus (180 degrees) and depended on the laterality of the tarsi stimulated. These results demonstrate that that the translational escape strategy used by crickets for heat stimuli is qualitatively different than the turning strategy used for looming strategy and suggests the hypothesis that the escape strategy used by insects may depend on whether the stimulus is local (e.g. tarsi) or global (e.g. wind).

Title: The roboscorpion-a method for inducing defensive behavior in giant desert hairy scorpions (hadrurus arizonensis)

Authors: *D. W. MILLER, G. GAGE;
Neurosci., Michigan State Univ., East Lansing, MI

Abstract: There is a significant lack of knowledge concerning the behavior of scorpions, despite being the largest biomass in several ecologies. Scorpions primarily access the world around them via mechanosensation, with legs highly sensitive to touch. Upon being touched, the scorpions engage in antipredator defensive behavior, which in this species entails movement away from the site of contact. By delivering positive voltage through silver wires implanted in the tarsal segment of H. arizonensis legs and exciting the leg?s mechanosensory neurons, the false

sensation of being touched can be induced in the scorpions. Utilizing the Backyard Brains Roboroach printed circuit board to provide electrical stimulation, up to 3.3 V and 65 Hz, to each of their legs in turn, multidirectional antipredator movement was induced and demonstrated in H. arizonensis.

Title: Neural correlates of spatial attention in the central complex of the praying mantis (Tenodera sinensis)

Authors: *J. P. MARTIN[1], A. WOSNITZA[2], D. BERTSCH[2], J. W. BOSSE[2], A. J. POLLACK[2], R. E. RITZMANN[2];
[1]Dept. of Biol., [2]Biol., Case Western Reserve Univ., Cleveland, OH

Abstract: Attention to a region of space is central to the survival of a predator. Praying mantises track and stalk small, often cryptic prey using mainly motion cues. Here we report that this behavior shares features of spatial attention found in other animals including vertebrates. Mantises (Tenodera sinensis) were observed tracking live prey (cockroach nymphs) and prey simulated on an LCD monitor positioned under the clear floor of an arena. Mantises initially oriented to moving stimuli anywhere in their visual field. Once a particular target was foveated, 1) the mantis became insensitive to movement in the periphery of the visual field, 2) response delay to prey movement was shorter, and 3) responses to movement in the periphery gradually returned if the target stopped moving. Extracellular recordings from the CX of freely-moving mantises identified CX neurons broadly or narrowly tuned to movement in regions of the visual field. Once the mantis oriented to a target, a subset of CX neurons stopped responding to the movement of other prey in the periphery. Some neurons initially responsive to movement in the center and the periphery became responsive only to movement of the foveated prey. When the

target prey stopped moving, responses of these cells gradually returned, often before a behavioral response was observed. These results suggest a role for the insect central complex in a behaviorally- and ecologically- relevant context requiring spatial attention.

Title: Robotic model used to investigate descending commands during hunting of the mantis tenodera sinensis

Authors: *N. S. SZCZECINSKI, D. J. BERTSCH, J. P. MARTIN, R. D. QUINN, R. E. RITZMANN;
Mechanical Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: Praying mantises perform visually-guided pivots to track and capture prey, actuating the head, thorax and legs to place the prey in the center of the visual field. Successful prey capture depends on the coordination of all leg joints with all of the body's degrees of freedom. In this behavior, neural mechanisms of sensorimotor integration interact with the biomechanics of the limbs to produce precise, rapid movement while maintaining equilibrium. To investigate these mechanisms, we have developed MantisBot, a robotic platform controlled by a real-time dynamic neural network model of insect thoracic ganglia circuits. The robot uses joint angle measurements from the servomotors and strain readings from each femur to produce posture. Rather than storing a map between body motion and leg joint angles, it commands its joints by fusing joint positions and load data with descending commands to pivot left or right. We use detailed, three-dimensional kinematics of the leg and body joints from high-speed video recordings of the animal to tune the neural network controller, ultimately achieving stable pivots that mimic the animal's movement. This hypothetical control structure can generate hypotheses

and test our understanding of how descending commands interact with motor circuits to produce visually-guided movements.

Title: Change in hunting strategy is mediated by insulin in the praying mantis (Tenodera sinensis)

Authors: ***D. J. BERTSCH**[1], J. P. MARTIN[2], A. C. CARDWELL[2], R. E. RITZMANN[2]; [2]Biol., [1]Case Western Reserve Univ., Cleveland, OH

Abstract: Successful predation requires adapting hunting strategy to both internal and external contexts. Some species of praying mantis are primarily sit-and-wait or ambush hunters, but will actively pursue prey if they have been deprived of food. Here, we report the sensory and motor changes that accompany this switch between strategies. Starved mantises were observed in an open arena as they hunted live (cockroach nymphs) or simulated prey (on an LCD screen positioned below the clear floor of the arena). Starved mantises oriented to more distant prey than satiated animals, performed whole-body pivots of larger amplitude during tracking, and were more likely to pursue prey than sated animals. Injection of bovine insulin into the hemolymph of a starved animal produced similar increase in the threshold for responses to visual prey-like stimuli and reduced movement in comparison to saline-injected controls. Importantly, both sated and insulin-injected controls would still strike at and consume prey. We also report on insulin-induced changes in central complex (CX) responses to prey-like stimuli, and anatomical details of the insulin and short neuropeptide F pathway in the mantis brain. These results suggest that large switches in strategy can result from relatively simple changes in sensorimotor processing.

Title: Feeding network excitation drives a progressive reconfiguration of the turn motor network in a predatory sea-slug

Authors: *J. W. BROWN[1], R. GILLETTE[2];
[1]Col. of Med., [2]Mol. and Integrative Physiol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Critical decisions in foraging for the predatory sea-slug *Pleurobranchaea californica* include approach-avoidance turning in response to salient stimuli and the suppression of turning during active, consummatory feeding. Our aim has been to elucidate the mechanisms of these actions by 1) identifying those elements in the feeding network that effect the reconfiguration of the turn network and 2) evaluating the roles played by a set of interneurons previously implicated in avoidance turning. It was previously shown that corollary output from the feeding network switched the polarity of the turn motor network from avoidance to orienting, thereby forming the basis of foraging approach-avoidance decisions. We found that members of a group of previously characterized buccal corollary discharge neurons activated during feeding exerted variable effects on turning behavior. In addition, bilateral avoidance turn command neurons, the A4s, were found to play no essential role in orienting turns. By contrast, bilateral serotonergic neurons known to modulate and sustain avoidance turns, the As2/3s, exhibited greater stimulus-driven activation when avoidance was converted to orienting turning. At sufficiently high levels of excitation in the feeding network, all identified turn elements were inhibited and turning was suppressed, consistent with suppression of turning during active feeding behavior. These results were synthesized in a model relating how interactions between the two networks drive foraging decisions.

Title: Correlating kinetics and kinematics of earthworm peristaltic locomotion

Authors: *E. N. KANU[1], K. A. DALTORIO[2], R. D. QUINN[2], H. J. CHIEL[3];
[2]Mechanical & Aerospace Engin., [3]Biol., [1]Case Western Reserve Univ., Cleveland, OH

Abstract: The soft-bodied common earthworm, Lumbricus terrestris can bend and contort its body in response to its environment in order to navigate heterogeneous terrain and squeeze into narrow, constrained spaces. At the same time, the earthworm can exert forces radially and laterally against its environment to break up compacted soil, create and enlarge burrows, and resist extraction from its burrow by predators. In this poster, we quantitatively studied the coupling of kinematics and kinetics in earthworm peristalsis. We hypothesized there is a strong correlation between worm segment shape and variable, non-uniform load distribution of worm weight. Peristalsis, a wave of contractions that move posteriorly down the worm body, is the primary mechanism of earthworm locomotion. As segments contract laterally, they simultaneously increase circumferentially in diameter, while the segments anterior to them protrude laterally and decrease radially. We expect that, in order to minimize frictional drag losses, the segments with the widest diameter, being the “anchoring” segments (Miller 1988), will carry most of the load and consequently exert the maximum observed force normal to the ground. This leaves the non-contracting moving segments bearing the least amount of weight and thereby experiencing minimal frictional forces. This presumably leads to variable friction forces across the body. By utilizing video-tracking and measuring the vertical forces exerted by the worm segments while in motion, we correlated changes in segment shape to forces exerted by each segment. In our preliminary data, the anterior segments exhibit a correlation between segment diameter expansion and peak vertical forces exerted on the ground. The rear segments also exhibit variation in ground reaction forces; however, they display a more complicated relationship between segment expansion and exerted vertical force. Future work will explore this phenomenon. Understanding the way the worm exerts these forces may help us implement peristalsis in robots in diverse real-world environments.

Abstract: Mimicking and better understanding the way an earthworm uses its many segments will help in designing new soft robots for a wide variety of applications. This is a challenging problem in robotics and biological insights can be valuable in both control and mechanical design. Here, we develop a new type of robotic platform for investigating these problems: Compliant Modular Mesh Worm (CMMWorm). The robot's body utilizes a compliant mesh that couples decreases in diameter with increases in length. The function of the mesh parallels the hydrostatic skeleton of an earthworm. Because of this diameter-length coupling, as waves of radial contraction travel down the cylindrical body, our robot advances along ground or in pipes with peristaltic locomotion. The mesh consists of rhombuses whose sides are polycarbonate rods or nylon tubes. The vertices of the mesh are 3-D printed and permit pin-joint rotation of the rhombus sides. Each segment of the robot is individually controlled using a smart servo actuator attached to cables for both longitudinal (contraction) and circumferential (extension) motion. The modular mesh enables the robot to achieve a large strain range comparable to that of an earthworm. In an earthworm, the minimum segment diameter is 50-60% smaller than its maximum diameter, while the mesh of CMMWorm is capable of actively deforming 52% relative to its maximum diameter. With six segments, our modular robot can crawl on smooth, flat substrates and pipes. The smart servos provide load sensing, which in combination with simple kinematic models, can provide the basis for responsive behaviors. Individual segments can detect the wall of a pipe, estimate its diameter, and return to its initial position using a load-sensing algorithm. To provide immediate response to multisensory perturbations while coordinating multiple degrees of freedom, we are exploring stable heteroclinic cycles (SHCs) as a dynamical architecture. CMMWorm is an ideal platform for comparing the performance of SHCs with finite state machines and limit cycle oscillators.

Title: Controller design for a soft-bodied peristaltic locomotion robot

Authors: ***K. A. DALTORIO**[1], A. D. HORCHLER[1], A. KANDHARI[2], H. J. CHIEL[3], R. D. QUINN[1];
[1]Mechanical Engin., [3]Biol., [2]Case Western Reserve Univ., Cleveland, OH

Abstract: The type of soft-body locomotion used by earthworms and slugs could be valuable for robots that inspect pipes, crawl through collapsed tunnels, or assist in endoscopy. The sequential pattern of muscle contraction that generates this motion is called peristalsis. However, if the pattern of rearward traveling waves is not responsive to the environment, the body's progress will be stalled by small obstacles, changes in diameter of the substrate, or other irregularities. Here, we have designed a responsive controller based on a mutually inhibitory dynamic architecture in a simplified simulation environment that determines body segment actions based on contact feedback. Control and simulation of worm robots is notoriously challenging because of their many ground contacts, hyper-redundancy, and highly nonlinear and interdependent deformation. Our simulation uses several simplifying assumptions to make this problem tractable including: 1) each segment is a simple rhombus whose increases in length cause decreases in height, 2) stiffness interdependence is limited to nearest neighboring segments, 3) contact forces are modeled with Coulomb dry friction and can be sensed by the controller, and 4) the robot and surrounding environment are radially symmetric. The controller determines how to apply actuation forces to each segment rhombus. Stable heteroclinic channels (SHCs) are continuous

dynamical systems capable of generating rhythmic output of varying period in response to sensory inputs or noise. This feature can be used to control state transitions smoothly. Here, each segment must anchor, extend, or retract. The contact feedback is connected to the SHC, which controls the timing of transitions between these actions. We demonstrate that our SHC controller allows for improved adaptation to a change in pipe diameter with more rapid movement and less energy loss. In an example narrowing pipe, this controller loses 40% less energy to slip compared to the best-fit sine wave controller. This controller design informs our ongoing biological experiments and robotic worm designs.

Title: Brain-wide attractor dynamics represent the motor command sequence in *C. elegans*

Authors: ***S. KATO**, H. KAPLAN, T. SCHRODEL, M. ZIMMER;
IMP - Res. Inst. of Mol. Pathology, Vienna, Austria

Abstract: Behavior is a continuous output of the nervous system, yet a prevailing approach to describe behavior defines discrete modules assembled into action sequences. This raises the question of how this higher level of organization might be represented by neural activity. Using single-cell resolution brain-wide calcium imaging in Caenorhabditis elegans, we show that the continuous, spontaneous activity of most interneurons and motor neurons in the worm brain

organizes into widely shared, coordinated population dynamics. The neural state evolves as a cyclical trajectory, tracing out a sub-volume, or manifold, indicative of attractor-like dynamics. Distinct regions of the manifold capture differential neuronal recruitment patterns; the participating neurons exhibit cell class-specific phase relationships with the global oscillation. We imaged the activity of representative neurons in freely moving animals and found that they reliably encode both motor behavioral state and graded metrics of motion, like crawling speed and posture. This information enables us to map instantaneous brain state, on a single-trial basis, to motor command state. Decisions between alternate behavioral commands manifest as branching trajectory bundles. The neural state manifold is robust to decoupling from motor output, as well as salient sensory input, which entrained the global brain oscillation. Both results indicate that the time evolution of behavioural commands is stably maintained by intrinsic population dynamics. Directional flow on the manifold corresponds to the temporal sequence of actions, thereby establishing a continuous embedding of the action sequence in neural state space. This study defines the function of the global brain signal in this system: to maintain a representation of the holistic motor command sequence.

Title: Octopuses hold their head in a fixed horizontal orientation relative to the world likely to simplify the control of locomotion with flexible arms

Authors: ***G. LEVY**, B. HOCHNER;
Dept. of Neurobio., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Octopus vulgaris has a soft body lacking any rigid skeleton and a very complicated morphology, including eight long, slender, flexible arms. Each arm has an enormous number of degrees of freedom (DOFs) and is thus very complicated to control. Due to the very flexible body, the position and posture of the head relative to the motoric system (the arms) is highly

variable and thus could be a hindrance for locomotion control that must coordinate the motoric and visual systems. Here we analyzed the kinematic parameters of the posture of the octopus head during various spontaneous and evoked behaviors. Octopuses were videotaped with two or three video cameras positioned at different angles. Video images were loaded into dedicated Matlab software we developed specifically to analyze octopus head position, posture, and orientation. Reconstructing the 3D position of the eyes in each time frame revealed that during all behavior octopuses always keep the head horizontally orientated relative to the ground, regardless of substrate slope or orientation; the two eyes, which lie at a fixed position in the head, were always at the same height relative to the ground. This means that octopuses keep their visual system at a fixed 2D horizontal orientation relative to the world. This head orientation is maintained even when some arms are in contact with fixed reference points during crawling, standing, and walking. Because the octopus head cannot appreciably move or rotate relative to the body and the arm bases, the orientation of the head is controlled only by the arms (while they are supporting the body). Therefore, the orientation of the head must be continuously controlled by dynamically adjusting the chord distance between the point of contact of the arm with the supporting environment and the head. Fine adjustment of the chord length can be achieved, for example, by controlling the level of arm stiffness. It is most likely that head orientation relative to gravity is controlled by the statocysts of the octopus vestibular system. Our results therefore imply that the statocysts are an important part of the motor programs controlling the arms during the various locomotory and static behaviors. Using the statocysts simplifies arm control as it constrains the number of DOFs in the interaction of the arms with the environment. In addition, the fact that the sensory and motor control centers in the head are at a fixed reference position relative to the world reduces the number of DOFs involved in the interactions of the octopus with the environment.

Title: A surprisingly rich behavioral repertoire for an animal without a brain - the sea anemone Stomphia coccinea

Authors: *W. N. FROST[1], R. T. PORTER[2], Y. ISMAIL[2];
[1]Dept Cell Biol. and Anat., The Chicago Med. Sch., North Chicago, IL; [2]Dept. Biol., Lake Forest Col., Lake Forest, IL

Abstract: Sea anemones are considered to be the first group of organisms in animal evolution exhibiting a nervous system. They have no brain or CNS. Instead, they make do with a primitive nerve net consisting of diffusely distributed neurons. Like all anemones, *Stomphia coccinea* uses stinging nematocysts on its tentacles to subdue and capture prey. *Stomphia* is also well known for its remarkable ability, unusual in anemones, to flee from its own predators by detaching and then swimming via a series of alternating body flexions that propel it away to safety. Intrigued by its ability to generate such complex behavior with a nonspecialized, diffuse nerve net, we decided to more fully characterize *Stomphia's* behavioral repertoire. This involved comparing its responses to two very different predators: the seastar *Dermasterias imbricata* and the nudibranch mollusk *Aeolidia papillosa*, an anemone specialist. Several responses of eight Stomphia to each of these predators were filmed. Stomphia's response to *Dermasterias* was always defensive, consistent with prior literature, and consisted of rapid tentacle withdrawal and oral disk closure, followed by column extension, pedal disk detachment, and swimming. Prior reports have also documented escape swimming of *Stomphia* to *Aeolidia*. Comparing the responses to the two predators, we found that *Stomphia* employed a very different strategy upon detecting *Aeolidia*. In the large majority of encounters, *Stomphia* responded aggressively, with one or more directed bends to sting the predator. This was often followed by rapid withdrawal of the tentacles and closure of the oral disk for 10s of seconds, after which the anemone frequently reemerged to attack again. Occasionally it would also bend over and whirl its tentacles around the column base, sweeping them in a circular search pattern. Most of the time these attack behaviors were successful at driving away the nudibranch. In a third of the cases (10 of 33) they weren't, and *Stomphia* switched tactics by detaching and swimming away. Collectively, these observations indicate that *Stomphia* employs two very different behavioral strategies in response to the two predators. To the larger sea star it always flees. To the smaller nudibranch *Stomphia* nearly always attacks first, often driving it off. If unsuccessful, it then switches strategies and flees. These diverse behavioral strategies are impressive for an animal equipped with only a diffuse nerve net.

Title: Impacts of elevated environmental manganese on crayfish behavior and neurophysiology

Authors: A. C. LEFEVRE, A. PARSONS-WHITE, *B. L. ANTONSEN;
Biol. Sci., Marshall Univ., Huntington, WV

Abstract: Each year millions of tons of manganese (Mn) are extracted for use in steel production, which is a vital part of the Appalachian region's economy. However, the Mn that is deposited into the air and water ways during manufacturing could be harmful to the health of residents in the area. Although Mn is an essential nutrient, high amounts of Mn in the water and air have shown to have neurotoxic effects in humans with symptoms similar to those of Parkinson's disease and ADHD, such as, tremors, disrupted balance, and hyperactivity. The EPA has a maximum allowable concentration of 0.05 ppm for drinking water, but currently there are no federally recommended aquatic life criteria for Mn. Concentrations exceeding 10 ppm have been detected in surface streams near mining activities. This research involves determination of the effects elevated Mn has on the escape response and relevant neurotransmitter distribution/concentration of crayfish. Because crayfish are a keystone species, negative effects on their behavior can cause disruption to entire ecosystem. Crayfish are exposed to ecologically relevant concentrations of Mn, up to 10 ppm for chronic (2 week) and acute (2 day) periods to simulate chronic exposure downstream from industrial sites and from runoff or spills that are short term, respectively. Crayfish are exposed in aquaria and are tested for latency to, duration of, and trajectory of first tail flip. Nerve cords are then removed and immunolabeled for serotonin and dopamine, because these neuromodulators are known to influence changes in crayfish posture and motor control. Crayfish treated with low levels of Mn for acute exposure times did not show any detectable behavioral change. However, chronic exposure effects escape trajectory and latency. A dose dependent response is seen in chronically treated crayfish where latency decreases as concentration of Mn increases. This suggests that elevated concentrations of Mn may lead to increased escape circuit excitability in crayfish.

Title: Advances in high-resolution, high-throughput whole mouse brain volume electron microscopy

Authors: ***S. MIKULA**[1], S. K. MIKULA[1], M. MUELLER[1], N. NEEF[2], J. TISLER[1], J. TRITTHARDT[1], W. DENK[1];
[1]Electrons - Photons - Neurons, Max-Planck Inst. For Neurobio., Martinsried, Germany; [2]Max-Planck Inst. For Med. Res., Heidelberg, Germany

Abstract: Currently only electron microscopy provides the resolution necessary to reconstruct neuronal circuits completely and with single-synapse resolution. Because almost all behaviors rely on neural computations widely distributed throughout the brain, a reconstruction of brain-wide circuits and ultimately the entire brain is highly desirable. However, these reconstructions require the undivided brain to be prepared for electron microscopic observation. Recently, a preparation, BROPA (brain-wide reduced-osmium staining with pyrogallol-mediated amplification), was described that results in the preservation and staining of ultrastructural details throughout the brain at a resolution necessary for tracing neuronal processes and identifying synaptic contacts between them (Mikula & Denk, 2015). Here, we present recent progress towards volume imaging the whole mouse brain using a high-throughput (>1 GHz imaging rate) 91-beam scanning electron microscope, a custom-built in-vacuo whole-brain microtome and an evaporative metal coater, all of which are integrated into a fully automated workflow using an in-chamber robot. Our method may be suitable for generating a high-resolution whole mouse brain volume electron microscopy dataset that would serve as the basis for a complete neural circuit reconstruction. This work was funded by the Max Planck Society.

Title: Human brain anatomy post mortem with a whole-brain 9.4T RF-coil: towards mesoscale resolution with MRI

Authors: *A. ROEBROECK[1], S. SENGUPTA[1], M. BASTIANI[1], S. SCHILLAK[4], B. TRAMM[4], M. WAKS[4], A. LATASTER[2], A. HERRLER[2], D. TSE[3,5], B. POSER[1]; [1]Cognitive Neurosci., [2]Dept. of Anat. & Embryology, [3]Dept. of Neuropsychology and Psychopharmacology, Maastricht Univ., Maastricht, Netherlands; [4]Life Services, LLC, Minneapolis, MN; [5]Dept. of Radiology, Maastricht Univ. Med. Ctr., Maastricht, Netherlands

Abstract: Introduction The investigation of whole human brains post mortem with large bore MRI systems can achieve resolution considerably superior to that achievable in-vivo. Here the aim is i) to design and construct a specialized 9.4T 8Ch parallel transmit (pTX), 24Ch receive RF-coil for whole post mortem human brains and ii) to show that its use in pTX-mode enables high resolution anatomical imaging of the whole human brain. **Methods** A single formalin fixed human brain was used from a male donor giving informed consent under the Maastricht University, Department of Anatomy & Embryology Body donation program (death to formalin fixation: ~12h, fixation to scanning: ~12 months). A 3D conformal container for post mortem human brains was created and a former (accommodating 24Ch RX and 8Ch TX) was modeled around the container (fig. 1A). Experiments were performed with a 9.4T 820cm bore human MR scanner (Magnetom 9.4T, Siemens Medical Solutions, Erlangen, Germany). High resolution MRI was performed with a 3D gradient echo pulse sequence with a kt-points pTX pulse [1] with imaging parameters: matrix 448x510x448, FA=6deg, 4avgs. T1w: TR=8.4ms, TE=3.6ms TA=1h49m; T2*w: TR=32ms, TE=10,15,20,25ms, TA/echo=7h09m. **Results & Conclusion** High signal and contrast is achieved at high resolution in the entire brain with T1 weighted (fig. 1B) and T2* weighted (fig. 1C) contrast. PTX Homogenized RF fields enable stable contrast with enough detail to distinguish hippocampal layering and cerebellar folia. The constructed imaging setup for whole post mortem human brains, which combines a high magnetic field (9.4T), specialized RF-coil and parallel transmit, enables high resolution neuroanatomical investigations of the intact human brain. **References** 1.Cloos, M.A., et al. Title: Whole brain mapping of the direct inputs and axonal projections of pomc and agrp neurons

Authors: *D. WANG;
Natl. Inst. of Biol. Sci., Beijing, China

Abstract: Pro-opiomelanocortin (POMC) neurons in the arcuate nucleus (ARC) of the hypothalamus and nucleus tractus solitarius (NTS) of the brainstem play important roles in suppressing food intake and maintaining energy homeostasis. Previous tract-tracing studies have revealed the axonal connection patterns of these two brain areas, but the intermingling of POMC neurons with other neuron types has made it challenging to precisely identify the inputs and outputs of POMC neurons. In this study, we used the modified rabies virus to map the brain areas that provide direct inputs to the POMC neurons in the ARC and NTS as well as the inputs to the ARC AgRP neurons for comparison. ARC POMC neurons receive inputs from dozens of

discrete structures throughout the brain, and mainly from the hypothalamus. The brain areas containing the presynaptic partners of ARC POMC neurons largely overlap with those of ARC AgRP neurons, although POMC neurons receive relatively broader, denser inputs, which suggest ARC POMC and AgRP neurons may be regulated by some similar upstream nuclei. Furthermore, the direct inputs to POMC neurons in the NTS are predominantly located in the brainstem, demonstrating very different innervation patterns for POMC neurons in the ARC and NTS, which may explain their functional differentional, especially in regulating energy metabolism. By selectively expressing fluorescent markers in the ARC and NTS POMC neurons, we also found that almost all of their major presynaptic partners are innervated by POMC neurons in the two areas, suggesting that there are strong reciprocal projections among the major POMC neural pathways. Overall, our data depicted the whole-brain connections of the projection neurons of the central melanocortin system in a cell-type-specific manner. More importantly, POMC and AgRP neurons are involved in multiple physiological functions and behaviors, thus a comprehensive mapping of their connections lays the foundation for studying the functional roles of specific neural pathways.

Durham, NC; [6]Univ. of California, San Francisco, CA; [7]Univ. of California, Davis, CA; [8]Cell Biol. and Physiol., Univ. of North Carolina, Chapel Hill, NC

Abstract: New light and electron microscopy methods are now enabling the first structural and molecular measurements across large CNS synapse populations at the single-synapse level. Accumulating evidence that CNS synapses are highly diverse in structure, protein composition, function, and neuropathologic susceptibility points to an urgent need for integrated "synaptomic" survey tools. The Open Synaptome Project (OSP; http://opensynapto.me) is an endeavor of a consortium of investigators at the Allen Institute, Johns Hopkins, Johns Hopkins Applied Physics Laboratory, UNC Chapel Hill, Duke, UC Davis and UC San Francisco aimed at building broadly accessible foundations for single-synapse analysis of CNS synapse populations. Our current efforts concentrate on advancing and disseminating methods for array tomography (ATomo) immunofluorescence microscopy, as these seem especially suitable for high-throughput proteometric analysis of the diverse and volumetrically dense synapse population encountered in the mammalian CNS. Given the importance of mouse models of human brain function and human mental and neurological disorders, the OSP's initial work focuses on neocortical structures in mouse and human. The goal is to build an open and broadly useful platform to more quantitatively understand similarities and differences between CNS synapse populations in those species. The OSP's present work includes efforts to (1) improve methods for preparing specimens of mouse and human neocortex for ATomo analysis, (2) expand and validate synapse-relevant antibody panels, (3) develop faster and more automated ATomo imaging methods, (4) deploy advanced petascale image database methods, (5) improve methods for automated synaptomic analysis of ATomo image data, (6) develop cell-biologically principled taxonomies of mouse and human synapse types, and (7) establish web portals for sharing of methods, data, taxonomies, and other resources across broad communities of synapse biologists and for any other neuroscientists grappling with basic mechanisms and disorders of synaptic network function. This poster describes OSP status in each of these areas. See neighboring posters for more details.

Abstract: New experimental technologies are rapidly changing the nature of data available in neuroscience. These techniques are yielding big neuroscience data: For example, CLARITY allows imaging of the whole mouse brain at micrometer resolution, requiring ~500 gigabytes of storage. Even large workstations are unable to load the entire datasets into memory, therefore breaking the standard data analytic workflow. We present here an alternative strategy using the Open Connectome Project (OCP) infrastructure. First, we ingest each raw dataset into its own OCP database, building an image pyramid including isotropic resolutions, and store on our high-throughput data store. This enables Webvisualization capabilities, including pan and zoom in orthogonal cutting planes. The images were registered to the Allen Institute's Mouse Brain Atlas using nonlinear registration (Bsplines based nonlinear multiresolution registration strategy). Then, for each region of interest, we compute contrast and text features. The texture analysis features act directly on the raw data, avoiding the challenging preprocessing of detecting activation via unknown and data/region-dependent thresholds. Features were clustered, and the quality of clustering was evaluated using Adjusted Rand Index. We found that a small number of features (13) are sufficient for accurate classification among the classes of data (Figure 1). Moreover, the methods developed for this application are readily applied to other datasets. To that end, all data, code, and data derivatives will be made available after publication through the OCP website, http://openconnecto.me.

Title: Open connectome project: lowering the barrier to entry big data neuroscience

Authors: *J. T. VOGELSTEIN[1], S. J. SMITH[2], W. GRAY RONCAL[3], R. VOGELSTEIN[4], R. BURNS[1], K. A. LILLANEY[1], A. D. BADEN[1], G. KIAR[1], P. MANAVALAN[3];

[1]Johns Hopkins Univ., Baltimore, MD; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]Johns Hopkins Applied Physics Lab., Laurel, MD; [4]IARPA, Laurel, MD

Abstract: Recent technical progress allows neuroexperimentalists to collect ever more detailed and informative anatomical and physiological data from brains of all sizes. With classical approaches it was feasible for neuroscientists to draw their results on paper, but modern experiments are amassing terabytes of data. These datasets span experimentally accessible spatiotemporal scales, ranging from nanometers to meters, and millisecond to monthly sampling rates. These large datasets create significant challenges for our community at every step of the data analysis pipeline, including (i) image data storage and management, (ii) metadata capture, (iii) visualization, (iv) image pre-processing, (v) scene parsing, (vi) statistical analysis, and (vii) dissemination. The *Open Connectome Project* has been developed to lower the barrier to entry into big data neuroscience. We have designed and built a computational ecosystem to enable petascale neuroscience. This includes several reference workflows, including images-to-graphs from various experimental paradigms, ranging from serial electron microscopy to multimodal MRI. Moreover, anyone in the world with Internet access can now visualize, download, analyze, upload, or otherwise interact with all public datasets. We are in the process of scaling up the number of datasets, the range of experimental modalities, and the Web-services we enable. We are now embarking on a new thread called the Open Synaptome Project (http://opensynapto.me) which will provide joint electron microscopy, immunofluorescence, and physiology data across species, at sub-micrometer resolution. Work underway will provide pre-packaged cluster environments—1-click deployable on local or commercial cloud computing infrastructures—so that others can replicate and modify our services internally. All of our code and data are available online at http://openconnecto.me, in accordance with open science standards. Please come to our poster or booth if your current scientific workflows are breaking under the weight of big data.

Title: Light sheet microscopy of whole mouse brains with improved clearing and optics

Authors: *H.-U. DODT[1,2], C. HAHN[1,2], K. BECKER[1,2], S. SAGHAFI[1], N. JÄHRLING[1,2], M. PENDE[1,2], I. SABDYUSHEVA LITSCHAUER[2], M. WANIS[1];
[1]Tech. Univ. Vienna, Vienna, Austria; [2]Med. Univ. Vienna, Vienna, Austria

Abstract: Visualization of complete neuronal networks in the brain is an important goal of neuroscience. To this end clearing and recording of mouse brains with light sheet microscopy has become increasingly popular in recent years. Various water based clearings have been developed which have certain advantages like good fluorescence preservation but also certain disadvantages like incomplete clearing or complicated and unreliable procedures. We developed the first brain clearing 8 years ago which was then based on organic solvents. By clearing neuronal tissue with benzyl alcohol and benzyl benzoate (BABB) after dehydration, we could visualize GFP-labelled neuronal networks in the whole brain (Dodt et al., 2007). Improving our clearing technology by using tetrahydrofuran (THF) for dehydration and dibenzylether (DBE) for clearing (3DISCO) we were able to image GFP-labelled axons even in heavily myelinated neocortex and spinal cord (Becker et al., 2012, Ertürk et al. 2012). However both BABB and DBE based clearings quench GFP fluorescence to a certain extent, making it necessary to keep clearing times as short as possible and eventually compromising complete clearing. We found now a way to stabilize GFP fluorescence in DBE for weeks with neglegible bleaching during recording by sDISCO (stabilized 3DISCO clearing). With sDISCO we were able to visualize very delicate neuronal structures like the finest neuronal branches of the axonal network in the neocortex as well as dendritic spines. As the sDISCO clearing procedure is very reliable and the cleared brains are very solid and stable we expect sDISCO to become a standard procedure for brain clearing. In addition we developed optical devices for correcting existing air objectives used for imaging of brains in clearing solutions. To improve the axial resolution of our recordings we further developed optics for the generation of longer and thinner light sheets. The resistance to bleaching in the sDISCO clearing allowed us to record and combine several images for every optical section with laterally shifted best fields of view of the light sheet (x-focussing). With the combination of improved clearing and improved optics we were able to record neuronal networks in mouse brains with unprecedented details.

Title: HeadLight: A tool chain to analyze & visualize whole mouse brain data

Authors: *K. UMADEVI VENKATARAJU[1,2], A. NARASIMHAN[1], P. OSTEN[1], Y. KIM[1], J. TARANDA[1], L. KADIRI[2];

Abstract: With the advent of whole brain imaging techniques, there is necessity to develop methods to analyze and visualize these datasets. The tool chain "HeadLight" will provide necessary tools to create an whole brain atlas, do automated cell counting and visualize the counting. Firstly, the registration part will help to register a reference brain to other brains imaged using a new imaging assay and further to port the markups of existing atlas labels to the newly generated atlases. Such atlases give the ability to compare datasets spatially in the same reference space. Secondly, we propose 2D and 3D cell counting methods to count cells in these brains using deep learning algorithms. Finally to visualize the datasets, we propose an cross platform utility built based on CMake, C++, ITK and VTK. It has the ability to see cell distribution patterns in the whole brain, compute cell density measurements, axonal densities and finally visualize statistical significance analysis. The tool also has capabilities for visual query on these datasets. In the last few years, many methods have been invented to study the mouse brain with optical imaging methods. These assays are a combination of novel optical clearing methods and microscopy techniques. We propose to quantify the variabilities in these procedures by establishing ground truth and methods to measure these metrics. In this method, we propose to use an MRI atlas as ground truth to define variabilities in shape and size of the mouse brain. We define the shinkage/bloat in various regions of the brain by calculating the dice coefficient of the same region before and after registration. We further want to quantify the efficiency of optical clearing or immunostaining penetration by measuring cell counts of the proposed assays compared to ground truth from a similar brain imaged using serial two-photon tomography. The analysis and visualization are done using HeadLight tool chain.

Title: A whole-brain atlas of inputs to inhibitory and excitatory neurons in prefrontal cortex

Authors: ***Y. XUAN**, S. ÄHRLUND-RICHTER, D. FÜRTH, K. MELETIS, M. CARLÉN; Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Prefrontal cortex (PFC) is involved in various aspects of cognition, including attention, memory and decision-making. Those processes are shaped both by the balance of inhibitory and excitatory actions in the local network and by long-range inputs from other brain regions. We map for the first time the whole-brain input circuitry controlling three central populations of inhibitory (parvalbumin, somatostatin and vasointestinal peptide expressing) and excitatory (calcium/calmodulin-dependent protein kinase IIα expressing) neurons in PFC. We have developed a two-vector system (one adeno-associated virus (AAV) and one rabies vector) for retrograde tracing of monosynaptic inputs to genetically defined populations of neurons. The

AAV has been modified to enable reliable identification of starter cells and the EGFP expressing input neurons can be plotted in the three dimensional space onto a reference atlas using our recently developed software suit[1]. Our preliminary data shows that the three types of inhibitory neurons and the excitatory neurons receive a surprisingly high degree of similar inputs. The main input to both excitatory and inhibitory neurons in PFC is derived locally, but all four types also receive extensive long-range input from the rest of cortex. Sub-cortically the basal forebrain and thalamus provide most prominent input. We found a distinct subpopulation of globus pallidus (GP) neurons, which sits along the border with internal capsule, sends inputs to PFC. We are currently performing detailed analysis of the molecular characteristics of key input areas to establish how specific cell-types provide input to the PFC circuitry. In summary, our comprehensive yet detailed circuit analysis provides a connectivity map reflecting the cellular and physiological underpinning of cognition. 1 Pollak Dorocic, I. *et al.* A whole-brain atlas of inputs to serotonergic neurons of the dorsal and median raphe nuclei. *Neuron* **83**, 663-678, doi:10.1016/j.neuron.2014.07.002 (2014).

Abstract: The complex anatomical structures of individual neurons and their synaptic connections form the signal transmission and processing pathway of the nervous system, and therefore are basis for understanding brain functions. However, existing imaging methods cannot cover the huge extension of neurons in mammalian brain with a resolution sufficient to identify connection sites (the pre- and postsynaptic structures). Here we proposed the chemical sectioning (CS) method that enables whole-mouse-brain imaging of genetically defined neuron subsets at synaptic resolution. For the first time, we show the successful reconstruction of individual neurons extending axonal projections throughout the brain, including all dendrites, centimeter-extended axonal main stems, terminal arborizations, intensive dendritic spines and axonal boutons, and putative synapses. Our method enables quantitative analysis of the morphology, projections, and connectivity of genetically defined neurons. We found that three typical projections (the corticospinal, corticostriatal and corticothalamic projections) can be covered by one layer-V pyramidal neuron.

Title: High-speed volumetric imaging of neuronal network activity in awake behaving mice

Authors: *L. KONG[1], M. CUI[2];
[1]HHMI/Janelia Res. Campus, Ashburn, VA; [2]Howard Hughes Med. Inst., Ashburn, VA

Abstract: Neural computations rely on the spatiotemporal properties of the densely-interconnected neuronal network. To study the neuronal ensemble activity, several 3D optical imaging techniques have been proposed. But due to the motion artifacts, it is still challenging for high-speed imaging of neuronal network activity in awake behaving animals. Meanwhile, fast 3D imaging with behaving animals is highly desired to study behavior or task related neuron activity. We recently developed a high-speed volumetric imaging technique with high spatiotemporal resolution. Combining an optical phase-locked ultrasound lens and a conventional two-photon fluorescence microscope, we achieved a cross-sectional frame rate of ~1 KHz, which enables high-speed volumetric imaging of biological dynamics in deep tissue.

Here we apply this technique to fast 3D imaging of neuronal network activity in head-restrained awake behaving mice with high temporal and spatial resolution.

Title: Microglia 3D reconstruction with planar fluorescence microscopy and CLARITY histology

Authors: ***G. M. ARISI**, F. ZANINI;
Univ. Federal De Sao Paulo - UNIFESP, SAO PAULO, Brazil

Abstract: Introduction Microscopy and histological techniques greatly advanced our understanding of the fine cellular structure of nervous tissue. Nonetheless, the complex tridimensional organization of neurons, glial cells and vasculature is lost in sectioning the brain in order to analyze it under the microscope. Laborious and time-consuming methods are employed to reconstruct the 3D organization of cells. Objective and Methods Advanced histological techniques like CLARITY, that preserves the cellular protein structure *in situ* and renders the nervous tissue transparent to light by removing the cellular lipid layers, will allow studies encompassing large volumes of different brain regions. Combining this histology to Selective Plane Illumination Microscopy (SPIM), or planar (light-sheet) fluorescence microscopy, makes possible a laser scanning of different immune labeled proteins of interest in large cellular populations. FIJI software can perform morphological quantitative analysis on digital images. Results Ten female rats were perfused (IACUC/CEUA 6744240414) and after thermal polymerization the brains were positioned in a electrophoretic chamber for lipid removal at 37 ºC and 40 V for 4 days and in 37 ºC bath for more 4 days rendering the tissue transparent. Immunohistochemistry for Iba-1 (Wako, lot 019-19741) was performed in 1 mm blocks and visualized in laser microscopy. Microglial cells were visible in large areas of both cortex and hippocampus. FIJI was employed to cell count in different brain areas and analysis of morphometric parameters. Discussion Transparent blocks of nervous tissue allow study of large cell populations; this histological preparation saves time in 3D studies of complex structures.

Nonetheless a new kind of microscopy has to be developed to fully take advantage of CLARITY histology. A standard confocal laser scanning fluorescent microscope was employed to visualize the labeled cells while our lab implement the light-sheet microscope. In practical time frames is possible to map glial and neuronal cellular structures in the brain. Development of open platforms using common off-the-shelf parts will create local trained personnel able to build and maintain the OpenSPIM setups. CLARITY, OpenSPIM, and FIJI constitutes powerful tools for neuroscience research labs. Financial support FAPESP 14/21984-1

Title: See-through cortex: flattening technique improves clearing speed and imaging

Authors: *J. L. BALSOR[1], J. M. MATTINA[2], S. MOLOT-TOKER[1], K. M. MURPHY[2]; [1]McMaster Integrative Neurosci. Discovery and Study, [2]Psychology, Neurosci. & Behaviour, McMaster Univ., Hamilton, ON, Canada

Abstract: Innovative tissue clearing techniques make it easy to render the brain see-through and visualize its detailed neuroanatomy. For example, columnar and area specific features in the cortex are preserved so their full 3-D anatomy can be studied. But it can take several weeks to clear the entire brain and imaging that 3-D structure relies on expensive microscopes that are not widely available. We have taken a different approach to solve these problems for studying cortical neuroanatomy by combining unfolding and flattening of the cortex with a simple tissue clearing method -- passive clarity technique (PACT). To validate the approach we first asked if PACT clears the cortex uniformly. We perfused rats with PBS, removed the brain, resected the cortical hemispheres, and gently flattened them between glass slides. The cortex was fixed by placing it in 4% paraformaldehyde for 30 minutes, then removing the slides and leaving the cortex in fix for an additional 3-5 hours. The fixed cortex was then infused with a hydrogel monomer solution of 4% acrylamide in PBS for 2 days. The monomer-infused tissue was heated for 4 hours to polymerize the hydrogels. The cortex was cleared by transferring samples to an 8% SDS solution, and applying gentle agitation while maintaining a constant temperature of 37°C. The clearing process was monitored by imaging the cortex on a flatbed scanner every 4-8 hours and quantifying the optical density across the cortex. There was uniform clearing of the

cortex over 4 days and it became optically transparent following an exponential decay (y=0.16+1.16*exp(-x/10.14). Next, we determined if anatomical features in the cleared flat cortex could be imaged using readily available scanning and microscopy techniques. We labeled the see-through cortex with fluorescent stains and imaged at low magnification using a fluorescent scanner (LiCor Odyssey) and at higher magnification (10x) with a fluorescent microscope and a confocal microscope. These imaging techniques worked well for visualizing cortical anatomy over a range of magnifications. Our results show that combining PACT with unfolding and flattening of the cortex significantly accelerates the clearing process, and makes it easy to image cortical anatomy.

Title: This is a brain-wide precision imaging method

Authors: *H. GONG, X. LI, A. LI, J. YUAN, Q. LUO;
Wuhan Natl. Lab. For Optoelectronics, Hubei, China

Abstract: Brain-wide Precision Imaging Method for type-specific circuits with cytoarchitectonic landmarks High-precision and highly accurate methods are necessary to study organisms with extremely complex structures, particularly when studying the brain. The study of neural circuits that distributed in the brain through neurites, i.e. axons and dendrites, is essential to understanding how the brain operates when healthy, injured or diseased. However, current knowledge about the intricate patterns of neural circuits is extremely sparse. For investigating these distributions, it would be ideal not only to be able to visualize neural circuits consisting of local and long-distance connections at single neuron resolution in a entire mouse brain but also achieve the neuron location information simultaneously. In fact, this kind of tracing requires continuously imaging the fine structures of neurites across the whole brain with one-micron voxel resolution. In this presentation, we introduce a fluorescence wide-field large-volume tomography (WVT) method. Combined with block sectioning, a fast and robust and high precision fluorescence imaging was achieved by a structured illumination microscopy. We also introduced a novel resin-embedding method optimized for fluorescent protein labelled mouse

brain to provide both adequate specimen hardness and fluorescence intensity. With these techniques, we acquired two colors whole brain datasets of an 8-week-old C57BL/6J mouse injected of the adeno-associated virus vector plasmid (AAV, expressing GFP) into the cingulate cortex (Cg) with voxel size of 0.32× 0.32 × 2 m^3 in 3 days. We could not only show a group of axonal projection pathways, but also discovered a new axonal long-distance projection from a neuron oriented in the Cg. With advanced labelling techniques, our method is believed to open an avenue to exploring both local and long-distance neural circuits and cell types that are related to brain functions and brain diseases down to the neurite level.

Title: Imaging the mouse spinal cord cyto- and chemoarchitecture with CLARITY

Authors: *G. SENGUL[1], H. LIANG[2], G. PAXINOS[2];
[1]Ege Univ. Sch. Med., Izmir, Turkey; [2]Neurosci. Res. Australia, Sydney, Australia

Abstract: The organization of the mouse spinal cord, with ten Rexed laminae and thirteen spinal cord nuclei, has been shown in detail in our recent publication Atlas of the Spinal Cord of the Rat (Sengul, Tanaka, Watson, Paxinos, Academic Press Elsevier, 2013). Until recently, the only way to visualize the spinal cord in 3D was to do serial sections and reconstruct these. However, tissue sectioning and subsequent imaging of individual sections have various limitations. CLARITY is a new technique developed in the Deisseroth Lab at Stanford. The present study was designed to show organization and chemo-architecture of the mouse spinal cord in 3D using CLARITY, to reveal new details and be a guide for further cord studies using this technique. C57BL/6J mice were perfused with ice cold hydrogel solution, spinal cords cut into 2-3 mm segments and washed with clearing solution until optically transparent as described by Chung et al. (Nature Methods 10:508-513,2013) and imaged using a multiphoton microscope. Calbindin,

calretinin, parvalbumin, CGRP, ChAT, serotonin, glycine, GAD67, NOS and GABA immunostaining revealed details of the 3D organization and chemo-architecture. Neurons in different laminae were observed with their projections in 3D, e.g., expressing calbindin, calretinin, ChAT, CGRP, GABA, glutamate, glycine and NOS in lamina 1, calbindin, calretinin, ChAT, GABA, glutamate, glycine, NOS and parvalbumin in lamina 2, calbindin, calretinin, CGRP, GABA, glycine and NOS in lamina 4, CGRP, GABA, CGRP, glycine, NOS and parvalbumin in lamina 5-6, calbindin, calretinin, GABA, glycine, NOS, and parvalbumin in lamina 7, CGRP and ChAT in lamina 9, and calbindin, calretinin, CGRP, GABA, glycine, NOS and parvalbumin in lamina 10. With this study, the cyto- and chemo-architecture of the mouse spinal cord have been observed in 3D for the first time using CLARITY.

Title: A platform for brain-wide imaging and reconstruction of individual neurons

Authors: ***M. N. ECONOMO**[1], N. G. CLACK[1], L. D. LAVIS[1], C. R. GERFEN[2], K. SVOBODA[1], E. W. MYERS[3], J. CHANDRASHEKAR[1];
[1]HHMI/Janelia Res. Campus, Ashburn, VA; [2]Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Max Planck Inst. of Mol. Cell Biol. and Genet., Dresden, Germany

Abstract: The structure of axonal arbors controls how signals from individual neurons are routed within the brain. However, the arbors of very few long-range projection neurons have been reconstructed in their entirety. In mammals, axons with diameters as small as 100 nm arborize in target regions dispersed over millimeters of tissue. For this reason, visualizing complete axonal arbors requires the determination of structure over length scales spanning many orders of magnitude. We describe a platform for high-resolution, three-dimensional fluorescence imaging of large, complete tissue volumes that enables the visualization and reconstruction of long-range axonal arbors. This platform relies on a high-speed two-photon microscope integrated with a tissue vibratome and a suite of computational tools for large-scale image data as well as novel methodology for optical clearing of brain tissue. We demonstrate the power of this

approach by reconstructing the axonal arbors of multiple individual motor cortex neurons spanning all cortical lamina within a single mouse brain.
