Title: Generation and characterization of a human neuronal model of Spinocerebellar Ataxia Type 6 via induced Pluripotent Stem Cell differentiation

Authors: *C. BAVASSANO[1], A. EIGENTLER[1], R. STANIKA[2], S. BOESCH[3], R. NAT[1], G. DECHANT[1];

Abstract: Spinocerebellar Ataxia Type 6 (SCA6) is an autosomal dominant neurodegenerative disease characterized by late onset, slow progression and pure cerebellar ataxia. SCA6 is an allelic disorder associated with the CACNA1A gene, coding for the alpha 1 A (α1A) subunit of P/Q type voltage-gated calcium channel CaV2.1, which, in the brain, is particularly highly expressed in the cerebellum. SCA6 mutation consists of a short expansion of a polyglutamine stretch located in the cytoplasmic C-terminal tail of the channel protein. Extensive studies, both using heterologous expression systems and transgenic animal models, have highlighted the complexity of the pathogenic molecular mechanism of SCA6. Currently, the cause of the disease remains elusive, and no therapy is known for SCA6. We hypothesize that the analysis of patient-derived neurons expressing SCA6-CaV2.1 channels in their endogenous human neuronal microenvironment will help to shed light on the molecular cause/s of the disease. To this end, the aim of our study is to characterize the biophysical, cellular, and molecular properties of SCA6 patient-derived neurons differentiated from induced Pluripotent Stem Cells (iPSC). Control and SCA6 patient-derived iPSC were generated using Yamanaka´s reprogramming factors. Neuronal differentiation was achieved following a milestone-based protocol, and each stage of differentiation was defined by morphological criteria and the expression of stage-specific markers. In addition, a genetically encoded fluorescent reporter for the expression of the synaptic protein synapsin was used for the identification of mature neurons. The resulting SCA6 patient-derived neurons expressed the typical proteins of differentiated neurons, including cytoskeletal proteins (tau, MAP2, beta tubulin III), synaptic proteins (PSD95, synapsin, synaptophysin), voltage-gated ion channels (KV1.1, NaV1.1, NaV1.2), neurotransmitter-related enzymes and transporters (GAD67, VGLUT1, VGLUT2). Patch clamp recordings revealed the capability of firing action potentials and eliciting voltage-dependent calcium currents, and CaV2.1 channel

protein was expressed both in control and SCA6 neurons. The characterization of this human model includes the analysis of CaV2.1 currents, synaptic transmission, CaV2.1 channel protein subcellular distribution and differential gene expression, both in control and SCA6 neurons. In summary, we have generated functional SCA6 patient-derived neurons expressing the disease relevant protein via differentiation of iPSCs. This model will help to understand the effect of SCA6 mutation on CaV2.1 channel protein functionality in human neurons.

Abstract: There are many challenges involved in the production of valuable, consistent cell products that may be used to model diseases across different laboratories. We have addressed some of these challenges by creating a human induced pluripotent stem cell (iPSC)-derived motor neuron production core for disease modeling studies and translational work. In particular, we are focusing our efforts on producing banks of motor neurons derived from patients with motor neuron diseases such as amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy (SMA) using cutting-edge differentiation techniques for derivation and banking. We describe our banking and quality control methodology with a focus on batch-to-batch consistency. Key aspects to the process include: standard operation procedure development and implementation, barcoded sample and metadata tracking throughout the manufacturing process using custom inventory software, and rigorous purity, potency and identity assays. Alongside these differentiation protocol optimizations, we are also developing genome-wide methods to assay global mRNA and protein expression in these cells. These analyses aim to sensitively gauge

technical variability across batches, assess similarities to *in vivo* motor neurons, and detect biologically meaningful differences between disease and control conditions. Rigorous accounting of all these factors will be crucial for effective motor neuron disease modeling.

Abstract: Traditional tissue culture techniques for growing neurons and glia involve plating in a 2-D system with a large volume of static growth media. This is far from the normal environment of the living brain - in which the cells are within a three dimensional environment with limited extracellular space and high concentrations of extracellular matrix materials available to the cells. In order to mimic this environment, we have combined Organs-on-Chips technology with the proprietary iPSC differentiation protocols to more accurately model the *in vivo* environment. We have shown that we can successfully co-culture brain microvascular endothelial cells (iBMEC), neurons and astrocytes in a more physiologically relevant manner within the chip. The dynamic nature of the chip facilitates the creation of a more appropriate environment for growth and differentiation . The iBMEC, iMNs and astrocytes survived within the chips and differentiated appropriately. Astrocytes sent processes through the membrane pores to contact iBMECs in the adjacent channel. This model provides a unique platform to study the interactions between endothelial cells and neural tissue, forms the basis for a new Blood Brain Barrier-on-

Chip (BBB) model, and moves towards disease specific chip models using iPSCs derived from patients with ALS or Parkinson's disease.

Title: Induced pluripotent stem cells to examine the c9orf72 repeat expansion in skeletal muscle

Authors: *E. SWARTZ, J. BAEK, M. PRIBADI, G. COPPOLA;
Neurosci., UCLA, Los Angeles, CA

Abstract: The hexanucleotide repeat (rGGGGCC) expansion in the gene C9orf72 is the most common cause of frontotemporal dementia (FTD), motor neuron disease (MND), and FTD/MND. Induced pluripotent stem cells (iPSCs) offer a way to explore the pathogenic mechanisms caused by specific genetic mutations in the tissues of interest. It is currently unknown how rGGGGCC impacts skeletal muscle in FTD/MND or whether skeletal muscle mimics pathology seen in motor neurons. As such, we sought to model rGGGGCC-related FTD/MND *in vitro* via reprogramming fibroblasts into iPSCs from (1) rGGGGCC carriers, (2) individuals diagnosed with sporadic FTD, and (3) healthy controls. We developed a novel protocol for differentiation of iPSCs into multinucleated, Myogenin positive skeletal muscle cells. We use this protocol to show that skeletal muscle derived from rGGGGCC carriers contain RNA foci, yet lack mislocalized TDP-43 and endogenous dipeptide repeat pathology. We additionally investigate acetylcholine receptor clustering, calcium release through internal ryanodine receptors, the presence of enlarged late endosomes, and the establishment of

functional neuromuscular junctions using complimentary iPSC-derived motor neurons seeded on opposing sides of microfluidic plates.

Title: Subcellular localisation of schizophrenia susceptibility protein ZNF804A in human neurons

Authors: *P. M. DEANS, S. HALAI, P. RAVAL, K. WARRE-CORNISH, K. SELLERS, G. D. COCKS, J. PRICE, D. P. SRIVASTAVA;
Neurosci., Inst. of Psychiatry, Psychology & Neurosci., London, United Kingdom

Abstract: Genome-wide association studies (GWAS) have been extensively used to identify candidate genes for schizophrenia. One of the first genetic variants achieving genome-wide significance for psychosis was rs1344706 in the zinc finger binding protein 804a (ZNF804a). The gene ZNF804a is highly expressed in the brain and encodes a protein of unknown biological function. The protein is predicted to contain a C2H2 zinc finger domain, suggesting a potential role in the regulation of gene expression through DNA and/or RNA binding. Consistent with this, functional knockdown of ZNF804a in human neural progenitor cells results in the dysregulation of cell adhesion molecules, suggesting a role in neural migration, neurite outgrowth and synapse formation. Critically, these cellular functions are thought to play a critical role in the emergence of schizophrenia. However, the biological function of this gene is currently unknown. In order to gain an insight into the biological function of the ZNF804a, we have studied the subcellular localisation of the protein in a range of neuronal cell types by

immunohistochemistry. Specifically, we have investigated the localisation of this protein in neurons differentiated from a human neural progenitor cell line (CTXOE16) and human induced pluripotent stem cells as well as in primary rat cortical neurons. ZNF804a was found to localise to the nucleus of neuronal progenitor cells, young developing neurons as well as in neurons with a mature morphology, consistent with a role in regulating gene transcription. Remarkably, ZNF804a could also be observed in the soma of neurons indicating an extranuclear localisation. Furthermore, the protein could also be observed in distal portions of MAP2 positive dendrites, where it colocalised with putative synaptic markers. Critically, in mature primary rat cortical neurons ZNF804a was found to localize to dendritic spines, the site of excitatory synapses, and to colocalise with synaptic proteins. These data are the first to provide a detailed characterization of the subcellular localisation of the ZNF804a protein in human neurons. The extranuclear and synaptic localisation of ZNF804a is consistent with a role for this protein in the regulation of RNA, and potential additional cellular functions.

Title: Illuminating neuroglia signaling with genetically encoded indicators of neural activity in a human stem cell model of Down Syndrome

Authors: *G. SHI[1], P. JIANG[1], S. PAPADOPOULOS[1], A. BHATTACHARYYA[2], J. WEICK[3], W. DENG[1], L. TIAN[1];
[1]biochemistry and molecular medicine, UC Davis, sacramento, CA; [2]Waisman Ctr., Univ. of Wisconsin, Madison, Madison, WI; [3]Dept. of Neurosci., Univ. of New Mexico, Albuquerque, NM

Abstract: Down syndrome (DS) is the most common genetic cause of mental retardation, influencing 1 in 700 newborns in the U.S. It remains largely unknown how genetic changes lead to altered neurocognitive growth in DS brain. To elucidate neural network development associated with DS pathogenesis, we have established an imaging platform based on genetically

encoded indicators of neural activity for functional modeling of the developing neural networks taking advantage of induced pluripotent stem cell (iPSC) technology. Through functional imaging of this model system, we described a hyper-calcium activity associated with DS specific astroglia, which presumably imposes cytotoxicity of co-cultured neurons including decreased synaptogenesis and dampened neuronal activity. These morphological alterations of neurons recapitulated those found in human postmortem tissues. We next dissected the molecular basis of abnormal astrocytic calcium homeostasis related to DS and discovered novel molecular targets involved in the altered neuron-astrocyte crosstalk. For example, DS astroglia displayed stronger response to mGluR5 agonists, which is consistent with higher mGluR5 expression. In addition, we found that overexpression of S100β, a calcium binding protein located on the chromosome 21, evokes spontaneous, hyper-calcium activity released by ER stores in DS astroglia. Selective knocking-down of S100β in DS astroglia abolished elevated spontaneous calcium activity and in turn rescued inhibited neuronal activity. This study demonstrated the logic of neuron-astrocyte crosstalk in directing neuronal network maturation and function underlying DS pathogenesis. It will enable an experimental platform from which other brain disorders leading to cognitive impairment may be similarly examined in human cellular models.

Abstract: A major challenge in understanding human neuropsychiatric disorders has been the lack of viable cells and tissues for analysis. Patient-derived induced pluripotent stem cells (iPSC) now offer the opportunity to examine the full complement of neural tissues and the prospect of identifying underlying disease mechanisms. To study Bipolar Disorder (BD), we have derived and characterized iPSC from fibroblasts obtained from control (C) and patients with BD, and have differentiated them into neurons and glia. RNA from undifferentiated and differentiated iPSC were analyzed using microarray. Compared with the Allen Brainspan database, BD neurons have gene expression profiles most similar to 20-week brain whereas C were most similar to 16-week brain. Comparing microRNA expression in neurons between groups, 82 differentially expressed microRNAs were identified_many were mirtrons. We have also identified differences in neuronal lineage allocation between groups, with BD neurons favoring differentiation into ventral forebrain cells and C neurons forming dorsal cortical precursors. Because Shh signaling is responsible for ventral patterning of the CNS, and alterations in Hedgehog signaling pathway activity may reduce risk of developing BD, we examined expression of pathway members and the response of C and BD cells to Hedgehog pathway agonists, and observed increased responses in BD cells. We have also identified differences in calcium signaling in BD neurons, which are consistently more active than C neurons. Lithium pre-treatment significantly reduced calcium transients and wave amplitude in BD neurons, providing a tractable model system to examine the response of iPSC-derived neurons to pathway perturbagens and potential therapeutics. One of these is ketamine, which we are applying to iPSC-derived brain organoids to evaluate its effects on patterning and differentiation. Additional work examines the effects on CACNA1C expression associated with the AA genotype of rs1006737 -- the most replicated genetic risk factor for bipolar disorder -- in neuronal differentiation and function. We are also using CRISPR/Cas9 to edit BD cells with the AA genotype to the non-risk GG genotype, and assessing calcium signaling and differentiation potential. Finally, it is important to determine if our results are restricted to neurons. Co-culture of astrocytes and neurons may identify important differences in their behavior, or it is possible that both cell types are involved in BD. The overarching goal of our research is to identify novel disease phenotypes and mechanisms involved in bipolar disorder, with the ultimate aim of improving treatment.

Title: Aberrant DNA methylation in tumorigenic neural stem cells derived from human-iPS cells

Authors: *T. IIDA[1], A. IWANAMI[1], J. KOHYAMA[2], M. MATSUMOTO[1], H. OKANO[2], M. NAKAMURA[1];
[1]Dept of Orthop, Sch. of Med, Keio Univ., Shinjyuku-Ku Tokyo, Japan; [2]Dept of Physiology, Sch. of Med, Keio Univ., Shinjyuku-Ku Tokyo, Japan

Abstract: [Purpose] Recently, we have demonstrated the therapeutic potential of transplanting human induced pluripotent stem cell-derived neural stem/progenitor cells (iPSC-NS/PCs) for spinal cord injury (SCI) models in rodents and primates. However, we have found that some iPSC-NS/PCs' cell lines produce neurogenic tumors after transplantation (Nori et al, Stem Cell Reports 2015). Unfortunately, the tumors are not teratoma, and therefore, it is difficult to prevent the tumorigenesis even after excluding immature undifferentiated cells completely. The purpose of this study is to investigate the genomic alterations in iPSC-NS/PCs that may be related to cancer pathogenesis through DNA methylation analyses. [Method] Samples were prepared as follows: four iPS cell lines (253G1, 201B7, 836B3, 414C2) established in Kyoto University, and divided into two groups of iPSC-NS/PCs (tumorigenic cell lines (TC); 253G1-NS/PC & 836B3-NS/PC, and non-tumorigenic cell lines (Non-TC); 201B7-NS/PC & 414C2-NS/PC) based on our previous findings. Illumina Infinium® Methylation 450 Bead Chip were used to evaluate genome wide DNA methylation analyses of these iPSC-NS/PCs. [Result] Distinct differences in DNA methylation pattern were observed between the TC and Non-TC lines. Furthermore, some genes that had large differences of DNA methylation status between TCs and Non-TCs were involved in Wnt signaling & MAPK signaling- related cancer genes. Interestingly, the DNA methylation patterns were affected not only by the difference in cell lines but also by the difference in the passage numbers. [Conclusion] We have previously detected a difference in the expression levels of a specific gene between TC and Non-TC using transcriptome analyses (Nori et al, Stem Cell Reports 2015), but detailed mechanism of tumorigenicity remains to be unveiled. Here, we revealed a difference in DNA methylation pattern and difference in some genes' DNA methylation status, which may have some effects on tumorigenicity. These results enable us to establish criteria for quality control of iPS-NS/PCs in terms of their tumorigenicity.

Title: A transcriptional comparison of human iPSC and mouse models of ALS defines the impact of motor neuron maturation, aging and disease

Authors: ***R. HO**[1], S. SANCES[1], G. GOWING[1], M. AMOROSO[2], J. O'ROURKE[1], A. SAHABIAN[1], H. WICHTERLE[2], R. BALOH[1], D. SAREEN[1], C. N. SVENDSEN[1]; [1]Cedars-Sinai Med. Ctr., Los Angeles, CA; [2]Columbia Univ., New York, NY

Abstract: Modeling neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS) with human induced pluripotent stem cells (iPSCs) or with transgenic mice aims to reenact the embryonic development, maturation, aging, and subsequent degeneration of spinal motor neurons (spMNs). Several studies have reported molecular pathways affected by ALS conditions in both model systems as well as in post-mortem human spMNs. However, the extent to which these ALS models faithfully capture pathways observed in human spMNs has not been closely examined. Specifically, the maturity of human spMNs derived from iPSCs *in vitro* has not been directly compared to human spMNs *in vivo*, and whether a difference in maturity levels impacts faithful disease modeling has yet to be addressed. Furthermore, while transgenic mice have effectively modeled genetic forms of ALS, it is unclear to what extent this *in vivo* system faithfully captures all aspects of human spMN development and degeneration. Here, we compared global transcriptional profiles among human iPSC-derived spMNs, fetal and adult spinal tissues as well as orthologous tissues from mice. By comparing gene expression changes in ALS conditions across iPSC-derived spMNs, human spinal cord tissue and mouse spMNs, we highlight that iPSC and mouse ALS models affect some shared and some distinct pathways. Our comparative analysis among cells spanning embryonic to adult spMN states indicated that iPSC-derived spMNs are similar to fetal rather than aged adult spinal tissue. Additionally, gene co-expression network analysis identified gene modules that tightly associate with spMN fetal development, maturation, or aging. Interestingly, some of these modules enrich for clinical spMN disease genetic variants, revealing that maturation and age-related pathways may play roles in disease presentation. Collectively, these analyses suggest that more effective iPSC models of ALS necessitate strategies to further mature and age iPSC-derived spMNs. Lastly, we demonstrate that while the global expression of orthologous genes involved in spMN fetal development and maturation are largely parallel between human and mouse systems, only maturation but not fetal development gene co-expression networks are well-conserved between the two species. This analysis thus provides a more sensitive interrogation of gene-to-gene expression relationships underlying human and mouse spMN physiology. Overall, our findings support the idea that iPSC and mouse models of ALS are useful systems to study motor neuron

development and degeneration, but also highlight important differences that can guide more effective disease modeling.

Title: Combined application of induced neural stem cell and gene therapy in stroke model

Authors: ***Y. YUN**[1], J. OH[1], J. KIM[2], Y. HA[1];
[1]Yonsei Univ., Seoul, Korea, Republic of; [2]Stem Cell Res. Ctr., Daejeon, Korea, Republic of

Abstract: Objective: Recently, neural stem cell which is directly converted from human epidermal cell takes advantages in several ways. In addition to potential therapeutic effect of neural stem cell, gene therapy was combined to improve synergic effect on stroke disease. Vascular endothelial growth factor (VEGF) therapeutic gene under neuron-specific promoter can be inducible in induced neural stem cell (iNSC). Methods: After confirm the neural differentiation potential using several small molecules, plasmid containing neuron-specific enolase (NSE) promoter was transfected and cultured under normoxia or hypoxia conditions. After promoter activity was measured using luciferase, gene was replaced to VEGF. Results: Induced neural stem cell from human epidermal cells was differentiated into neuron. Luciferase assay revealed that neuron-specific promoter showed strong gene expression in iNSC. Moreover, iNSC transfected pNSE showed higher gene expression under hypoxia conditions mimic stroke disease *in vitro*. Replaced VEGF gene also showed high gene expression level under hypoxia conditions and with neuron-specific promoter *in vitro* and *in vivo*. Conclusion: iNSC has a great potential in cell therapy to treat neural degeneration disease. According to gene expression level, neuronal promoter showed strong activity in iNSC. Moreover, NSE promoter enhanced gene expression under hypoxia conditions. It indicates that applied cell and gene therapy represent a promising combined treatment in neural disease. Title: Acidic fgf promotes neurite outgrowth of cortical neurons and improves neuroprotective effect in a cerebral ischemic rat model

Authors: *H. CHENG;
Taipei Veterans Gen Hosp, Taipei, Taiwan

Abstract: Acidic fibroblast growth factor (aFGF) is a neurotrophic factor which is a powerful neuroprotective and neuroregenerative factor for nervous system. Prior study had shown that the levels of FGFs significantly increase following ischemic injury, reflecting a physiological protection mechanism. However, few reports demonstrated the efficacy of applying aFGF in cerebral ischemia. A recent report showed that the intranasal aFGF treatment improved neurological functional recovery; however, it did not significantly reduce the lesion size in ischemic rats. The present study examines the neuroprotective effect of aFGF on cortical neuron-glial cultures under oxygen glucose deprivation (OGD)-induced cell damage and investigates whether epidural application of slow released aFGF could improve benefit on ischemic stroke injury in conscious rats. We used topical application of aFGF mixed in fibrin glue, a slow release carrier, over the peri-ischemic cortex and examined such treatment on cerebral infarction and behavioral impairments of rats subjected to focal cerebral ischemia (FCI). Results demonstrate that aFGF effectively protected cortical neuron-glial cultures from OGD-induced neuronal damage. Neurite extension from cortical neurons was significantly enhanced by aFGF, mediated through activation of AKT and ERK. In addition, topical application of fibrin glue-mixed aFGF dose-dependently reduced ischemia-induced brain infarction and improved functional restoration in ischemic stroke rats. Slow released aFGF not only protected hippocampal and cortical cell loss but reduced microglial infiltration in FCI rats. Our results suggest that aFGF mixed in fibrin glue could prolong the protective/regenerative efficacy of aFGF to the damaged brain tissue and thus improve the functional restorative effect of aFGF.

Title: Exploring electrophysiological properties of upper motor neurons and astrocytes in amyotrophic lateral sclerosis

Authors: *D. J. RUSHTON[1], G. M. THOMSEN[1], S. HOLLEY[2], G. G. GOWING[1], J.-P. VIT[1], O. SHELEST[1], P. SUEZAKI[1], M. LEVINE[2], C. N. SVENDSEN[1];

Abstract: We have recently shown that exclusive knock-down of mutant SOD1 (mSOD1) in the cortex of a mSOD1 rat model of amyotrophic lateral sclerosis (ALS) results in a significant delay in the onset of disease pathology and extended survival. This novel finding implicates the brain and upper motor neurons as important players in initiating the mechanisms that result in motor circuitry breakdown in ALS disease. Here, our work builds on this finding by exploring the mechanisms underlying the brain's involvement in ALS in both this rat model and human induced pluripotent stem cell (iPSC)-derived models. Our aim is to understand fundamental electrophysiological aberrations and elucidate their contribution to ALS pathology. We are investigating whether upper motor neurons exhibit altered function at different time points relative to disease onset in acute cortical slice cultures from the mSOD1 rat. Previous iPSC-derived models have studied lower spinal motor neurons and required primary rodent astrocytes to develop significant levels of excitability, but consistent with these models being of early developmental stages, studies have observed hyperexcitability. In order to assess the functional properties of developing neural cell types in ALS within the human context, we generated iPSC-derived upper motor neurons and astrocytes from ALS patient lines carrying the C9orf72 mutation. We are developing a co-culture system of both human disease and wild-type iPSC-derived upper motor neurons and astrocytes. The global aim of these related rodent and human studies is to provide a deeper understanding of excitability phenotypes in ALS in the cortical components of the motor circuit so that we can further elucidate the mechanisms involved in initiating the cascade of events associated with disease pathology.

Title: Hyperexcitability in stem cell-derived neurons from Dup15q autism and Angelman syndrome patients

Authors: ***J. J. FINK**, T. M. ROBINSON, K. A. BOLDUC, E. S. LEVINE;
Neurosci., Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: Individuals with a duplication of the 15q11-q13 chromosomal region present with a neurodevelopmental disorder known as Dup15q, which represents the most common copy number variant associated with autism. In addition to the autistic-like symptoms such as intellectual disability and language delay, >50% of Dup15q patients suffer from some form of seizure disorder. Similarly, patients with maternal deletion of the same chromosomal region present with Angelman syndrome (AS), a related neurodevelopmental disorder in which a majority of the patients also develop seizures at some point in their life. Although the genetic cause of Angelman syndrome has been identified as the UBE3A gene, the specific gene or set of genes directly responsible for the Dup15q phenotype remains less clear, though UBE3A is thought to play an important role in Dup15q pathophysiology. Even less clear are the downstream UBE3A targets that might mediate these disease phenotypes, though several synaptic targets have been reported. Given the seizure phenotype associated with these disorders, we examined the excitability of neurons derived from Dup15q and AS patients using genomic reprogramming of human somatic cells into induced pluripotent stem cell (iPSC) lines. We have previously identified significant differences in resting membrane potential (RMP) and spontaneous synaptic transmission in neurons derived from AS patients compared to control

neurons, impairments that could cause hyperexcitability in these cells. For this reason, we measured these same properties in Dup15q neurons using electrophysiological and calcium imaging approaches. A 17-week electrophysiological characterization of 2 Dup15q patient lines and 2 control lines showed a more depolarized RMP at weeks 15-20 in Dup15q neurons, as well as alterations in the frequency and amplitude of spontaneous synaptic activity, similar to our findings in AS-derived neurons. Perhaps most interestingly, neurons derived from Dup15q patients also seemed to be more excitable than neurons derived from control subjects as measured by single-cell patch clamp recordings and population calcium imaging. Overall, these approaches may prove useful for identifying novel targets for drug discovery and for screening potential therapeutics aimed at reversing the seizures, movement disorders, and language and cognitive impairments in Angelman syndrome and autism.

Title: Elucidating retinal ganglion cell development and disease modeling with human pluripotent stem cells

Authors: *S. OHLEMACHER[1], Y. XIAO[2], A. SRIDHAR[1], A. HOCHSTETLER[1], M. SARFARAZI[5], T. R. CUMMINS[2,3], J. S. MEYER[1,2,4];

Abstract: The ability to derive retinal ganglion cells (RGCs) from human pluripotent stem cells (hPSCs) provides an unlimited supply of cells for the study of RGC development and disease, with important implications for drug screening, disease modeling, and cell replacement strategies. However, as this ability has been largely overlooked to date, the ability of hPSCs to yield a population of RGCs was explored in the current study. hPSCs were induced to

differentiate towards a retinal fate following previously established protocols and RGCs were subsequently characterized for the expression of RGC related features. Within 40 days of differentiation, RGCs could be readily identified due to the expression of RGC-associated markers as well as their documented transition through a highly enriched retinal progenitor stage. Analysis of hPSC-derived RGCs revealed that these cells expressed numerous morphological, phenotypical, and physiological characteristics of RGCs. In addition, skin fibroblasts were obtained from a glaucoma patient exhibiting an E50K mutation in the OPTN gene, and these fibroblasts were used to generate patient-specific OPTN iPSCs via mRNA reprogramming methods. OPTN iPSCs were differentiated to a retinal lineage in a stepwise fashion that allowed for the definitive identification of RGCs based upon gene expression patterns. Phenotypic differences between wild type and OPTN iPSC-derived RGCs were explored, including changes in golgi fragmentation, apoptosis, and autophagy. The data presented demonstrates the ability of hPSCs to serve as a reliable source of RGCs, including those derived from glaucoma patient sources, as seen by their ability to yield a population of cells possessing a full complement of RGC-associated characteristics. These results will facilitate future studies into the disease-related degeneration of RGCs and as such, will be instrumental as a tool for the study of optic neuropathies, as well as the development of future therapeutic approaches.

Title: A human pluripotent stem cell-derived neuron model as a functional assay for botulinum neurotoxin intoxication

Authors: *K. M. HOFFMAN, K. HUBBARD, P. BESKE, E. GLOTFELTY, J. GRYNOVICKI, P. MCNUTT;
MRICD, Aberdeen Proving Ground, MD

Abstract: Neurons derived from human pluripotent stem cells (hPSCs) have the potential to provide a physiologically relevant platform for investigating the human pathophysiological responses to chemical and biological threat agents. While in theory a networked population of *in vitro*-derived human neurons would combine the biological relevance of primary neurons with the flexibility of continuous cell lines, reproducible methods to generate synaptically active and electrically excitable human neurons have not been reported without the required presence of additional neural populations (i.e. primary neurons or astrocytes or implantation into the CNS). Therefore, we sought to develop conditions sufficient to generate functionally networked cultures of human stem cell-derived neurons (hSNs). Beginning with several hPSC lines, we used a variety of methods to derive hSNs and evaluated their morphological and functional characteristics out to 12 weeks. While most methods produced hSNs that exhibited unambiguous neurotypic markers and morphologies, the majority of cells lines failed to generate network activity and miniature post-synaptic currents. Transmission micrographs suggested that, in some cases, this failure was attributable to stalled presynaptic maturation. However, we did identify a combination of hPSC lines and differentiation methods that reliably produce mPSCs by 7 weeks, generating excitatory AMPA receptor-mediated currents (occurring at 0.1 - 1 Hz) that were eliminated by treatment with CNQX. In detailed studies, production of mEPSCs proved to be time- and density-dependent. Treatment with botulinum neurotoxin serotype A (BoNT/A), BoNT/B and tetanus neurotoxin (TeNT), which specifically block presynaptic release, resulted in cognate SNARE protein cleavage and eliminated mEPSCs, confirming that apparent synaptic activity resulted from synaptic neurotransmission and network activity. We are currently undertaking a detailed transcriptomic, morphological and functional characterization of synapse maturation and network behaviors in these lines with the goal of identifying developmental pathways that produce hSNs functionally appropriate for human neurotoxicological studies. Collectively, these data suggest that human-induced pluripotent stem cell-derived neurons may provide a physiologically relevant, synaptically active platform appropriate for the development of novel therapeutics for biological and chemical threat agents.

Abstract: Objective: Syntaxin-binding protein 1 (STXBP1) is essential for synaptic vesicle exocytosis. Mutations of its encoding gene, STXBP1, are among the most frequent genetic causes of epileptic encephalopathies. However, the precise pathophysiology of STXBP1 haploinsufficiency has not been elucidated. Using patient-derived induced pluripotent stem cells (iPSCs), we aimed to establish a neuronal model for STXBP1 haploinsufficiency and determine the pathophysiologic basis for STXBP1 encephalopathy. Methods: We generated iPSC lines from a patient with Ohtahara syndrome (OS) harboring a heterozygous nonsense mutation of STXBP1 (c.1099C>T; p.R367X) and performed neuronal differentiation. Biochemical and morphological analyses were conducted on iPSC-derived neurons with STXBP1 mutation. Written informed consent was obtained from the parent and ethical approval for this study was obtained from the Review Board of Kyoto Prefectural University of Medicine and Kyoto University. Results: Both STXBP1 mRNA and STXBP1 protein expression levels of OS-derived neurons were approximately 50% lower than that of control-derived neurons, proving that OS-derived neurons are a suitable model for elucidating the pathophysiology of STXBP1 haploinsufficiency. Through western blot and immunocytochemistry assays, we found that OS-derived neurons show reduced levels and mislocalization of syntaxin-1, a component of soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins. In addition, OS-derived neurons have impaired neurite outgrowth. Significance: This model enables us to investigate the neurobiology of STXBP1 encephalopathy throughout the stages of neurodevelopment. Reduced expression of STXBP1 leads to changes in the expression and localization of syntaxin-1 that may contribute to the devastating phenotype of STXBP1 encephalopathy.

Title: Isogenic iPSCs from an individual with SCN1A mutation mosaicism revealed aberrant dopamine levels in Dravet syndrome neurons

Authors: *H. MAEDA[1], T. CHIYONOBU[1], M. YOSHIDA[2], S. YAMASHITA[1], M. ZUIKI[1], S. KIDOWAKI[1], K. ISODA[2], M. MORIMOTO[1], T. NAKAHATA[2], M. SAITO[2], H. HOSOI[1]; [1]Pediatrics, Kyoto Prefectural Univ. of Med., Kyoto, Japan; [2]Clin. Application, Ctr. for iPS Cell Res. and Application (CiRA), Kyoto Univ., Kyoto, Japan

Abstract: Background: Dravet syndrome (DS) is a severe childhood epilepsy typically caused by de novo dominant mutations in SCN1A, encoding for the voltage-gated sodium channel Nav1.1. Although DS is associated with severe cognitive and behavioral impairments, the precise pathophysiology of them has not been elucidated. There are wide phenotypic differences among individuals with SCN1A mutations, suggesting that the existence of genetic factors other than SCN1A mutation modify the phenotype. Additionally, as behavioral or cognitive disorders generally have subtle phenotypes *in vitro*, it is difficult to distinguish subtle disease-relevant phenotypic changes from unpredictable background-related variation. Therefore, well controlled cellular model system are required to improve our understanding of the mechanisms underlying DS. Methods: We generated induced pluripotent stem cell (iPSC) lines from an individual with SCN1A mutation mosaicism (Morimoto M, et al. Epilepsia, 2006) and separately cloned iPSC lines both with and without SCN1A mutation (DS and WT, respectively). These clones theoretically have the same genetic backgrounds, except for the SCN1A gene, and should serve as an ideal pair for elucidating the pathophysiology caused by SCN1A mutation. Then we performed *in vitro* neuronal differentiation. Written informed consent was obtained from the subject and ethical approval for this study was obtained from the Review Board of Kyoto Prefectural University of Medicine and Kyoto University. Results: The differentiated cells expressed the neuronal marker beta-III-tublin, and there was no prominent difference in the differentiation propensity between DS and WT cells. Quantitative RT-PCR and western blot

analysis revealed that both TH mRNA and TH protein expression levels of DS-derived neurons were higher than that of WT-derived neurons. Moreover, dopamine concentrations in media collected from DS-derived neuronal cultures, which were determined by ELISA, were higher than that from WT-derived neuronal cultures. Conclusion: This model enables us to investigate the neurobiology of DS throughout the stages of neurodevelopment. SCN1A mutation leads to changes in the dopamine system that may contribute to the behavioral abnormalities in DS.

Abstract: Bipolar disorder (BD) is a hereditary neuropsychiatric disorder characterized by extreme fluctuations in mood, alternating between mania and severe depression. The etiology of BD is thought to be neurodevelopmental, but it is not known what specific cell type(s) of the brain contribute to the condition. Numerous studies of postmortem brain samples from patients with neuropsychiatric disorder suggest that astrocytes may play a major role in the pathophysiology of these conditions. The directed neural differentiation of patient-derived induced pluripotent stem cells (iPSC) provides us with a developmental model to better understand the role of astrocytes in BD. Several iPSC lines from BD and controls were treated

via dual SMAD inhibition to induce neural differentiation, and maintenance of neural precursors as attached rosettes or suspended spheres in N2-containing medium resulted in an enriched population of dividing early astrocytes. Passaging and expansion in FGF-2 and EGF resulted in a population of which up to 99% were positive for the immature astrocyte marker CD44. CD44-positive cells were sorted by FACS and treated with ciliary neurotrophic factor (CNTF), which induced expression of the mature astrocyte-specific marker glial fibrillary acidic protein (GFAP). Currently, we are analyzing early and mature astrocytes for differences in gene and protein expression, as well as glialtransmitter release from mature astrocytes and measurements of oxidative stress.

Title: Identifying neural cell phenotypes of Tuberous Sclerosis Complex using patient-derived stem cells

Authors: ***A. ZUCCO**[1], V. DAL POZZO[1], A. AFINOGENOVA[1], B. CROWELL[1], M. SHELDON[2,3], O. DEVINSKY[4], G. D'ARCANGELO[1,3];
[1]Dept. of Cell Biol. and Neurosci., [2]Genet., Rutgers Univ., Piscataway, NJ; [3]Human Genet. Inst. of New Jersey, Piscataway, NJ; [4]NYU Comprehensive Epilepsy Ctr., New York Univ. Langone Sch. of Med., New York City, NY

Abstract: Tuberous sclerosis complex (TSC) is a developmental disorder characterized by tumor susceptibility in multiple organs, brain malformations, and neurological manifestations. Despite considerable progress in understanding the genetic and signaling mechanisms underlying the

disease, effective treatments are still lacking, particularly with regard to the control of neurological symptoms such as epilepsy, autism, and intellectual disability. The most frequent genetic defects in TSC consist of heterozygous mutations in the TSC1 or TSC2 gene, leading to reduced expression of these proteins in all cells of the body. While loss of heterozygosity is sometimes observed in focal brain malformations or in lesions that develop in other organs, it is presently unclear whether this 'second hit' event is required to elicit neurological symptoms. At the molecular level, homozygous loss of TSC1 or TSC2 results in the activation of the rapamycin-sensitive mTORC1, a major growth-promoting mTOR-containing complex. This is because TSC1 and TSC2 proteins form a complex that inhibits mTORC1 by suppressing the function of the small GTP-binding protein Rheb, which is required for its activity. In the complete absence of either the TSC1 or TSC2 protein, mTORC1 is thus upregulated, promoting cell growth or proliferation through the phosphorylation of several cellular targets. However, the great majority of brain cells in TSC patients are heterozygous for TSC1 or TSC2 mutations, do not appear overgrown or dysplastic on pathological examination, and do not exhibit obvious upregulation of mTORC1 activity. Thus, it is not presently known whether or not they are abnormal. To help define the mechanisms of neurological disease in TSC, in this study we established induced pluripotent stem cells (iPSCs) from three sets of matched patients and sibling controls, and then derived neural stem cell (NSC) lines and differentiated neurons. These cell lines provided us with unprecedented insights into the cellular abnormalities that occur in the developing brain of TSC patients, and may facilitate the identification of new forms of treatments for these patients.

Title: Establishment of the *in vitro* myelination model using human iPS cell-derived oligodendrocytes

Authors: ***T. YAMASHITA**[1], T. ONO[1], A. DOI[1], S. KOBAYASHI[1], Y. MIYAMOTO[2], J. YAMAUCHI[2], Y. BANDO[3], S. YOSHIDA[3], H. AOYAMA[1], T. ARAKI[1], Y. KATO[1], T. SHIRAKAWA[1], Y. SUZUKI[1], N. SATO[1], Y. KOGUCHI[1];

[1]Discovery Res. Labs., Mitsubishi Tanabe Pharma Corp., Yokohama, Japan; [2]Dept. of Pharmacol., Natl. Res. Inst. for Child Hlth. and Develop., Tokyo, Japan; [3]Dept. of Functional Anat. and Neurosci., Asahikawa Med. Univ., Asahikawa, Japan

Abstract: Oligodendrocytes myelinate axons to increase salutatory conduction and to regulate neural function. The disruption of interaction between neurons and oligodendrocytes causes a serious neural dysfunction categorized as white-matter deficits such as multiple sclerosis, Alzheimer's disease, depression, and autism. Neural dysfunction in these diseases is marked by biological complexity. In addition, species' differences exist in brain structure and myelin remodeling; therefore, the establishment of the *in vitro* myelination model from human cell source should be essential for elucidating the molecular mechanism of these diseases. Human pluripotent stem cell (PSC)-derived oligodendrocytes have a great potential to provide valuable sources for myelination studies. In our previous work, we have developed a proprietary single-cell and feeder-free (SFF) culture system for human induced pluripotent stem cells (iPSCs), which is a reliable platform to prepare several functional cells including oligodendrocytes. We herein establish cocultures using human iPSC-derived oligodendrocytes. We generated oligodendrocyte progenitor cells (OPCs) from human iPSCs maintained in the SFF culture within three months. These OPCs could be cryopreserved and initially enable to differentiate into O4-positive cells. And eventually, MBP-positive oligodendrocytes emerged in one month. Furthermore, we developed the *in vitro* myelination model. When the oligodendrocytes were cultured with neurons to be attached with axons, they were wrapped with glial cell plasma membranes. Collectively, the oligodendrocytes possess myelogenic potency in culture. Further investigation will be needed to expedite the establishment of this model which mimics human brain's physiological conditions. The *in vitro* myelination model using human iPSC-derived oligodendrocytes would substantially contribute to clarifying the physiological function and become the promising tool for drug discovery.

Abstract: Spinal muscular atrophy (SMA) is an inherited pediatric neuromuscular disease characterized by degeneration of spinal motor neurons (MNs). SMN protein, the ubiquitously expressed SMN1 gene product mutated in SMA, specifically affects MNs via unknown mechanisms. Previously, patient fibroblasts and animal models were utilized to study the protein level consequences of reduced SMN. We derived human motor neurons (iMNs) from multiple individuals with SMA and healthy controls (CTR) by creating their induced pluripotent stem cells (iPSCs). Quantitative mass spectrometry on their iMNs revealed increased expression of 63 proteins in control iMNs compared to respective fibroblasts, whereas 30 proteins were increased in SMA iMNs versus their fibroblasts. Notably, UBA1 was significantly decreased in SMA iMNs, supporting evidence for ubiquitin pathway defects. Sub-cellular distribution of UBA1 was predominantly cytoplasmic in SMA iMNs in contrast to nuclear in control iMNs; suggestive of neurodevelopmental abnormalities. Additional proteins diminished in SMA iMNs were associated with neuronal development and differentiation including, βIII-tubulin and UCHL1. These neuron-specific consequences of SMN depletion were not evident in fibroblasts highlighting the importance of iPSC technology. The proteomic differences identified here will provide useful resource to explore the molecular basis of neurodevelopmental defects and develop novel biomarker therapeutic targets for SMA.

Title: Impairment of motor behavior in young mice undergoing postnatal dopaminergic insult

Authors: ***B. R. SOUZA**[1,2], L. O. MATOS[1,2], L. O. GUARNIERI[1,2], G. S. PEREIRA[1,2]; [1]Univ. Federal De Minas Gerais, Belo Horizonte, Brazil; [2]Nucleo de Neurociencias, Belo Horizonte, Brazil

Abstract: Imbalance in dopamine-mediated neurotransmission, as well as neurodevelopmental abnormalities, are both features of schizophrenia and ADHD. Different neurodevelopmental windows are critical moments for the formation of the nervous system, such as the neuronal proliferation, differentiation and migration, synaptogenesis and pruning. It is well known that dopaminergic receptors are expressed in the developing brain and that dopamine plays an important role in the process of cell differentiation, migration and maturation. Thus, dopaminergic signaling might have diverse functions in the different developmental windows.

Studies using knockout animal models for dopaminergic receptors show behavioral changes in adult animals. However, it is impossible to know if the behavioral changes are consequences of the lack of the protein in the signaling process in the moment of the behavior, or if it is the consequence of the lack of the protein expression during the development. We have recently shown that dopamine regulates the development of GABAergic system and motor behavior in the zebrafish larvae. In this study, we hypothesized that early post-natal dopaminergic stress can affect the development of the brain and the emergence of motor behavior in young and adult swiss mice. To test this hypothesis, we injected levodopa intraperitoneally (10 mg/kg, 25 mg/kg and 50 mg/kg) for five days, from the day of birth until day 5 (P5). We investigated the motor behavior of young (4 weeks) and adult (8 weeks) mice by open-field test. We observed an increase of motor behavior in young females but not adult females and males. These results will help shape our understanding of the role of dopamine in brain development and provide new mechanistic insights for further assessing the neurodevelopmental origin model of neuropsychiatric disorders.

Title: Sensory feedback by spontaneous twitches in the neonatal rat: spinal cord network dynamics

Authors: ***A. R. INACIO**[1], A. NASRETDINOV[2], J. LEBEDEVA[2], R. KHAZIPOV[1,3]; [1]INMED, INSERM UMR 901, Marseille Cedex 09, France; [2]Lab. of Neurobiology, Kazan Federal Univ., Kazan, Russian Federation; [3]Kazan Federal Univ., Lab. of Neurobio., Kazan, Russian Federation

Abstract: During the critical period for development of sensorimotor function, sleep is a predominant state, and behavior is dominated by spontaneous twitches, short contractions in atonic muscles. Twitches participate in activity-dependent formation of spinal cord circuits and trigger oscillatory patterns in the developing somatosensory cortex, delta-brushes in human fetuses and neonates, as well as spindle-bursts and early gamma oscillations in neonatal rats. It has thus been proposed that twitches originate sensory feedback, but this hypothesis has not been directly tested. By simultaneously recording neuronal activity at the population level across all spinal cord laminae and limb twitches and movements of neonatal rats, we demonstrate the following network dynamics: activity bursts in the ventral horn (motor) → twitching → dorsal horn activity (sensory). This phenomenon is disrupted following transection of sensory afferents: while bursts at the level of the ventral horn precede twitches and twitching frequency remains unaltered, activity at the level of the spinal dorsal horn is abolished. Our results provide direct evidence for twitches-triggered sensory feedback in activation of dorsal spinal cord neurons.

Title: Characterizing the Role of Beclin1/BEC-1 in Neurons of *C. elegans*

Authors: *A. POWERS, A. HOLGADO;
Dept. of Biol. Sci., Southwestern Oklahoma State Univ., Weatherford, OK

Abstract: For the past decades, scientists noted that many neurodegenerative disorders, such as Alzheimer's, Huntington and Parkinson 's disease are characterized by pathological accumulations of protein aggregates. More recently, analyses from brain autopsies and animals models show that the accumulation of toxic protein aggregates form with a reduced protein and macromolecule recycling machinery. Autophagy, the primary focus of the research summarized

herein, involves the removal of cell debris and the recycling of protein aggregates in health and disease. BEC-1, a Caenorhabditis elegans protein conserved from human to yeast, was shown to play an essential in autophagy and recycling of nutrients under starving conditions. Furthermore, recent research suggested that BEC-1 may link recycling of nutrients in nerve cells with maintenance of neurons. To test this probable link, we characterized the neuronal structure and function of *C. elegans* nematodes exposed to tissue specific bec-1 RNAi. In summary, animals expressing a double stranded RNA transporter in gabaergic motor neurons were treated with feeding bec-1 RNAi techniques and the phenotype of the tissue specific know down was evaluated. Collectively, we found that bec-1 knock down nematodes have developmental and functional defects at the level of motor neurons. Imaging analysis with epifluorescent microscopy revealed a reduction in the number of the D type motor neurons. Quantification of motor function showed varying levels of penetration of locomotion defects. Currently underway are studies of the effects of knocking down neuronal bec-1 under starving conditions.

Title: Examining the link between axonal elongation and autophagy

Authors: ***L. VAN**, A. HOLGADO;
Dept. of Biol. Sci., Southwestern Oklahoma State Univ., Weatherford, OK

Abstract: Despite the wealth of information surrounding axonal elongation and guidance, autophagy, and cell survival, it is still unclear why neuronal components shown to work at the level of axonal outgrowth and cytoskeleton stability bind to components of the autophagy machinery. Moreover, it is undetermined why autophagy gene products, first characterized in yeast as Atg1, 6, 8, 9, 13, 18, are enriched in the nervous system of multicellular organism *C. elegans*. To shed some light into the intersection of autophagy in neurons and axonal extension,

herein, we present the research outcomes from investigations of three neuronal molecules: UNC-33, beclin1, and LK. The unc-33 gene encodes three conserved members of the CRMP/TOAD/Ulip/DRP family of proteins that includes mammalian CRMP2. Investigations of *C. elegans* UNC-33 isoforms demonstrated that these proteins mediate axonal guidance and axonogenesis in sensory, motor and interneurons. Beclin1 is the ortholog of yeast Atg6, a protein shown to regulate the lipid kinase Vps-34, and to promote formation of beclin1-Vps34-Vps15 core complexes, thereby inducing autophagy. In nematodes, BEC-1 (*C. elegans* homolog of vertebrate beclin1) is essential for survival, autophagy, and locomotion. LK is a brain metabolite and neurotrophic agent that according to our published and preliminary results binds to CRMP2, promotes axonal outgrowth, and induces the interaction of CRMP2-beclin1. In this study, we tested the hypothesis that the autophagic factor beclin1/BEC-1 and key neuronal molecules LK and UNC-33 control both autophagy and axonal elongation. We also investigated the role of neuronal autophagy in the context of UNC-6/Netrin mediated axonal guidance. By testing these hypotheses, we found that LK partially rescues the axonal elongation defects characterizing unc-33 mutants. Additionally, we determined that LK treatment enhances the expression of autophagy genes and the starvation induces expression of UNC-33. Lastly, analysis of the effects of autophagy on growth cone extrusion and repulsion is currently in progress. Together, these studies take us one step closer to the understanding of the link between autophagy and axonal elongation.

Title: Investigating the interplay of the axonal elongation protein unc-33/crmp and autophagy

Authors: *E. JANSING, A. HOLGADO;
Dept. of Biol. Sci., Southwestern Oklahoma State Univ., Weatherford, OK

Abstract: Collapsin response mediator proteins (CRMPs), are cytoskeletal adaptor molecules involved in a variety of normal cellular functions including alteration of cell shape and cell communication. UNC-33, the *C. elegans* CRMP, was first identified as a neuronal protein essential for axogenesis and axonal elongation. Since then, UNC-33 and the CRMP protein family have been associated with pathological disorders and neurological diseases. For instance, reports show that CRMP2 protein collects in cytoskeletal tangles in Alzheimer's disease, which may contribute to neural degeneration in this disorder. In other examples, differences in CRMP2 expression have been documented in some subsets of patients suffering paranoid schizophrenia. Lastly, the anticonvulsive drug lacosamide (VimPat) was found to act by binding to CRMP2, which unmasked an unknown function for CRMP2 in epilepsy. To further investigate CRMP mode of action in the nervous system, we continued with the characterization of unc-33 mutants and examined strategies for rescuing the mutant phenotype. Previous report from our laboratory demonstrated that lanthionine ketimine ester (LKE), a byproduct of aminoacid biosynthesis, partially rescue unc-33 mutants' axonal elongation defects. Herein, we describe that this rescue could be explained by an unknown mechanism that directly/indirectly stimulates the expression of genes involved in autophagy. Quantitative real time PCR result shows that genes atg-7, atg-18, bec-1, and lgg-1 are significantly induced in unc-33 mutant animals treated with LKE. Currently under work are analysis of the protein profiles of nematodes with defective or enhanced autophagy. Together this analysis leads us to determining the molecular mechanism underlying LKE effects on unc-33 mutants and the understanding of the bioactivity of LKE and its potential in therapeutics.

Title: Assessing the role of Autophagy in *C. elegans* neurons

Authors: *J. GREGSTON, A. HOLGADO;
Dept. of Biol. Sci., Southwestern Oklahoma State Univ., Weatherford, OK

Abstract: Macroautophagy (autophagy) is the process by which unneeded and damaged cellular components are catabolized and recycled. Autophagy begins with the formation of the phagophore, which encloses the targeted protein or damaged organelle forming an autophagosome. A lysosome then fuses with autophagosomes, breaking down and recycling the autophagosomal content. Autophagy plays an essential role in recycling cell materials needed for normal development, differentiation, and maintenance. Moreover, recent studies have shown that autophagy may degrade of Beta-amyloid plaques in the brain of patients suffering Alzheimer's disease. To gain more insights into the understanding of autophagy in neurons and it's potential role in normal and pathological conditions, we began monitoring autophagy induction in *C. elegans* neurons using a fluorescent LGG-1 protein. To this end, we first microinjected nematodes with the plasmid pAR-40.1 coding for LGG-1 fused to red fluorescent protein into animals expressing a green fluorescent protein (GFP) in D type motor neurons. Additionally, we crossed transgenic nematodes expressing LGG-1 fused to GFP with animals expressing a red fluorescent in D type motor neuron. Preliminary analysis of LGG-1 fused to GFP (LGG-1::GFP) demonstrates that we can monitor the induction of autophagy by measuring the density of the puncta of LGG-1::GFP as it lipidizes during autophagosome formation. Currently underway are experiments deciphering whether enhanced autophagy and recycling of cellular components aid in the rescue of nematodes defective in axonal pathfinding and elongation. Specifically, we are testing unc-51, unc-14, and unc-33, nematode mutant strains with aberrant axonal elongation defects and with homologs acting on a conserved autophagy pathway. Together this investigation is designed to test a potential link between autophagy and the development of proper neuronal circuitry in living multicellular organisms. Ultimately, understanding the bases of the interplay of autophagy in neurons will shed light into the workings of the nervous system in health and disease.

Title: Exposure to ketamine during development heightens zebrafish growth spurt

Authors: *G. TORRES[1], J. R. LEHESTE[2];
[2]Biomed. Sci., [1]NYIT COM, Old Westbury, NY

Abstract: Ketamine is a dissociate anesthetic capable of inducing post-operative hallucination, psychosis and cognitive deficits in healthy individuals that bear an uncanny resemblance with those observed in schizophrenic patients. Yet, ketamine also appears to exert rapid and relatively sustained antidepressant-like effects in patients with major depression. Because ketamine is an antagonist of the N-Methyl-D-Aspartate (NMDA) ion-channel receptor, one of several subtypes of the glutamate receptor system, it is thought that derangements in glutamate neurotransmission may contribute to the pathophysiology of both schizophrenia and major depressive disorder. Previously, our laboratories provided behavioral and molecular evidence for the actions of ketamine using a new vertebrate model for psychiatric disorders: the zebrafish (Zakhary et al., Synapse 65: 160-167, 2011). Here, we provide further and new evidence for the actions of ketamine during vertebrate development. We document that zebrafish eggs exposed to sub-anesthetic doses of ketamine for 3-5 days post-fertilization, show a heighted somatic growth curve at 2 moths of development. These findings provide a cellular and molecular context to understand the consequences of prenatal ketamine exposure, and further support the use of zebrafish for understanding preclinical risk factors affecting candidate signaling pathways of psychological dimensions.

Title: Activation of distinct exploratory patterns by nicotine in larval zebrafish: evaluation of a novel testing methodology

Authors: B. CHEN, *F. M. SCALZO;
Bard Col., Annandale, NY

Abstract: The larval zebrafish is emerging as a useful model to assess neurobehavioral toxicity. A variety of behavioral assays have been developed to characterize normal behavior and the acute and chronic effects of several compounds. To date, such behavioral assays have been limited to relatively simple behavioral measures (e.g., swimming activity in a single well). The

present experiment describes methodology to assess exploratory behavior in 5 days-post-fertilization (5-dpf) larval TU zebrafish using a six-chamber, complex well-plate. In addition, the effect of acute nicotine exposure on exploratory activity in this complex environment was examined. Larvae were treated with either 0, 16.25 μM or 48.75 μM nicotine and were observed for 15 minutes. General Locomotor Activity, Zone Preference, Thigmotaxis (outer zone preference), Thigmotaxis Path Type, Chamber Transitions, and Latency to enter the Center Zone were measured using a Noldus tracking system. Larvae dosed with either 16.25 μM (2017±129) or 48.75 μM (2342±181) nicotine exhibited an increase in general locomotor activity relative to controls (1182±93). However, the pattern of locomotor activity was different between low and high dose nicotine. Larvae dosed with 16.25 μM nicotine exhibited more thigmotaxis coupled with an increase in overall exploratory behavior compared to controls, whereas the 48.75 μM larvae moved more than controls but did not exhibit a significant difference in thigmotaxis compared to controls. Both high and low dose nicotine treated larvae exhibited reduced latency to enter the center zone of more distant chambers than controls. These results demonstrate (1) the utility of this novel testing methodology in differentiating specific types of exploratory behavior, (2) that a low and high dose of nicotine increased exploratory behavior in a complex environment and (3) dose-dependent and time-dependent behavioral changes due to nicotine treatment suggesting altered control of a specific type of exploratory behavior. This study demonstrates a difference in the effects of low dose and high dose nicotine on larval zebrafish behavior and describes a new methodology that can be used to study complex behaviors in larval zebrafish.

Title: Altered cortical thickness in pediatric hemiplegia

Authors: *R. L. HAWE[1], J. P. A. DEWALD[2];
[1]Physical Therapy and Human Movement Sci., [2]Northwestern Univ., Chicago, IL

Abstract: Pediatric hemiplegia results from a lesion occurring early in childhood. To date, research has focused on changes to white matter tracts in the brain, and largely ignored changes in cortical structures. However, subcortical lesions acquired during early development could potentially impact the cortical gray matter, by altering the course of development, or through degeneration or reorganization. Cortical thickness measures the distance between the pial surface and the border between grey and white matter. The developmental trajectory for cortical thickness has been established in typically developing children, and it has been shown to be a sensitive measure to changes in individuals with disorders including ADHD, autism, and schizophrenia. In this preliminary study, we use cortical thickness as a measure of cortical structural changes in children with lesions acquired early in development. Six participants (age 14.33 ± 8.87 years) with pediatric hemiplegia due to a prenatally or perinatally acquired subcortical lesion underwent magnetic resonance imaging using a MPRAGE sequence on a 3T scanner. FreeSurfer software was used to create cortical models and derive measures of cortical thickness. Average thickness measures were found for each sensorimotor Brodmann area, and percent differences between the lesioned and nonlesioned cortices were calculated for each participant. Cortical thickness was found to be increased on the lesioned side compared to the nonlesioned side across all sensorimotor regions. Brodmann areas 3a and 3b demonstrated the greatest increases in cortical thickness, with a 19.8% increase on the lesioned side. In typically developing children, sensorimotor cortices have an initial increase in cortical thickness followed by a steady decrease throughout development, which is associated with synaptic pruning and refinement. The relative increase in cortical thickness on the lesioned side compared to non-lesioned suggests that the subcortical lesion interfered with cortical development and normal activity-dependent pruning did not occur. The large differences seen in the sensory regions emphasize the need to look at both sensory and motor impairments in children with hemiplegia.

Title: A minimal neural mechanism for explorative behavior in songbirds and human babies

Authors: *R. DARSHAN[1,2], B. WOOD[2], S. PETERS[3], A. LEBLOIS[2], D. HANSEL[2];
[1]ELSC, Hebrew Univ., Jerusalem, Israel; [2]Lab. of Neurophysics and Physiol., Paris, France;
[3]Duke Univ., Durham, NC

Abstract: Motor behavior appears to be disorganized during early stages of development and is thought to be initially purely explorative. According to current theories, such exploration is essential for learning sensorimotor transformations. We combine data analysis and modeling to study the central neuronal mechanism that underlies explorative behaviors, focusing on babbling-like behaviors in human and non-human vocal learners. We quantify the temporal structure of babbling in four vocal learners with different levels of complexity in their adult vocalizations: zebra finches, swamp sparrows, canaries and human babies. We show that: 1) In all these learners, gesture duration distributions during early babbling are well fitted by a decaying exponential (in line with previous reports in zebra finches; Aronov et al., 2008) ; 2) interspecies differences in the temporal features of early babbling are to a large extent accounted for by time rescaling. These findings point to the existence of a central mechanism underlying explorative behavior which is common to all these learners and therefore robust with respect to anatomical and physiological differences between individuals and species. We investigate possible mechanisms for motor exploration in a theoretical model of the neuronal circuit that activates the effectors producing babbling in songbirds. It comprises a premotor and a motor network representing the avian cortical-like areas LMAN and RA, each consisting of a large number of excitatory and inhibitory spiking neurons. The premotor network projects to the motor network which in turn activates a small number of effectors as is the case in songbird anatomy. We argue that requiring the circuit to autonomously and robustly generate random activation of the effectors constrains its architecture and dynamics strongly. We show that this implies that: 1) the premotor as well as the motor area are recurrent networks operating in a regime where excitation and inhibition are balanced and 2) the feedforward projections from the former to the latter and then to the effectors are topographic. Under these conditions, the motor network exhibits temporally irregular firing with substantial correlations between neurons that activate the same effector. Importantly, correlations emerge from the recurrent dynamics of the circuit without any fine- tuning of parameters. When connected to a non linear model of a syrinx, the circuit generates explorative behavior with statistics similar to those exhibited in the data. Finally, we validate our theory by testing its predictions regarding the spatiotemporal patterns of activity in LMAN and RA in neuronal recordings in singing finches.

Title: Oculomotor nuclear organization in the larval zebrafish, Danio rerio

Authors: ***M. GREANEY**, D. SCHOPPIK;
New York Univ. Med. Ctr., New York, NY

Abstract: The oculomotor nucleus (nIII) comprises four of six motoneuron populations that innervate major muscles of the vertebrate eye. In adults, these populations are organized into spatially discrete subnuclei, suggesting a developmental origin with potential functional consequences. Developmentally, larval zebrafish (Danio rerio) ocular motoneurons form connections with particular extra ocular muscles ~3 dpf, and possess a functional vestibulo ocular reflex (VOR) by 4 dpf. Spatial organization of ocular motoneurons − or lack thereof − might provide clues as to how upstream vestibular neuron axons identify their appropriate downstream motoneuron partners. Here, we mapped nuclear organization of nIII motoneurons at two time points in early larval development: 5-7 dpf and 14 dpf. To target individual nIII subpopulations, we severed ocular motoneurons near their muscle attachment point. We then filled severed axons retro-orbitally with fluorophore-conjugated dextran crystals. We imaged dye-filled somata in the midbrain/hindbrain using a confocal microscope. By comparing the location of filled cells with the selective expression pattern of the islet1:GFP motoneuronal marker, we were able to classify many filled cells with respect to their target muscle (n=2171, 5-7dpf; n=344, 14dpf). We identified a spatially contiguous cluster of motoneurons innervating the contralateral superior rectus (SR), that by 5 dpf was positioned ventromedially within nIII and remained so at 14dpf. At both time points, we found slight overlap between this cluster and neurons of the other three oculomotor populations: medial rectus (MR), inferior rectus (IR), and inferior oblique (IO). In contrast, at 5-7 dpf, we observed MR, IR, and IO somata scattered throughout nIII. Initial findings in 14 dpf fish suggest that IR and MR neurons occupy most of dorsolateral nIII at this stage, with IR possibly more rostral than MR, while IO neurons cluster at the lateral edge of ventral nIII. Finally, we identified the superior oblique (SO) motoneurons that

comprise the trochlear nucleus (nIV) just caudal to the midbrain-hindbrain boundary. We conclude that the aggregation of superior motoneuron populations (SR/SO) concludes by 5 dpf. In contrast, aggregation of the MR/IR/IO motoneurons into subnuclei must occur later in development. Intriguingly, our data suggest that functional innervation of target extraocular muscles is complete by 5 dpf. Further, the ability of larval fish to perform a VOR suggests that upstream vestibular projections are similarly functional. Ongoing work aims to collect functional data from motoneurons executing the VOR while fish experience a vestibular stimulus.

Title: From M1 to Cerebellum: What effect does hand-preference have one the local volumes of motor related structures?

Authors: ***J. GERMANN**[1], R. PATEL[1], G. A. DEVENYI[1], M. M. CHAKRAVARTY[1,2,3]; [1]Cerebral Imaging Centre, Douglas Mental Hlth. Uni, Verdun, QC, Canada; [2]Dept. of Psychiatry, McGill University, Montreal, QC, Canada; [3]Dept. of Biomed. Engin., McGill University, Montreal, QC, Canada

Abstract: People preferentially choose one of their hands to perform tasks and there is a strong bias towards dominance of the right hand (90% of population). This bias develops early and is

stable throughout the lifetime. Is this hand preference associated with asymmetries throughout the brain regions associated with motor control? MRI images of the brains of 17(6f) right handers (RH) and 14(7f) left handers (LH) were used. To estimate the extent of the hand area of M1 the sulcal ribbon along the hand-knob was manually labelled. Volumes of the Basal Ganglia, Thalamus and Cerebellar Regions were extracted for all individuals using MAGeTBrain a multi-atlas based automated segmentation tool. The central sulcus shows a strong significant asymmetry ($p<.05$). The sulcal region (depth x length) of the hand is 12% larger in the left in RH and 40% larger on the right in LH. The basal ganglia unexpectedly showed large variation and no significant results. A trend was found in the thalamus ($p<.1$). The relative (left vs right) size of the right thalamus increases in LH. The results of the cerebellar regions were surprising. A strong significant effect was found showing that RH have a larger cerebellum bilaterally ($p<.003$) most pronounced in the Crus I regions. Two possible processes might be involved in the local volume differences demonstrated in this study: plastic changes associated with practise and differences in neuronal development that give rise to hand preference. The strong effect found in the M1 region combined with findings that training has a marked effect on regions of the motor cortex leads us to believe that life-long practice and brain plasticity is at work here. The strong effect found on general cerebellar volume though is most likely an indication for a deviation from “normal” early in development that causes both, smaller cerebellar volumes and left-handedness. Our results suggest that hand preference and associated local volume differences might not only reflect differences in motor behavior but are also caused by the genetic/developmental processes involved in determining hand preference.

	Left-handers	Right-handers
Left primary hand area (mm^2)	450	558
Right primary hand area (mm^2)	630	494
Total cerebellar (mm^3)	166653.8	177460.4

A shows the manual segmentation of the central sulcus hand area in an individual subject. The area of the sulcal ribbon drawn along the hand-knob was used for analysis. **B** shows the segmented subcortical and cerebellar areas using MAGeT in the same individual. The table above summarized the most prominent significant results: The hand area shows strong asymmetry with the dominant hand having a larger area. This asymmetry is reversed in LH.
RH have a larger Cerebellum!

Title: Changes in swimming parameters during the development of Xenopus tadpoles

Authors: *S. HÄNZI[1,2], L. HOFFMAN[3], M. PAULIN[4], H. STRAKA[2];
[1]Grad. Sch. of Systemic Neurosciences, Planegg, Germany; [2]Dept. Biol. II, Ludwig-Maximilians-University, Munich, Germany; [3]Dept. of Head & Neck Surgery, Geffen Sch. of Med. at UCLA, Los Angeles, CA; [4]Dept. of Zoology, Univ. of Otago, Dunedin, New Zealand

Abstract: Morphological changes during ontogeny are often associated with alterations in physiological parameters such as locomotor performance, dynamics and behavioral repertoire. Amphibian development is a particularly good example, where the maturation and improvement of the undulatory tail-based swimming during progressive larval development is succeeded after metamorphosis by a limb-based locomotor pattern in adult frogs. Moreover, any change in locomotor performance or strategy requires a concurrent adaptation of the vestibular system for appropriate neuronal encoding of the motion profile generated by the locomotion. Here, we studied the swimming behavior of Xenopus laevis tadpoles, and examined whether the morphological changes of the larval body plan are accompanied by concurrent changes in locomotor parameters and behavioral adaptations. High-speed video images (up to 200 frames/s) of swimming sequences were captured at different developmental stages of larval (stage 47-59) and young adult frogs (stage 61). The swimming trajectory of young larvae (stage 47-49) essentially covered most of the tank area. In contrast, older larvae (> stage 53) and adult frogs showed thigmotaxis represented by locomotor trajectories that generally followed the walls of the tank. This change in swimming pattern correlated with the progressive bilateral outgrowth of touch-receptive tentacles in older larvae and reflects a behavioral adaptation of the larval life style, even though the two appendages disappear after metamorphosis. The growth of the larvae was also accompanied by an increase in forward locomotor speed and head angular velocities during undulatory swimming. These changes were reflected in the statistics of head kinematics extracted from sequences of free swimming. For instance, peak angular head velocities reached several hundred degrees per second during fast undulatory swimming. These measures provide more naturalistic representations of head motion profiles exhibited by these animals that will serve to establish naturalistic stimuli for probing vestibular responses and neuronal computation underlying sensory-motor transformation in peripheral and central circuits. Moreover, the high

frequency and velocity components of the locomotor profile suggests the presence of neuronal elements in the vestibular system with coding capabilities that ensure faithful neural representation of the respective kinematic components.

Title: Orexinergic modulation on the cervical network regarding the fetal movement using rat brainstem-spinal cord preparation

Authors: *A. ARATA[1,2], H. SHIMOMURA[3], M. ITO[2], A. NISHIYAMA[2], Y. TAKESHIMA[3], A. YAMANAKA[4];
[2]Dept. of Physiol., [3]Dept. of Pediatrics, [1]Hyogo Col. of Med., Nishinomiya, Japan; [4]Dept. of Neurosci. II,, Res. Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan

Abstract: Orexin system is particularly important for maintenance of wakefulness because orexin deficiency results in narcolepsy. In late fetal stage, fetal movement in sleep begins to be synchronous with rapid eye movement, and this state is called the prototype of REM sleep. In neonatal REM stage, it is known that the exciting system in spinal cord such as locomotion is inhibited. We would examine the role of orexin in the relationship between fetal movement and REM sleep. In fetal rat isolated brainstem-spinal cord preparation, our previous study already reported two kinds of activities recorded from 4th cervical nerve root (C4); one is respiratory activity that is comparatively rhythmic activity corresponding to phrenic nerve activity, and the other is non-respiratory activity (NRA) which is not rhythmic, accompanied by high amplitude, and that was corresponding to the fetal movement. Additionally in after birth, we could not observe the NRA, but the similar activity as NRA was induced by strychnine application (Shimomura et al, 2015). The critical point of the disappearance of NRA existed at E19-20 and NRA was abolished by application of an antagonists of strychnine-insensitive glycine binding site on the NMDA receptor. The NRA was controlled by the excited glycine via NMDA receptor glycine binding site and by the inhibition via Cl-channel related glycine receptor. Orexin depressed the NRA and potentiated respiratory activity. On the other hand, application of

strychnine showed increase of respiratory rate and showed no alteration of NRA. The increase of orexin level induced the NRA inhibition. After removal of brainstem from this preparation, NRA still existed but decreased the frequency. NRA in the spinal cord was also depressed by orexin. In fetal stage, orexin might modulate inhibitory system in the cervical circuit, and also might modulate formation of wakefulness and REM sleep.

Title: Lipopolysaccharide-induced IL-6 and TNFalpha expression in neonatal rat nucleus tractus solitarii (NTS)

Authors: J. CLAY, M. CUSTER, R. JOHNSON, *C. G. WILSON;
Ctr. for Perinatal Biol., Loma Linda Univ., Loma Linda, CA

Abstract: Lipopolysaccharide (LPS), or endotoxin, is commonly used to induce an inflammatory response in animal models. In premature infants, systemic infection (sepsis) causes tachypnea and an increase in the number of apneas over time but the mechanism by which sepsis alters breathing control is unknown. Our laboratory has previously shown that LPS instilled into the trachea of neonatal rats causes changes in IL-1beta expression in brainstem regions associated with breathing control_including the rostral medulla, nucleus tractus solitarii (NTS), and the hypoglossal (XII) motonucleus. We hypothesize that increased expression of interleukin-6 (IL-6) and tumor necrosis factor alpha (TNFa) are upregulated in the rostral ventro-lateral medulla (RVLM) and NTS after injection of LPS into the trachea and these changes are correlated with dysregulation of breathing. To test this hypothesis, we performed immunohistochemistry on brainstems harvested from 10 to 12 day old rat pups (Sprague-Dawley) two hours after injection of LPS (0.5 mg/kg in 10 microliters of saline) into the trachea. Breathing pattern was monitored via diaphragm EMG during the LPS injection and recovery from surgery. We cut brainstems using a cryostat (20 micron sections) and acquired sections that included RVLM, XII, and the NTS. We performed overnight immunohistochemistry runs to label IL-6 and TNFa. We acquired images of the sections using a Zeiss upright microscope and all images were analyzed using a custom ImageJ plug-in to identify and count the stained cells.

We saw that the RVLM and NTS had an increase in IL-6 and TNFa expression when compared to sham surgery and control animals. IL-6 was 33.0% ($p \leq 0.001$) higher in RVLM when compared to sham. TNFa was 17.3% ($p \leq 0.001$) greater than sham. In the NTS, IL-6 was 31.4% ($p \leq 0.002$) [N=3 for all groups] greater and TNFa 28.2% ($p \leq 0.0006$) greater pixel density than sham groups. The changes in IL-6 and TNFa cytokine activity may exacerbate the changes in breathing pattern seen during apnea of prematurity or periodic breathing. We do not yet know what mechanism is responsible for changes in breathing during neuro-inflammatory up-regulation but the downstream signaling pathway from these early inflammatory markers is an obvious choice for further investigation.

Title: Investigation of the *in vivo* effect of classical and new psychotherapeutic approaches on the behavioural and neurochemical profile of a rat model of Tourette syndrome and control animals - an MRS study

Authors: *F. RIZZO[1], E. NESPOLI[2,5], A. ABEI[3], I. BAR-GAD[6], V. RASCHE[3], B. HENGERER[5], T. BOECKERS[4], A. G. LUDOLPH[2];

Abstract: Tourette syndrome (TS) is a neurodevelopmental disorder characterized by motor and vocal tics and a high comorbidity-rate with ADHD (attentional deficit/hyperactivity disorder). One third of children with TS experience an improvement of tics during adolescence until young adulthood but a substantial part of patients remains symptomatic after the second decade of life. In both, children and adults, pharmacologic intervention is suggested if tics are distressing and/or interfere with psychosocial function. Different guidelines suggest neuroleptics and alpha-2a agonists as drugs of first-choice. Beside their efficacy on tics, such interventions show severe

side effects. New treatments are required. Aripiprazole, a partial D2 agonist, has been found to be effective in tic-management. Dopamine (DA) metabolism is dysfunctional in TS, but imaging data give definite hints that other neurotransmitters take part in tic generation: histamine, serotonin, norepinephrine, glutamate and GABA, Gutamate and DA metabolism is closely interconnected. The glutamatergic modulator riluzole exerts neuroprotection against glutamate excito-toxicity both *in vitro* and *in vivo*. Clinical trials in TS are ongoing. We compare the effect of neuroleptics (aripiprazole) and glutamatergic drugs (riluzole) on the behavior and cerebral glutamate metabolism during development using MR spectroscopy (MRS) in a TS rat model versus control rats. The recently published model clearly satisfies the face validity criterion in modelling TS. This study will also provide information regarding its predictive validity. WKY rats and spontaneous hypertensive rats (SHR), an ADHD animal model, undergo instrastriatal bicuculline (GABA antagonist) microinjections that induce an acute tic-session. Control animals are sham-operated. MRS spectra are acquired in each group (ARI 1.5mg/kg; RILU 6 mg/kg and vehicle) from PND 35 to 50, covering the evolving period from childhood to young adulthood in rats. Preliminary data on glutamate, GABA, glutamine and lactate absolute quantification in the left dorsal striatum and prefrontal cortex are presented. Preliminary behavioral data of the treated groups - compared to vehicle and sham operated animals - are presented. No differences in the body weight or brain weight in any of the treated groups compared to the vehicle are observed after 15 days of sub-chronic treatment with both drugs. Differences in the MR spectra acquired in rats treated with aripiprazole (classical neuroleptic approach) and riluzole (possible new option) give hints on which cerebral metabolites are influenced by the two different compounds during brain development.

Title: Altered formation and function of striatal circuitry in the absence of Sox8

Authors: *P. MERCHAN SALA[1], T. L. SCHAEFER[3], A. A. ASHWORTH[3], M. WEGNER[4], K. CAMPBELL[2];

[1]Developmental Biol., [2]Divisions of Developmental Biol. and Neurosurg., Cincinnati Children's Med. Ctr., Cincinnati, OH; [3]Div. of Psychiatry, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [4]Inst. of Biochem., Univ. of Erlangen, Nurnberg, Germany

Abstract: The striatum is the major component of the basal ganglia and is well known to play a key role in the control of motor function via the indirect (striatopallidal) and direct (striatonigral) output pathways. Imbalances in the activity of these pathways are thought to underlie the behavioral abnormalities observed in a number of neurological disorders including attention deficit hyperactivity disorder (ADHD) and other classical motor disorders. Little is known about the molecular genetic mechanisms that control the formation and function of the direct and indirect pathways. In this respect, we have recently found that the SoxE family member, Sox8, is expressed in the developing and adult striatum. Moreover, we have found that Sox8 marks the direct pathway already at early embryonic stages using Sox8 GFP BAC transgenic mice from GENSAT. By analyzing Sox8lacZ mutant mice, we found that there is a dramatic reduction in the projections of the direct pathway in both homozygous and heterozygous animals, despite the fact that the striatum appears normal in size. To further confirm the specificity of the defect, we crossed Drd1-EGFP (direct pathway marker) BAC mice from GENSAT with the Sox8lacZ mice and our preliminary findings suggest that the EGFP+ fibers terminate prematurely in the globus pallidus (GP, the normal target of the indirect pathway) of homozygous mutants, suggesting that Sox8 is required for long axon growth of direct pathway fibers. In support of this notion, we observed substance P-positive fibers abnormally terminating within the GP of Sox8 mutants. Although basal ganglia circuitry is normally associated with the regulation of motor function, recent studies have suggested roles in social and cognitive behaviors. Because the Sox8 mutants have very specific defects in the formation of the direct pathway, we have conducted several behavioral tests to examine the requirement for normal formation of this pathway in motor, social and cognitive function. Interestingly, Sox8 homozygous and heterozygous mice exhibit increased basal locomotor activity as well as deficits in the social preference assay and the Morris water maze, demonstrating a role for normal striatal circuitry in multiple aspects of brain function.

Title: Exploring neurodevelopmental aspects of tics in a juvenile rat model of repetitive behavior

Authors: *E. NESPOLI[1,2], F. RIZZO[1], A. LUDOLPH[1], B. HENGERER[2];
[1]Child and Adolescent Psychiatry, Universitätsklinikum Ulm, Ulm, Germany; [2]CNS research, Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany

Abstract: Tourette Syndrome (TS) is a neurodevelopmental disorder which affects 0.4-1% of the population. It is defined by the presence of multiple motor and at least one vocal tic, typically starting during childood. TS is not only about tics. Indeed, up to 90% of all TS patients experience psychiatric comorbidities, mainly ADHD and OCD, but also behavioral disturbances. The exact cause of TS remains elusive, but tics are supposed to be caused by an abnormal regulation of the motor loop activity, which consequentially leads to the hyper-excitability of motor regions of the brain cortex . Dopamine (DA) appears to have a central role, more likely through its fine regulation of the direct and indirect striatal pathways, which in turn regulate voluntary and involuntary movements. Unilateral 6-hydroxidopamine (6-OHDA) lesion in adult rats is a well-established model used in Parkinson´s Disease research. In this model, selective degeneration of nigrostriatal dopaminergic neurons is chemically induced through the administration of 6-OHDA. Subsequent chronic application of dopaminergic agonists challenge leads to the development of repetitive involuntary movements. This is a consequence of striatal increased sensitivity to DA, which is also a putative pathological mechanism of TS, and is induced in this model via previous DA deprivation. The repetitive involuntary movements observed are sudden, rapid and brief, and occur repeatedly at irregular intervals, mainly involving the contralateral forepaw, face and mouth. During the period of levodopa efficacy, the movements change in intensity and frequency, but not in location. Animals can be distracted, and the involuntary movements reduce when they focus on something. The phenotype was challenged using different dopaminergic and non-dopaminergic agents, with a special emphasis on modulators of metabotropic glutamate receptors. Several pharmacological approaches have been shown to interfere with the repetitive movements, either worsening or improving the phenotype, indicating possible lines of therapeutic actions, or co-pathogenic mechanisms. This model could allow the evaluation of the consequences of an altered striatal regulation occurring during development, and could also be employed in the investigation of new therapeutic options for tic disorders.

Title: Movement learning processes provide potential etiology for neurological disorders

Authors: *J. V. JOSE[1], D. WU[2];
[1]Office of the Vice President for Res., [2]Physics, Indiana Univ., Bloomington, IN

Abstract: Motor deficits are widely reported in people with social interaction problems suffering from neurological disorders (like Autism Spectrum Disorders (ASD)), suggesting a strong link between motor control and cognitive abilities. In our previous ASD studies, we uncovered small speed fluctuations that break the continuity of speeds versus time profiles via minute speed-Spikes (s-Spikes) at millisecond time scales. Statistical analysis of s-Spikes' results from natural pointing movement trials provided quantitative biomarkers for ASD subjects correlating well with their spoken verbal abilities. Here we ask the general questions: How does the brain maintain or not the continuity of physical movements at millisecond time scales? How does learning a new motor skill modify the smoothness and statistical properties of the speed profiles in subjects with neurological disorders versus typical controls at millisecond time scales? More importantly, how do these motor control mechanisms go awry in neurologic disease? Here we aimed to explore answers to these questions providing information about the possible origins of the s-Spikes. We studied s-Spikes statistics during well-defined movement learning processes, questioning and comparing how and whether or not achieving movement smoothness occurs for both typical controls and subjects with neurological disorders. Our studies aim to shed light on the origins of the s-Spikes statistical differences previously found between typical controls and subjects with neurological disorders, linking movement smoothness to cognitive abilities, and to the potential etiology of the disorders.

Title: Essential roles of leucine-rich glioma inactivated 1 in the development of embryonic and postnatal cerebellum

Authors: *Y. XIE[1], L. ZHOU[1], J. K. COWELL[2], Y. SHEN[1];
[1]Neurobio., Zhejiang Univ., Zhejiang, China; [2]Cancer Ctr., Georgia Regents Univ., Augusta, GA

Abstract: Leucine-rich glioma inactivated 1 (LGI1) is a secreted protein that interacts with ADAM transmembrane proteins, and its mutations are linked to human epilepsy. The function of LGI1 in CNS development remains undefined. Here, we report novel functions of LGI1 in the generation of cerebellar granule precursors (CGPs) and differentiation of radial glial cells (RGCs) in the cerebellum. A reduction in external granule layer thickness and defects in foliation were seen in embryonic and new-born LGI1 knockout (KO) mice. BrdU staining showed an inhibited proliferation of CGPs in KO embryos, which might be explained by the reduced Sonic hedgehog in embryos. In addition, the differentiation of RGCs into Bergmann glias was suppressed in KO mice. Enhanced Jagged1-Notch1 signaling in KO mice via reduced β-secretase proteolysis suggests that altered phenotype of RGCs is due to abnormal Notch1 signaling. Together, our results demonstrate that LGI1 is an essential player in the cerebellar development.

Hosp. Lyon-Sud, Hospices civils de Lyon, Pierre-Bénite, France

Abstract: In the newborn macaque the areal distribution of corticospinal neurons (CSN) is more widespread than that observed in the adult, but overall CSN are mainly found in areas that project in the adult (Galea et al. 1995). Here we have investigated whether the newborn areal distribution of CSN is the consequence of a process of refinement during the 165 days of *in utero* development. The retrograde tracer fast blue was injected at cervical levels of the spinal cord of cynomolgus monkeys at embryonic day (E) 95, E105 and adulthood. At all ages, the soma of the labeled pyramidal CSN were restricted to layer 5; the highest density of labeling was observed in presumptive motor cortex. In the fetal monkeys, the distribution of CSN was considerably more widespread than in the adult with dense projections from regions which do not project in the adult. At E95, CSN form a continuous band spanning prefrontal, frontal, cingulate and parietal cortices. At this developmental stage no CSN were observed in striate cortex and only a few scattered CSN were observed in the inferior temporal region. At E105, the tangential extent of CSN labeling was reduced with respect to the distribution at E95, and neurons were no longer observed in the inferior temporal and prefrontal regions. In the adult, CSN were restricted to motor, somatosensory, cingulate and insular regions, a pattern previously reported in the literature (Galea et al. 1995). Acetylcholinesterase histochemistry allowed to positively identify primary visual (area 17) and auditory cortex. In area 17 there was a complete absence of CSN both at E95 and E105. In contrast, an important number of labeled CSN was observed in primary auditory cortex at both fetal ages. Our results reveal a substantial refinement of the tangential extent of CSN occurring during a restricted developmental time window. This indicates that the restricted areal pattern of CS projections that characterize the postnatal and adult macaque cortex is established subsequently to a sustained and fast elimination of CS projections. The fact that area 17 is free of transient CS projections fits with the absence of transient callosal projecting neurons in this area throughout development (Dehay et al., 1988). In order to gain insight into the developmental mechanisms shaping the CS projections ongoing analysis aims to determine if in the fetus the extensive regions that will show complete loss of corticospinal neurons during later development have significantly lower densities of CSN compared to regions that maintain these connections into adulthood. Title: Roles of Runx1 transcription factor in axonal projection of mouse embryonic hypoglossal motoneurons

Authors: *M. YOSHIKAWA[1], S. OZAKI[2], M. TOMOYUKI[2], M. MATSUKAWA[1], M. IMADA[1], S. AIZAWA[1], T. SHIGA[2];
[1]Nihon Univ. Sch. of Med., Tokyo, Japan; [2]Fac. of Medicine, Univ. of Tsukuba, Tsukuba, Japan

Abstract: Runx1, runt-related transcription factor, plays important roles in the cell type specification and axonal projections of the nociceptive dorsal root ganglion (DRG) neurons. Runx1 is also expressed in the central nervous system as well as the peripheral nervous system, but little is known about the roles in the brain development. In our present study, we found that Runx1 was expressed in the ventrocaudal part of hypoglossal nucleus (nXII) at embryonic day (E) 17.5 and examined the axonal projection and terminal formation of the hypoglossal neurons in the tongue muscles in *Runx1*-deficient mice using antibodies against neurofilament-H and vesicular acetylcholine transporter (VAChT; a presynaptic marker for motor axon terminals). Hypoglossal axon projections to the intrinsic vertical (V) and transverse (T) tongue muscles were sparser in *Runx1*-deficient mice at E17.5 compared with age-matched wild-type mice. Also, the areas immunoreactive for VAChT were reduced in the V and T tongue muscles in *Runx1*-deficient mice. The abnormalities in axonal projection in *Runx1*-deficient mice were not caused by reduction of neurons and abnormality of tongue muscles. We also examined the expression of two markers of cranial motoneurons, c-Met and c-ret. Althouth Runx1 regulates c-Met and c-ret expression in DRG neurons, Runx1 deficiency did not change the expression of these markers in hypoglossal neurons. Thus, it is unlikely that the altered axonal projection from nXII in *Runx1*-deficient mice is associated with c-Met or c-ret dysfunction. Recent studies reported that the Wnt receptor Frizzled3 (Fzd3) also contributes to axonal projection of hypoglossal neurons, so we examined the expression of Fzd3. Fzd3 expression was reduced in the nXII of *Runx1*-deficient mice, suggesting that Runx1 promotes Fzd3 expression. Further studies are necessary to determine whether Fzd3 is involved in the regulation of hypoglossal axonal projection by Runx1. Taken together, our results suggest that Runx1 is involved in targeting ventrocaudal hypoglossal neurons to specific tongue muscles, possibly by interacting with Fzd3.

Abstract: It is generally believed that direct corticomotoneuronal connections are present only in higher primates, which serve as the basis for their dexterity. Here, we show direct corticomotoneuronal connections in juvenile mice. Retrograde monosynaptic tracing with a recombinant rabies virus from the forearm-innervating motor neurons showed that the corticomotoneuronal cells were widely distributed in the cerebral cortex including the rostral and caudal forelimb area of the motor cortices as well as the primary and secondary somatosensory cortices. Whole cell patch clamp recordings for the forearm-innervating motor neurons detected monosynaptic excitatory postsynaptic current in response to optogenetic stimulation of the corticospinal axons in the spinal cord slices prepared from the postnatal day 8-10 animals. In the fourth postnatal week, however, labeled premotor neurons in the cerebral cortex were not found as far as examined by monosynaptic tracing. Premotor neurons including interneurons in the spinal cord and bulbospinal neurons in the lower brainstem were successfully labeled by monosynaptic tracing. These results suggest that the corticospinal neurons transiently form synapses with forearm-innervating motor neurons in the early postnatal period, which is subsequently eliminated by approximately a month after birth.

Title: Looking at a Vglut2/Pitx2 subpopulation of the subthalamic nucleus - from development to behavior

Authors: *M. PAPATHANOU, N. SCHWEIZER, E. ARVIDSSON, S. PUPE, A. WALLEN-MACKENZIE;
Unit of Functional of Neurobio. - Dept. of Comparative Physiol., Uppsala Univ., Uppsala, Sweden

Abstract: The subthalamic nucleus (STN) is an important area of the basal ganglia known to modulate motor and non-motor aspects of brain functions. Its important role in locomotion has been shown by the successful use of high-frequency stimulation (HFS) of the STN, as treatment for Parkinson's disease, however the mechanisms by which HFS modulate STN activity is unknown. Recently we were able to identify a subpopuplation of the STN, characterized by co-expression of Vglut2 and the paired-like homeodomain2 (Pitx2). Conditional knockout (cKO) of this subpopulation in mice resulted in the manifestation of hyperlocomotion and decreased latency in the initiation of movement. There was decrease of Vglut2 expression and reduction of glutamate transmission. Moreover a closer histological analysis of the cKO mice showed an altered morphology, although it remains unknown whether the changes in morphology and behaviour are attributed to disrupted developmental processes. It is also unclear whether the alteration in the morphology is associated with a loss in a specific subpopulation of the STN. In a

recent screen we were able to identify STN specific markers, which are being analysed in wild-type and cKO mice both at embryonic and young adult stages. Overall our results demonstrate that limiting, but not eliminating, the expression of Vglut2 in the STN is sufficient to achieve results similar to STN high frequency stimulation. However identification of further markers of the STN may improve our basic understanding of this nucleus and may help unravel whether specific subpopulations are responsible for the different core functions of the STN (motor, limbic and associative). This may ultimately provide key insights into the mechanisms underlying deep brain stimulation efficacy and possibly minimize the side-effects that current patients are experiencing.

Title: Neuroanatomical differences between adults who stutter and adults who do not stutter

Authors: *A. DALIRI, E. GOLFINOPOULOS, J. A. TOURVILLE, F. H. GUENTHER; Dept. of Speech, Language, and Hearing Sci., Boston Univ., Boston, MA

Abstract: A growing body of literature suggests that developmental stuttering is associated with neuroanatomical abnormalities, particularly in regions that are involved in speech planning and production (see Bloodstein & Ratner, 2008). Using voxel-based morphometry, several studies have reported abnormalities in both gray matter volume and white matte volume of adults who stutter (AWS) (see Beal et al., 2015). Studies have also reported atypical sulcal morphology in AWS (Cykowski et al., 2008). However, it remains unknown whether AWS who have abnormal grey matter volume also have abnormal white matter volume or atypical sulcal morphology. Therefore, in this study, we examined neuroanatomical differences between AWS and adults who do not stutter (AWNS) using a variety of morphometric measures_cortical thickness, cortical gyrification, grey matter volume, and white matter volume. Moreover, we examined the relationships between different morphometric measures in both AWS and AWNS. Participants were 28 right-handed AWS and 28 right-handed, age- and sex-matched AWNS. The Stuttering Severity Instrument, Fourth Edition (SSI-4) was used to determine stuttering severity of the AWS. Image segmentation, cortical surface reconstruction, surface-based registration, and

surface parcellation were performed using the Freesurfer 5.3 software package. Regional measures of cortical thickness, curvature, gray matter volume, and white matter volume were extracted for specific brain regions of interest (ROI) involved in speech planning and production. In addition, we extracted grey matter volume for subcortical structures. We used general linear models (GLMs) for between-group comparisons. Pearson correlation coefficients were calculated to examine the relationships between different morphometric measures in each group, and between stuttering severity and morphometric measures for the stuttering group. Our preliminary results revealed several morphometric differences between AWS and AWNS. We found increased grey matter volume for AWS in left anterior dorsal premotor cortex, left posterior middle frontal gyrus, and left frontal operculum. We also found increased cortical thickness for AWS in left frontal operculum and right presupplementary motor area. In addition, we found increased cortical curvature for AWS in left posterior middle frontal gyrus, right anterior central operculum, and right parietal operculum. These preliminary results showed that stuttering individuals with atypical grey matter volume are also likely to have atypical cortical curvature and atypical cortical thickness.

Title: The COE-type transcription factor UNC-3 cooperates with HOX proteins to generate motor neuron diversity

Authors: *P. KRATSIOS, S. KERK, R. MOURAO, O. HOBERT;
Columbia Univ., New York, NY

Abstract: The motor circuit of *Caenorhabditis elegans* provides an ideal model system to probe the question of how neuronal diversity is generated during development. Similarly to vertebrates, *C.elegans* motor neurons (MNs) are organized into distinct classes that display remarkable functional and anatomical diversity. The underlying basis of such diversity is the differential expression of MN class-specific terminal identity genes (e.g. ion channels, neurotransmitter receptors) that define the specific properties of a functional MN class throughout life. We have previously shown that the evolutionarily conserved COE (Collier, Olf, Ebf) - type transcription factor (TF) UNC-3 is required for diversity in the *C. elegans* ventral nerve cord (VNC) MNs by directly regulating the expression of MN class-specific terminal identity genes. The ability of UNC-3 to activate directly – through its cognate binding site (COE motif) – distinct terminal identity genes in specific MN classes predicts the presence of as yet unknown regulatory factors needed to cooperate with UNC-3 and activate its targets in specific MN classes. Supporting this prediction, transgenic animals carrying a multimerized version of the COE motif fail to show reporter gene expression in any MN class. To reveal the identity of such factors, we followed a candidate approach and found a novel role for HOX genes in MN diversity. Animals lacking gene activity of more anteriorly expressed HOX genes, such as *lin-39*/Scr/Dfd and *mab-5* (Antennapedia-type HOX gene), failed to express terminal identity genes specific to MN classes positioned within the *lin-39* and *mab-5* expression domains. Similarly, the posterior HOX gene *egl-5*/Abd-B is required for expression of terminal identity genes specific to MNs positioned at the posterior end of the VNC. Genetic removal of the HOX cofactor *ceh-20*/Exd/Pbx resulted in similar effects. The presence of HOX/PBX binding sites in proximity to COE motifs in the *cis*-regulatory region of UNC-3 target genes point to a coactivation principle where UNC-3, HOX and PBX factors activate the expression of MN class-specific terminal identity genes, thereby generating MN diversity.

Title: Dab1 modulates grooming duration in mice

Authors: A. DELPRATO[1,2], B. BONHEUR[1], M.-P. ALGÉO[1], L. LU[3], R. W. WILLIAMS[3], *W. E. CRUSIO[1];
[1]Univ. Bordeaux and CNRS, Bordeaux (Pessac), France; [2]BioScience Project, Wakefield, MA; [3]Dept. of Genetics, Genomics and Informatics, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: We used the BXD recombinant inbred strains to map quantitative trait loci (QTLs) underlying behaviors associated with open field exploration. Over 900 males and females from 53 strains were observed for 20 min in a rectangular open field (108*49*49 cm). We identified a significant QTL on mouse chromosome 4 influencing grooming duration in both males and females. This narrow interval contains only two genes with different alleles in the C57BL/6 and DBA/2 parental strains: Zcchc11 and Disabled-1 (Dab1). Zcchc11 has no obvious connection to the nervous system or its development. In contrast, Dab1 is a key component of the Reelin signaling pathway that regulates neuronal migration and positioning by activating intracellular signaling cascades and cytoskeletal rearrangement. Dab1scm mutant mice (scrambler) have neuroanatomical abnormalities including degeneration of the cerebellum, hippocampus, and neo-cortex, with concomitant behavioral problems such as ataxia and body tremors. In addition, it has been found that scrambler mice show reduced grooming duration when compared to wild-type controls (Strazielle et al., 2012, Behav Brain Res. 233:24-28). Taken together, this provides strong evidence that the strain difference in grooming duration between C57BL/6 and DBA/2 is, at least in part, caused by allelic variation in the Dab1 gene.

Title: Role of BDNF and TrkB in the excitatory-inhibitory imbalance during the critical period of postnatal respiratory development in the rat

Authors: H. ZHANG[1], X.-P. GAO[1], *M. T. WONG-RILEY[2];
[1]Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, Milwaukee, WI; [2]Med. Col. Wisconsin, Milwaukee, WI

Abstract: Previously, we found that P12-13 is a critical period of respiratory development in the rat, when abrupt neurochemical, metabolic, ventilatory, and physiological changes occur in the respiratory system. During this critical period, there is a distinct imbalance between suppressed excitatory postsynaptic currents (EPSCs) and enhanced inhibitory postsynaptic currents (IPSCs) in respiratory-related hypoglossal motoneurons (HMs). We hypothesized that such an imbalance is contributed by a reduced expression of brain-derived neurotrophic factor (BDNF) and its high-affinity tyrosine kinase B (TrkB) receptors, which normally enhance excitation and suppress inhibition. Indeed, the levels of BDNF and TrkB are significantly down-regulated in multiple respiratory-related brain stem nuclei during the critical period, and the synaptic imbalance was partially reversed by the application of a TrkB agonist (7,8-DHF). To further test our hypothesis, the current study used whole-cell patch-clamp recordings on HMs in brain stem slices of normal rats and those that received i.p. injections of a TrkB antagonist (ANA-12). Results showed that: 1) When ANA-12 was given before the critical period (once a day at P6 and P7, and recordings were done on P8), the amplitude and frequency of sIPSCs were not significantly changed, but the amplitude and frequency of sEPSCs were significantly decreased by 13.03% and 27.89%, respectively. 2) When ANA-12 was given close to the critical period (once a day at P10 and P11 or at P11 and P12, and recordings were done on P12 and P13, respectively), the amplitude and frequency of sIPSCs were significantly increased by 50% and 17.74%, respectively (at P12), and by 20.85% and 16.38%, respectively (at P13). Moreover, the amplitude and frequency of sEPSCs were significantly decreased by 17.32% and 37.3%, respectively (at P12), and by 17.48% and 36.74%, respectively (at P13). 3) When ANA-12 was given after the critical period (once a day at P14 and P15, and recordings were done on P16) , the amplitude and frequency of sIPSCs were also significantly increased by 37.72% and 18.04%, respectively, whereas the amplitude and frequency of sEPSCs were significantly decreased by 19.48% and 28.38%, respectively. Thus, our results indicate that *in vivo* application of ANA-12 significantly aggravates the imbalance during the critical period and exaggerates synaptic inhibition even after the critical period. These findings are consistent with our hypothesis that reduced expressions of BDNF and TrkB directly contributes to the synaptic imbalance within respiratory-related nuclei during the critical period of respiratory development in the rat.

Title: Engrailed 1 is required for maintaining proper isthmus positioning

Authors: *W. M. KOUWENHOVEN, J. V. VEENVLIET, L. P. VAN DER HEIDE, J. A. VAN HOOFT, M. P. SMIDT;
Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Dopaminergic en serotonergic neurons are located in the ventral mesencephalon and rostral metencephalon of the vertebrate brain. Dysfunction in these monoaminergic systems are associated with several severe disorders (e.g. Parkinson's, autism and depression). As such, knowledge on the fundamental and pathological, developmental mechanisms is crucial in the advancement of our understanding of these diseases. For the proper induction of the entire mid- and hindbrain region, Engrailed 1 (En1) homeodomain transcription factor is particularly important. Its expression pattern spans the isthmic organizer (IsO), which is the intracellular signaling center that forms a border between the embryonic midbrain and hindbrain. It is a linear boundary, expressing molecular signals such as fibroblast growth factor family (Fgf)8 and Wnt1. The IsO shapes the development of mesodiencephalic dopaminergic neurons rostral of the IsO and the development of serotonergic neurons caudal of the IsO. Up until now, the investigation into the role of En1 in patterning was hampered due to the perinatal lethality of this mouse model in a Sv/29 background. In the current work we fill that hiatus by investigating the viable, single En1KO embryo and adult animal, using *in situ* histochemistry and electrophysiological recordings. We observed a disrupted IsO in the En1KO animal, leading to the presence of fully functional dopaminergic neurons in the rostral hindbrain, and a simultaneous loss of serotonergic neurons. This establishes the importance of En1 in stabilizing the IsO and in proper patterning of the mid-hindbrain region.

Abstract: Understanding the emergence and developmental trajectories of early social skills and the neural circuits underlying them is critical to unravel the etiology of devastating social disorders such as Autism Spectrum Disorder (ASD), but is still poorly understood, due to limitations of longitudinal, repeated imaging of the infant human brain. Here, we present preliminary findings characterizing the developmental trajectories of social visual engagement neural pathways in a highly translational nonhuman primate (NHP) animal model. Six infant male rhesus monkeys were recruited for this longitudinal resting state functional MRI (rs-fMRI) study. Subjects lived with their mothers in large social groups preserving critical species-specific social experiences. Neuroimaging data were collected at 2, 4, 8, 12, 16, 20 and 24 weeks of age after birth, on a 3T Siemens TrioTim MRI scanner, using an echo planar imaging (EPI) sequence sensitive to BOLD contrast (TR/TE=3sec/30msec, 2x15min, voxel size: 1.5x1.5x1.5mm). Functional connectivity between regions of interest (ROIs) along the visual perception pathway (from V1 to V4 to TEp), the biological motion pathway (from V1 to MT), and their projections to the amygdala (AMY), as well as the spatial attention pathway (from V1 to V3 to LIPv) and its connection to dorsolateral prefrontal cortex (dlPFC, Area 46) were analyzed after top-up distortion correction. Our findings revealed that the primary visual cortex (V1) already shows strong functional connections with other visual cortical areas (V3, V4) at 2 weeks and remains relatively stable with age. Results suggest no age-related changes on the caudal part of the visual pathways, but changes were observed on the rostral part of these pathways from week 2 to 24.

We also found that the AMY-PFC FC becomes stronger during the first 3 months of life, and weaken thereafter. Our results suggest that maturation of the visual pathways in NHPs is likely to continue throughout the first six months of life, in parallel with axon regression and myelination. Increased knowledge on the critical periods of typical development during which early social and visual skills emerge and mature give us opportunity to further understand the neurobiological source of developmental disorders, such as ASD.

Title: Sulcal pits differentially contribute to the development of functional regions in high-level visual cortex

Authors: ***V. S. NATU**, J. GOMEZ, M. A. BARNETT, A. STIGLIANI, K. GRILL-SPECTOR, K. S. WEINER;
Stanford Univ., Stanford, CA

Abstract: The functional architecture of high-level visual cortex is highly consistent relative to cortical folding patterns (Grill-Spector & Weiner 2014). For example, in adults, the parahippocampal place area (CoS-places/PPA) is consistently located in the collateral sulcus (CoS). While the gross anatomical structure and functional topology of high-level visual cortex do not qualitatively change across development, some functional regions quantitatively change, e.g., face- and place-selective regions increase in size and selectivity aross development (Golarai et al., 2007; Scherf et al., 2007). However, it is unknown if quantitative changes of cortical folding occur past age 2 (Meng et al., 2014) and if these developmental changes contribute to the observed structural-functional coupling in adulthood. One quantitative feature of cortical folding is the deepest point in a sulcus, known as the sulcal pit. While sulcal pits have not garnered

attention in research of high-level visual cortex, they are hypothesized to be functionally-relevant (Regis et al., 2005; Im et al., 2010; Auzias et al., 2015; Leroy et al., 2015). We used functional and anatomical MRI in 12 adults (20-40 years old) and 13 children (5-11 years old) to examine (1) if sulcal pits in high-level visual cortex develop, (2) if there is a correspondence between sulcal pits and functional regions, and (3) if such a relationship varies across development. We focused on two regions of the place-selective network - the retrosplenial complex (RSC) and the PPA - because they are both located within primary sulci, the parieto-occipto sulcus (POS) and the collateral sulcus (CoS), respectively. Results reveal that sulcal pits of the CoS and POS develop differentially: the sulcal pit in the CoS is deeper in adults compared to children ($p<0.001$), whereas the sulcal pit of the POS is of similar depth across children and adults ($p=0.64$). Notably, the structural-functional coupling of the sulcal pit and place-selectivity varies across development and anatomical regions. The sulcal pit of the CoS is significantly closer to CoS-places/PPA in adults than in children (mean distance between the pit and the nearest place-selective voxel: adults: MA=0.4±0.2mm, children: MC=5.9±1.7mm, $p < 0.001$), but there was no age difference in the distance between the sulcal pit of the POS and POS-places/RSC (MA=3.9±1.3mm, Mc=4.7±1.2mm, $p=0.62$). These results support a novel hypothesis that the deepening of sulcal pits is an anatomical constraint that may contribute to the functional development of high-level visual cortex where this process occurs along different developmental trajectories depending on the anatomical location.

Title: Transient photoreception in the hindbrain is permissive to hatching in Atlantic halibut

Authors: ***J. HELVIK**[1], O. DRIVENES[2], L. O. E. EBBESSON[3], M. EILERTSEN[1];
[1]Dept. of Biol., Univ. of Bergen, Bergen, Norway; [2]Dept. of Mol. Biol., Univesity of Bergen, Bergen, Norway; [3]Uni Res. AS, Bergen, Norway

Abstract: Photoreception in animals is often linked to light sensory organs such as the retina to generate images or the pineal to regulate biological rhythms. These structures appear early in development and provide the organism with vital information throughout life. In the past decade

it has become evident that deep brain photoreceptors open for a direct regulation of biological processes within the brain, but few studies have described the existence of light driven pathways. The light-regulated hatching process of Atlantic halibut provides a unique model for studying such direct brain driven processes. In this study we detected a bilateral cluster of photoreceptive cells in the hindbrain of halibut by *in situ* hybridization (ISH). We show that this is a transient cluster that appears just prior to hatching. By a combination of fluorescent ISH and immunohistochemistry we demonstrate that the hindbrain cluster is connected to a neuronal network that projects out into the yolk sac to a narrow band of hatching glands. Our studies with photo-arrested eggs show that dark induced hatching activates the immediate early gene *c-fos* in the hindbrain cluster and in the hatching glands. Strikingly, we show by fluorescent double labelling ISH that the cells of the hindbrain cluster are dual photoreceptive.The cells express both vertebrate ancient opsin and melanopsin that are believed to belong to different classes of photoreceptor pigments normally found in rhabdomeric and ciliary photoreceptor cells, respectively. We here present for the first time in vertebrates that the mRNAs of both photopigments are expressed in the same cells. Taken together our studies show that a transient and dual photoreceptive cell group in the hindbrain mediates hatching in halibut, proposing that transient photoreceptor cells can control specific life history transitions. Further on, the dual photoreceptor cells in a vertebrate can reflect an ancient photoreceptor linage that exists transiently in the hindbrain to control hatching. The concept that an organism can develop transient light sensitivity in specific cell types to target critical aspects of life history transitions provides a new landscape to investigate seasonal timing in animals.

Title: Somatostatin-expressing interneurons in primary visual cortex undergo a developmental switch in neuromodulated excitation

Authors: *C. E. YAEGER, D. L. RINGACH, J. T. TRACHTENBERG;
UCLA, Los Angeles, CA

Abstract: We find that somatostatin-expressing (SOM) interneurons, which inhibit pyramidal (PYR) cell dendrites, receive excitatory neuromodulatory input in early postnatal development that is lost with age. Using resonant scanning two-photon excitation, SOM and PYR cells expressing Gcamp6 were simultaneously imaged in layer 2/3 of the primary visual cortex in critical period-age mice (p28-p30) and adult mice (p40 and older). During imaging, mice were fully awake and able to freely move on a spherical treadmill. Movement and pupil diameter were monitored. Visual stimulation evoked responses in SOM cells at all ages; however, in adult mice SOM cell responses were suppressed during locomotion, whereas in young mice locomotion enhanced evoked responses even in the absence of visual stimulation. Vasoactive intestinal peptide-positive (VIP) interneurons, which innervate and inhibit SOM neurons in adult cortex, do not change activity throughout this developmental time course and do not appear to inhibit SOM cells in young mice. Our data define two large-scale changes in cortical circuit architecture that coincide with the closure of critical period in primary visual cortex: a loss of excitatory neuromodulation to SOM cells and the establishment of VIP-mediated inhibition. Together, these changes shift the effects of locomotion and arousal on SOM cell activity from excitatory during the critical period to inhibitory thereafter. The age-dependent shift in SOM inhibitory activity is expected to profoundly alter dendritic integration and synaptic learning rules.

Title: Gap junctions shape recurrent activity in the tadpole optic tectum

Authors: Z. LIU[1], C. M. CIARLEGLIO[2], C. D. AIZENMAN[2], *K. G. PRATT[1];
[1]Dept. of Zoology and Physiol., Univ. of Wyoming, Laramie, WY; [2]Neurosci., Brown Univ., Providence, RI

Abstract: The neurons of the Xenopus tadpole optic tectum are organized into layers, with the deepest layer nearest the ventricular surface, and the outer-most layer adjacent to the neuropil. Using a modified horizontal brain slice preparation and focusing on the neurons of the outer layer, we have identified several physiologically distinct populations of neurons. Here we describe one especially distinct population of excitatory neurons that show elevated levels of intrinsic excitability. Similar to well-described deep-layer tectal neurons, these neurons receive relatively strong monosynaptic input from the retinal ganglion cells (RGCs) in the eye, but unlike common deep layer neurons, they receive minimal polysynaptic input - the portion of the RGC-evoked response comprised of recurrent tectal-tectal connections. This suggests that although these neurons receive direct input from RGCs, they receive very little synaptic input from other tectal neurons. Also, by filling these neurons with biocytin, we observed that these neurons display dye-coupling, implying that they could be electrically coupled. Consistent with this, preliminary results indicate that 18beta-glycyrrhetinic acid (18beta-GA), an established gap-junction (GJ) blocker that is known to block electrical coupling in Xenopus tadpole spinal motoneurons, prevents the dye coupling. The unusual pattern of connectivity, elevated intrinsic excitability, and the fact that they are dye coupled, led to the hypothesis that these neurons could synchronize the extensive recurrent portion of the RGC-evoked response received by the common deep layer neurons. To test this we recorded RGC-evoked responses from common deep layer neurons in the presence of 18beta-GA to block the putative electrical coupling. Compared to controls, 18beta-GA significantly reduced the amount of evoked recurrent activity received by deep layer neurons of stage 45-47 tadpoles - the stage when the recurrent portion of the RGC-evoked response is known to be unrefined and longer-lasting. Importantly, 18beta-GA elicited no noticeable effect on the passive electrical properties of individual tectal neurons, ruling out a cell autonomous mechanism, and also did not alter the strength of the monosynaptic portion of the RGC-evoked response. This suggests that gap junctions are a major generator of recurrent activity. A circuit wiring diagram that incorporates these findings places these GJ-coupled outer-layer neurons in a modulatory role that adds a temporal component to the maturing and refining RGC-evoked recurrent activity.

Title: Visual nucleus-specific targeting and refinement of retinal ganglion cell axons through the cadherin-catenin pathway

Authors: *D. Q. DAO[1], T. H. DAVIS[2], E. M. ULLIAN[1];
[1]Neurosci., Univ. of California, San Francisco, San Francisco, CA; [2]American Type Culture Collection, Manassas, VA

Abstract: Retinal ganglion cells (RGCs) project to central nervous system nuclei, to which they convey visual information from the periphery. Within the image-forming pathway, both ipsilaterally projecting (ipsiRGCs) and contralaterally projecting RGCs innervate relay neurons in the dorsal lateral geniculate nucleus (dLGN), as well as cells of the superior colliculus (SC). In the dLGN, the ipsilateral axons terminate within a territory surrounded by contralateral fibers, while in the SC, the ipsilateral axons pattern themselves ventrally to a larger superficial contralateral territory. The final organization of retinogeniculate (RG) and -collicular (RC) axons requires a highly active process that involves refinement of exuberant axons and synaptic contacts and depends on instructive cues derived from spontaneous retinal activity. Despite a modest yet reasonable understanding of the activity requirements, the molecular events that govern these highly dynamic phenomena remain enigmatic. Due to a trail of evidence that suggests involvement of the cadherin-catenin pathway in activity-mediated synaptic refinement, particularly within visual circuits, we investigated this pathway as a possible mediator of this process. A gene profiling study identified E-Cadherin as a molecule that is modulated by spontaneous activity in the dLGN. Using a Nestin-Cre driver in mice to drive ubiquitous neuronal deletion of floxed genes, we found that while the loss of E-Cadherin does not confer defects in the eye-specific segregation (ESS) of RG axons, the additional loss of p120ctn results in impaired ESS in the dLGN. ESS in the SC was not affected by the double deletion of E-Cadherin and p120ctn, nor was ESS affected in mice with a single p120ctn deletion in either the dLGN or SC. This result is consistent with the hypothesis that redundant cadherin-catenin mechanisms exist in the brain to promote proper circuit development. Using a Cre-driver expressing in ipsiRGCs to exclude presynaptic effects, we demonstrated that the dLGN-specific defect in E-Cadherin/p120ctn null mice likely stems from postsynaptic mechanisms. Furthermore, we showed that another catenin molecule, β-catenin, is an important regulator of both synaptic targeting, as well as refinement in the dLGN. The presynaptic loss of β-catenin results in aberrant multiple ipsilateral dLGN territories as well as ESS defects. Meanwhile, proper ESS is maintained in the SC. Altogether, these data suggest an importance of the cadherin-catenin pathway in targeting and refinement of RG connectivity, while RC circuits,

which are formed from branchings of the same retinofugal axons, are not modulated by this pathway.

Title: Protocadherins control the modular assembly of neuronal columns in the zebrafish optic tectum

Authors: ***M. R. EMOND**[1], S. COOPER[2], B. LIEBAU[2], M. WOLMAN[3], J. JONTES[2]; [1]Ctr. Molec Neurobiol, [2]Ohio State Univ., Columbus, OH; [3]Univ. Wisconsion, Madison, Madison, WI

Abstract: The assembly of neural architecture during development requires cell-cell recognition to establish and maintain both regional and cellular identities. It is believed that the differential expression of homophilic cell adhesion molecules organizes the patterns of connectivity in developing neural circuits. However, the mechanisms by which cell-cell interactions influence circuit assembly during development are poorly understood. The δ-protocadherins comprise a family of neural adhesion molecules that have been implicated in a range of neurodevelopmental disorders, and mutations in human PCDH19 cause a female-limited form of infant-onset epilepsy. Here we show that the expression of δ-protocadherins partitions the zebrafish optic tectum into radial columns of neurons. Using *in vivo* 2-photon imaging of BAC transgenic zebrafish, we show that pcdh19 is expressed in discrete columns of neurons, and that these columnar modules are derived from proliferative pcdh19+ neuroepithelial precursors. Elimination of pcdh19 results both in a disruption of columnar organization, as well as defects in visually-guided behaviors. Our results demonstrate that the inherited expression of a δ-protocadherin defines neuronal columns and, thus, δ-protocadherins act as molecular tags, both conferring an identity on columns and regulating their development. As we show that other δ-protocadherins define similar columns, this likely represents a fundamental mechanism for organizing the developing nervous system; subdivision of the early neuroepithelium into

precursors with distinct molecular identities would allow the autonomous development of parallel neuronal units, and organize the development of neural circuitry and behavior.

Federal de Pernambuco, Recife, Brazil

Abstract: The fine-tuning of visual subcortical connections develop through the selective elimination of misplaced axons and the maintenance of correct axonal branches. In the present work, we studied the impact of a dietary restriction of omega-3 fatty acids on the development of eye specific segregation and topographical specificity of retinofugal pathways. We also studied the impact of low omega-3 diets on the differentiation of retinal layers, cholinergic markers in the developing retina. Female Lister Hooded rats and their litters were fed with either control (soy oil) or restricted (coconut oil) omega-3 diets. At various postnatal ages, rat pups received eye injections of neuronal tracers to visualize retinal axons at their brain targets. Lipid analysis indicated that the experimental diet led to a selective reduction in DHA content in the visual system whereas fish oil supplementation within a specific time window restored DHA levels. Omega-3 restriction induced an increase in the density of retinal axons in the superficial layers of the SC. This effect was observed throughout the stratum griseum superficiale (SGS), including the ventral and intermediate SGS layers at PND13, PND28 and PND42. The same pattern of expanded terminal fields was observed in the retinogeniculate pathways. The supplementation

with fish oil (DHA) for two weeks was able to reverse the abnormal expansion of the retinocollicular projection. Omega-3 restricted groups showed a decrease in RXRα content and CREB phosphorylation (pCREB) in the visual layers of the superior colliculus. Retinal differentiation was also affected by omega-3/DHA deprivation including a reduction in rhodopsin immunolabeling, reduced labeling of cholinergic markers such as VAchT and β2-nicotinic receptors. The data indicate, therefore, that the chronic dietary restriction of omega-3 fatty acids delays axonal elimination and retinal cholinergic differentiation, leading to abnormal development of retinofugal connections. Title: Glutamatergic (stage III) retinal waves and their role in visual development *in vivo*

Authors: *A. GRIBIZIS[1], J. B. ACKMAN[2,1], M. C. CRAIR[1];
[1]Yale Univ., New Haven, CT; [2]Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract: In the developing visual system, neighboring retinal ganglion cells (RGCs) fire in correlated bursts of action potentials observed as propagating waves across the retina. These spontaneous waves of activity are thought to be crucial to normal formation of visual system circuitry. Based on *in vitro* experiments in mice, early neonatal ('stage II') waves depend on retinal acetylcholine receptors, while from P10 until around the time of eye opening ('stage III') retinal waves depend on glutamate receptors. Here, we report on our experiments examining the existence and properties of stage III waves in mice *in vivo*. Using optical imaging techniques, we have quantitatively characterized the properties of retinal waves by measuring retinal ganglion cell axon terminal activity in the superior colliculus *in vivo* during the second postnatal week. Our data suggest that stage III retinal waves are more frequent and smaller than stage II waves,

however they still propagate in a wave like fashion, which was not readily apparent from *in vitro* experiments. We have also examined the effects of pharmacological manipulations in the eye on the propagation of retinal waves to the superior colliuclus and higher order visual circuits. These results demonstrate that stage III waves are sensitive to glutamate antagonists *in vivo*, and have unique trans-synaptic propagation compared to earlier (stage II) spontaneous activity, which may be essential in the patterning of circuits throughout the visual system *in vivo*.

Title: Critical period for the effect of visual deprivation on the surface area of visual cortex in animals and humans

Authors: ***A. K. ANDELIN**[1], C. KROENKE[2], E. TABER[2], A. STEVENS[2], J. OLAVARRIA[1]; [1]Psychology, Univ. of Washington, Seattle, WA; [2]Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Human MRI studies show that blindness has profound effects on the development of the visual system. A limitation of this work is that the subjects are typically grouped into early and late blind even though the age at blindness onset ranges from anophthalmia to blindness starting at 10 or more years of age. Moreover, the early and late categories are not defined with

reference to specific developmental milestones and often do not correspond well across studies. It is therefore difficult to assess the importance that the age at blindness onset has on the nature and variability of anomalies detected with MRI. Mapping out the periods during which visual input is critically needed for the normal development of specific visual structures is important for understanding the role the eyes have during human development. Animal studies have the potential to contribute importantly to this issue because they have demonstrated the existence of different critical periods for several deleterious effects of blindness. Blindness during development induces a reduction in the area size of primary visual cortex (V1) in humans and animals. Using histological and MRI techniques we measured the reduction in the size of V1 induced by bilateral enucleation (BE) at different ages in rats and ferrets, and characterized how the magnitude of the reduction of V1 surface area depends on blindness onset. In sighted and BE rats the size of V1 at maturity was measured from tangential sections of the flattened cortex, while in sighted and BE ferrets the size of V1 at maturity was measured from cortical surfaces derived from post mortem MRI scans. From postnatal day (P) 0 through P12 we observed a graded reduction in the magnitude of the effect of enucleation on the size of V1 in rats. A similar graded response was observed in ferrets enucleated at P7, P20, and P31. Translating the post conceptional timelines of rats and ferrets reveals a quantitatively similar developmental dependence of V1 size on blindness onset in both species. Translating this information to the human post conceptional time line suggests that pathologies inducing blindness at 6 postnatal months or later may have little or no effect on the size of V1. The magnitude of the effect of blindness on the size of V1 is consistent with our MRI measurements from blind subjects affected with retinopathy of prematurity, as well as with MRI data from previous studies. Estimating the critical periods for the deleterious effects of blindness may not only facilitate the interpretation of abnormal MRI data from humans blinded at different ages, but may also help focus therapeutic or restorative efforts on developmental processes that are still plastic at blindness onset.

Title: Ecologically relevant scoring of binocular receptive field development by innate learning

Authors: I. ADORNO[1], G. KRATZ[2], A. OAKLEY[2], *M. V. ALBERT[2];
[1]Illinois Math and Sci. Acad., Aurora, IL; [2]Computer Sci., Loyola Univ. Chicago, Chicago, IL

Abstract: In previous computational work, we have shown how spontaneous patterns of neural activity prior to eye-opening can be used as a training pattern for early visual development (so-called "innate learning"). To demonstrate the ecological validity of such a paradigm, we apply a behaviorally relevant scoring approach to evaluate visual codes resulting from various patterns; these patterns are generated in an abstract, but biologically plausible manner. To emphasize the applicability of this principle beyond retinal waves, we have generalized this approach to binocular spontaneous activity, which is known to be present in a wide variety of animals in the LGN and V1 prior to eye opening. Traditionally, success in matching computational to experimental receptive fields focuses on parameter descriptions of derived receptive fields (e.g. spatial frequency) or their response properties (e.g. orientation bandwidth). However, our binocular model provides us with an additional means of scoring the resulting filters, by observing how well the resulting filters can be used to estimate depth. For spontaneous activity generation, we use an abstract, 4-parameter binocular model similar to a percolation network for wave activity but with communication between eye-layers. By varying the cross-talk between layers we vary the correlation between patterns across eye-layers, with an adult-like distribution of disparity selective cells between these extremes. Most importantly, we demonstrate how receptive fields generated from moderately correlated eye layer activity provide the best depth estimation in a stereogram depth estimation task.

Title: Postmitotic regulation of sensory area patterning in the mammalian neocortex by Lhx2

Authors: *A. B. ZEMBRZYCKI[1], C. G. PEREZ-GARCIA[1], C.-F. WANG[2], S.-J. CHOU[2], D. D. M. O'LEARY[1];
[1]Salk Inst. MNL-O, La Jolla, CA; [2]Inst. of Cell. and Organismic Biol., Academia Sinica, Taipei, Taiwan

Abstract: The mammalian neocortex is divided into specialized modality-specific areas that are responsible for the processing of sensory information. This architecture is critical, because altered area size affects normal sensory function and behavior in animals and humans. Current knowledge suggests that cortical sensory area identity is controlled by transcription factors (TFs) that specify area features in progenitor cells and subsequently their progeny in a one-step process. However, how neurons acquire and maintain these features is unclear. We have used conditional inactivation restricted to postmitotic cortical neurons in mice to investigate the role of the TF LIM-homeobox 2 (Lhx2) in this process and report that in conditional mutant cortices area patterning is normal in progenitors but strongly affected in cortical plate (CP) neurons. We show that Lhx2 controls neocortical area patterning by regulating downstream genetic and epigenetic regulators that drive the acquisition of molecular properties in CP neurons. Our results question a strict hierarchy in which progenitors dominate area identity, suggesting a novel and more comprehensive two-step model of area patterning that incorporates these revelations and define the relevance of postmitotic mechanisms in determining the functional properties of cortical areas: In progenitors, ‘patterning TFs’ prespecify sensory area blueprints. Sequentially, sustained function of ‘alignment TFs’, including Lhx2, is essential to maintain and to translate the blueprints into functional sensory area properties in cortical neurons postmitotically. In summary, our findings add novel insights into the sequence and hierarchy of mechanisms that regulate the layout of the cortex into sensory areas postmitotically and reemphasize critical roles for Lhx2 that acts as one of the terminal selector genes in controlling principal properties of neurons. The revised model has major implications for the understanding and for the further investigation of the complex neurodevelopmental mechanisms that establish proper sensory circuits and their functions.

Title: 5HTTLPR modulates transient non-canonical SERT expression and connectivity in the developing macaque brain

Authors: *M. K. CAFFREY CAGLIOSTRO[1], R. BANSAL[3], S. GERUM[4], K. WALSH[2], N. SEPULVEDA[2], A. ZIOLKOWSKI[1], V. ARANGO[2], D. GUILFOYLE[4], J. A. GINGRICH[1], M. S. ANSORGE[1];

Abstract: Alteration of serotonin (5-HT) signaling during development is believed to influence risk for certain psychiatric disorders. One way in which 5-HT signaling is modulated is through expression of the serotonin transporter (SERT), which sequesters extracellular 5-HT. Although in adulthood SERT is produced by classic 5-HTergic neurons of the raphe nuclei, during development rodents display a transient, non-canonical expression of SERT throughout sensory and limbic systems. This non-canonical SERT expression is essential for proper sensory system development in mice, and is proposed to modulate limbic system development as well. Here we investigated if non-canonical SERT expression is evolutionarily conserved and studied SERT expression in the developing macaque (macaca mulatta) brain. Because the macaque genome harbors a homologue of the human 5HTTLPR, a polymorphism in the promotor region of the gene encoding SERT, we also studied if SERT expression is affected by its allelic composition. To investigate if the 5HTTLPR broadly affects brain development, we also performed diffusion tensor imaging (DTI). We find a robust and widespread expression of SERT throughout limbic and cortical regions during GD100, which decreases across development. We furthermore find reduced SERT expression in limbic regions of s allele carriers. Lastly, we detected a robust effect of the 5HTTLPR on GD100 and PN40 DTI measures, with reduced connectivity in individuals carrying two “s” alleles compared to individuals carrying at least one “l” allele. Taken together our data suggest that the 5HTTLPR influences structural aspects of brain development through altering non-canonical developmental SERT expression, which might impact risk for adult psychopathology.

Title: Social rank and diet affect amygdala functional connectivity with prefrontal cortex during infancy in female Rhesus Macaques

Authors: *M. PINCUS[1], J. GODFREY[1], E. FECZKO[1], E. EARL[2], Y. SHI[3], M. STYNER[3], L. LI[1], B. HOWELL[4], D. FAIR[2], K. ETHUN[5], M. WILSON[1], M. SANCHEZ[1];
[1]Emory Univ., Atlanta, GA; [2]Oregon Hlth. & Sci. Univ., Portland, OR; [3]Univ. of North Carolina, Chapel Hill, NC; [4]Inst. of Child Development, Univ. of Minnesota, Minneapolis, MN; [5]Emory University, Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: Connectivity between the prefrontal cortex (PFC) and amygdala (AMYG) is critical for emotional and stress regulation, and alterations in this circuitry are implicated in anxiety and mood disorders. Because the maturation of these neural circuits is protracted during childhood, the development of PFC-AMYG connectivity may be particularly susceptible to social stress. Recent research demonstrates that obesity may also compromise the development of these circuits, which is associated with greater incidence of anxiety and mood disorders. Given that stress is a risk factor for obesity in children, the presence of both conditions could synergistically impair the development of emotion regulation circuits. Because disentangling the effects of social stress versus diet on brain development is difficult in human studies, the aim of this study was to use a naturalistic model of psychosocial stress (social subordination) with or without access to a calorically dense diet (CDD) to examine the impact of each of these factors on the neurodevelopment of PFC-AMYG functional connectivity. Thus far, subjects are 14 socially-housed infant female rhesus macaques, whose mothers are either dominant (DOM, n=7) or subordinate (SUB, n=7). Within each rank category, a subset of subjects and their mothers had access to a low-calorie diet (LCD) only, and the other had access to both a CDD and LCD (CHOICE), resulting in four rank-diet groups (n = 2 DOM+CHOICE, n = 5 DOM+LCD, n = 4 SUB+CHOICE, n = 3 SUB+LCD). As infant rhesus monkeys actively nurse but begin to wean at ~ 2 mo of age, resting-state functional MRI scans (2 x 15 mins) were obtained at 6 mo of age to

examine effects of rank and diet on the development of PFC-AMYG functional connectivity (FC). FC was extracted and analyzed with a region of interest (ROI)-based analysis, using medial PFC (Brodmann areas (BA) 24, 10, 32), orbitofrontal cortex (OFC; BA 11, 13), and AMYG as the a priori ROIs. Preliminary analysis of the data with our current sample suggests that SUB monkeys had decreased FC between OFC (BA 13) and AMYG relative to DOM monkeys. Intake of a CDD diet during infancy was associated with increased FC between the OFC (BA 13) and AMYG across all subjects. SUB monkeys in the CHOICE condition had higher connectivity between mPFC (BA 10) and AMYG, relative to SUB monkeys fed only the LCD. Because OFC-AMYG circuitry plays a role in reversal learning and goal-directed behavior, our data suggests that consumption of CDD and social stress may affect these behaviors by altering this circuitry in infant female macaques. Further analysis will assess whether the observed PFC-AMYG FC differences are related to feeding behavior and emotion regulation.

Title: Epigenomic dissection of sexually dimorphic neural circuits

Authors: *R. BRONSTEIN, M. V. WU, J. TOLLKUHN;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Our lab is interested in understanding the molecular and epigenomic events governing sex differences in the brain and behavior. Neural circuit nodes controlling sex-specific behaviors are shaped by the gonadal hormones estrogen and testosterone. Male critical periods of CNS sexual differentiation occur just after birth, and are reliant upon the conversion of circulating testosterone to estrogen in the brain, in an aromatase-dependent manner. Females represent the default neural circuit template, only during puberty does estrogen begin to shape the sexual maturation of their brains. In adulthood both males and females require their cognate hormonal streams to finely tune and maintain a rich array of sex-specific social behaviors. Following gonadectomy, although these behaviors are heavily diminished - the underlying neural circuits persist and behavior can be restored following exogenous treatment with hormones. However,

the genes and regulatory mechanisms utilized by these hormones to activate behavioral circuitry are not known. Two key brain regions that integrate olfactory information from conspecifics to mediate the display of sex-specific behaviors are the bed nucleus of the stria terminalis (BNST) and the medial amygdala (MeA). We use genetic strategies to perform ChIP-seq and RNA-seq specifically in Cre-defined populations of neurons from these brain regions in males and females at distinct developmental time points. Ultimately our goal is to identify novel cis-regulatory DNA elements (promoters, enhancers etc.), as well as trans-acting chromatin modulators, which in unison function to underpin diverse sex-specific behavioral repertoires.

Title: Roles of thalamocortical interactions in the development of mouse prefrontal cortex

Authors: A. PROUE, *Y. NAKAGAWA;
Dept Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: The thalamus and the neocortex establish reciprocal connections during early development. Recent studies discovered that interactions between these two brain regions are crucial not only for adult brain functions, but also for the development of the neocortex. This has been best demonstrated in primary sensory areas, where area-specific thalamocortical projections play a role in establishing characteristic patterns of gene expression in these areas and the neuronal fate appropriate for the source of the incoming thalamocortical afferents. However, it is unknown whether the thalamus plays a similar role in the development of other neocortical areas. The prefrontal cortex (PFC) is a center for higher cognitive functions and emotions, and defects of its development are implicated in many developmental brain disorders including schizophrenia and autism. In this study, we sought to determine if thalamocortical interactions are required for proper PFC development. In previous studies, we showed that the mice that lack the homeobox gene Gbx2 in a thalamus-specific manner have defects in thalamocortical

projections and that characteristic expression patterns of genes including RORβ, Cdh8 and Lmo4 in primary sensory areas are altered at early postnatal stages so that these areas no longer exhibit clear boundaries with the surrounding higher-order sensory areas. Interestingly, however, expression of these molecular markers appeared unchanged in the PFC in thalamus-specific Gbx2 mutant mice. This result prompted us to identify several genes that are preferentially expressed in the developing PFC. We found that one of these genes, Cyp26b1, which encodes an enzyme that degrades retinoic acid, was specifically reduced in layer 6 of the medial and ventral PFC at postnatal day 8, but unaltered in other parts of the rostral and medial neocortex as well as in the hippocampus. In contrast, mice that ectopically express tetanus toxin light chain in a thalamus-specific manner showed no obvious reduction of Cyp26b1 expression in the PFC, whereas in primary sensory areas, these mice showed defects in gene expression similar to those found in Gbx2 mutant mice. These results suggest that the developing PFC requires interactions with the thalamus that are fundamentally different from those used for the development of the sensory neocortex. Our results also implicate that the thalamus may control retinoid signaling in the PFC by regulating the expression of Cyp26b1.

Title: PAX6 haploinsufficiency association with reduced amygdala volumes

Authors: ***F. M. LALONDE**[1], A. RAZNAHAN[1], J. A. BUTMAN[2], J. HAN[3];
[1]Child Psychiatry Br., NIMH, Bethesda, MD; [2]Clin. Center, Radiology and Imaging Sci., NIH, Bethesda, MD; [3]Le Bonheur Children's Hosp., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: The *PAX6* gene is known to play a critical role in eye and brain development. It acts as a transcription factor ensuring successful neurogenesis and occulogenesis. *PAX6+/-* patients have characteristic aniridia due to inadequate regulatory activity during the formation of the lens and retina. Mutation of this gene in mice also affects the migration and differentiation of cells involved in the morphogenesis of the amygdaloid complex. The present study investigated possible associations between heterozygous *PAX6* mutation and amygdala volumes as measured by morphometric analysis of MRI brain scans. Twenty-three healthy controls (HV) and twelve *PAX6+/-* patients with heterozygous point mutations or intragenic deletions within *PAX6*

underwent MRI brain scans. Mean ages for the HV and *PAX6+/-* groups were 21.2 (SD 12.3) and 28.9 (SD 13.4), respectively. MRI brain scans were obtained using a Philips Achieva 3 Tesla scanner paired with an 8-channel head coil. T1-weighted whole brain volumes consisting of one hundred and seventy 1-millimeter thick sagittal slices with an in-plane resolution of .9375 by .9375 were collected using a 3D T1-TFE pulse sequence (TR=4.85 msec.; TE=2.17 msec.; flip angle= 15 degrees). Amygdala volumes were generated by processing the brain images through FreeSurfer (version 5.3) subcortical segmentation. Although the groups did not significantly differ with respect to age, age as well as sex were entered as covariates in the analysis. Right and left amygdala volumes were summed together to form a total amygdala volume measure. ANOVA with age and sex as covariates revealed a highly significant difference between the two groups ($F = 14.76$, $p < .001$). The *PAX6* group had a mean total amygdala volume of 3173 cubic millimeters compared to the larger HV group mean of 3684 cubic millimeters. Both age ($F = 0.50$, $p = .825$) and sex ($F = 2.56$, $p = .119$) covariates were not significant. These results support previous findings from animal studies demonstrating the critical role of *PAX6* in the development of specific nuclei in the amygdaloid complex (Tole, Remedios, Saha, & Stoykova, 2005). Tole, S., Remedios, R., Saha, B., & Stoykova, A. (2005). Selective requirement of Pax6, but not Emx2, in the specification and development of several nuclei of the amygdaloid complex. *J Neurosci*, 25(10), 2753-2760.

Abstract: Maternal care is vital in primates for proper socioemotional and cognitive development. Maltreatment during infancy is associated with increased risk for psychopathology, and social and cognitive deficits. This is perhaps due to alterations in cortico-limbic circuits (i.e. prefrontal cortex (PFC) and amygdala connectivity) critical for emotional and stress regulation, which are sensitive to early experience and stress due to their protracted development. How these effects unfold during early development is not well understood and difficult to study in humans. This study utilized a well-established nonhuman primate model of maternal maltreatment (MALT), which consists of comorbid physical abuse and rejection, leading to infant distress. In macaques, the highest rates of abuse in the first three months of life co-occur with rapid brain development and maturation of PFC-amygdala circuits. MALT leads to long-term effects on emotional reactivity and social behavior, as well as alterations in white matter development. To disentangle the effects of experience from those of inheritance we used a unique cross-fostering experimental design with random assignment of half of the rhesus monkey infants to control or maltreating foster mothers at birth. This study further delves into the effects of MALT on the developmental trajectory of PFC-amygdala functional connectivity (FC) throughout infancy. Structural MRI and resting state fMRI scans were collected at postnatal ages 2 weeks and 3, 6, 12, and 18 months in 13 MALT (7 males, 6 females) and 13 control infants (6 males, 7 females). Correlated activity between these regions was found to have strong hemispheric differences, both developmentally (left hemisphere FC stronger, more positive, than right) and between experimental groups (MALT had weaker, less positive, FC than controls). In control animals, amygdala FC with medial PFC (mPFC) and dorsolateral PFC (dlPFC) became less positive with age, reaching close to zero or negative correlations by 18mos, while the connectivity with orbitofrontal cortex (oPFC) became more positively correlated. Amygdala-PFC FC was less positively correlated in both hemispheres of MALT animals in comparison with controls, and showed increasingly negative correlation throughout development in the right hemisphere, especially in mPFC and dlPFC. The oPFC, however, showed stronger positive FC through development in MALT than controls. These findings suggest alterations in functional coupling of amygdala-PFC regions (i.e. reduced FC) during infancy and the early juvenile period in MALT subjects, which could influence their emotional, cognitive, and behavioral development.

Title: A role for the zinc finger transcription factor Tshz1 in the migration and differentiation of the intercalated cells (ITCs) of the amygdala

Authors: *J. KUERBITZ[1], S. EHRMAN[1], A. N. GARRATT[3], R. R. WACLAW[2], K. CAMPBELL[1];
[1]Developmental Biol., [2]Cancer Biol. and Neural Tumors, Cincinnati Children's Hosp., Cincinnati, OH; [3]Inst. of Cell Biol. and Neurobio., Charite Universitatsmedizin Berlin, Berlin, Germany

Abstract: The intercalated cell (ITC) groups of the amygdala are clusters of GABAergic interneurons that surround the basolateral complex of the amygdala and have been shown to modulate amygdalar control of anxiety responses. Previous studies have demonstrated that ITCs originate in the embryonic dorsal lateral ganglionic eminence (dLGE) at embryonic time points. The zinc finger transcription factor Tshz1 is expressed in a subpopulation of cells in the embryonic dLGE and in mature ITCs. However, the importance of *Tshz1* expression for ITC development remains unknown. We have utilized germline *Tshz1*^{GFP} knock-in/knock-out mice to follow the normal development of ITCs and to investigate whether *Tshz1* expression is necessary for proper development of ITCs. E18.5 *Tshz1* knockout mice (*Tshz1*$^{GFP/RA}$) show an ectopic cluster of GFP positive cells at the dorsal, medial border of the Lateral Amygdala (LA) and a severe reduction of ITC cells on the lateral side of the basolateral complex and in the main intercalated nucleus. These findings suggest that ITCs can be generated in the absence of Tshz1 but their migration and settling patterns in the amygdala are dependent on its function. Furthermore, many of the clumped ITCs in the mutant amygdala ectopically express the dLGE transcription factors Sp8 and Pax6 suggesting that Tshz1 plays a role in the down-regulateion of these factors as they migrate toward the amygdala. Additionally, the remaining, but misplaced, Tshz1^{GFP} expressing cells show reductions in the ITC markers FoxP2 and Meis2, suggesting an impaired ability to develop into mature ITCs. Postnatal mice harboring *Dlx1-cre* mediated, basal

forebrain specific loss of *Tshz1* show continued mislocation of amygdalar GFP expressing cells, which show nearly complete loss of FoxP2 expression as well as ectopic expression of the striatal projection neuron marker FoxP1. Our data suggest that *Tshz1* may play an important role in regulating migration and gene expression in developing ITCs. We are currently performing gene-expression analysis on migrating ITC progenitors in *Tshz1* mutants to identify additional genes functioning downstream of *Tshz1* during ITC development. Future studies will determine the effect of the ITC phenotype in Tshz1 mutants, on fear and anxiety behaviors.

Title: Collapsin response mediator protein 4 (CRMP4) knockout mice showed physiological alterations related to olfactory function

Authors: *A. TSUTIYA[1], M. NISHIHARA[3], Y. GOSHIMA[4], R. OHTANI-KANEKO[1,2]; [1]Grad. Sch. of Life Sci., Toyo Univ., Gunnma, Japan; [2]Bio-Nano Electronics Res. Ctr., Toyo Univ., Saitama, Japan; [3]The Univ. of Tokyo, Tokyo, Japan; [4]Yokohama City Univ., Kanagawa, Japan

Abstract: Members of the collapsin response mediator protein (CRMP) family (CRMP1-5) were reported to be involved in the pathogenesis of various neuronal disorders including schizophrenia and autism spectrum disorder (ASD). One of them, CRMP4, is reported to participate in aspects of neuronal development such as axonal guidance. However, no physiological or behavioral phenotypes in Crmp4 knockout (Crmp4-KO) mice have been identified, making it difficult to elucidate the *in vivo* roles of CRMP4. We previously found strong expression of Crmp4 mRNA in the olfactory bulb (OB) during the early postnatal period, suggesting crucial roles for CRMP4

in OB development. In this study, we aimed to test whether Crmp4-KO pups would exhibit abnormal olfaction. In addition, we tried to reveal the possible mechanisms underlying any impaired olfactory ability found. In order to investigate olfactory ability, we assessed ultrasonic vocalizations (UVs) emitted by wild-type (WT) and Crmp4-KO pups, which are one of the easily detectable olfaction-dependent behaviors in pups. We revealed that Crmp4-KO pups at postnatal day 7 (PD7) had impaired olfactory ability for discriminating between familiar and unfamiliar nest-bedding odors. Next, we compared the physiological features of the OB between WT and Crmp4-KO pups by studying the expression of c-Fos, an activity-dependent neuronal marker, in the OB after olfactory stimulation of ethyl acetate (EA), a commonly used non-biological odorant. We found that the EA-elicited c-Fos expression in the OB at PD7 is much greater in Crmp4-KO pups than in WTs, indicating abnormal activity of the OB neurons in Crmp4-KO pups. In addition, the mRNA and protein expression levels of glutamate receptor 1 (GluR1) and GluR2 were exaggerated in Crmp4-KO pups relative to other excitatory and inhibitory receptors and transporters, raising the possibility that enhanced expression of these excitatory receptors contributes to the hyperactivity phenotype and impairs olfactory ability. This study provides an important animal model for elucidating the roles of CRMP4 in the development of higher brain functions. GluR1 and GluR2 have been implicated in many nervous system disorders associated with development, including ASD. It has also been suggested that increased activity in excitatory neurons gives rise to the social and cognitive deficits observed in ASD. In addition, impaired olfaction has been reported in ASD. Therefore, we hypothesized that Crmp4-KO mice exhibit behavioral abnormalities relevant to ASD. To test the hypothesis, we next performed several animal behavioral tests including social interaction test.

Title: Long-term effect of neonatal isoflurane exposure on the olfactory system in rats

Authors: *J. LEE[1,3], J. ZHANG[1], Z. WEI[1,3], L. WEI[1,2], S. YU[1,3];
[1]Dept. of Anesthesiol., [2]Neurol., Emory Univ., Atlanta, GA; [3]Ctr. for Visual and Neurocognitive Rehabil., Atlanta VA Med. Ctr., Decatur, GA

Abstract: Isoflurane is a volatile anesthetic agent widely used in infants and neonates. Emerging data from preclinical and clinical studies have shown that anesthetic exposure of neonates may cause neuronal degeneration in the developing brain, leading to functional deficits such as learning and memory disabilities later in juvenile and adulthood. However, the effect of neonatal exposure to isoflurane on olfactory cells and olfactory function is obscure. In the present study, we investigated the effect of isoflurane exposure on olfactory system in neonatal rats. Wistar rat pups were exposed to 1.5% isoflurane for 3 hr at postnatal day (P) 3, P4, and P5, respectively. At the juvenile age of P26-27, buried food finding test showed that animals previously exposed to isoflurane took significantly longer times to locate buried food compared with normal animals. Consistently, impaired odor distinguishing function was seen in juvenile rats that were exposure to isoflurane. The expression of olfactory marker protein (OMP) normally found in mature olfactory sensory neurons was significantly reduced in the olfactory bulb and epithelium in juvenile rats with neonatal isoflurane exposure. In addition, TUNEL staining revealed an increase of neuronal degeneration in the granule cell layer (GCL) and glomerular layer (GL) of rats with neonatal isoflurane exposure compared to normal animals. Increase of activated caspase-3, caspase-8, and caspase-9 were observed in the olfactory bulb in juvenile rats with neonatal isoflurane compared with normal animals, indicating increased apoptotic cell death. Furthermore, these cell deaths in the olfactory bulb were accompanied by the selective death of the GABAergic neurons. Lastly, to examine the effect of neonatal isoflurane exposure on neurogenesis, 5-bromo-2-deoxyuridine (BrdU) was administered to all animals once daily until sacrifice. In juvenile rats with neonatal isoflurane exposure, there was a significant decrease in the number of NeuN+/BrdU+ cells compared with the normal animals, indicating reduced neurogenesis. Taken together, our initial findings suggest that neonatal isoflurane exposure causes not only increased olfactory neuronal degeneration but also reduced neurogenesis, probably leading to olfactory functional deficit in juvenile rats.

Title: Expression of the TrkB receptor declines before birth dividing taste neurons into two equal subpopulations

Authors: *J. RIOS-PILIER, R. F. KRIMM;
Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: Taste neurons (which carry chemical information from taste buds of the tongue to the brain) could be a single subpopulation of similar neurons whose function is dictated solely by which receptor cells they innervate. Alternatively, taste neurons could differentiate into subtypes during development defined by differences in expression and function. Embryonically, brain-derived neurotrophic factor (BDNF) regulates the development of most taste neurons, but postnatally, BDNF becomes restricted to subpopulations of taste receptors cells with specific functions. We speculated that the primary receptor for BDNF, TrkB, may also become developmentally restricted to a specific neuronal subtype. To test this possibility, we used a combination of genetic labels, one that identifies taste neurons (Phox2b-Cre::tdtomato) and one for TrkB (TrkB-GFP) to quantify TrkB receptor expression in taste neurons. We found only half of the Phox2b-positive taste neurons (399 vs 203) were TrkB-positive in whole-mount geniculate ganglia. Since at E11, all geniculate ganglion neurons express TrkB, BDNF must be developmentally down-regulated. To determine when this occurs, we quantified the TrkB receptor in taste neurons at E13.5, E15.5, E17.5, P0, P20 and P60 (adult). Most taste neurons expressed TrkB during embryonic stages (E13.5=96%, E15.5=91%, E17.5=90%). By P0, only 58%±7 of taste neurons still expressed TrkB, which was similar to adults (52%±1). Thus, TrkB is down-regulated during late embryonic development. Many non-taste neurons (P2X3-positive, Phox2b-negative) of the geniculate ganglion also expressed TrkB, but did not down-regulate TrkB to the same extent as taste neurons. These findings indicate that there is a specific decline in TrkB expression during development of taste neurons just before birth. Since neurotrophin signaling can regulate neuronal differentiation, it is possible that differential TrkB-signaling regulates the differentiation of a subpopulation of taste neurons with specific functions. Since not all gustatory neurons are embryonically TrkB-dependent, it is possible that neurons which down-regulate TrkB during development also survive in its absence, we are currently testing this idea with a combination of genetic labels and conditional TrkB knockouts. These findings suggest that taste neurons are not a homogenous population but can be divided into separate subpopulations based on TrkB-expression and dependence; future studies will determine how differences in taste neuron differentiation are reflected in taste function.

Title: Next-gen sequencing and an evolution-based search for neocortical layer 4 genes

Authors: *S. D. BRISCOE[1], C. B. ALBERTIN[1], J. J. ROWELL[1], C. W. RAGSDALE[2];
[2]Dept. of Neurobio., [1]Univ. of Chicago, Chicago, IL

Abstract: The long-distance axon projections of mammalian neocortical layer 5 (L5) cells allowed for the identification of novel marker genes through retrograde tracing and cell sorting. A parallel search for layer 4 (L4) markers has been hindered by the absence of such projections. We took advantage of connectional and molecular studies that demonstrate neocortical L4 homologs are present in specific nuclei in the avian dorsal telencephalon. The avian brain offers important advantages over the neocortex for the identification of novel marker genes: 1) the large size of avian L4-like nuclei allows for their dissection with minimal contamination by unwanted cell types and 2) marker genes conserved across mammals and birds are likely to be functionally important. We carried out Illumina sequencing on E14 chicken brain tissue isolated from two L4-like nuclei (entopallium and field L), one L5-like nucleus (arcopallium), and one control nucleus of unknown homology (mesopallium). Reads were assembled with Trinity and abundance estimations were calculated using RSEM. Progressive filtering of the transcripts based on pairwise comparisons of expression levels produced a list of transcripts enriched in the L4-like nuclei. We selected the most highly expressed protein-coding genes from this list as candidate genes to be validated by *in situ* hybridization on E14 chicken telencephalon. Of the 21 genes tested to date, 19 are highly enriched in L4-like nuclei. This approach also recovered *cEAG2,* a previously known selective marker gene for neocortical L4 and avian L4-like nuclei. These data will be extended to other taxa to identify genes with conserved expression. Our findings indicate that next generation sequencing provides reliable quantitative data on gene expression and is an effective tool for the identification of avian nuclear marker genes.

Title: Visual cortex activation in early monocular and binocular blind macaque: a BOLD-fMRI study during auditory tasks

Authors: *Z. TANG, L. WU;
Eye & ENT Hosp. of Fudan Univ., Shanghai, China

Abstract: Objective: To study adaptive plasticity and reorganization in the visual cortex of the early monocular or binocular blind macaque using task-based blood oxygenation level dependent function MRI (BOLD-fMRI). Methods: Six healthy neonatal macaques were randomly divided into three groups. One group served as control group (group A). Optic nerve transecting was performed in the right eye of another group to establish the monocular blind model (group B), and also the same operation was performed in the binocular optic nerve of the last group for establishing the binocular blind model (group C). Sixteen months after the operation, BOLD-fMRI was used for examining visual cortex activation of each macaque (in group A, B and C) during auditory stimulation of pure tone and bird sounds, respectively. All of BOLD response changes in both visual cortex and auditory cortex of all three groups were further compared with the immunofluorescent staining findings, respectively. Results: During two kind of auditory tasks, greater BOLD activity was noted in the visual cortex of macaque in group B and group C compared with group A, while BOLD responses were higher in the left visual cortex than in the right one of same macaque in group B. Whereas, compared with group A, lower BOLD activity was found in the auditory cortex of group B and group C during the same auditory stimulations. All of these findings can be further confirmed by the immunofluorescent staining using c-fos antibody. Additionally, parietal lobe and frontal lobe BOLD activity were also observed in the group B and group C. Conclusions: Both monocular and binocular blindness macaque can recruit visual cortex to carry out the auditory tasks after their visual deprivation, which indicated the establishment of cross-modal plasticity within visual and auditory cortex.

Sciences, Sch. of Med., Tsinghua Univ., Beijing, China; [6]Dept. of Biol., Indiana University, Purdue Univ., Indianapolis, IN; [7]Dept. of Chem., Princeton Univ., Princeton, NJ

Abstract: Down syndrome (DS) is the most common chromosomal abnormality disorder in humans caused by a triplication of all or part of chromosome 21. DS is associated with physical growth delays, characteristic craniofacial abnormalities and intellectual disability. Although much is known regarding physiological aberrations associated with DS, far less is known about the molecular mechanisms mediating the disease. Although DS is clearly marked by deficits in neural plasticity and increased neurodegeneration, few treatments exist that adequately reverse neuronal impairments and/or cognitive deficits. Given that several neurological disorders associated with cognitive impairment (e.g., DS, ATRX syndrome, Rett syndrome, etc.) result in disruptions in gene regulation, in part, via epigenetic processes, further mechanistic studies of neuronal specific histone function promise to provide clues into the underlying causes of neurodevelopmental pathology. Here, we identify chromatin-associated BRWD1 as a neuronally enriched 'reader' protein putatively involved in DS associated neurological deficits. BRWD1 is a WD40 repeat and bromodomain-containing protein that is encoded within the Down syndrome critical region 2 on chromosome 21 in humans, and to date, very little is known regarding its function. Since WD40 propeller domains have previously been shown to interact with histone methylation signatures, we sought to identify whether it might act as a multivalent binding protein that can recognize and simultaneously associate with multiple distinct histone posttranslational modifications, many of which (e.g., H3K4me1, H3K27me3 and H4K20me3) we have found to be significantly altered in human DS neurons (iPSC derived) and in forebrain tissues from a mouse model of DS (Ts65Dn mice with segmental trisomy 16, which are at a dosage imbalance for genes corresponding to human chromosome 21q21-22.3, including BRWD1, and exhibit mild to moderate learning and behavioral deficits). Recombinant human BRWD1 WD40 and bromodomains were purified, and custom histone PTM peptide arrays, as well as individual peptide IPs, have confirmed high affinity and specific interactions with these marks *in vitro*. Using a combination of classic chromatin biochemistry, chemical/structural biology and functional neuroscience approaches, we are investigating the consequences of BRWD1 triplication in DS in relation to altered patterns of gene expression in affected

individuals, with the hope that such information may aid in the development of improved therapeutics aimed at alleviating DS associated pathologies.

Title: Patterns and gradients of neurogenesis in the avian dorsal thalamus

Authors: *L. L. BRUCE, A. M. LYNN, D. A. SCHNEIDER;
Biomed. Sci., Creighton Univ., Omaha, NE

Abstract: The dorsal thalamus relays sensory and motor information between areas of the brainstem and the telencephalon. Although all vertebrates have a dorsal thalamus, which is believed to be derived from a common ancestral anlage, the extent to which the various nuclei are comparable in birds and mammals has been strongly debated. One approach to addressing this question is to compare the thalamic gradients and patterns of neurogenesis. To characterize these in the avian dorsal thalamus, a single application of a low dose of bromodeoxyuridine (BrdU) was delivered to each chick between embryonic day (E)3 and 8 (stage 21 and stage 34), followed by survival to E10 (stage 36). Comparisons of anti-BrdU labeling patterns across the different injection days suggest that nearly all dorsal thalamic neurons are born early in chick embryogenesis, between E3 and 8. Furthermore, neurons in the lateral, dorsal, and posterior parts of the dorsal thalamus are generally born earlier than those in the medial, ventral, and anterior parts. Analyses of the birthdates for nine thalamic regions show that the general pattern of neurogenesis in the avian dorsal thalamus resembles that of homologous regions within the rodent thalamus, with the exception of the auditory region, nucleus ovoidalis, which is born earlier than the mammalian auditory medial geniculate nucleus. Neuronal production begins at a similar time throughout the thalamus, but is completed earlier in the posterior thalamus. The nucleus tractus septomesencephalici and lateral geniculate are formed earliest wave of neurogenesis, followed by rotundus, and then the dorsal group. Nucleus ovoidalis and the medial thalamic group are formed in the last wave. The similar pattern of neurogenesis in birds and mammals may represent a highly conserved developmental pattern that was present in the

common ancestor of living birds and mammals, or may represent independently derived states. Additional studies in reptiles and amphibians are needed to distinguish between these evolutionary histories.

Title: DSCAM promotes cell death

Authors: *S.-F. YOU[1], S.-K. CHEN[2];
[2]Life Sci., [1]Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Each type of neuron except photoreceptor rods and cones in the retina forms "Retinal mosaics" that cover whole retina with an even spatial distribution. This pattern assures every horizontal cell, amacrine cell and retinal ganglion cell well-arranged within their layer, covering entire retina without blind spot with minimum dendritic field overlapping. However, the mechanism behind the phenomenon remains unknown. Recent researches find apoptosis may involve in the formation of retina regularity. The constant numbers of retina neurons rely on steady proliferation and apoptosis. Mice with the pro-apoptotic gene *bax knockout* or overexpress of the anti-apoptotic gene *bcl-2* showed disrupted spatial pattern. Intriguingly, the same phenotype has been reported in the *dscam* (Down's syndrome Cell Adhesion Molecules) knocked out mice. Furthermore, the dendrites of neighboring cell severely tangle together. Therefore, we hypothesize that DSCAM is involved in the retina apoptotic pathway by homophilic interaction between the same cell types which lead to apoptosis-depended retina mosaic formation. Using *in vitro* experimental setup, we found that overexpressing of DSCAM could promote cell death. This research could provide a further detail of the formation retinal mosaic.Key word: Retina tiling, Retina mosaics, eye development

Title: Regulation of interneuron distribution by the fate of cortical projection neurons

Authors: Z.-X. NIOU, *S.-J. CHOU;
Academia Sinica, Taipei, Taiwan

Abstract: Mammalian cerebral cortex is comprised of distinct cortical regions, for example six-layered neocortex that processes vision, audition and somatosensation, and three-layered paleocortex, including piriform cortex (PC) that processes olfaction. Neocortex and PC both arise predominantly from dorsal telencephalic (dTel) progenitors of an Emx1 lineage that express Lhx2, a LIM homeodomain transcription factor in a graded, position-dependent level. We showed previously that Lhx2 controls a binary fate decision of dTel progenitors to generate neocortex versus PC. When Lhx2 is deleted by Emx1-Cre in the dorsal telencephalon in the Lhx2 conditional knockout (cKO), the lateral neocortex is refated to form an ectopic piriform cortex. Inhibitory cortical interneurons (INs), which use γ-amino butyric acid (GABA) as their main neurotransmitter, are primarily generated in the medial ganglionic eminence (MGE) of ventral telencephalon (vTel) and enter the cortex by tangential migration. The migration of INs from the MGE to cortex is controlled by a complex combination of long-range and short-range attractant and repelling signals. The mechanisms regulating the migration of INs to their final destination are not fully understood. Using a panel of IN makers, we investigate the distribution of INs in Lhx2 cKO cortex. We observed changes in IN distribution in the cKO cortex when compared with wild type littermates. This suggests that the fate of cortical projection neurons plays a role in regulating IN distribution.

Title: Variation in neuron numbers across the marsupial and primate isocortex: evidence of shared and derived characters across mammals

Authors: *C. J. CHARVET[1], C. D. STIMPSON[1], M. A. RAGHANTI[2], A. H. LEWANDOWSKI[3], F. M. KRIENEN[1], C. C. SHERWOOD[1];
[1]Ctr. for the Advanced Study of Human Paleobiology, The George Washington Univ., Washington, DC; [2]Kent State Univ., Ohio, OH; [3]Cleveland Metropolis Zoo, Cleveland, OH

Abstract: It is generally assumed that marsupial mammals exhibit few cortical neurons under a unit of cortical surface area, yet relatively few marsupials have been examined and little is known about cross-cortical variation in neuron numbers in this diverse clade. We used the optical disector method to investigate the number of neurons per unit of cortical surface area across several marsupial mammals (i.e., red kangaroo, parma wallaby, koala). We compared these findings to those previously obtained for primates with other mammals. In contrast to the notion that the marsupial isocortex has fewer neurons compared with eutherian mammals, we found that neurons per unit of cortical surface area in marsupial mammals overlap with those found in eutherian mammals (e.g., rodent, cat). Similar to what has been observed in eutherian mammals, most of the variation in neuron numbers across the width of the cortex of marsupial mammals is accounted for by upper layer (layer II-IV) neurons. Furthermore, the cortex of marsupial mammals is characterized by more neurons in the caudo-medial pole of the lateral cortex and the primary somatosensory cortex than in lateral and medial regions. This is in contrast with primates where neurons per unit of cortical surface area increase from the rostral to the caudo-medial pole. A comparison of previous reports examining neurogenesis timing in marsupial, rodents and primate species suggests that, with the exception of the primary somatosensory cortex, evolutionary changes in neuron numbers across the adult cortex coincide with evolutionary changes in the pattern of neurogenesis timing in development. Taken together, these findings highlight that evolutionary changes in the spatial pattern in developmental duration account for evolutionary changes across the cortex of mammals.

Title: Activation of Non-LTR retrotransposons specific transcripts in rats in response to stress

Authors: *S. MUKHERJEE, JR[1], D. SHARMA[2], K. C. UPADHYAYA[1];
[2]Scool of Life Sci., [1]Scool of Life Sciences, Jawaharlal Nehru Universit, New Delhi, India

Abstract: Objectives Basic objectives were to analyze the transcriptional regulation of L1Rn elements in response to stresses. Methods Real time PCR analysis using RNA isolated from various brain regions and various tissues from old and young wistar rats was carried out to determine the change in L1 transcripts. Results There was no significant change in the expression of L1Rn in various brain regions of 2 month old and 18 month old rats except cerebral cortex. The heavy metals nickel, cadmium, lead, mercury and aluminum upregulates the expression of L1 in tissue specific and age dependent manner. Conclusions The results of this investigation conclusively prove that LINE1 retroelements are transcriptionally activated in response to stress.

Title: Do the Sexiest Dancers Have the Largest Little Brain?: Associations between display complexity and both brain volume and cerebellar granular layer volume in manakins(Pipridea)

Authors: *G. PANO[1], W. R. LINDSAY[2], L. B. DAY[1];
[1]Biol., The Univ. of Mississippi, Oxford, MS; [2]The Univ. of Gothenburg, Gothenburg, Sweden

Abstract: Lekking male manakins (Pipridae) attract mates using non-vocal acrobatic displays that require precise motor control with complexity varying widely across species. These displays often involve high-speed flight, production of mechanical sounds, and cooperative dance among

males. There is sexual dimorphism of the brain in at least one manakin species with complex display, Manacus vittellinus. In this species, a visuomotor integration area is larger in females that fly to specific perch sites to track the fast moving display of males, and females are known to select mates on the basis of 10s of milliseconds differences in performance of a display element. Males have larger arcopaliums and marginally significant larger cerebellae, sensorimotor and motor coordination brain regions, respectively. Previous studies have shown that bowerbirds, (oscines that build complex display sites "bowers"), have a positive association between bower complexity and both brain and cerebellum volume. To determine whether we would find similar results in the suboscine manakin, which performs practiced acrobatic displays (rather than learned bower building) we measured brain volume and attributes of cerebellar (CB, "the little brain") morphology in 12 manakin species and a closely related fly-catcher. We have previously shown that brain weight is positively associated with manakin display complexity. Brain volume is highly correlated with brain weight ($r=0.87$, $p<.0001$) and can provide generalizations and replication of our previous findings. Brain volume adjusted for bird weight was positively related to display complexity ($R2=.30$, $p<0.05$), supporting the positive association found between brain weight and complexity. As no significant phylogenetic signal between brain weight and display complexity was detected in our previous study and brain weight and brain volume are highly correlated, it is unlikely that phylogenetic corrections are needed for the brain volume/complexity associations. Measurements of CB granular layer and CB molecular layer volumes show a marginally positive association between the granular layer volume and display complexity ($R2=0.267$, $p=0.071$), but no association between the molecular layer volume and complexity. Correction for phylogenetic non-independence of samples is incomplete and may change this result. Our data confirm that sexual selection can act on motoric displays resulting in coevolution of larger brains, and possibly larger "little brain" cells for motor planning and coordination.

Abstract: It is generally assumed that the expansion of the mammalian neocortex during evolution correlates with the increase in intelligence. To fit into a limited cranium, expanded cortical surfaces are folded to form gyri and sulci. The molecular mechanisms underlying the expansion of the cortex remain poorly understood. Recent cross-species studies have shown the emergence of an outer subventricular zone (OSVZ) in the primate cortex, consisting of a massive pool of proliferating basal progenitors (BPs), which are rare in lissencephalic murine cortex. The radial and lateral expansion of BPs is thought to be the cause of cortical folding of gyrencephalic species, although direct experimental evidence is still lacking. Here, we report that a hominoid-specific gene HSG1 promotes generation of BPs and induces gyrus-like structures when expressed in the mouse cortex. Expression of HSG1 in cortical progenitors in the ventricular zone of the mouse embryo via in-utero electroporation disrupted adherens junctions and caused delamination of ventricular radial glia by down-regulating the expression of N-cadherin. Immunostaining of mitotic markers and real-time imaging showed that HSG1-expressing delaminated basal cells underwent self-renewal and exhibited the morphology of typical outer (basal) radial glia, the most abundant type of BPs in primates. Furthermore, we observed extensive cortical folding and gyrus formation in transgenic mice expressing HSG1 as well as in mice electroporated with HSG1 in cortical progenitors. Thus, we have identified a duplicated gene in humans that regulates the expansion and folding of the cortex and delineated the molecular and cellular mechanisms underlying its action.

Title: Development of neocortical interhemispheric connections in a pre-callosal marsupial

Authors: *R. SUAREZ[1], A. PAOLINO[1], L. MORCOM[1], P. KOZULIN[1], L. R. FENLON[1], L. J. RICHARDS[1,2];
[1]Queensland Brain Inst., [2]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: The most remarkable evolutionary innovation in the brain of placental mammals was the rewiring of interhemispheric connections through the corpus callosum. This provided a shorter route for integration of bilateral circuits, significantly increasing the speed of information processing. We found that marsupials share an ancestral template of commissural wiring with monotremes, despite being more closely related to placentals. Therefore, here we studied the development of these connections in a marsupial model, the fat-tailed dunnart, to elucidate what events could have triggered callosal evolution. By EdU birth-dating and *in vitro* retrograde labeling, we find that olfacto-recipient structures pioneer commissural formation. Then, deep-layer neocortical neurons send axons that are followed by upper-layer axons, as revealed by sequential in-pouch electroporation of reporter genes. Deep-layer axons wait at the subplate to innervate the cortical plate at the same time as upper-layer axons. An interesting finding is the co-existence of independent neuronal populations with laterally- and medially-oriented axonal projections, suggesting the existence of a proto-callosal phenotype in the common ancestors of marsupials and placentals. We discuss these findings in terms of general developmental processes directing commissure formation in mammals and possible developmental scenarios explaining evolution of the corpus callosum.

Title: Detection of drowsiness in driving simulation using EEG and fNIRS

Authors: ***S. AHN**[1], T. NGUYEN[2], H. JANG[1], J. KIM[1,2], S. JUN[1];
[1]Sch. of Information and Communications, [2]Dept. of Med. Syst. Engin., Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: Drowsiness is the main cause of car accidents compared to other factors such as over-speed or inattention. Generally, it is hard to shake off drowsiness and we are going to drowsy state regardless of our intention. Therefore, we need to predict driver's drowsiness and detect the symptom of drowsy state before falling sleep to reduce the car accidents. In this study, we investigated the drowsiness in terms of brain signal by performing virtual driving simulation using simultaneous EEG and fNIRS recording. Subject took a virtual driving simulator designed by Hyundai Motor Company and drove about 20 minutes. To make subject drowsy, subject did not sleep whole night and participate in experiment in the morning. Sixty-four EEG channels were attached on entire scalp and custom-built 12 channels fNIRS system was used hemodynamic changes on forehead in 0.5 seconds sampling interval. We adopted modified Beer-Lambert law and converted intensity of light into concentration changes. In EEG analysis, we applied independent component analysis to remove artifacts generated by moving and calculated the relative power level (RPL) which powers of specific frequencies divided by total power of 1-50Hz range. In this study, theta (4-7Hz) and alpha (8-13Hz) RPLs were calculated because drowsiness is most related to these frequency bands. In figure 1(a) depicted hemodynamic changes corresponding to oxy/de-oxy/total hemoglobin changes on 2 channels among 12 channels. Yellow and green-colored regions indicate awake and drowsy state, respectively. These states are accord with manually inspection by experimenters. Oxyhemoglobin concentration changes (HbO) gradually increase in drowsy state and return to base line in awake state and deoxyhemoglobin concentration changes (HbR) reamain in baseline. Total hemoglobin (THb) is simple summation of these two values. Figure 1(b) described the theta and alpha RPL corresponding to each state of fNIRS results. Theta RPL in drowsy state increases around central region compared to awake state and alpha RPL has lower values on whole regions in drowsy state.

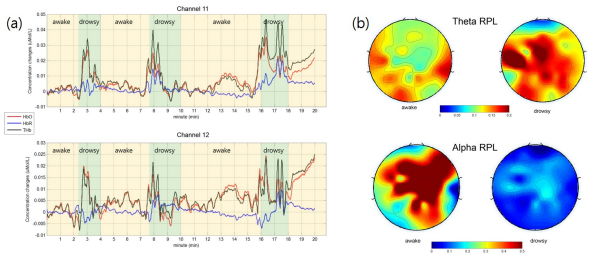

Figure 1. (a) : Concentration changes of fNIRS data. Yellow and green-colored indicate the awake and drowsy state, respectively.
(b) : Theta and alpha RPLs of EEG data. Each topography means relative power in awake and drowsy state.

Title: Influence of aromatic moieties linked to piperazine ring of tetrahydrobenzo[d]thiazole based hybrid compounds impacts efficacy of dopamine D2/D3 agonists at D3 receptors

Authors: ***M. E. REITH**[1,2], J. ZHEN[1], T. ANTONIO[1], J. C. JACOB[3], D. GRANDY[4], A. K. DUTTA[5], D. E. SELLEY[3];
[1]Psychiatry, New York Univ. Schl Med., New York, NY; [2]Biochem. & Mol. Pharmacol., New York Univ. Sch. Sci., Wayne State Univ. Applebaum Coll. Pharm. & Hlth. Sci., Detroit, MI

Abstract: The work described here addressed the question as to whether small structural differences in agonists at D_2 and D_3 dopamine receptors can affect their intrinsic efficacy. We compared two compounds developed in our earlier work (Ghosh et al., 2010; Biswas et al., 2008): D-264 and D-301. Both contain the tetrahydrobenzo[d]thiazole moiety, connected through a (propyl)N-ethyl linker with a piperazine biphenyl moiety (D-264) or a piperazine isoquinolin moiety (D-301). The first series of experiments involved WT mice in which both D_2 and D_3 receptors contribute to G protein activation, and D_2 KO mice in which the D_2 component has been removed. Both agonists produced similar maximal stimulation of [^{35}S]GTPγS binding in caudate-putamen (CPu) (52-53%) and nucleus accumbens (NAcc) (30-34%) of WT mice. In D_2 KO mice, however, the D-301 E_{max} value was significantly greater than that of D-264 (17% versus 5%, respectively) in CPu. In NAcc, only D-301 significantly stimulated [^{35}S]GTPγS binding in D_2 KO mice (E_{max} ~ 10%), whereas D-264 did not stimulate [^{35}S]GTPγS binding above basal levels. These results suggest that D-301 activates D_3 receptors more efficaciously than D-264. In the second series of experiments, D-264 and D-301 appeared to act in the [^{35}S]GTPγS assay as full agonists at D_2 and D_3 receptors expressed in CHO-cells; it is well known that partial agonists can display full agonist behavior at receptors overexpressed in cell

systems. By comparing K_i values from [^{35}S]GTPγS assays with EC_{50} values from [^{3}H]spiperone binding assays under identical conditions, we were able to determine intrinsic activity which is determined in part by K_i/EC_{50}, i.e. receptor reserve (Selley et al., 1998). D-301, but not D-264, showed a K_i/EC_{50} ratio statistically greater than unity (similarly to DA itself) in D_3 but not in D_2 receptor-expressing cells. Because $G\alpha_o$ is highly expressed in the brain and is important in D_3 G protein coupling, $G\alpha_o$ was transiently co-expressed in CHO cells. At D_3 $G\alpha_o$ led to an intrinsic efficacy significantly higher than unity for D-301 but not D-264; DA itself had a higher than unity intrinsic activity both in the absence and presence of $G\alpha_o$. D-301 had a 64% greater intrinsic activity than D-264 in D_3 $G\alpha_o$ cells; no such difference was seen in D_2 $G\alpha_o$ cells. The results from the two series of experiments combined indicate that D-301 has a greater intrinsic efficacy at D_3 than D-264, whereas the two compounds act on D_2 with similar intrinsic efficacy. This D_3 intrinsic efficacy difference manifests as different E_{max} values for G-protein activation in striatum of D_2 KO mice, where D_3 receptor density is low and $G\alpha_o$ expression is high relative to transfected CHO cells.

Title: The putative cannabinoid receptor GPR55: expression, modulation of hippocampal plasticity and behavior

Authors: *K. M. HURST, C. BADGLEY, M. YOUNG, Z. COWAN, J. CALL, J. WELCH, T. ELLSWORTH, J. EDWARDS;
BYU, Provo, UT

Abstract: Learning and memory occur due experience-dependent changes in our brain in response to our environment. These changes are mediated by synaptic plasticity, particularly within the hippocampus. Plasticity can either strengthen or weaken synapses, known as long-

term potentiation (LTP) or long-term depression (LTD) respectively. While many forms of plasticity are NMDA-dependent, endocannabinoids mediate several new forms of hippocampal synaptic plasticity. Endocannabinoids bind to receptors such as cannabinoid receptor 1 (CB1) and transient receptor potential vanilloid 1 (TRPV1) in various brain areas including the hippocampus. However, research has demonstrated a non-CB1/TRPV1-dependent endocannabinoid synaptic plasticity in the hippocampus. While the receptor(s) involved is currently unknown, several potential candidate receptors that bind the endocannabinoid anandamide have been identified. These are among the orphan G-protein coupled receptors (GPRs) whose distribution in the brain and/or function is not well known. GPR55 is of particular interest as it activates second messenger systems, including IP3-mediated increases in intracellular calcium. Using quantitative RT-PCR, electrophysiological and memory behavioral tasks we examined hippocampal GPR55 expression and function. GPR55 is expressed in hippocampus of both rats and mice. Interestingly, application of the GPR55 agonist LPI (2 μM) to wild-type mice demonstrates a significant enhancement of LTP in brain slices. This LPI effect was absent in GPR55 knock-out (KO) mice, which exhibit significantly ($p < 0.05$) smaller LTP (146%) than wild-type (WT) (181%). The GPR55 antagonist, CID 16020046, (10 μM) also blocked LPI enhancements in WT mice. While examining CA1 LTD preliminary data illustrate no significant difference to this point between KO and WT mice. GPR55 also appears to increase release probability (Sylantyev et al., PNAS, 2013), denoting a presynaptic role. Therefore, we examined paired-pulse ratios (PPR) between KO and WT mice in the presence and absence of LPI. Indeed, while there is only a slight difference between KO and WT PPRs, after application of LPI there is a significant increase in PPR of WT mice not noted in KO mice. Behaviorally, KO and WT mice did not differ in the novel object recognition test, but we are now investigating spatial navigation, using radial arm maze to examine spatial memory. These data suggest GPR55 is expressed and physiologically relevant in the hippocampus. Because enhanced LTP is usually associated with better memory performance in rodents, this provides a potential target to enhance the cellular mechanism associated with memory formation.

Title: Elevation of intracellular Ca^{2+}mediated by methylmercury toxicity was delayed by dopamine receptor antagonists in pheochromocytoma cells (PC12)

Authors: *D. WIWATRATANA[1], W. D. ATCHISON[2];
[1]Michigan State Univ., Comparative Med. and Integative Biol., East Lansing, MI; [2]Michigan State Univ., Pharmacol. and Toxicology, East Lansing, MI

Abstract: Perturbation of synaptic transmission is a pathophysiologic mechanism by which methylmercury (MeHg) - induced toxicity occurs. In the brain, the dopamine (DA) system appears to be affected by MeHg as exhibited by 1) increased of DA release, 2) inhibited DA uptake, 3) altered DA synthesis and metabolism and 4) reduced type II dopamine receptor D2R expression. Still, no study has tested for direct effects of MeHg on DA receptor functions. This study aimed to examine effects of acute exposure to MeHg on D1R and D2R regulation of [Ca2+]i. The D1R antagonist SCH23390 or D2R antagonist raclopride were applied to differentiated PC12 cells for 30 min before MeHg administration. Real time [Ca2+]i changes were analyzed using Fura2-AM microfluorimetry. Normally in PC12 cells, MeHg application causes a multiphasic increase in fura-2 fluorescence; at least two kinetically-distinct phases occur. Application of 1μM SCH23390 delayed the onset of 1μM MeHg- induced [Ca2+]i elevation in both 1st phase ($t(4) = 6.623$, $p < 0.05$) and 2nd phase ($t(4)= 2.884$, $p <0.05$). Raclopride (1μM) also delayed the onset of 1μM MeHg- induced [Ca2+]i in both 1st phase ($t(35) = 3.322$, $p <0.05$) and 2nd phase ($t(35) = 4.256$, $p < 0.05$). The effect of raclopride was also replicated in undifferentiated PC12 cells which indicated the 1μM Raclopride delayed the onset of 2μM MeHg- induced [Ca2+]i elevation in both 1st phase ($t(4) = 3.735$, $p <0.05$) and 2nd phase ($t(4) = 3.874$, $p < 0.05$). These results suggest that acute exposure to MeHg perturbed DA-regulated [Ca2+]i elevation. MeHg may act as D1R activator and D2R uncompetitive inhibitor. Consequently, MeHg could overly stimulate neurons due to the imbalance of excitation and inhibition leading to loss of [Ca2+]i homeostasis, and eventual cell death. Besides, these data implicates MeHg potentially affecting DA signaling which regulates the motor control circuit.

Title: Transactive response DNA binding protein 43 modulation of Cannabinoid type 1 receptor trafficking and signaling

Authors: *A. G. ROBINSON[1], M. R. DESHOTELS[2], P. WEED[2], B. OGUNLADE[1], P. WINSAUER[2], J. J. GUIDRY[2], C. M. FILIPEANU[1];
[1]Pharmacol., Howard Univ., Washington, DC; [2]Pharmacol. and Exptl. Therapeut., Louisiana State Univ., New Orleans, LA

Abstract: Mutations in transactive response DNA binding protein 43 (TDP43), a transcriptional repressor, lead to formation of cytosolic aggregates in neuronal cells, pathological characteristics observed in Amyotrophic Lateral Sclerosis (ALS) and Frontotemporal Lobar Degeneration (FTLD), two major progressive neurodegenerative diseases which are currently missing a reliable therapy. Activation of cannabinoid type 1 receptor (CB1R) has been proposed for the treatment of two other major neurodegenerative disorders, Multiple Sclerosis (MS) and Parkinson's Disease (PD). Currently, the possible therapeutic role of cannabinoid receptors in ALS and FTLD is under debate. In humans, CB1R is expressed as three different isoforms, with the lesser prominent subtypes CB1AR and CB1BR being different in the composition of the N terminus compared to the widely expressed CB1R. To identify novel molecular chaperones involved in CB1R trafficking and signaling, we performed a proteomic analysis in transfected HEK293T cells in similar manner as previously described by us. Surprisingly, only one protein, TDP43 was found to interact preferentially with CB1R over CB1AR. This differential interaction was confirmed in co-immunoprecipitation experiments. Interestingly, CP55940, a CB1R agonist, further increased the interaction of CB1R and TDP43. Similar interactions between endogenously expressed CB1R and TDP43 were found in crude rat spinal cord. TDP43 overexpression in HEK293T cells also enhanced CB1R ubiquitination to similar extent as CP55940 stimulation. Further, in HEK293T cells, overexpression of TDP43 significantly decreased CB1R cell surface expression as determined by radioligand binding and ELISA experiments, although it did not change the total cellular receptor levels. This diminished plasma membrane localization of CB1R resulted in reduced effects of CP55940 on cAMP and P-ERK1/2 cellular levels. In contrast, TDP43 overexpression enhanced the effects of CB1R stimulation on P-CREB levels. The same results were obtained after TDP43 overexpression in Neuro-2A cell line on endogenous CB1R localization and signaling. Confocal microscopy experiments in CB1R transfected HEK293 and spinal cord motor neurons demonstrated co-localization of TDP43 and CB1R in heat shocked cells (42^{o}C), but not at physiological temperature. The present results are the first demonstration that TDP43 is a molecular chaperone of CB1R, modulating intracellular receptor trafficking and cellular responses to cannabinoid

ligands. In addition, our data may serve as cellular and molecular basis to better understand the role of CB1R in the patho-physiology of ALS and FTLD.

Title: Interplay between serotonergic and L1-mediated signaling in regulation of neuronal morphology and functions

Authors: *D. GUSEVA[1], Y. SCHILL[1], B. MONIKA[2], J. WLODARCZYK[2], E. PONIMASKIN[1];
[1]Hannover Med. Sch., Hannover, Germany; [2]Nenski Inst., Warsaw, Poland

Abstract: Stress-related disorders are shown to be associated with functional disturbance of neuronal adhesion molecule L1. The L1-mediated neuronal migration, development, and regeneration based on homo/ heterophilic L1 interactions seems to be depended on presentation of L1 either as a membrane-bound form or as a proteolytic fragments. We have identified the neuronal L1 as a proteolytic substrate for the matrix metalloproteinase-9 (MMP-9) and demonstrated that L1 fragments generated by MMP-9 cleavage are involved in spine formation in dissociated hippocampal neurons. Together with the observation that the L1 can initiate neurite outgrowth via phosphorylation of actin-binding protein cofilin, this data suggests that MMP-9-mediated proteolysis of L1 might be involved in L1-initiated signaling pathway regulating actin rearrangement in neurons. Serotonergic system has been identified as crucially important to the pathophysiology and the treatment of mood disorders. Neurotransmitter serotonin (5-HT) is involved in neurite outgrowth, growth cone motility and synaptogenesis, and operates via activation of multiple 5-HT receptors. Here we focused on the 5-HT4 receptor (5-HT4R). In the mammalian brain this receptor contributes to regulation of learning and long term memory and is involved in various central and peripheral disorders, including neurodegenerative disease and depression. In our preliminary results we have shown that stimulation of 5-HT4R induces the release of enzymatically active MMP-9 in hippocampal neurons, where 5-HT4R and L1 are tightly co-localized at the synapses. These results demonstrate that 5-HT4R might regulate L1 shedding in an MMP-9-dependent manner, thereby modulating the

homo/heterophilic interaction and paracrine function of L1. We have previously shown that 5-HT4R stimulation results in activation of the small GTPase RhoA, leading to cell rounding and neurite retraction. In our preliminary experiments we have also demonstrated that this effect can be mediated by phosphorylation of cofilin. Thus, cofilin may represent a common downstream effector for both 5-HT4R and L1 suggesting that 5-HT4R, MMP-9 and L1 belong to the same signaling module involved in regulation of neuronal morphology. Taken together, our results demonstrate that 5-HT4R might regulate L1 shedding in an MMP-9-dependent manner, and can thus represent a novel molecular mechanism by which serotonin can regulate the formation and plasticity of neuronal networks and a novel targets for pharmacological intervention into stress-related disorders such as depression.

Title: Expression analysis of the orphan receptor Gpr139 in the mouse brain

Authors: *A. W. HARRINGTON, S. W. SUTTON, P. BONAVENTURE, C. LIU, T. LOVENBERG;
Janssen R&D, San Diego, CA

Abstract: GPR139, also known as GPRg1 or PGR3, is an orphan GPCR whose mRNA expression in mouse brain has been characterized previously using *in situ* hybridization techniques. Because of potential non-specificity often observed with riboprobes in certain brain regions, we sought to develop new tools to more accurately characterize GPR139 receptor expression and protein localization. A specific rabbit polyclonal antibody was generated to GPR139 using the N-terminus of the receptor as an antigen. In addition, two mouse lines were used to identify GPR139 mRNA-expressing neurons: a lacZ knockin in which the lacZ gene replaces the GPR139 locus; and an EGFP knockin, in which EGFP replaces the GPR139 locus. Using these tools combined with immunohistochemistry, we have confirmed GPR139 expression in two brain regions also shown by *in situ* hybridization: the medial habenula and the lateral septum. Conversely, several regions of the brain positive for expression by *in situ* hybridization did not confirm using these tools. These results provide a clearer picture of the brain regions and

location of GPR139 expression. Subsequent work is aimed at characterizing the identity of GPR139 expressing neurons and understanding the physiological role of the receptor.

Abstract: Olfactory marker protein (OMP) is highly expressed in olfactory as well as non-olfactory tissues, such as testis, blood vessel, and pancreas. In this study, we evaluated the role of OMP on glucagon secretion from pancreatic islet. The expression of both OMP and glucagon were increased in high glucose treated αTC1-9 cells as assessed using RT-PCR. Moreover, high throughput RNA sequencing showed that OMP and some specific olfactory subtypes were increased in high fat diet induced diabetic rat compared with those of standard diet fed BL6 mice. OMP expression in the pancreatic α-cells was more prominent in diabetic patients compared with that in normal subjects. Furthermore, silencing the OMP using the si-RNA transfection reduced glucagon secretion in αTC1-9 cells despite of high glucose treatment. Our findings demonstrate that OMP regulates glucagon secretion in α-cells of the mouse pancreatic islets, suggesting that OMP and its related olfactory receptors (ORs) may be an important therapeutic target for metabolic diseases.

Title: A hydrogen bond in 5-HT1A/D4 selectivity of WAY-100635 analogues: in silico and experimental studies

Authors: *J.-F. LIEGEOIS[1], S. DILLY[2,3];
[1]Univ. of Liege Drug Res. Center-Medicinal Chem. Lab., Liege, Belgium; [2]GIGA-Neuroscience Lab. Pharmacol., [3]C.I.R.M. - Medicinal Chem., Univ. of Liège, Liège, Belgium

Abstract: WAY-100635 is a prototypical antagonist of 5-HT1A receptors and has been used widely as a pharmacological probe to investigate the distribution and function of these receptors (1). However WAY-100635 also displays affinity and activity at D4 dopamine receptors, and that "off-target" activity confounds its use in pharmacological studies, particularly when both receptors are present (2). In this context, a previous study explored various chemical modifications of the WAY-100635 structure and revealed analogues with improved 5-HT1A versus D4 selectivity while others presented higher D4 receptor affinity (3). In order to rationalize this increase in D4 affinity, a recent study combining in silico analysis and mutagenesis was conducted and revealed the key role of a hydrogen bond in the interaction of quinoxaline derivatives with a serine residue (S 7.36) of the D4 receptor binding site (4,5). To further confirm the importance of this hydrogen bond, newly synthesized aza analogues of WAY-100635 have been tested in an *in vitro* binding assay using both the native and the S7.36A mutant D4 receptors. These investigations validate the preliminary data but also precise the right position of the nitrogen atom for the formation of the hydrogen bond. References: (1) Forster et al,. Title: Gβγ binds to the extreme C-terminus of SNAP-25 to mediate the action of Gi/o-coupled GPCRs

Authors: *Z. ZURAWSKI[1], S. RODRIGUEZ[2], K. HYDE[1], S. ALFORD[2], H. HAMM[1]; [1]Pharmacol., Vanderbilt Univ., Nashville, TN; [2]Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Gi/o-coupled G-protein coupled receptors (GPCRs) can exert an inhibitory effect on vesicle release through several G-protein driven mechanisms, more than one of which may be concurrently present in individual presynaptic terminals. The synaptosomal-associated protein of 25 kDa (SNAP-25) is a key downstream effector of G protein betagamma (Gβγ) subunits. It has previously been shown that proteolytic cleavage of SNAP-25 by botulinum toxin A (BoNT/A) reduces the ability of Gβγ to compete with the calcium sensor synaptotagmin 1(Syt1) for binding to SNAP-25 in a calcium-dependent manner. These truncated SNAP-25 proteins sustain a low level of exocytosis, but are unable to support serotonin-mediated inhibition of exocytosis in lamprey spinal neurons. Here, we generate a SNAP-25 extreme C-terminal mutant that is deficient in its ability to bind Gβγ while retaining normal calcium-dependent Syt1 binding to SNARE and vesicle release. The SNAP25Δ3 mutant, in which residue G204 is replaced by a stop codon, features a partial reduction in Gβγ *in vitro* as measured by the Alphascreen protein-protein interaction assay as well as a partial reduction in the ability of the lamprey 5HT1b-type serotonin receptor to reduce excitatory postsynaptic current (EPSC) amplitudes, an effect previously shown to be mediated through the interaction of Gβγ with SNAP-25. Syt1 binding to SNAP25Δ3, as measured by GST-pull downs, was not different from wild-type. Next, to begin characterization of the potential pathophysiological roles of the Gβγ-SNAP25 interaction, we produced a transgenic mouse containing the SNAP25Δ3 mutation in the wild-type Snap25 locus utilizing the CRISPR/Cas9 reaction. Preliminary characterization of the mouse with regards to viability, metabolic, neurological and secretory phenotypes are ongoing. We conclude that the extreme C-terminus of SNAP-25 is a critical region for the Gβγ-SNARE interaction.

Title: Distinct signaling cascades underlie 5-HT6 receptor regulation of neuronal morphology

Authors: ***A. J. LESIAK**, M. BRODSKY, J. F. NEUMAIER;
Psychiatry and Behavioral Sci., Univ. of Washington, Seattle, WA

Abstract: 5-HT6 serotonin receptors can modulate cognition and emotional behaviors, including anxiety, depression, habitual behaviors and reward learning. The 5-HT6 receptor is an excitatory GS-coupled metabotropic receptor that is found almost exclusively in the brain, most abundantly in the striatum, cortex, and hippocampus. Interestingly, 5-HT6 receptor protein is restricted to primary neuronal cilia unless it is heterologously expressed overabundantly, in which case it spills out into the cell membrane. The primary cilium is thought to act like an antenna, receiving chemical and mechanical signals from the surrounding extrasynaptic environment. Since primary cilia may play a critical role in many disorders, including Huntington's and Alzheimer's disease, they may represent a novel therapeutic target for neurocognitive disorders. However, little is known about the mechanisms by which primary cilia regulate neuronal function. The 5-HT6 receptor is known to stimulate two distinct signaling pathways, the canonical cAMP-dependent signaling cascade and the Fyn kinase/Cdk5 signaling pathway. Recently, 5-HT6 receptor antagonism and inhibition has been shown to decrease cilia length in primary neuronal cultures. Additional evidence suggests that strong heterologous overexpression of 5-HT6R can stimulate neurite outgrowth in cell lines via Cdk5 and CDC42 activation. In the present study, we used mature primary neuronal cultures from wild-type and 5-HT6 knockout mice to examine the role of 5-HT6R signaling in neuronal morphology, taking care to avoid excessive heterologous expression so that 5-HT6R remains restricted to the primary cilia as seen with the endogenous receptor. Preliminary data suggests that agonism of endogenous 5-HT6R stimulates an increase in dendritic outgrowth and branching. Likewise, rescue of 5-HT6R expression in 5-HT6R-KO

neurons is sufficient to increase dendritic outgrowth relative to 5-HT6R-KO neurons transfected with empty vector. Expression of a Gs-coupled signaling 5-HT6R mutant was also able to stimulate dendritic outgrowth in 5-HT6R-KO neurons, while expression of FynKinase-signaling deficient 5-HT6R mutant did not. Ongoing experiments will attempt to further dissect the role of these 5-HT6R-dependent signaling events in primary neuronal cilia on cilia and dendritic morphology.

Title: The atypical antidepressants mianserin and mirtazapine induce ERK1/2 signaling and anti-apoptotic effects through activation of the lysophosphatidic acid LPA_1 receptor in mouse hippocampal HT22 cells

Authors: ***M. C. OLIANAS**, S. DEDONI, P. ONALI;
Univ. Cagliari, Monserrato, Italy

Abstract: A large body of evidence indicate that the bioactive phospholipid lysophosphatidic acid (LPA) affects neurogenesis, synaptic plasticity and anxiety-related behaviour by activating specific G-protein coupled receptors, termed LPA_{1-6}, which are expressed in the developing and adult brain. However, relatively little is known on whether the LPA receptor system can be targeted by drugs used to treat neuropsychiatric diseases. We have previously reported that different antidepressants promote growth factor receptor transactivation and cell proliferation in CHO-k1 fibroblasts and glia cells. In the present study, we show that in immortalized mouse hippocampal HT22 cells the atypical antidepressants mianserin and mirtazapine trigger ERK1/2 phosphorylation and protect against apoptosis through LPA_1 receptors. ERK1/ 2 phosphorylation induced by acute exposure to either mianserin, mirtazapine or LPA was inhibited by cell pre-treatment with pertussis toxin, indicating the involvement of G proteins of the $G_{i/o}$ family. LPA, mianserin and mirtazapine also promoted the phosphorylation of the transcription factor CREB,

a downstream effector of ERK1/2 signaling. Cell treatment with either AM966, a selective LPA_1 receptor antagonist, or Ki16425, which preferentially blocks LPA_1 and LPA_3, significantly inhibited ERK1/2 and CREB phosphorylation elicited by mianserin and mirtazapine. Serum withdrawal-induced apoptosis of HT22 cells was markedly attenuated by either LPA, mianserin or mirtazapine, as indicated by the decreased cell death, decreased percentage of annexin V-positive cells, inhibition of pro-caspase activation and poly-(ADP ribose) polymerase cleavage. AM966 reduced the protective effects of mianserin, mirtazapine and LPA against HT22 cell apoptosis. Moreover, cell treatment with the MEK inhibitor PD98059 prevented the anti-apoptotic effect of LPA and mianserin. These data provide further evidence for the involvement of the LPA_1 receptor in the pharmacological action of antidepressants.

Title: Classification of dopamine receptor genes in vertebrates - Nine subtypes in Osteichthyes -

Authors: *K. YAMAMOTO, R. FONTAINE, C. PASQUALINI, P. VERNIER;
CNRS - Paris-Sud University, Neuro-PSI (UMR9197), Gif-sur-Yvette, France

Abstract: Dopamine neurotransmission regulates various brain functions, and at a cellular level, its regulatory roles are mediated by two classes of G-protein coupled receptors (GPCR), D1 and D2 receptor classes. The two classes of dopamine receptors were originally defined on pharmacological ground. Although they both have high affinity for dopamine, D1 and D2 receptor classes are not phylogenetically more related to each other than to other classes of monoamine receptors. In mammals, the D1 receptor class comprises two receptor subtypes (D1 and D5, as known as D1A and D1B in non-human species), and the D2 receptor class comprises three receptor subtypes (D2, D3 and D4). Our phylogenetic analyses of dopamine receptor genes strongly suggest that the common ancestors of Osteichthyes (bony jawed vertebrates) possessed

four subtypes in the class D1, and five subtypes in the class D2. Mammals have secondarily lost almost half of the ancestral genes whereas non-mammalian species kept many of them. Thus the mammalian situation is an exception among Osteichthyes, although the current classification and characterization of dopamine receptors are based on mammalian studies. For meaningful comparison of the data between mammalian and non-mammalian species, we reconstructed an evolutionary scenario of dopamine receptor genes and propose a new classification reflecting correct phylogenetical relationship. In order to simplify one to one comparison of orthologous genes among different vertebrate species, we propose to refer to the four D1-class dopamine receptors as D1, D5, D6 and D7, and to the five D2-class dopamine receptor genes as D2, D3, D4, D8 and D9. Although the nomenclature with numeric suffix reflects only chronologic order of gene discovery and does not take into account the two different dopamine receptor classes, it requires minimal changes from the currently accepted nomenclature. This comparative perspective is crucial to correctly interpret data obtained in animal studies on dopamine-related brain disorders, or more fundamentally, to understand the characteristics of dopamine neurotransmission in vertebrates.

Title: Mechanisms of cannabinoid cb2 receptor-mediated modulations in mouse vta dopamine neurons

Authors: ***J. WU**[1], B. LARSON[1], F. GAO[1], Z. XI[2], M. GAO[1];
[1]Barrow Neurolog Inst., Phoenix, AZ; [2]NIDA, Baltimore, MD

Abstract: Growing evidence suggests that brain cannabinoid CB2 receptors (CB2Rs) are importantly involved in several dopamine (DA)-related behaviors and DA-related CNS disorders. We recently reported that brain CB2Rs modulate cocaine's action, including

intravenous cocaine self-administration, cocaine-enhanced locomotion and extracellular DA in the nucleus accumbens in mice. In addition, CB2Rs are recently identified in mouse VTA DA neurons, and activation of CB2Rs in the VTA reduces DA neuron excitability and firing rates in both *in vitro* and *in vivo* preparations. However, the cellular and molecular mechanisms underlying the CB2R-mediated reduction in VTA DA neuronal excitability are unknown. In the present study, we addressed this issue by using patch-clamp electrophysiological recording technology. We first recorded spontaneous excitatory or inhibitory presynaptic currents (sEPSCs, sIPSCs) in VTA DA neurons in midbrain slides. We found that that bath-applied JWH133 (a selective CB2R agonist) significantly reduced the frequency of sEPSCs but not sIPSCs, suggesting that the activation of CB2Rs eliminates presynaptic glutamate release probability, which may in part underlie the CB2R-mediated reduction of VTA DA neuron firing rate. We then used perforated patch-clamp recording in single acutely-dissociated VTA DA neurons to study the effects of JWH133 on the intrinsic membrane properties of VTA DA neurons. We found that bath-applied JWH133 produced an enhancement of M- and A-type K+ channel currents, but failed to alter G-protein coupled inwardly-rectifying K+ (GIRK) current. This effect is mediated by activation of CB2Rs in VTA DA neurons because co-administration of AM630, a selective CB2R antagonist, or genetic deletion of CB2Rs (using CB2R knockout mice) blocked the JWH133-induced potentiation on M- and A-type K+ currents. Collectively, the present findings suggest the important synaptic and intrinsic mechanisms, that CB2R-mediated reduction of presynaptic glutamate release and enhancement of K+ currents appears to play an important role in modulation of VTA DA neuron excitability, DA neuronal firing, DA release in the nucleus accumbens, and subsequent cocaine-seeking behavior.

Abstract: To identify novel ligands for the D_2 dopamine receptor (D2R), we screened small molecule chemical libraries using high throughput screening. These screens identified a hit compound that selectively activates the D2R in a functionally biased fashion. Chemical optimization resulted in a lead compound (VU207) that exhibits full agonist activity in three different D2R signaling assays: Ca^{2+} mobilization (Gqi5), inhibition of forskolin-stimulated cAMP accumulation (Gi/o), and β-arrestin recruitment. However, VU207 fails to activate D2R-Gβγ-mediated responses including GIRK potassium channel activation and adenylyl cyclase potentiation. Using the β-arrestin recruitment assay, VU207 was also found to exhibit potent D3R antagonism with no functional activity at other dopamine receptors. Further, behavioral paradigms (hypothermia and yawning) indicates that VU207 penetrates the brain and acts as a D2R agonist and a D3R antagonist *in vivo*. Using *ex vivo* brain slices, we investigated the functional activity of VU207 at D2Rs located on dopaminergic neurons. These cells express D2Rs on the cell bodies and dendrites (somatodendritic D2Rs), which activate GIRK channels whereas the D2Rs located on the nerve terminals (presynaptic D2Rs) inhibit dopamine release through activation of Kv1 potassium channels. We found that VU207 failed to activate GIRK currents through somatodendritic D2Rs and, in fact, acted as an antagonist of this D2R response. Notably, in contrast, VU207 acted as an agonist at inhibiting dopamine release via the D2Rs at the nerve terminals. This latter response was absent in tissue from "autoD2R" knockout mice that lack D2R expression in dopaminergic neurons, thus confirming its specificity for D2Rs. These findings suggest that VU207 is a functionally selective agonist and exhibits a unique form of spatial or location bias acting as either an agonist or an antagonist depending on where in the neuron (cell bodies vs. terminals) the D2R is located. It is expected that more cases of location/spatial bias will be observed upon further analyses of receptor-mediated signaling in cells with complex morphologies, especially neurons.

Title: Presynaptic strength is increased by platelet activating factor via PKC, elevated intracellular calcium, and synapsin phosphorylation

Authors: *J. W. HAMMOND, S.-M. LU, H. A. GELBARD;
Ctr. for Neural Develop. and Dis., Univ. of Rochester, Rochester, NY

Abstract: Platelet activating factor is an inflammatory phospholipid signaling molecule has been implicated in synaptic plasticity, learning and memory, and neurotoxicity. However, little is known about the intracellular mechanism mediating PAF's physiological or pathological synaptic facilitation. Here we show that the PAF receptor is localized to the synapse. Using fluorescent reporters of presynaptic activity we show that PAF enhances synaptic vesicle release from individual presynaptic boutons by increasing the size of the releasable pool of vesicles. PAF also activates previously silent boutons resulting in vesicle release from a larger number of terminals. The underlying mechanism involves elevated calcium within presynaptic boutons and PKC activation. Furthermore, PAF increases synapsin phosphorylation at sites 1 and 3, (both sites associated with elevated calcium) and increases dispersion of synapsin from the presynaptic compartment during stimulation, freeing synaptic vesicles for subsequent release. In aggregate, these findings provide a conceptual framework for how PAF can modulate synapses during normal and pathologic synaptic activity.

Title: G Protein-Coupled Receptor 35 agonists mediate analgesic effects through modulation of hyperpolarization-activated cyclic nucleotide gated channels in rat DRG neurons

Authors: *D. PELLEGRINI-GIAMPIETRO, F. RESTA, A. MASI, M. SILI, A. LAURINO, F. MORONI, G. MANNAIONI;
Univ. of Florence, Florence, Italy

Abstract: Hyperpolarization-activated Cyclic Nucleotide gated (HCN) channels have been recently proposed as the "pacemakers" of pain. HCN2 channel are controlled by cAMP levels and are largely expressed in small Primary Sensory Neurons (sPSN), the majority of which are nociceptors. Intracellular elevation of cAMP levels have been reported to activate HCN-mediated current (Ih), which depolarizes the membrane potential enhancing neuronal excitability and pain sensation. GPR35 is a Gi/o coupled receptor, highly expressed in sPSN, whose activation inhibits adenylate cyclase activity leading to a reduction of intracellular cAMP. We tested the hypothesis that selective GPR35 agonists could exert anti-nociceptive action through the cAMP-mediated modulation of HCN channels in sPSN. Performing patch clamp recordings on cultured rat sPSN isolated from rat dorsal root ganglia, we investigated the effect of GPR35 activation on Ih current and neuronal excitability in control conditions and following stimulation with forskolin (FRK), an adenylate cyclase activator, or prostaglandin E2 (PGE2), a powerful pro-inflammatory mediator. Kynurenic acid, the GPR35 endogenous agonist, and zaprinast, a potent GPR35 synthetic agonist, antagonized the FRK-induced depolarization of resting membrane potential by preventing Ih-mediated depolarization. In the same model GPR35 agonists prevented the PGE2-induced, Ih-mediated depolarization and the resulting increase in overall excitability. Finally, we tested the analgesic effect of the GPR35 agonists in an *in vivo* model of PGE2-induced thermal hyperalgesia. Both GPR35 agonists showed a dose dependent analgesic effect thus confirming the *in vitro* results. Furthermore, we studied GPR35 activation effects in oxaliplatin-induced neuropathy in rats. Our preliminary data showed an increased HCN mediated current in oxaliplatin treated rat sPSN, and a significant antinociceptive effect of ivabradine, the clinically used HCN blocker, on oxaliplatin-induced mechanical allodynia and thermal hyperalgesia. In conclusion, GPR35 activation, through cAMP-dependent inhibition of Ih, leads to reduced excitability of sPSN *in vitro* and exerts a dose-dependent analgesic action *in vivo*, thus representing a promising new target for the development of new analgesic drugs.

Title: Dopamine receptor/sodium channel protein complex, a target for antiepileptic mood stabilizers?

Authors: *G. FAKHFOURI, T. DEL'GUIDICEDEL'GUIDICE, A. BARBEAU, M. CHAHINE, J.-M. BEAULIEU;
Psychiatry and Neurosci., Laval Univ., Québec, QC, Canada

Abstract: Background: Although the antiepileptic drugs lamotrigine and valproate are widely prescribed for the management of bipolar disorder, the underlying mechanisms of their mood stabilizing effects are unclear. This hampers the research for the development of newer and safer treatments. Voltage gated sodium channels (Nav) represent a major target of these mood stabilizers. We have previously shown that lithium inhibits a beta-arrestin mediated modality of dopamine D2 receptor (D2R) signalling. Furthermore dopamine receptors have been shown to interact with different type of ion channels. Therefore, we investigated a possible interaction of D2R/Nav. **Methods:** Using an array of protein:protein interaction methods and biochemical assays as well as behavioural paradigms in KO mice and their WT littermates, we explored a potential interaction between Nav and D2R *in vitro* and *in vivo* and the functional consequences. **Results and conclusion:** Our findings demonstrate that the mood stabilizers lamotrigine and valproate inhibit the beta arrestin-2 mediated Akt/GSK-3 signalling downstream of D2R to exert their anti-manic and anti-depressive effects in mice. At the molecular level, Na channels form a complex with D2R leading to alterations in the pharmacological properties of D2R which are sensitive to Nav blockade by lamotrigine and valproate.

Title: Sleep deprivation induces changes in 5-HT actions and 5-HT1A receptor expression in the rat hippocampus

Authors: V. SUEN[1], H. AZIZI[1], A. KWOK[1], A. NGUYEN[1], N. KANG[1], R. SOMVANSHI[2], U. KUMAR[2], *B. SASTRY[1];
[1]Univ. British Columbia Fac Med., Vancouver, BC, Canada; [2]Fac. of Pharmaceut. Sci., The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Sleep deprivation is becoming increasingly common among adolescents, shift workers, and those with busy schedules. Sleep seems to be required for memory consolidation in the hippocampus. Recent studies in our laboratory revealed that hippocampal expression of two prominent G protein-coupled receptors (GPCRs), metabotropic glutamate receptor 1α (mGluR1α) and γ-aminobutyric acid B receptor subunit 1 ($GABA_BR1$), are increased following sleep deprivation. In addition, a hetero-dimerization was observed between the two. Given that GPCRs are known to be dynamically regulated, we investigated whether other GPCRs undergo similar changes. 5-hydroxytryptamine (5-HT) is implicated in modulating sleep and appears to contribute to anxiety, depression and psychosis. 5-HT receptors are largely GPCRs, with $5\text{-}HT_{1A}$ being the most widespread in the hippocampus. The objectives of this study were to examine whether $5\text{-}HT_{1A}$ expression and actions of applied 5-HT in the hippocampus change following sleep deprivation and, if so, whether these changes are reversible. Male Wistar rats were (a) allowed normal sleep (NS), (b) subjected to a 12-hour sleep deprivation (SD), or (c) sleep-deprived for 12 hours followed by a 24 or 48 hour recovery. Stratum radiatum stimulation-induced field excitatory post-synaptic potentials (fEPSPs), in the CA1 pyramidal layer in hippocampal slices, were measured in the presence of bath-applied 5-HT (0 to 40 μM) to construct a dose-response curve. In slices from NS animals, 5-HT depressed the fEPSP in a dose-dependent manner. In slices from SD animals, the depressant action was potentiated. Recovery sleep during a 24 hour period was able to reverse this effect. $5\text{-}HT_{1A}$ expression in the hippocampus was investigated with Western blot and immunohistohemistry. Both methods showed significantly increased expression of $5\text{-}HT_{1A}$ following SD. Almost no reversal of receptor expression was seen following 24 hour recovery sleep and 48 hour recovery sleep resulted in only partial recuperation. In co-immunoprecipitation studies, no hetero-dimerization was observed between mGluR1α or $GABA_BR1$ and $5\text{-}HT_{1A}$. These results indicate that a 12 hour SD results in an upregulation of $5\text{-}HT_{1A}$ receptors and a potentiation of 5-HT's depressant action in the rat hippocampal CA1 area. While there is a recovery from the effect of applied 5-HT in 24 hours, the SD-induced change in $5\text{-}HT_{1A}$ receptors persists. Whether other 5-HT receptors (like $5\text{-}HT_{2A}$) also change with SD and account for the potentiation of 5-HT's action require further

investigation. These results have implications for therapies involving drugs targeting 5-HT pathways.

Title: Persistent adenosine A1 receptor activation within the habenular complex enacts downstream p38 MAPK activation to modulate HCN function and expression and provoke neuronal death

Authors: *D. M. FERGUSON, J. STOCKWELL, X. QIN, F. S. CAYABYAB;
Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: In the CNS, the inhibitory adenosine A1 receptor (A1R) is widely regarded as neuroprotective in hypoxia or ischemia, when extracellular adenosine levels increase. We recently reported that prolonged A1R stimulation in hippocampus leads to p38 MAPK-dependent alterations in the excitatory glutamate AMPARs to promote neurodegeneration. Another region where A1Rs are highly expressed is the habenular complex, where hyperpolarization-activated cyclic nucleotide-gated channels (HCNs) are also widely distributed. Since previous studies demonstrated that p38 MAPK regulates HCN function, we hypothesized that prolonged A1R stimulation of habenular complex leads to a p38 MAPK-dependent downregulation of HCNs and a resultant increase in neuronal excitability. In adult male SD rats, following intraperitoneal injections (i.p.) of the A1R agonist CPA (2mg/kg i.p., once daily for 2 days), we observed massive hippocampal and habenular neurodegeneration as shown by Fluoro-Jade B and propidium iodide staining. In both the lateral and medial habenula, this increased neuronal loss after 48hr CPA treatment, was reduced by additional i.p. injections of the A1R antagonist DPCPX (2mg/kg i.p. 1hr after CPA injections). Compared to vehicle-control animals (DMSO in equal values of saline i.p., once daily for 2 days) and CPA + DPCPX treatments, the CPA-treated rats showed reduced HCN1, HCN2, and HCN4 expression in both lateral and medial habenular subnuclei quantified by confocal immunofluorescence microscopy. Moreover, we observed increased activation of p38 MAPK in habenular nuclei in CPA-treated rats, which was prevented by DPCPX co-administration. As increased levels of co-localization between

HCNs and p38 MAPK were also observed in the habenular complex after A1R stimulation, these results suggest a potential role for A1R-mediated downregulation of HCN channels contributing to the observed habenular neurodegeneration. Given the well-established role of the habenular complex in maintaining circadian rhythm and integrating basal ganglia- and cortico-limbic-dependent cognition, these results raise the possibility that pathological elevation of CNS adenosine levels may be sufficient to induce A1R-dependent habenular neurodegeneration and functional deficits to impair such processes.

Title: Adenosine A1 receptors are required for the adenosine A2A receptor-mediated post-hypoxia synaptic potentiation in the rat hippocampus

Authors: ***X. QIN**[1], J. STOCKWELL[1], D. M. FERGUSON[2], F. S. CAYABYAB[2];
[1]Hlth. Sci., [2]Surgery, Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: The mechanism by which adenosine modulates synaptic transmission in hypoxic/ischemic injury remains poorly resolved. Elevation of extracellular adenosine in the hippocampus during ischemia or hypoxia stimulates both adenosine A1 receptors (A1Rs) and A2A receptors (A2ARs), and adenosine-mediated neuroprotection or neurodegeneration are due to A1R and A2AR stimulation, respectively. We recently reported that hippocampal A1Rs and excitatory AMPA receptors (AMPARs) are downregulated through dynamin-dependent, clathrin-mediated endocytosis, while A2ARs are upregulated after a 20-min hypoxic insult or focal cortical ischemia using a pial vessel disruption procedure. Moreover, A1Rs and AMPARs are physically coupled, whereas A2ARs and AMPARs are not. Following hypoxia during normoxic washout, we observed A2AR-dependent synaptic potentiation, and therefore hypothesized that A1R stimulation is required for subsequent adenosine-induced post-hypoxia synaptic potentiation (APSP). We found that a 20-min hypoxia treatment followed by 45-min normoxic washout/reperfusion produced elevated APSP (150-160%), which was abolished by

treatment with either DPCPX (100nM), an A1R antagonist, or SCH442416 (5nM), an A2AR antagonist. Accordingly, using propidium iodide to label dead cells, hypoxia alone caused significant neuronal death, which was significantly reduced by pre-incubation in DPCPX or SCH442416. Hippocampal slices treated with Dynasore (50μM), a dynamin inhibitor, prior to hypoxia blunted the APSP levels (near 120% vs. 150%) and reduced neuronal death, suggesting that prior stimulation of functional A1Rs and subsequent A1R internalization are required for full expression of APSP. A2AR-dependent APSP was accompanied by increased surface expression of GluA1-containing AMPARs. Surprisingly, APSP was not blocked by philantotoxin-74 (50μM) or NASPM (50-100μM), both calcium-permeable AMPAR inhibitors, or by MK-801 (5μM), an NMDAR antagonist, but was abolished by the non-NMDA glutamate receptor antagonist DNQX (10μM). These results suggest a currently unidentified downstream target of the A1R, which is linked to A2AR function; this A1R-A2AR cross-talk contributes to post-hypoxia adenosinergic signaling that enhances synaptic activity and neurodegeneration.

Topic: B.03. G-Protein Coupled Receptors

Title: G-protein coupled activation of the volume-activated anion channel in human astrocytoma cells

Authors: C. E. MOORE[1], G. LI[2], *J. E. OLSON[2];
[1]Dept Neuroscience, Cell Biology, and Physiol., Wright State Univ., Dayton, OH; [2]Dept Emergency Med., Wright State Univ. Boonshoft Sch. Med., Dayton, OH

Abstract: When osmotically swollen, mammalian cells can regain their normal volume through a process termed regulatory volume decrease (RVD). Volume regulated anion channels (VRAC) have been implicated in controlling cell volume during RVD, but the mechanisms which activate this current are not completely understood. In this study, we examined the role of G protein-coupled signaling via P2Y2 purine receptors for activation of VRAC in osmotically swollen human astrocytoma cells. Methods: Whole cell patch clamp recordings were performed on 1321N1 cells stably transfected to express the human P2Y2 receptor. Cells were sequentially perfused with isoosmotic (290 mOsm) and hypoosmotic (200 mOsm) solutions containing 100

mM CsCl as the major electrolyte. Osmolality was adjusted with added sucrose. The same CsCl concentration was used in the isoosmotic patch electrode solution. Voltage clamp recordings lasting 100 msec were made in 20 mV steps between -100 mV and +100 mV every 30 sec. For some experiments, 100 μM DCPIB, 100 μM suramin, 100 μM ATP, 5 U/ml thrombin, 100 μM carbenoxolone, or 100 μM meclofenamate was added to the perfusate solutions. In others, 1 μg/ml pertussis toxin was added to the patch electrode solution. Results: Hypoosmotic exposure evoked an outwardly rectifying current which inactivated over time at the higher membrane voltages and was inhibited by DCPIB; characteristics ascribed to VRAC. A smaller VRAC current was observed when cells were perfused with a 250 mOsm hypoosmotic CsCl solution. VRAC was not activated by adding ATP or thrombin to isoosmotic solutions; however, adding ATP, but not thrombin, to hypoosmotic solutions increased the VRAC current. VRAC activation was completely blocked by adding suramin to the hypoosmotic solution or pertussis toxin to the patch electrode solution. Carbenoxelone also blocked VRAC activation, but adding ATP or thrombin did not rescue cells from this inhibition. In contrast, meclofenamate had no effect on the VRAC response to hypoosmotic exposure. Discussion: We conclude G protein coupled receptors are necessary for VRAC activation in these human astrocytoma cells. Exogenous ATP enhances the VRAC response in swollen cells but is not sufficient to activate this current in isoosmotic conditions. The lack of an effect by thrombin exposure suggests protease-activated receptors are not coupled to VRAC in these tumor cells. If endogenously released ATP is responsible for VRAC activation via the P2Y2 receptor, it is not effluxed via gap junction hemichannels. Future studies are needed to measure ATP release during hypoosmotic exposure and identify the specific G protein coupled receptor that mediates VRAC activation.

Title: Neurotoxicity through prolonged adenosine A1 receptor activation: cellular, synaptic plasticity, and behavioral implications in the rat hippocampus

Authors: *J. STOCKWELL[1], D. M. FERGUSON[2], X. QIN[3], Z. MING[1], Z. CHEN[1], F. S. CAYABYAB[4];
[2]Psychology, [3]Hlth. Sci., [4]Surgery, [1]Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Although the adenosine A1 receptor (A1R) is widely accepted as a neuroprotective adenosine receptor in the hippocampus, through inducing synaptic depression during times of metabolic stress, we previously found data to suggest that A1R activation may contribute to widespread neuronal death following focal cerebral ischemia. We first treated acute rat hippocampal slices with the selective A1R agonist CPA, alone or with a subsequent glutamate insult. We found that CPA treatment alone induced significantly more neuronal death than time-matched control slices, and compared to glutamate alone, CPA enhanced the degree of neuronal death caused by glutamate. Using a small tat peptide (YG) designed to prevent A1R-induced AMPA receptor endocytosis, both CPA- and glutamate-induced neuronal death was prevented. We then injected male SD rats with CPA (1mg.kg, i.p. injection daily for 2 days) and saw significant global neuronal death 48 hours following injection, including a high degree of neuronal death within the vulnerable hippocampus. Rats that were injected with the A1R antagonist DPCPX (5mg/kg, i.p.) following CPA treatment showed significantly reduced neuronal death. Additionally, fEPSP electrophysiology experiments on hippocampal slices from CPA-treated rats had impaired chemical LTP (cLTP) induction, whereas DPCPX with CPA-treated rats showed no such impairment. Finally, rats subjected to a small pial vessel disruption (PVD) focal cortical ischemia procedure were tested using a hippocampal-dependent Y-maze behavioral paradigm 48 hours following PVD surgery. PVD caused significantly lower performance compared to sham-operated rats, and animals given DPCPX one hour following PVD surgery had no significant memory deficits. Electrophysiology and post-mortem tissue analysis revealed significantly impaired cLTP and more neuronal death compared to both sham and PVD with DPCPX brains. Together, these results show that persistent adenosine A1R activation induces both neuronal death and memory deficits in the hippocampus. From these studies, we conclude that although the A1R may be neuroprotective in the short term during metabolic stress, prolonged A1R activation triggers an adenosine-mediated excitotoxic potential to ischemia-related neurodegeneration.

Title: Time-of-day dependent expression profile of purinergic receptors in the suprachiasmatic nucleus of the mouse

Authors: *J. J. LOMMEN, A. STAHR, M. INGENWERTH, C. VON GALL;
Heinrich-Heine-University, Inst. of Anat. II, Düsseldorf, Germany

Abstract: Background: Purinergic receptors (PR) mediate the signaling of purines such as adenosine triphosphate (ATP) and adenosine. PR subtypes $P2X_{1-7}$, $P2Y_{1-2}$, $P2Y_4$, $P2Y_6$ and $P2Y_{11-14}$ are highly expressed in the brain and have been implicated in learning and memory, locomotor and feeding behavior, and sleep. As all of these functions follow a 24h rhythm, we tested the hypothesis that PRs are expressed in the circadian rhythm generator, the suprachiasmatic nucleus (SCN), in a time-of-day dependent manner. **Methods:** In order to analyze time-of-day dependent fluctuations of PRs, C57Bl/6 (WT) mice, were kept in a standard 12h light/12h dark (12L:12D) cycle. Zeitgeber time (ZT) 0 is defined as the onset of the light phase (6:00 am). Animals were sacrificed in 4 h intervals throughout the day (ZT02, 06, 10, 14, 18, 22). Expression of 15 PR subtypes ($P2X_{1-7}$, $P2Y_{1-2}$, $P2Y_4$, $P2Y_6$, $P2Y_{11-12}$, $P2Y_{13-14}$) were analyzed by immunohistochemistry. In order to test whether time-of-day dependent fluctuations were driven by light as an external stimulus or endogenously driven by the SCN molecular clockwork, additional animals were kept in constant darkness (DD) and sacrificed 2 hours after (CT02) or before (CT22), the former onset of the light phase, respectively. **Results:** Four of 15 PRs, namely $P2X_3$, $P2X_4$, $P2Y_2$ and $P2Y_{12}$, showed a significant time-of-day dependent fluctuation of the immunoreaction signal. Whereas, $P2Y_2$ exhibits peak expression levels during the light/rest phase (ZT02), $P2Y_{12}$, $P2X_3$ and $P2X_4$ show peak expression levels during the dark/activity phase (ZT22). Interestingly, in DD condition expression levels of all PRs were equally low. This suggests a light-dependent regulation of PRs expression in the mouse SCN. **Conclusions:** 1) $P2Y_2$, $P2Y_{12}$, $P2X_3$ and $P2X_4$ are rhythmically expressed in the mouse SCN. 2) This rhythmic expression is externally driven by the light/dark cycle.

Abstract: Midbrain dopamine neurons are an essential component of the basal ganglia circuitry, playing key roles in the control of fine movement and reward. Recently, it has been demonstrated that γ-aminobutyric acid (GABA), the chief inhibitory neurotransmitter, is co-released by dopamine neurons, however, the mechanisms underlying GABA co-release remains unknown. Here we show that GABA co-release in dopamine neurons does not utilize the conventional GABA synthesizing enzymes, glutamate decarboxylases GAD65 and GAD67. Instead, our experiments reveal an evolutionarily conserved GABA synthesis pathway mediated by aldehyde dehydrogenase 1a1 (ALDH1a1). These findings provide new insights into the functional role of GABA co-release in midbrain dopamine neurons, which may be essential for motor control, reward-based behavior and addiction.

Title: *In vivo* structure-function analysis of neuroligin-2 at GABAergic synapses of somatosensory cortex

Authors: *A. X. YEE[1], T. SÜDHOF[2,3], L. CHEN[4];
[1]Neurosciences Program, Stanford Univ., Stanford, CA; [2]Mol. and Cell. Physiol., [3]Howard Hughes Med. Inst., [4]Dept. of Neurosurg., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Autism Spectrum Disorders (ASDs) and Schizophrenia affect 1-2% of the population, and yet the mechanisms causing these neuropsychiatric disorders are largely unknown. Neuroligins (NLs) are trans-synaptic molecules that mediate synapse formation and maturation, and have been found altered in patients of both ASDs and Schizophrenia. Specifically, it is known that one of the NLs, NL2, affects development of GABAergic synaptic transmission. Studies addressing the structure-function of NLs differ as to whether the extracellular versus intracellular domain is sufficient for NL function (Soler-Llavina 2011, Shipman 2011, Futai 2013). This may be in part due to the fact that previous studies of the structural basis for NL function have been done using overexpression or rescues on a knockdown background, which could be subject to caveats such as dimerization of mutant protein with endogenous NL2. We will therefore perform structure-function analysis of NL2 using *in vivo* viral-mediated rescue in a recently-developed conditional knockout (cKO) mouse, where NL2 can be genetically deleted by Cre-mediated excision (Liang 2015). We have confirmed that as in constitutive NL2 knockouts, postnatal deletion of NL2 leads to reductions in GABAergic transmission onto layer 4 stellate/pyramidal cells of somatosensory cortex (S1). AAV-Cre or ΔCre control was delivered by stereotaxic injection at postnatal day 0 (P0) and GABAergic transmission assayed by acute slice recording of miniature IPSCs (mIPSC) and unitary IPSCs at fast-spiking to pyramidal cell synaptically connected pairs (FS-pyr uIPSC). After 21 days of NL2 deletion, mIPSC frequency and amplitude were both decreased, and FS-pyr uIPSC success rate was decreased at higher presynaptic firing rates (10Hz-20Hz). After 40-60 days of NL2 deletion, the magnitude of mIPSC decreases were similar to 21 days of deletion; decreases in FS-pyr uIPSCs success rate were no longer seen, but prominent decreases in amplitude appeared across a range of presynaptic firing frequencies (1Hz-20Hz). Having established that synaptic transmission is altered at mature GABAergic synapses after NL2 deletion, we will next perform rescues with at least a full-length, wildtype NL2, the extracellular domain of NL2, and a chimera containing the extracellular domain of NL2 and the intracellular domain of NL1. Together, these rescue

experiments should (a) verify the ongoing function of NL2 at GABAergic synapses by rescue in a complete knockout background, and (b) shed light onto whether the intracellular or extracellular domain of NL2 is required for this function.

Title: The gephyrin-interacting protein synArfGEF regulates "mismatched" GABAergic synapses in primary hippocampal neurons

Authors: ***S. FRÜH**, S. K. TYAGARAJAN, J.-M. FRITSCHY;
Inst. of Pharmacol. and Toxicology, Univ. of Zurich, Zurich, Switzerland

Abstract: Postsynaptic differentiation is an important developmental process during synapse formation which is essential for proper synaptic transmission. The accumulation of transmitter-specific receptor, scaffolding and signaling proteins in the postsynaptic density (PSD) depends on transsynaptic signals but is still incompletely understood. *In vivo*, guidance cues as well as transsynaptic adhesion molecules ensure appropriate postsynaptic differentiation corresponding to the presynaptic terminal. However, the absence of such signaling in dissociated neuronal cultures leads to the formation of mismatched synapses, allowing the study of sorting mechanisms between different types of synapses. The guanine nucleotide exchange factor (GEF) synArfGEF was described to be located in GABAergic synapses, although it was first found in the glutamatergic PSD. We report here that synArfGEF can bind to gephyrin, a postsynaptic scaffolding protein specific to GABAergic (and glycinergic) synapses. Coexpression of tagged synArfGEF and eGFP-gephyrin in rat primary hippocampal neurons lead to accumulation of synArfGEF in the GABAergic PSD. Quantitative cluster analysis revealed that coexpression of synArfGEF caused a decreased density of gephyrin and GABAA receptor clusters not apposed to GABAergic terminals. Conversely, overexpression of a catalytic synArfGEF mutant resulted in an increase of VGluT-apposed gephyrin and GABAA receptor cluster density. No change in apposition of GFP-PSD-95 clusters was detected, arguing that synArfGEF specifically regulates the GABAergic PSD. IQ motif in synArfGEF was required both for reduction of mismatched

gephyrin cluster density and for interaction with apocalmodulin. The postsynaptic protein synArfGEF thus regulates GABAergic PSD clustering depending on presynaptic innervation, presumably by activating the small GTPase Arf6. This regulation may be modulated by neuronal activity in glutamatergic synapses as it is dependent on an apocalmodulin-binding motif. Together, our results implicate the postsynaptic protein synArfGEF in differentiation of appropriately matched GABAergic PSDs. Support: UZH-FK grant and SNSF.

Title: Temporal and spatial integration of GABAergic and glutamatergic synaptic inputs in dendrites

Authors: *Y. DEMBITCKAYA[1], Y.-W. WU[2], A. SEMYANOV[1];
[1]Univ. of Nizhny Novgorod, Nizhny Novgorod, Russian Federation; [2]Dept. of Neurosurg., Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: The notion that GABA is main inhibitory neurotransmitter significantly simplifies the repertoire of GABA effects on neuronal computations. In adult brain, GABA can have both depolarizing and hyperpolarizing actions depending on the cell type. The depolarizing GABA inhibits the cell by shunting associated with increased membrane conductance during activation of $GABA_A$ receptors. However, depolarizing GABA can also activate voltage-dependent conductances (e.g. Na^+-channels) bringing the cell to the firing threshold. Which effect will dominate depends on amount of associated $GABA_A$ conductance. If this conductance is high, the shunting inhibition overpowers the excitatory action of GABA. Here we investigated how excitatory or inhibitory actions of GABA depend on temporal and spatial properties of $GABA_A$ receptor mediated membrane depolarization and membrane conductance. We studied the effect of dendritic integration of GABAergic and glutamatergic inputs using mathematical modelling and whole-cell current clamp recordings in CA1 pyramidal neurons or granular cells in mouse hippocampal slices. The intracellular chloride was set to achieve depolarizing effect of GABA.

GABAergic inputs were mimicked by local GABA puff, glutamatergic inputs were mimicked by local glutamate uncaging (uEPSPs). Rapid change in postsynaptic membrane conductance associated with $GABA_A$ receptor activation causes ionic current that gradually polarizes the membrane according to the membrane time constant. When the current (conductance) ceases, the membrane gradually repolarizes. Thus, depolarizing GABA can potentially have excitatory effect during such conductance-free repolarization. However, we could not confirm excitatory action of GABA puff on colocalized uEPSPs during any phase of GABA mediated depolarization. Possibly, the GABA depolarization is relatively small at 'conductance-free' phase to have detectable excitatory action. On the other hand, the conductance is restricted to the location of activated GABAA receptors, while polarization spreads over some distance along the dendrite according to membrane length constant. We found that although GABA puff suppressed colocalized uEPSPs, GABAergic depolarization summed with uEPSP at the distance from the puff. We conclude that depolarizing GABAergic postsynaptic potentials have inhibitory action at the synapse location regardless of coincidence time with EPSP, but excitatory action at the distance from the synapse.

Title: A spatio-temporal analysis of the GABAa receptor-dependent and independent membrane potential response to a gamma-band burst stimulus in area CA1 of hippocampal slice: a VSDI study

Authors: *T. TOMINAGA, Y. TOMINAGA;
Inst. of Neuroscience, Tokushima Bunri Univ., Sanuki, KAGAWA, Japan

Abstract: The gamma-band oscillation occurs in the hippocampus during voluntary behaviors and is thought to relate to learning and the memory process. A stimulation that mimics the

oscillation can induce long-term potentiation in the CA1 region in hippocampal slices, such as a tetanic stimulation and theta burst stimulation. Hence, we aimed to examine the neuronal relevance of the gamma-band neuronal activation with a voltage-sensitive dye (VSD; Di-4-ANEPPS) imaging method. APV (50 μM) was applied to suppress NMDA receptor channels throughout the study. Forty pulses of 100 Hz high-frequency stimulation (HFS) to Schaffer collateral (Sch) caused a long-lasting depolarization in the entire CA1 region, most prominently in the middle of the stratum radiatum (SR), along Sch. The depolarization accompanied the progressive suppression of excitatory postsynaptic potentials (EPSPs) and the supra-recovery of EPSPs after the stimulation. The long-lasting depolarization and the modifications of synaptic transmission were diminished by the application of a GABAa receptor blocker (100 μM PITX). A lasting PITX-sensitive inhibitory postsynaptic current (IPSC) carried by Cl- was recorded from a pyramidal cell with a whole-cell clamp condition. Thus, we concluded that the so-called depolarizing GABA-mediated potential is responsible for the long-lasting depolarization. However, the origin of the IPSC and the cause of the membrane potential reversal from a negative toward a positive direction were not known. To further examine the action of the GABAa response, we applied an AMPA-receptor blocker (10 μM CNQX) and observed 50 ms of hyperpolarization that was followed by long-lasting depolarization. In order to confirm if the potential shift was dependent on the GABAa current, we added PITX. The resulting hyperpolarization took place through the transient depolarization. The inward current not carried by the Cl- current was observed from a pyramidal cell under a whole-cell clamp condition. Low calcium ACSF diminished the transient depolarization, suggesting that the depolarization has a synaptic response. Both hyperpolarization in CNQX + APV and depolarization in PITX + CNQX + APV were more prominent in the perisomatic region than in the SR. The distribution of membrane potential change suggests that the synaptic connections responsible for the inward current have a different distribution than that of the main pathway of Sch. The cellular mechanisms will be discussed.

Title: Striatal dopamine synapses are neuroligin-2-mediated heterologous contacts between dopaminergic presynapse and GABAergic postsynapse

Authors: *M. UCHIGASHIMA, M. WATANABE;
Hokkaido Univ. Sch. of Med., Sapporo, Japan

Abstract: Midbrain dopaminergic neurons send massive projections to the striatum and play an important role in motor and cognitive functions. Although so-called dopamine synapses are formed on striatal projection type neurons, medium spiny neurons (MSNs), dopamine receptors are distributed extrasynaptically, and the molecular organization at synaptic specializations remains elusive. Here we examined the molecular composition of dopamine synapses in the mouse dorsolateral striatum. The presynapse of dopamine synapses was phenotypically dopaminergic, and further expressed active zone protein CAST, and presynaptic adhesion protein neurexin. On the other hand, the postsynapse consisted of GABAergic postsynaptic proteins including GABAA receptor alpha1, its scaffold protein gephyrin, and postsynaptic adhesion protein neuroligin-2. By combining immunofluorescence with single neuron tracing with lentivirus vectors, we found that dopamine synapses were preferentially formed on denditic elements of MSNs where dopamine receptors D1R and D2R were highly expressed. Among postsynaptic molecules expressed at dopamine synapses, neuroligin-2 could induced the presynaptic differentiation in axons of primary midbrain dopaminergic and striatal GABAergic neurons in culture. By sparse knockdown of neuroligin-2 in the striatum, dopamine synapses significantly decreased with reciprocal increase of GABAergic synapses on MSN dendrites. This suggests that neuroligin-2 controls synapse formation in the striatum by giving competitive advantage to heterologous dopamine synapses over conventional GABAergic synapses. Furthermore, the formation of heterologous dopamine synapses may subserve to increasee the target selectivity and potency of dopaminergic modulation through anchoring dopamine release sites to dopamine-sensing striatal neurons.

Title: A-type potassium channels regulate the impact of GABAergic inhibition in pyramidal neurons

Authors: *J. T.-Y. CHANG[1,2], M. J. HIGLEY[1,2];
[1]Dept. of Neurobio., [2]Program in Cell. Neuroscience, Neurodegeneration and Repair, Yale Univ., New Haven, CT

Abstract: Synaptic integration of glutamatergic excitation and GABAergic inhibition forms the basis of neuronal computation in cortical circuits. A large body of evidence demonstrates that dendritic voltage-dependent conductances play an important role in the spatiotemporal integration of excitatory signals. For example, A-type potassium channels restrict the antidromic propagation of somatic action potentials into distal dendrites. Less is known, however, about the role that potassium channels play in the regulation of inhibitory signaling. Here, we combine electrophysiology, optical uncaging of GABA, and two-photon calcium imaging to investigate the actions of A-type voltage dependent potassium channels on inhibitory GABAergic signaling in layer 5 pyramidal neurons of mouse visual cortex. Our results show that blockade of these channels enhances the somatic inhibitory postsynaptic potential (IPSP) evoked by GABA uncaging on either the apical or basal dendrites. In addition, blockade of these potassium channel increases the impact of inhibition on dendritic calcium signals evoked by back-propagating action potentials. These findings provide additional insight into the cellular mechanisms of synaptic integration in neocortical dendrites, and suggest that neuronal activity may dynamically regulate the efficacy of inhibitory synapses.

Title: Evidence that the theory of predictive homeostasis explains the observed strength and decay rate of synaptic inhibition

Authors: J. K. KIM, *C. D. FIORILLO;
KAIST, Daejeon, Korea, Republic of

Abstract: We recently proposed a theory of membrane excitability based on maximizing the information conveyed by spikes from the neuron's point of view (Fiorillo et al., 2014). In order for spikes to be maximally sensitive to the amplitude of synaptic excitation, a large diversity of voltage-gated and synaptic ion channels are proposed to implement "predictive homeostasis" of membrane excitability. The homeostatic ideal is achieved when excitability is such that the peak of an excitatory postsynaptic potential (EPSP) reaches precisely to spike threshold, so that the slightest variation in the amplitude of synaptic excitation determines whether or not there is a spike. This requires that synaptic inhibition and other homeostatic mechanisms accurately predict and counterbalance the amplitude of synaptic excitation, which naturally varies on a timescale of about 1 ms. The theory should allow us to predict the optimal biophysical properties of ion channels and synapses that contribute to homeostasis. Here we characterize the optimal amplitude and decay time of synaptic inhibition. By simulating a single compartment neuron using NEURON software we found the parameter values that minimized 'distance' from the homeostatic ideal at which EPSP peak is at spike threshold. The onset of synaptic inhibition was 1.0 ms after synaptic excitation, as observed experimentally (e.g., Wehr and Zador, 2003; Blitz and Regehr, 2005). Synaptic inhibition maintained homeostasis better than the optimal leak conductance. For synaptic excitation frequencies of 20 to 800 Hz, we found optimal inhibition-excitation peak conductance ratios (I/E) of 0.6 to 2.6 and optimal decay time constants of 2 to 20 ms. As synaptic excitation frequency increased, the optimal I/E increased and synaptic decay time decreased. These theoretical optima are in quantitative agreement with experimental observations. Our results support the theory of predictive homeostasis and illustrate how it can be used to predict biophysical properties.

Title: Inhibitory interneurons differentially contribute to spontaneous network activity in the developing hippocampus dependent on their embryonic lineage

Authors: *J. C. WESTER, C. J. MCBAIN;
NIH, Bethesda, MD

Abstract: Spontaneous, internally generated network activity occurs during postnatal development throughout the central nervous system and importantly guides synapse formation. In the hippocampus, which is crucial for learning and memory, this activity is characterized by giant depolarizing potentials (GDPs) during the first postnatal week. GDPs consist of rhythmic bouts of sustained depolarization that last several hundred milliseconds and propagate as a wave. Although immature excitatory pyramidal cells (PCs) are important for GDP generation, GABAergic interneurons also contribute due to a depolarized reversal potential for chloride, which renders them excitatory. Recently, it was discovered that non-overlapping subtypes of interneurons are generated during embryogenesis from the medial and caudal ganglionic eminences (MGE and CGE). In this study, we investigate how MGE versus CGE interneurons are integrated into the hippocampal circuit and contribute to GDPs during the first postnatal week. Using transgenic Nkx2.1-Cre and 5HT3A-Cre mice to target MGE and CGE interneurons, respectively, we performed whole-cell patch recordings in acute slices from postnatal day 5 to 7 mice. To monitor GDPs, we recorded synaptic currents in an interneuron and neighboring PC. We optogenetically silenced MGE and CGE interneurons by expressing cre-recombinase dependent archearhodopsin which generates a non-inactivating, hyperpolarizing current in response to green light. We found that silencing MGE interneurons strongly suppresses GDPs (frequency reduced by 70%), while those that remain are reduced in duration. In contrast, silencing CGE interneurons has a much less dramatic effect on GDP generation (frequency reduced by 30%), with no effect on GDP duration. In order to understand how MGE versus CGE interneurons differentially contribute to GDPs, we performed dual-whole cell patch clamp recordings to test for synaptic connections between interneurons and PCs. Importantly, immature MGE interneurons and PCs are connected with much greater probability (20% MGE to PC; 16% PC to MGE) than CGE interneurons (4% CGE to PC; 2% PC to CGE). Post hoc morphological analysis revealed that MGE interneurons often target the perisomatic region of PCs, while CGE interneurons do so rarely. Our results reveal that interneurons derived from the MGE integrate into the hippocampal circuitry earlier than those from the CGE, synapse near the spike initiation zone, and crucially contribute to GDP generation.

Title: Impaired synaptic integration in the Ts65Dn mouse model of Down Syndrome is rectified by negative modulation of α5 subunit-containing GABAA receptors

Authors: *J. M. SCHULZ[1], F. KNOFLACH[2], A. THOMAS[3], M.-C. HERNANDEZ[2], J. BISCHOFBERGER[1];
[1]Dept. of Biomedicine, Univ. of Basel, Basel, Switzerland; [2]Roche Pharma Res. and Early Development, Discovery Neurosci., Basel, Switzerland; [3]Small Molecule Research, Roche Innovation Ctr. Basel, Basel, Switzerland

Abstract: GABAergic hyperinhibition has been suggested to contribute to cognitive deficits in mouse models of Down syndrome (Ts65Dn). Specifically, RO4938581, a negative allosteric modulator selective for the α5 subunit-containing GABAA receptors (α5-NAM) has been shown to improve disturbed synaptic plasticity and spatial learning in Ts65Dn mice (Martinez-Cue et al., 2013). However, the underlying circuit mechanisms are largely unknown. Therefore, we investigated synaptic transmission onto CA1 pyramidal neurons in brain slices from Ts65Dn mice and wildtype (wt) littermates. The ratio of inhibitory postsynaptic currents (IPSC) measured at 0 mV to excitatory PSC amplitude measured at -70 mV after Schaffer Collateral (SC) stimulation was 1.4 ± 0.2 (n=7) in Ts65Dn mice, significantly larger than 0.6 ± 0.1 (n=9) in wt littermates ($P<0.01$). Stimulation of local inhibitory inputs showed that the α5-NAM specifically reduced slow dendritic IPSCs evoked in stratum lacunosum moleculare to 64.4 ±14.4% of the control amplitude, whereas somatic IPSCs evoked in stratum pyramidale remained unaffected. We confirmed the dendritic nature of the α5-NAM-sensitive inputs, using spatially localized GABA release in the presence of TTX from VGAT-channelrhodopsin expressing interneurons. Remarkably, application of the α5-NAM increased excitatory postsynaptic potentials evoked by burst stimulation up to 137.0 ±15.8% (n=8) in TS mice similar to wt mice (148.7 ±14.5%, n=9). Furthermore, impaired theta-burst stimulation-induced LTP in Ts65Dn mice (110.1 ± 3.1%, n=19; wt: 127.1 ± 7.2%, n=14; $P<0.05$) was rectified by acute application of the α5-NAM (122.9 ± 6.2%, n=11). These results demonstrate that α5-NAM counteracts increased dendritic inhibition in Ts65Dn mice to allow for normal dendritic integration of synaptic inputs essential for synaptic plasticity and learning. Title: Reciprocal circuits linking the prefrontal cortex and thalamus

Authors: ***J. J. MARLIN**, A. G. CARTER;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The prefrontal cortex (PFC) communicates with multiple brain areas to regulate cognitive function. Bidirectional interactions between the PFC and thalamus play a key role in working memory and attention. While multiple thalamic nuclei are associated with the PFC, the cellular and synaptic properties of these connections are unknown. Here we use anatomical tools, whole-cell recordings, two-photon microscopy and optogenetics to study these circuits. We identify new populations of corticothalamic neurons in the PFC that project to both dorsal and ventral thalamus. We determine how these neurons are differentially innervated by reciprocal inputs from these regions. We next examine the properties of thalamocortical neurons in both dorsal and ventral thalamus that project to the PFC. We also show how these neurons selectively respond to reciprocal inputs from the PFC. Finally, we assess the extent to which this circuitry allows the PFC to serve as a bridge between dorsal and ventral thalamus. Our findings reveal novel neurons and connections that link the PFC and thalamus, which have important implications for our understanding of cognitive processing.

Title: Excitatory and inhibitory circuits regulating interactions between the PFC and BLA

Authors: *L. M. MCGARRY, A. G. CARTER;
New York Univ., New York, NY

Abstract: The prefrontal cortex (PFC) plays a key role in cognitive and emotional behavior, as highlighted in multiple neuropsychiatric diseases. Control of emotion is thought to critically depend on long-range interactions between the PFC and basolateral amygdala (BLA). Axons from the BLA ramify throughout distinct layers of the PFC, where they are poised to contact multiple neurons. Here we combine whole-cell recordings and optogenetics to study this influence within the adult mouse PFC. We first characterize the properties of different projection neurons that project to distinct downstream nuclei. We determine that BLA inputs make much stronger connections onto corticoamygdala neurons (CA) that project back to the BLA. We then examine the properties of different interneurons that can control circuit activity in the PFC. We show that BLA inputs make unique connections onto parvalbumin (PV) and somatostatin (SOM) interneurons compared to nearby projection neurons. We then assess how these two interneuron subtypes make selective connections onto different types of projection neurons. Finally, we establish the sequence by which BLA inputs activate projection neurons and interneurons in the PFC. Together, our findings reveal the functional properties of both long-range and local circuits in the PFC, with important implications for function and disease.

Title: Characterization of inhibitory and excitatory synaptic input recruited by neocortex or amygdala stimulation in perirhinal and entorhinal neurons *ex vivo*

Authors: *J. G. WILLEMS, P. CHAMEAU, T. R. WERKMAN, W. J. WADMAN, N. L. M. CAPPAERT;
Swammerdam Inst. for Life Sci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The insular cortex (neocortical area, NC) and lateral amygdala (LA) both project to the perirhinal (PER) and entorhinal (EC) network. The NC input first recruits all layers of the PER and subsequently the EC. Input from the LA primarily recruits the deep layers of the PER/EC network and subsequently the superficial layers (Willems et al., SfN, 2014-752.03). This study compared synaptic responses and the inhibitory-excitatory (I-E) balance evoked by NC or LA electrical stimulation in PER and lateral EC (LEC) deep layer neurons, in order to address how the PER/EC local circuitry is recruited by NC and LA inputs. Whole-cell voltage-clamp recordings were made in deep layer principal neurons in the PER and LEC in horizontal mouse acute brain slices. Synaptic responses were evoked by electrical stimulation of the NC or LA. NC stimulation evoked a larger peak current amplitude than LA stimulation in both PER and LEC neurons, clamped at -70 mV (PER: NC 268 ± 55 pA, LA 72 ± 21 pA, $p = 0.0015$, $n = 10$; LEC: NC 198 ± 66 pA, LA 66 ± 21 pA, $p = 0.019$, $n = 9$). Furthermore, the latency of NC evoked responses in PER neurons (6 ± 0.4 ms) was smaller than in LEC neurons (13 ± 2.7 ms, $p = 0.001$). LA evoked response latency was similar in PER (9 ± 1.6 ms) and LEC (10 ± 1.4 ms) deep layer neurons. Linear decomposition of the total evoked synaptic conductance separated the excitatory (gE) and inhibitory conductance (gI) in PER and LEC neurons. The NC evoked peak gI and gE were larger than LA evoked conductances in PER and LEC neurons. The latencies of the peak gI and gE evoked by NC stimulation were similar in PER and LEC neurons. The latency of the peak gI evoked by LA stimulation was larger than for the peak gE in PER (gI: 25 ± 4 ms, gE: 15 ± 3 ms, $p = 0.016$), but not LEC neurons (gI: 16 ± 3 ms, gE: 13 ± 2 ms). The I-E balance was defined as the fractional inhibition (I/I+E) calculated from each conductance integrated over the first 75 ms after stimulus. The I-E balance in PER and LEC neurons combined was similar for NC and LA stimulation (I-E balance: NC 70-30 ± 4%, LA 75-25 ± 3%, $n = 19$). Cortical circuits often maintain a critical I-E balance. In PER and LEC neurons that receive both NC and LA input, NC stimulation recruited larger synaptic currents than LA stimulation. NC stimulation sequentially recruited first PER and then LEC neurons, which could be explained by a longer axonal distance for LEC projections. LA stimulation synchronously recruits neurons in the deep layers of PER and LEC. Despite these intricate NC and LA evoked response differences, the recruited I-E balance seems to be maintained on around 73-27%, suggesting that NC and LA inputs recruit a comparable local circuitry in both the PER and LEC.

Title: Differential synaptic connectivity and physiology at layer 5 pyramidal neurons in the prefrontal cortex

Authors: P. G. ANASTASIADES, J. J. MARLIN, *A. G. CARTER;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The prefrontal cortex (PFC) is populated by multiple types of pyramidal neurons, which project to diverse cortical and subcortical targets. Recent studies indicate that corticocortical neurons in layer 5 are distinct from adjacent corticothalamic neurons. For example, corticocortical neurons have more compact dendritic morphology and greatly reduced h-current. However, questions remain about the engagement of these neurons by both local and long-range synaptic inputs. Here we use a combination of whole-cell recordings, two-photon microscopy and optogenetics to examine synaptic responses at neighboring corticocortical and corticothalamic neurons in mouse PFC. We find cell-type specific differences in responses to long-range excitatory inputs from both the cortex and thalamus. We also observe different responses to local inhibitory inputs from both parvalbumin (PV) and somatostatin (SOM) expressing interneurons. Finally, we show that h-current plays a critical role in shaping the responses to these different types of synaptic inputs. Together, our findings illustrate several unique functional properties of different populations of pyramidal neurons in the PFC, with important implications for the function and modulation of neural circuits.

Title: Non-linear synaptic integration on striatal spiny projection neuron dendrites is supported by clustered corticostriatal inputs

Authors: *Y.-W. WU, R. LALCHANDANI, J. B. DING;
Dept. of Neurosurg., Stanford Univ., Palo Alto, CA

Abstract: The dorsolateral striatum of the basal ganglia plays a critical role in action selection and motor control. Striatal spiny projection neurons (SPNs) receive convergent glutamatergic inputs from both motor and sensory cortices, and these inputs form intermingled synapses throughout SPN dendrites. However, how functional inputs from distinct cortical regions are distributed and integrated on the dendrites of SPNs remains largely unknown. Here, we use optogenetic activation of neurons in the primary motor (M1) or primary sensory (S1) cortex combined with two-photon calcium imaging to identify the subcellular distribution of functional corticostriatal synapses. We found that inputs from S1 and inputs from M1 form clusters on SPN dendrites. Simultaneous activation of clustered excitatory inputs using two-photon glutamate uncaging resulted in non-linear integration of excitatory postsynaptic potentials (EPSPs), which could lead to an all-or-none dendritic plateau potential that was dependent on NMDA receptor activation. Our study thus suggests that corticostriatal inputs from functionally relevant cortical areas form clusters onto the dendrites of striatal SPNs to support non-linear synaptic integration in the striatum.

Title: Subthreshold electrical signaling in dendritic spines: modeling and measurements

Authors: M. A. POPOVIC[1], N. T. CARNEVALE[2], *D. ZECEVIC[1];
[1]Dept Cell & Mol. Physiol, [2]Dept Neurobio., Yale Univ. Sch. Med., New Haven, CT

Abstract: Thousands of dendritic spines on individual neurons process information and mediate plasticity by generating electrical input signals using a sophisticated assembly of transmitter receptors and voltage-sensitive ion channel molecules. Our understanding, however, of the electrical behavior of spines is limited because it has not been possible to record input signals from these structures with adequate sensitivity and spatiotemporal resolution. Current interpretation of indirect data and speculations based on theoretical considerations are controversial and inconclusive. On the conceptual level, a key question that has not been answered is whether the hypothetical electrical isolation of synapses on spine heads caused by a narrow spine neck is responsible for specific functions which are not supported by synapses on dendrites. Here we use multicompartmental modelling approach based on widely accepted electrical behavior of dendritic cables and experimentally determined dendritic diameters from live neurons to predict the amplitude and the time course of EPSP_spine, EPSP_dendrite, and attenuation ratio AR= EPSP_spine/ EPSP_dendrite for a given synaptic current (I_synapse) for spines at all dendritic locations. Because the calculated dendritic input resistance (Z_dendrite) in the model was much larger than R_neck in most parts of the dendritic tree, the AR was close to unity in these regions. Additionally, because our model shows relatively small spine neck resistance and comparatively high and variable dendritic impedance, the spatial pattern of EPSP_spine amplitudes follows the classical spatial distribution of local dendritic input impedance. To test theoretical predictions by experimental measurements, we developed a technique based on an electrochromic voltage-sensitive dye which can be thought of as a transmembrane optical voltmeter with a linear scale capable of monitoring directly and simultaneously electrical signals from individual spines and parent dendrites. In agreement with modelling predictions, the measurement results demonstrated that synapses on spines are not electrically isolated by the spine neck to a significant extent. Electrically, they behave as if they are located directly on dendrites. Our data agree with old and new evidence based on 2-photon measurements of diffusional resistance of the spine neck as well as with recent 2-photon calcium measurements showing a clear lack of correlation between spine neck lengths and the EPSP rise

time and associated Ca signal in the spine head. At the same time, our data argue against a number of hypothetical functional implications based on large spine neck resistance.

Title: A-type K^+ channels impede supralinear summation of clustered glutamatergic inputs in basal and oblique neocortical dendrites

Authors: A. BIRO[1], A. BREMAUD[2], J. FALCK[2], *A. RUIZ[2];
[1]Pharmacol., [2]UCL Sch. of Pharm., London, United Kingdom

Abstract: Dendritic A-type K^+ channels narrow the time-window for synaptic integration. They reduce the amplitude of back-propagating action potentials and participate in several forms of synaptic plasticity. In neocortical layer 5 pyramidal cells, such channels restrain the spread of regenerative potentials and Ca^{2+} transients from apical and tufted dendrites, resulting in strong compartmentalization of signals. However, the functional significance of A-type K^+ channels present in the fine dendrites of cells located in superficial layers of the neocortex is poorly understood. Here, we use two-photon laser-scanning microscopy and glutamate uncaging in *ex vivo* mice brain slices to identify the A-type K^+ channel subtypes involved in signal integration within basal and apical oblique dendrites of layer 3 pyramidal cells. We combine it with computational modeling to examine how changes in dendritic electrical properties and A-type conductance density distribution affect the summation of synaptic potentials. Blocking Kv4.2 and Kv4.3 channels with phrixotoxin-2 enhances the responses elicited by glutamate uncaging at single spines. A millimolar concentration of 4-AP reported to block Kv1.4 has no effect. Both 4-AP and phrixotoxin-2 increase supralinear summation of glutamatergic potentials evoked by synchronous activation of neighboring spines. In a model, the effect of 4-AP is replicated using

either a homogenous distribution or a linear density gradient of dendritic A-type conductance. Thus, Kv4 channels modulate glutamatergic signals at single synaptic inputs whereas Kv1s require the synchronous activation of multiple inputs to regulate the gain of dendritic integration.

Title: Direct electrical recordings from dendritic spines using nano-pipettes

Authors: ***K. JAYANT**[1], J. J. HIRTZ[2], I. J.-L. PLANTE[3], D. M.-T. TSAI[4], W. D. BOER[3], A. SEMONCHE[2], D. PETERKA[2], J. S. OWEN[3], O. SAHIN[2], K. L. SHEPARD[4], R. YUSTE[2]; [1]Electrical Engin. and Biol. Sci., [2]Biol. Sci., [3]Dept. of Chem., [4]Electrical Engin., Columbia Univ., New York, NY

Abstract: Dendritic spines (volume~0.001-0.1 μm^3) are connected to the dendritic shaft through a narrow neck (diameter~0.1μm, length~1μm). Biochemical compartmentalization in spines has been observed by two-photon calcium imaging, however, their function as electrical compartments are still unclear. Neurotransmitter activation of receptors located on the spine head cause excitatory postsynaptic potentials (EPSPs) which eventually shape the downstream dendritic and somatic EPSP. The spine neck could play a major role during this signal processing by rectifying the EPSP as it invades the dendrite while allowing back propagating action potentials and dendritic signals to fully invade the spine. Previous work has supported this hypothesis either computationally or indirectly through optical indicators. The major reason for lack of direct evidence is the small size of the spine head and neck region which makes electrical readout through conventional patch clamp electrophysiology impossible. Here we report direct electrical recordings from dendritic spines using quartz nano-pipette electrodes (diameters ~15-30 nm). We used mouse hippocampal cultures (E18 or P0) and coronal neocortical slices (P7-P15) as experimental preparations. After establishing a conventional somatic patch clamp and backfilling the cell with a dye, dendritic spines (within 100μm from the soma) were located

along dendrites. Carefully compensated nano-pipettes (amplifier input impedance ~1,000GΩ, capacitance compensation ~7-10pF) coated with CdSe/CdS/ZnS quantum dots (QD's) were steered towards the chosen spine. This was entirely carried out under two-photon visualization, rendering the approach applicable in deep scattering tissue. The use of QD's allowed the tip of the nano-pipette to be localized. Upon entry into the spine head via a “touch and buzz” approach, we registered both bAP and spontaneous EPSPs. Resting membrane potentials ranged between -45 and -65 mV (mean ~-53mV). The effect of access resistance and filtering was deconvolved offline to reveal full bAP invasion into the spine. EPSP amplitudes ranged between 15-55mV (mean ~32mV) while simultaneous somatic EPSP amplitudes were very small (<1mV) and, in some cases, non-existent, indicative of strong electrical compartmentalization in the spine head. Additionally, since the impaled nano-pipette interface forms a resistance divider with the spine neck, we calculated neck resistance values through bAP amplitudes to reveal a range ~70-600MΩ (mean ~230MΩ). Our results suggest that dendritic spines behave as separate electrical compartments. **Supported by** NIH RO1 R01MH101218, ARO W911NF-12-1-0594 (MURI)

Abstract: Despite the great efforts of many researchers the functional circuitry of the visual system is still enigmatic. That is especially true regarding the small local functional circuits and the input characteristics of the visual cortical neurons. Knowledge about the incoming and outgoing information and their relation would add a lot to the understanding of visual processing and eventually to the understanding of the general principles of cortical processing. The new possibilities offered by fast 2 photon laser scanning microscopy and the use of genetically encoded neuronal indicators make possible to investigate the above synaptic processing in an unprecedented way to give new insights into the processing. We imaged calcium-indicator expressing neurons *in vivo* in the mouse visual cortex (V1) with two photon laser scanning microscope through a cranial window during active behavior. We mapped dendritic arbors of visual cortical neurons, determining the relationship between spine selectivity, branch selectivity and neuronal selectivity in several neurons in different cortical depths. We have used classical direction-selectivity paradigms, along with other stimulation paradigms. The near-cubic-millimeter scan range, with a high scanning speed (up to 500 pts per kHz), with 470 nm × 490 nm × 2,490 nm resolution in the center core and less than 1.9 μm × 1.9 μm × 7.9 μm resolution throughout the entire scanning volume allows us a very precise functional mapping at different areas and depths of the mouse visual cortex. We also had to develop a high-precision motion artifact compensation algorithm to make possible valid measurement of small neural tissue volumes during activity. Here we present the results, analysis and interpretation of this series of measurements along with the motion-compensation algorithm and its possible uses in *in vivo* experiments with behaving animals.

Title: The synaptic basis of the pattern-electroretinogram (PERG)

Authors: *N. TORRES JIMENEZ[1], E. GUSTAFSON[2], R. F. MILLER[2];
[2]Neurosci., [1]Univ. of Minnesota, Minneapolis, MN

Abstract: The pattern-electroretinogram (PERG) has been used for clinical diagnosis and scientific studies of retinal function because a patterned visual stimulus is unique in activating retinal ganglion (RGC) and amacrine cells. Although it is generally agreed that the PERG is generated by ganglion cells, the contribution of ganglion cell synaptic receptors has not been resolved with clarity. Our goal is to understand how different levels of D-serine determine the conditions under which the PERG signal reveals an N-methyl-D-aspartate (NMDA) and an Amino-3-hydoxy-5 methyl-4-isoxazolepropionic acid (AMPA) receptor component in the retina. We hypothesize that a reduction in D-serine reflects the NMDAR hypofunction found in schizophrenic patients, and that the lack of D-serine impacts the expression of NMDA receptors in the retina such that abnormities can be observed from PERG. In this study we conducted extracellular recordings from normal (SRWT) and D-serine deprived (SRKO) mice and pharmacologically reduced and enhanced the activity of NMDA receptors with antagonists to evaluate the NMDA component of the PERG. We performed extracellular recordings using an unanesthetized (after perfusion has started), perfused retina eye-cup preparation of male mice between 3 to 5 months of age. The group delineation is based on whether or not they received a pharmacological manipulation. Those mice in the experimental group were treated with D,L-AP7 (NMDAR antagonist) and NBQX (AMPAR antagonist) and D-serine (NMDAR co-agonist), while also blocking inhibitory inputs using a combination of strychnine (glycine receptor antagonist), picrotoxinin (GABAR antagonist) and TPMPA (GABAcR antagonist). Results from our pharmacological studies indicate that the positive component of the PERG, known as the P50 in clinical literature, is largely composed of NMDA and AMPA receptor contributions due to its elimination when the NMDA and AMPRA receptor antagonist were introduced. And, that D-serine deprived mice (SRKO) have a reduced positive component in comparison to wild-type. This study highlights the importance NMDA and AMPA receptors for generation of the positive component of the PERG.

Title: Astrocytes release glutamate or ATP depending on neuronal activity

Authors: *A. COVELO, A. ARAQUE;
Univ. of Minnesota, Minneapolis, MN

Abstract: Astrocytes are the most abundant cells in the brain and they are actively involved in brain function, playing important roles in synaptic formation, neurotransmitter uptake, water balance and blood flow control. During the last decades, increasing evidence has shown that astrocytes communicate with the pre and postsynaptic terminal, modulating synaptic transmission through the release of gliotransmitters. We have investigated whether a single astrocyte can release different gliotransmitters and characterized the conditions that lead to the release of specific gliotransmitters. We found that that the activation of one astrocyte induce the release of glutamate and ATP, which led to a temporal biphasic modulation (potentiation and depression) of the probability of neurotransmitter release at single CA3-CA1 hippocampal synapses. Activation of astrocytes by high frequency stimulation of Schaffer collaterals, neuron-released endocannabinoids or GABA induced an initial fast and transient (< 3min) synaptic potentiation mediated by glutamate followed by a slower and longer lasting (10-15 min) synaptic depression mediated by ATP/adenosine. The amplitude and time course of the synaptic potentiation and depression depended on the frequency and duration of the neuronal activation. These results indicate that single astrocytes decode neuronal activity pattern and consequently release distinct gliotransmitters that differentially regulate neurotransmission at single synapses.

Title: Modulation of sensorimotor gating through PnC afferent structures

Authors: *J. C. CANO, S. A. PACE, K. FENELON;
Biol. Sci., The Univ. of Texas At El Paso, El Paso, TX

Abstract: Sensorimotor gating is a neuronal sensory filtering process that is thought to be governed by central inhibitory mechanisms to help focus attention (Perry and Braff 1994; Swerdlow 1996). Sensorimotor gating is impaired in many psychiatric and neurological disorders including anxiety, schizophrenia, and post-traumatic stress disorder which affect populations worldwide. Patients suffering from these (otherwise unrelated) diseases all show attention deficits that negatively affect education, work, daily life, and social insertion/relations. At the present time, there is no treatment for sensorimotor gating deficits and the attention impairment associated with these diseases. Despite much scientific effort, the brain regions and neural circuits underlying sensorimotor gating are still ill defined, even in healthy subjects. Therefore, the objective here was to further identify the neural elements and connections of the caudal pontine reticular nucleus (PnC), a brain stem structure that is at the core of the sensorimotor gating circuit (Fendt et al., 2001). Better understanding the functional connection of this key brain region under normal conditions might reveal potential therapeutic targets for future medical interventions in diseases associated with attention deficits. We hypothesized that synaptic connections between the PnC and different brain regions essential for sensorimotor gating remained to be identified. To test our hypothesis, we performed a unilateral injection of the retrograde tracer Fluoro-Gold^{TM} (FG) in the PnC of adult mice (N = 5). Following a 1-week recovery period, thin brain sections (50 μm) were made and FG-labelled cell bodies were found, for the first time, in the basolateral (BLA) and the medioventral (MeV) amygdala. To further determine whether the amygdala sends excitatory inputs to PnC neurons, Channelrhodopsin-2 (ChR2) was injected in the amygdala of mice (N = 3), under the control of the CaMKIIα promoter. Extracellular field electrophysiology recordings showed that photostimulation of ChR2-labelled amygdala fibers induced excitatory synaptic responses in acute PnC slices. We conclude that excitatory afferents from the BLA and MeV projecting into the PnC have the potential to modulate sensorimotor gating.

Title: Nanocomposite biomaterials based on natural polysaccharides for the development of new cell-instructive 3D scaffold driving central nervous system (CNS) reconstruction

Authors: *M. MEDELIN[1], M. PULIN[1], D. PORRELLI[1], A. TRAVAN[1], M. BORGOGNA[1], M. COK[1], I. DONATI[1], E. MARSICH[2], S. PAOLETTI[1], S. BOSI[2], M. PRATO[2], R. SCARDIGLI[3], L. BALLERINI[4];

Abstract: The merging of technology and material sciences in modern neuroscience promoted significant progress in developing structural scaffolds functionally integrated to the CNS. In recent years we participated to an increased interest and an improved understanding in micro and nano-engineered materials developed to investigate emergent biological adaptive and integrated behaviours in neuronal networks. Our major goal is to develop a new generation of biomaterial-based multifunctional implants able to improve our exploring of fundamental biological phenomena as well as to contribute to biomedical and clinical applications. To this aim, we tested two natural polysaccharides, chitosan and alginate, and a natural-based polymer named chitlac, derived from N-alkylation of chitosan with lactose (D'Amelio et al., 2013), as possible candidates for the production of therapeutic implantable devices. Firstly, we selected a simplified network model, dissociated hippocampal cultures derived from P2-P3 rats, to study neurons interaction when interfaced with different 2D polymer substrates. Biomaterials biocompatibility was proved by immunofluorescence and electrophysiological experiments and, additionally, chitlac-based substrates gave rise to a significantly improved neuronal network reconstruction based on morphological and functional analysis. Moreover, to evaluate the possibility to integrate stem cells as source of neurotrophins in the future 3D bioactive scaffold we tested their impact on the neuronal network construction. Neurons co-cultured with mesangioblasts (MABs) producing BDNF or NGF (Su et al., 2012) developed differently leading to a synaptic activity characterized by increased frequency and amplitude of heterogeneous post-synaptic currents (PSCs). Taken together, these results highlight new strategies to be exploited in order to develop a novel implantable device for the CNS. The further incorporation of nanomaterials such as carbon nanotubes (CNTs; Fabbro et al., 2013) to compensate for natural polysaccharides limits, such as the lack of electrical conductivity, will make these biomaterials even more promising.

Title: Artificial 3D networks as novel tools to investigate plasticity phenomena in reconstructed neuronal networks

Authors: *R. RAUTI[1,2], S. BOSI[2], M. PRATO[2], D. SCAINI[2], L. BALLERINI[3];
[1]SISSA, Trieste, Italy; [2]Univ. of Trieste, Trieste, Italy; [3]sissa, Trieste, Italy

Abstract: The generation of genuine artificial 3D neuronal networks of primary neurons is a current challenge in neuroscience. Two-dimensional cultures of primary neurons have been extremely useful to study the molecular mechanisms modulating neuronal growth and survival, however they represent an oversimplification of the brain's sub regions structure [1]. Recently in our laboratory we succeeded in obtaining rat dissociated hippocampal cultures cultured in a novel biocompatible, elastomeric polymer based, scaffold able to foster 3D organization, in terms of cellular soma location and neuronal processes growth. Our results demonstrated the remarkable ability of the 3D geometry itself to boost signal transmission, when compared to the 2D counterpart, in terms of an increase in event-frequency and synchronization [2]. As a natural consequence of these discoveries we are now reporting on the effect of the 3D organization on long-term potentiation. LTP is of fundamental importance because of its implication in learning and memory as well as other physiological and pathological processes in real brain networks [3], by definition intrinsically three-dimensional. The question we wish to answer is if the 3D configuration could lead to a different way of learning by synaptic networks. For this reason, we have grown hippocampal neurons for 19-21 days-in-vitro and we investigated the induction of functional and morphological plasticity in the 3D networks comparing the Ca2+ signaling response of the network to its 3D organization via confocal and scanning electron microscopy (SEM) reconstructions. Following a brief glutamate application, we found a different reactivity to glutamate and a distinct activation of the different receptor types in the 3D networks when compared to control 2D systems. Title: Time translational invariance, the propagation of graded information and the structure of information coding in neural circuits

Authors: *A. T. SORNBORGER[1], Z. WANG[2], L. TAO[3];
[1]Dept Mathematics, Mathematics, Davis, CA; [2]Ctr. for Bioinformatics, [3]Centers for Bioinformatics and Quantitative Biol., Peking Univ., Beijing, China

Abstract: Neural oscillations can enhance feature recognition, modulate interactions between neurons, and improve learning and memory. Numerical studies have shown that coherent spiking can give rise to windows in time during which information transfer can be enhanced in neuronal networks. Unanswered questions are: 1) What is the transfer mechanism? And 2) how well can a transfer be executed? Here, we present a pulse-based mechanism by which a graded current amplitude may be *exactly* propagated from one neuronal population to another. The mechanism relies on the downstream gating of mean synaptic current amplitude from one population of neurons to another via a pulse. Because transfer is pulse-based, information may be dynamically routed through a neural circuit with fixed connectivity. We demonstrate the transfer mechanism in a realistic network of spiking neurons and show that it is robust to noise in the form of pulse timing inaccuracies, random synaptic strengths and finite size effects. We also show that the mechanism is structurally robust in that it may be implemented using biologically realistic pulses. The transfer mechanism may be used as a building block for fast, complex information processing in neural circuits. We demonstrate this by presenting a framework wherein neural information coding and processing can be considered as a product of linear maps

under the active control of a pulse generator. Distinct control and processing components combine to form the basis for the binding, propagation, and processing of dynamically routed information within neural pathways. Using our framework, we construct example neural circuits to 1) maintain a short-term memory, 2) compute time-windowed Fourier transforms, and 3) perform spatial rotations. We postulate that such circuits, with automatic and stereotyped control and processing of information, are the neural correlates of Crick and Koch's zombie modes.

Title: Precise balance between contrast tuning of excitation and inhibition enables reliable directional selectivity computation in the retina

Authors: *A. POLEG-POLSKY, J. S. DIAMOND;
Synaptic Physiol. Section, NIH/NINDS, Bethesda, MD

Abstract: Retinal direction selective ganglion cells (DSGCs) compare the ratio between synaptic excitatory/inhibitory (E/I) inputs to compute direction selectivity (DS). Their synaptic input is mediated primarily by direct bipolar and feed forward starburst amacrine cells (SACs) pathways. This circuitry can potentially bias synaptic signals in a contrast dependent manner unless the two pathways are not well balanced. Here we show that the E/I ratio in DSGCs is preserved over a wide contrast range. The mechanism that maintains the E/I balance is an enhanced contrast sensitivity of SAC inputs, which compensate for nonlinear synaptic processing in SACs. This phenomenon is mediated by differential contrast tuning between classes of bipolar cells but not within a single bipolar cell. Numerical simulations show that this network arrangement is crucial for an effective DS computation.

Title: The age of the astrocytes affects neuronal growth

Authors: *S. HASHEMIAN[1], J. PHILLIPS[2], S. AF BJÉRKEN[3], I. STRÖMBERG[3]; [1]Pharmacol. and Clin. Neurosci., Umea Univ., Umea, Sweden; [2]Univ. Col. London, London, United Kingdom; [3]Integrative Med. Biol., Umea, Sweden

Abstract: One obstacle with transplantation therapy in Parkinson's disease is the insufficient reinnervation of the host brain by the grafted dopamine neurons. A feasible strategy to overcome this barrier and unravel the underlying mechanisms is to monitor the prospective interaction between the donor fetal tissue and the adult host astrocytes *in vitro*. Therefore, ventral mesencephalic (VM) organotypic tissue cultures from embryonic days (E) 12, E14, and E18 were studied up to 35 days *in vitro* (DIV). In addition, co-cultures of E14 VM tissue and adult green fluorescent protein (GFP) -positive astrocytes were explored. Temporal appearance of tyrosine hydroxylase (TH) -positive nerve fibers from the tissue slice were the first non-glial-associated nerve fibers, followed by the second wave of outgrowth associated with migrated astroglia monolayer formed surrounding the VM tissue. Briefly, the results showed that the non-glial-associated nerve fiber outgrowth was dominant in E14 and absent in E18 cultures. The glial-associated-nerve fiber outgrowth, in E12 and E14 cultures, reached a plateau at 21 DIV. In E18 cultures, TH-positive neurons migrated onto the astrocytic monolayer and displayed short processes. In the co-cultures, the GFP-positive astrocytes were generally located distal to the monolayer of migrated fetal astrocytes; however, a few GFP-positive cells were placed within the fetal astrocytic monolayer and TH-positive neurons migrated towards them. Both the non-glial- and glial-associated-nerve fibers grew onto GFP-positive cells. It is concluded that the glial-associated nerve fibers have limited outgrowth compared to the non-glial-associated ones, while none of them were hampered by the mature astrocytes.

Title: Astroglial-mediated remodeling of the interhemispheric midline is exclusive to eutherian mammals and underlies the formation of the corpus callosum

Authors: *I. GOBIUS[1], L. MORCOM[1], R. SUAREZ[1], J. BUNT[1], P. BUKSHPUN[2], W. REARDON[5], W. B. DOBYNS[6], J. L. R. RUBENSTEIN[3], J. BARKOVICH[4], E. H. SHERR[2], L. J. RICHARDS[1,7];

Inst., Seattle, WA; [7]Sch. of Biomed. Sci., Univ. of Queensland, St Lucia, Australia

Abstract: The corpus callosum forms the primary connection between the cortical hemispheres in the brains of eutherian (or placental) mammals. Congenital absence (or agenesis) of this major fiber tract is a common neurodevelopmental disorder that affects neurological function, yet the etiology underlying this disorder is poorly understood. We identify that a key process required for midline crossing of callosal axons is the remodeling and degradation of the intervening interhemispheric fissure by astroglia during development. *In vivo* gain- and loss-of-function experiments in mice show that this process is initiated by Fgf signaling, which then activates downstream Nfi transcription factors via the Map kinase pathway. Activation of this pathway promotes the transition of radial glia into multipolar astroglia, which intercalate with one another and proteolytically degrade the intervening fibroblast tissue to provide a permissive substrate for callosal axon navigation. Neuroimaging studies suggest that defects in this process and consequent aberrant retention of the interhemispheric fissure are a predominant cause of human callosal agenesis. Furthermore, comparative analyses show that remodeling of the interhemispheric fissure does not occur in acallosal mammals, such as marsupials and

monotremes, strongly suggesting that this glial-mediated process is associated with the phylogenetic origin of the corpus callosum.

Title: The radial glia role on angiogenesis in the developing cerebral cortex

Authors: *J. SILVA, M. SIQUEIRA, D. FRANCIS, D. GISBERT;
Inst. de Ciências Biomédicas, Univ. Federal Do Rio De Janeiro, Rio de Janeiro, Brazil

Abstract: Angiogenesis during CNS development is an essential event to provide oxygen and nutrient support to brain tissue. In early stages of the developing CNS, precursor endothelial cells (ECs) from perineural vascular plexus, invade the neural tissue and migrate using the elongated processes of the Radial Glia (RG) neural stem cells as substrate to form the first blood vessels of the brain. Dysfunctional interactions between EC and RG cells impair EC invasion and migration to brain tissues which abrogates blood brain barrier (BBB) development. We previously showed that growth factor TGF-β1 is a potent regulator of RG morphology and differentiation into astrocytes, a cell element of BBB, *in vitro* and *in vivo*. Here we develop a protocol for isolation of murine cerebral ECs to analyze the role of RG-secreted TGF-β1 on angiogenesis in the developing cerebral cortex (Cc) and investigate the role of ECs on RG fate determination *in vitro*. ECs from P7 Swiss mice Cc were isolated and characterized by phase contrast microscopy, immunocytochemistry, RT-PCR, and endothelial tube formation in Matrigel. RG cultures were treated with TGF-β1 and ECs, previously labeled with Cell Tracker dye, were plated on the top of RG cells. In addition, ECs were subjected to Scratch migration assays in presence of RG-conditioned medium (CM). The expression of angiogenesis related genes by ECs, was analyzed

by real time RT-PCR. Further, we performed an Angiogenesis Proteome assay of RG-CM. Finally, we cultivated RG cells in the presence of EC-CM. Our results indicate that ECs isolated using our protocol, express EC markers (PECAM1, vWF, IB4, ZO-1, GLUT1) and form endothelial tubes in Matrigel. TGF- β1-treated RG cells becomes more permissible to EC's invasion/insertion to RG monolayers, as well as the RG-CM promotes a 4x increase in ECs migration on Scratch. Addition of TGF-β receptor inhibitior (SB431542) to RG-CM prevents EC migration. Real time RT-PCR showed that pro and antiangiogenic genes are modulated by the RG-CM (GPR124 and BAI-1, respectively). Further, Proteome identified 11 angiogenesis related proteins in the RG-CM that could be involved in these events. Interestingly, EC-CM treated RG cells showed a robust increment by 7x in GFAP+ cells (astrocytes) numbers. In this work, we established an efficient protocol for ECs isolation from brain tissue. We verified that RG cells promote invasion, migration, tube formation and gene expression by ECs. We also observed that ECs promotes astrocyte differentiation from RG cells, an event essential to ensure BBB formation. Together our results allow us to understand EC-RG interaction dynamics and the underlying molecular aspects involved in BBB formation.

Title: Increasing functional complexity and maturity of human iPSC-derived neuronal networks *in vitro* by glia co-culture and mixing different neuronal populations

Authors: A.-M. PIELKA, A. VOSS, C. EHNERT, *K. JÜGELT, O. H.-U. SCHROEDER, B. M. BADER;
NeuroProof GmbH, Rostock, Germany

Abstract: There is a high demand in preclinical drug development for novel alternatives to current labor- and animal-intensive behavior tests, and time-consuming brain slice models. *In vitro* neuronal cultures derived from human iPS cells are promising to serve as alternative to animal testing and additionally increasing predictability, selectivity and sensitivity for testing new chemicals and drugs. We aimed to validate hiPSC-derived neurons as a physiologically relevant stem cell-based screening platform incorporating the features of current neurotoxicity

testing in animals and improving current state-of-art by offering higher throughput and higher content. We cultured hiPSC-derived post-mitotic neurons from different commercial sources on multiwell micro-electrode arrays (Axion Biosystems). We co-cultured neurons with human astrocytes or mixed different neuronal populations such as GABAergic and glutamatergic with dopaminergic neurons in order to compare the functional maturation of network activity, survival and success rates after at least 4 weeks *in vitro*. We developed multi-parametric data analysis and pattern recognition methods and compared the functional complexity of hiPSC-derived neuronal activity with primary mouse activity patterns. We show that under certain culture conditions hiPSC-derived neurons functionally mature into networks which initiate complex bursting network activity comparable with those of primary neuronal networks. In conclusion, with our optimized culture protocols, human stem cell-derived neurons have the potential to meet the expectations in replacing current animal-based *in vitro* models or to be used for comparing drug-induced effects between rodent and human background, thus increasing predictability, selectivity and sensitivity, highly demanded for improved drug discovery.

Title: Characterizing Müller glia network assembly in mouse retina

Authors: *J. WANG, J. KAY;
Duke Univ., Durham, NC

Abstract: Astrocytes form a physical network with their arbors that pervades the entire central nervous system. This network engages in signaling among astrocytes, and mediates selective interactions with neurons, synapses, and blood vessels. These interactions have important roles in regulating neuronal and vascular physiology. Indeed, the universal presence of astrocyte arbors throughout both gray and white matter suggests their essential roles in nervous system function. However, the developmental mechanisms that ensure complete astrocyte tissue coverage remain unclear. As astrocytes have largely non-overlapping territories, a phenomenon known as "tiling," one possibility is that they simply grow until they touch their homotypic neighbors. We aim to test whether this homotypic recognition/repulsion model explains glial tissue coverage, and ultimately to develop a system for studying the molecular basis of such recognition. Since mouse retina is more experimentally accessible than brain, we began by asking if Müller glia (MG), the major astroglia-like cell of retina, might be a suitable model to address our aims. MG have a much more complex shape than astrocytes, so an initial question was whether MG, like astrocytes, exhibit tiling. Moreover, because MG traverse all retinal layers and ramify arbors with distinct morphology at each layer, we wanted to know: If MG tile, do they do it at all retinal layers? By utilizing the astroglia-specific Glast-CreER mouse line and a viral "Brainbow" strategy, we obtained multi-color images of adjacent MG that allowed us to delineate cell borders. We then measured the percentage overlap of the neighboring MG arbors and found that they indeed tile, as shown by minimal overlap (less than 5%). Moreover this tiling was found at all retinal levels. We then asked when tiling arises in development. Using a Cre reporter mouse line expressing membrane-targeted fluorescent proteins, we were able to visualize detailed MG morphology and uncover the initial time when they come in contact with one another. Our results set the stage to uncover the cellular and molecular mechanism of glial tiling in the retina, with implications for learning how brain glia form their ubiquitous networks.

Title: Midline glia express transient receptor potential channel subfamily M member 5 (TRPM5) during embryonic and early postnatal mouse brain development

Authors: *S. WEN, S. KUSUMAKSHI, U. BOEHM;
Inst. of Exptl. and Clin. Pharmacolog, Homburg/Saar, Germany

Abstract: Transient receptor potential channel subfamily M member 5 (TRPM5) is an important downstream signaling component in a subset of taste receptor cells. While TRPM5 has also been detected in extra-oral tissues, the function of non-gustatory TRPM5-expressing cells is less well understood. Interestingly, TRPM5 expression has also been reported in the central nervous system, however the individual cells in the brain that express this ion channel have not been identified. We recently developed a binary genetic strategy to report TRPM5 expression in mice. Specifically, we generated a novel TRPM5-IRES-Cre mouse strain to report TRPM5 expression using a Cre-activated τGFP reporter. To confirm faithful coexpression of τGFP and TRPM5 we generated and validated a new anti-TRPM5 antiserum enabling us to analyze acute TRPM5 protein expression. τGFP cells were found in taste bud cells of the vallate, foliate and fungiform papillae as well as in the palate as expected. We then used the animals to analyze TRPM5 expression in the central nervous system. Surprisingly, we find that TRPM5 expression persists in the ventral part of the mouse midbrain and hindbrain in a subpopulation of midline glial cells during late embryonic stages. These cells then gradually disappear at early postnatal stages and have completely vanished at postnatal day 14. Here we characterize these TRPM5-expressing midline glial cells and investigate their potential function during mouse brain development. To do so we express different tracer molecules in these cells to analyze their communication with other cells during late embryonic and early postnatal mouse brain development.

Title: Distinct roles of GLAST and GLT-1 in regulating cortical network formation and maturation

Authors: *J. SHIH[1,3], Y. YANG[2], N. C. DANBOLT[4], C. DULLA[2];
[1]Neurosci., [2]Dept. of Neurosci., Tufts Univ., Boston, MA; [3]Neurosci. Program, Sackler Sch. of Grad. Biomed. Sci., Boston, MA; [4]Dept. of Anat. & CMBN, Univ. of Oslo, Oslo, Norway

Abstract: The excitatory amino acid transporters (EAATs) GLAST and GLT-1 are responsible for the majority of the glutamate uptake in the brain. GLAST is the predominant mode of glutamate transport in the early postnatal brain, and the burden shifts over to GLT-1 as the brain matures. This developmentally timed expression of GLAST and GLT-1 contributes to proper structural and functional maturation of the brain. For example, loss of these transporters during the development of the mouse whisker barrel cortex disrupts its architecture and whisker representation. Our lab has shown that the normal developmental function and expression of GLAST and GLT-1 is altered in a model of cortical malformation. After freeze lesion injury, astrocyte density is decreased, presumably leading to a decrease in the number of available glutamate transporters. The remaining astrocytes have increased glutamate responsive areas and have an altered developmental progression of EAAT reliance. How these developmental changes in glutamate transporters might then influence cortical network organization and connectivity is not fully understood. To better understand the roles of GLAST and GLT-1 in handling extracellular glutamate during development, and whether changes in transporter levels affect neuronal migration and synapse refinement, we will use mice with partial genetic knockdown of the GLAST and GLT-1 genes (GLAST+/- and GLT-1+/-, respectively). These mice are viable and have roughly 68% of wild-type glutamate transporter protein levels when mature. We found that partial loss of GLAST during development leads to an abnormally excitable and epileptiform cortical field EPSP responses at P16-26, a time period after the shift from GLAST to GLT-1. However, we do not see this increased excitability with a partial loss of GLT-1. This hyperexcitability phenotype is similar and not additive to that seen in neonatal freeze lesioning, further suggesting that alterations in glutamate transporters plays a role in freeze lesion pathology. Our preliminary data also shows that glutamate transporter currents in Layer V cortical astrocytes are not different between GLT-1+/- and wild type, but have smaller amplitudes in GLAST+/-. These data suggest that there is a distinct, indispensable role of GLAST during development that prevents the formation of a hyperexcitable network, and that decreased GLAST expression leads to its altered function in the mature brain. Further investigation is required to understand what this specific role of GLAST is during development and how it is different from that of GLT-1.

Title: Neurodegeneration, gliosis, and glial proliferation in two models of temporal lobe epilepsy

Authors: J. L. LOEWEN[1,2], M. L. BARKER-HALISKI[3,2], E. DAHLE[3], H. WHITE[3,1,2], *K. S. WILCOX[3,1,2];
[1]Interdepartmental Program in Neurosci., [2]Pharmacol. & Toxicology, Univ. of Utah, Salt Lake City, UT; [3]Univ. Utah, ADD Program, Salt Lake Cty, UT

Abstract: In the Anticonvulsant Drug Development (ADD) Program, research is ongoing to identify animal models appropriate for the identification of novel compounds more efficacious in the large population of treatment-resistant patients. The corneal kindled mouse is a model of temporal lobe epilepsy (TLE) that allows for the rapid screening of investigational compounds. However, lack of information as to the specific inflammatory pathology resulting from corneal kindling in mice leaves research towards development of ASDs in this model uninformed. Likewise, the Theiler's murine encephalomyelitis virus (TMEV) model of infection-induced TLE may prove to be a useful model for screening, but quantitative assessment of neurodegeneration, glial reactivity, and cell-type-specific proliferation is lacking. Thus, the current study set out to test the hypothesis that these two very different mouse models would display distinctive neuropathological characteristics. C57BL/6 mice were injected intracranially with PBS or TMEV (3 X 105 PFU), monitored for seizures, and sacrificed 4 and 14 d post-injection (n=8 per group). CF1 mice were corneally stimulated until fully kindled, and sacrificed with unstimulated controls 1 d and 7 d after (n=8 per group). Serial 25 μm brain sections from each group were stained with antibodies directed against NeuN to evaluate neurodegeneration, and GFAP and Iba1 to determine the extent of astro- and microgliosis, respectively. In addition, antibodies directed against Ki67 were used to assess proliferation in glial cells. Z-stacks were collected in CA1, cortex, and DG with a confocal microscope and analyzed using ImageJ. In the hippocampus of TMEV-injected mice (4 and 14dpi) both microglia and astrocytes had significantly increased expression of Iba1 and GFAP, respectively; indicative of reactive gliosis. As previously described, there was also a significant degree of cell death in the CA1 region. In

contrast, there was no significant neurodegeneration or activation of microglia in CA1 of corneal kindled mice. Increases in GFAP expression were seen, however, suggesting that astrocytes are reactive in this model. Significant increases in the number of Ki67+ nuclei combined with colocalization analyses demonstrated that there was proliferation of microglia and astrocytes in the DG of TMEV-infected mice at 4 dpi. These results indicate different classes of ASDs could have varied effects on seizures observed in these two models, and the use of multiple mouse models of TLE in drug screening efforts is likely to be beneficial.

Title: Immunohistochemical analyses reveal changes in astrocytic density in the dorsal raphe nucleus after stress

Authors: *I. S. NICHOLS[1], C. O. OKERE[2], K. PAUL[3];
[1]Biol., [2]Clark Atlanta Univ., Atlanta, GA; [3]Neurosci. Institure, Morehouse Sch. of Med., Atlanta, GA

Abstract: The dorsal raphe nucleus (DRN) is an important component of the stress response circuit. In rats, acute stress alters nitric oxide synthase (NOS) activation in the DRN. Specifically, active NOS expression is enhanced in the caudal region. Astrocytes store and release the precursor for NOS to make nitric oxide (NO). Astrocytic organization in the DRN is important because it may help reveal the regulatory role of NOS on stress responses. Glial fibrillary acidic protein (GFAP), a marker for astrocytes, increases in other stress-sensitive brain areas during chronic stress. Our hypothesis is that there will be an increase in GFAP staining as a result of stress, revealing a unique organization among astrocytes. Following acute or chronic stress coronal sections (20 μm-thick) of the DRN from rat brains were stained with GFAP antibody and then visualized with avidin biotin complex and peroxidase (n=3-4). Using Image J,

density measurements were taken by measuring mean gray value for the rostral and caudal subregions. This analysis revealed differences in astrocytic density between acute and chronic stress for both rostral ($p=0.05$) and caudal ($p=0.02$) subregions. Under baseline conditions, astrocytic organization in the rostral DRN was different from the caudal region; the rostral staining was ubiquitous while the caudal staining was localized mostly to the midline and lateral wing regions. Although acute and chronic stress increased astrocytic density throughout the DRN, it did not change the organizational relationship between rostral and caudal regions. To conclude, this unique pattern of astrocyte distribution may suggest functional specialization for astrocytes in the DRN especially as a response to stress.

Title: Protein levels of cell adhesion molecules in the supraoptic nucleus of 1- and 4-month-old rats: implications for a role in axonal sprouting?

Authors: *P. KUBALL, E. BYE, M. MCCARTHY, A. AL SAEGH, J. ASKVIG;
Concordia Col., Moorhead, MN

Abstract: It has been demonstrated that a young brain can overcome injury by axonal sprouting; however, it is well understood that the mature brain has a reduced capacity for functional or structural reorganization following injury. To this point, following injury, uninjured axons from the supraoptic nucleus (SON) undergo collateral sprouting in the 35-day-old rat, but not in 125-day-old rats. Therefore, it appears that within the SON there are age-related changes that preclude the older rat from recovering following injury. Cell adhesion molecules have been previously demonstrated to play a role in axonal sprouting, both in a stimulatory and inhibitory manner. Thus, we compared protein levels of cell adhesion molecules in the 35 and 125-day-old SON using Western blot analysis. Our results demonstrated that in the 125-day-old SON, there was a significant increase in thy-1 protein levels, which is an anti-sprouting factor that interacts with integrins. Moreover, we determined the protein levels of cell adhesion molecules in the sprouting (35-day-old rat) and non-sprouting SON (125-day-old rat). Our results suggest that the observed increase in thy-1 protein levels in the SON with age may contribute to an environment that prevents axonal sprouting in the SON of an older rat.

Title: Electrophysiological effects of glial inhibition on pyramidal neurons in rat brain slices

Authors: *S.-. DARIANI SAEED[1], M. JANAHMADI[2];
[1]Tehran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of; [2]Neurosci. Res. Ctr. and Dept. of Physiol., Tehran, Iran, Islamic Republic of

Abstract: Glial cells play an important role in control of neuronal excitability. However, the cellular mechanism of this effect is not fully determined. In the present study, the electrophysiological alteration induced by glial inhibition in the CA1 pyramidal neurons of hippocampus using whole cell patch clamp recording was examined after application of minocycline. Results indicated that glial inhibition after minocycline inhibition (100μM) causes a significant reduction ($P<0.05$ (in the pyramidal neurons from 1.21±0.5 Hz in control group to 0.098±0.01 Hz in the presence of minocycline using whole cell patch clamp recording under current clamp condition, which was associated with an increase in the electrical discharge of cells. Minocycline treatment did not affect the resting membrane potential, but increased the cell input resistance from 82.6M Ω to 104.24M Ω. In addition, minocycline resulted in an insignificant reduction in both the amplitude of post stimulus after hyperpolarization potential and sag voltage evoked in response to depolarizing and hyperpolarizing current pulses, respectively. In summary it seems that glial inhibition causes severe alterations in cell excitability through changes in passive and active properties of hippocampal pyramidal cells.

Title: The cytokine IL-1ß is able to diminish amplitudes of cortical spreading depression (CSD) in adult rats

Authors: F. RICHTER[1], J. LEUCHTWEIS[1], A. EITNER[1], E. WEGNER[1], *A. LEHMENKUHLER[2], H.-G. SCHAIBLE[1];
[1]Inst. of Physiol., Univ. Hosp. Jena, Jena, Germany; [2]Pain Inst., Dusseldorf, Germany

Abstract: IL-1ß is thought to play an important pathophysiological role in the brain e.g. in stroke and neurodegenerative diseases. Here we tested, whether IL-1ß influences CSD, a neuronal mechanism of pathological hyperexcitability. We recorded in spontaneously breathing anesthetized adult rats (sodium thiopentone, 100 mg/kg, i.p.) CSD in cerebral cortex with two pairs of glass micropipettes (distance 5-6 mm) at depths of 1200 µm. CSD was elicited by a microinjection of 1 M KCl (tip diameter 5 µm, 100 kPa, 300 ms - 1 s). We administered in one group of rats 50 ng IL-1ß. In another group we applied 500 ng of an IL-1 receptor antagonist together with 50 ng IL-1ß after 30 min pretreatment with the receptor antagonist alone. We compared the effects of IL-1ß with the topical application of 2 µg lipopolysaccharide (LPS) and blocked the IL-1ß receptor as well. To elucidate possible modes of action of IL-1ß, we applied 1 µM of the GABAA receptor antagonist bicuculline topically to the cortical surface for half an hour and applied subsequently IL-1ß. All cytokine applications lasted 4 hours and CSD were elicited every 30 min in the first two hours and then every hour. In a subgroup, the cortices treated with IL-1ß were stained with Evans blue, and we looked for plasma extravasation and for the localization of the IL-1ß receptor. The application of IL-1ß decreased the CSD amplitudes in the treated area down to 55.2±7.4% of controls, but in the untreated area CSD amplitudes decreased only to 85.1±4.9% (mean±SEM, n=6). This decrease could be abolished by coapplication of IL-1ß and the IL-1 receptor antagonist. Interestingly, CSD amplitudes increased after that treatment in the treated area up to 125.8±5.9% of controls, whereas they decreased in the untreated area down to 89.1±8 % (n=4). Application of the receptor antagonist alone resulted in an increase of CSD amplitudes and spontaneously occurring CSD waves. Application of LPS caused a similar decrease of CSD amplitudes as IL-1ß. This decrease could be abolished by coapplication with the IL-1ß receptor antagonist as well. The GABAA receptor antagonist bicuculline slightly increased CSD amplitudes. After coapplication of bicuculline together with IL-1ß CSD amplitudes reached 125.8±5.9 % of controls (n=3). This indicates that inhibitory neurons might be involved in the action of IL-1ß on CSD. Histological observation showed the expression of IL-1ß receptors at neurons and microglia and plasma extravasation in the IL-1ß treated areas. These results suggest that IL-1ß could decrease CSD via the release of GABA and

via plasma extravasation. LPS induces a release of IL-1ß and influences CSD in this way. The plasma extravasation might be harmful for the brain.

Title: HIV-1 mediated disruption of Wnt/β-catenin signaling in astrocytes lead to neuronal injury

Authors: ***V. B. LUTGEN**, C. YU, S. NARASIPURA, L. AL-HARTHI;
Micro/Immuno, Rush Univ. Med. Ctr., Chicago, IL

Abstract: Neuronal injury characterized by synaptodendritic dysregulation and/or apoptosis is a prominent feature of HIV-Associated Neurocognitive Disorders (HAND). Neuronal injury may arise, in part, from impaired function of glial cells. Abnormal astrocyte activity will result in decreased neuroprotection due to increased release of inflammatory mediators, abnormal glutamate cycling and dysregulation of secretory factors critical for astrocyte-neuronal communication. Wnt/β-catenin signaling in astrocytes regulates a number of genes responsible for cell survival, structure and function. Neuronal β-catenin is important for the regulation of dendrite and spine morphology and synaptic activity. We previously showed that inflammatory mediators, HIV infection, and HIV Tat down regulate Wnt/β-catenin signaling in astrocytes. We evaluated here the impact of down regulation of astrocytic β-catenin signaling on neuronal injury. Towards this end, primary human fetal astrocytes (HFAs) were infected with HIVBaL or knocked down (KD) for β-catenin using siRNA and the astrocyte conditioned media (ACM) was added to Lund human mesencephalic (LUHMES) cells, which are differentiated into dopaminergic neurons. Further, HFAs KD for β-catenin were also co-cultured with LUHMES neurons then exposed to HIVBaL. Microtubule-associated protein 2 (MAP2) expression was assessed for neuronal dendritic integrity at 72 hrs post-treatment of ACM or HFAs by western blot and immunofluorescence. ACM from HIV infected or β-catenin KD HFAs resulted in ≈

80% decrease in neuronal β-catenin expression with no effect on the housekeeping protein GAPDH. ACM from HIV infected or β-catenin KD HFAs also resulted in reduction of MAP2 expression by ≈ 50 and 80%, respectively, as measured by WB. Co-culturing β-catenin KD astrocytes with neurons and HIVBaL infection also led to a significant reduction in neuronal MAP2 expression by immunofluorescence. Taken together, HIV-mediated disruption of Wnt/β-catenin signaling in astrocytes lead to significant neuronal injury, highlighting the importance of Wnt/β-catenin signaling in astrocytes for astrocyte-neuronal communication and neuroprotection. This work is supported by F32 NS0889442-01 (VL) and 5R01 NS060632-06 (LA).

Title: Identification of mineralocorticoid receptors as potential targets to modulate nociceptive neurons but not glia cells

Authors: ***S. A. MOUSA**[1], M. SHAQURA[1], X. LI[1], M. AL-MADOL[1], A. BEYER-KOCZOREK[2], S. MICHAEL[1];
[1]Dep. of Anesthesiology, Charite Univ., Berlin, Germany; [2]Anaesthesiology, Ludwig-Maximilians-University München, München, Germany

Abstract: From years back - in addition to the glucocorticoid receptor (GR) - the mineralocorticoid receptor (MR) has been reported to contribute to the relief of clinical symptoms in patients with inflammatory diseases (Mertin et al., 1972). More recently, there is some evidence that MR are expressed in neurons and/or glia cells and may modulate nociception (Dong et al., 2012). We investigated (by PCR, WB, IHC) in spinal cord, dorsal root ganglia, and peripheral nerve bundle of naïve Wistar rats the exact type of sensory neurons and glia cells that express MR. Upon intraplantar and intrathecal application of the MR agonist aldosterone with and without the antagonist spironolactone we examined alterations in mechanical thresholds by von Frey filament testing. Double immunofluorescence confocal microscopy revealed that MR colocalized with the sensory neuron marker calcitonin gene-related peptide (CGRP) in sensory

nerve terminals within the dorsal horn of the spinal cord, in dorsal root ganglia neurons, and in peripheral nerve terminals innervating skin epidermis. Importantly, MR were found to be expressed neither in satelitte cells nor in Schwann cells excluding the involvement of glia cells. Intraplantar as well as **i**ntrathecal injection of aldosterone resulted in a significant and dose-dependent reduction of mechanical thresholds consistent with previous reports about an increased excitability of sensory neurons. This effect could be abolished with the antagonist spironolactone. Taken together, we could identify MR predominantly in unmyelinated and thinly myelinated nociceptive fibres but neither in other sensory neurons nor in glia cells which - upon activation - leads to a lowering of mechanical thresholds. This suggests a crucial role of MR in the modulation of pain at the spinal and peripheral level of the nervous system. Supported by the Prof. KH René Koczorek Stiftung

Title: The role of the pre-Bötzinger complex astrocytes in central respiratory CO2 chemosensitivity

Authors: *S. SHEIKHBAHAEI[1,2], N. MARINA[2], V. RAJANI[3], S. KASPAROV[4], G. D. FUNK[3], J. C. SMITH[1], A. V. GOURINE[2];
[1]Cell. and Systems Neurobio. Section, Natl. Inst. of Hlth. (NIH)- NINDS, Bethesda, MD; [2]Neurosci. Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom; [3]Dept. of Physiology, Neurosci. & Mental Hlth. Institute,, Univ. of Alberta, Edmonton, AB, Canada; [4]Dept. of Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: Current models of respiratory CO2 chemosensitivity are centered around a function of a defined group of pH-sensitive neurons residing in the medullary retrotrapezoid nucleus (RTN) (Guyenet, 2014), though significant prior evidence suggests that the functional respiratory

chemoreceptors are also located in other brainstem areas including the rhythm-generating region of the medullary pre-Bötzinger complex (preBötC). There is also evidence that brainstem astrocytes are highly sensitive to changes in PCO2/[H+] and play a role in the mechanisms of RTN chemosensitivity. In this study we investigated whether astrocytes intermingled with the preBötC circuits contribute to the respiratory response to CO2. To interfere with astroglial signalling by blocking vesicular release mechanisms, preBötC astrocytes were targeted to express light chain of tetanus toxin (TeLC), which cleaves certain SNARE proteins responsible for vesicular docking and fusion. In conscious rats, bilateral expression of TeLC in preBötC astrocytes was associated with a significant reduction of the ventilatory response to 10% inspired CO2 (by 22%; n=5, p=0.008). In comparison, inhibition of RTN neurons expressing DREADD(Gi) receptors bilaterally by application of clozapine-N-oxide (CNO, 2.5 mg/kg), reduced the ventilatory response to 10% inspired CO2 by 19% (n=5, p=0.002). In anesthetized and artificially-ventilated rats, hypercapnia-induced increases in phrenic nerve activity were reduced (by 30.3%; n=5, p=0.034) in rats transduced to express TeLC in preBötC astrocytes. These data suggest that the activity of respiratory rhythm-generating circuits of the preBötC are controlled by neighboring astrocytes, which constitute an important component of the brainstem mechanisms underlying the CO2 drive to breathe.

Title: Aβ oligomers impacts astrocytic processes calcium excitability and structural plasticity nearby hippocampal synapses

Authors: A. BOSSON, S. BOISSEAU, A. BUISSON, *M. ALBRIEUX;
Grenoble Inst. des Neurosciences, Univ. Grenoble Alpes, Grenoble cedex 9, France

Abstract: Synaptic loss is thought to be one of the earliest events in Alzheimer's disease (AD). However, the key mechanisms that maintain synapse integrity or initiate synapse dysfunction in AD remain unknown. In early phase of AD, soluble amyloid β peptide (Aβ) is known to

selectively mediate impairment of synaptic plasticity and synaptic loss. Recent studies suggest that astrocytes contribute to morphological and functional changes observed during synaptic plasticity and play a major role in synaptic dysfunction. Our hypothesis is that Aβ acts directly on synaptic spine but also on its perisynaptic astrocytic partner emphasizing its impact on dendritic spine. In that context, we first studied the impact of oligomeric Aβ (Aβo) on astrocytes at both a functional and structural level. Combining confocal calcium imaging and electrophysiological experiments on mouse acute brain slices, we analyzed the impact of Aβo on calcium excitability in the hippocampal astrocytic network along with in single astrocyte focusing on astrocytic processes that are in close relationship with glutamatergic synapses. We showed that Aβo 100 nM for 5 min induced an increase of the proportion of active astrocytes in hippocampal stratum radiatum (28 % increase; $p < 0.05$) and an increase of the frequency of calcium signals within individual active astrocyte (56 % increase; $p < 0.05$). This leads to a global astrocytic hyperexcitability and excessive synchronization of the astrocytic network in hippocampal stratum radiatum. Concurrently, Aβo increased calcium excitability in astrocytic processes and modified the spatiotemporal dynamic of calcium signaling in these microdomains. A pharmacological approach allowed us to highlight some molecular actors involved in these compartmentalized calcium hyperexcitability within astrocytic processes. These functional impacts of Aβo on astrocyte excitability went along with structural remodeling of perisynaptic astrocyte processes. Thus, these results suggested that astrocytes are directly affected by Aβo exposure leading to both functional and structural consequences. Further work will be performed to monitor the repercussions of these astrocyte modifications on neighboring synaptic plasticity mechanisms such as long term potentiation. Identifying molecular actors involved in setting up plasticity impairments in both neuronal and astrocytic partners will allow us to decipher the beneficial and deleterious role of neuron-astrocyte interaction in AD synaptic impairments.

Title: Serial section electron microscopy of glia in adult neocortex

Authors: *D. R. BERGER, J. W. LICHTMAN;
Harvard, Cambridge, MA

Abstract: Using the Automated Tape-collecting Ultra-Microtome technique followed by imaging in a Scanning Electron Microscope (ATUM-SEM), we acquired a three-dimensional volume of adult somatosensory mouse cortex (~50 x 50 x 60 μm) at ultra-high resolution (3 x 3 x 29 nm per pixel) [Kasthuri et al., 2015] and used this image data to explore all the glia in this volume. We found that the volume intersected with 7 glial cell somata and 26 neuronal somata. The glia were classified by their electron microscopy appearance as three microglia, two oligodendrocyte precursor cells (NG2-OPCs), one oligodendrocyte and one astrocyte. We reconstructed the complex arbors of these cells by manual painting using freely available segmentation software that we developed for this project (VAST Lite, http://software.rc.fas.harvard.edu/lichtman/vast/). We found that each one of these glial cell types interacted with the neuronal elements in a different way. For each microglial cell our data suggested that many 100s of its terminal processes end close to the tips of dendritic filopodia. Consistent with this finding, 28% (range 4.2% - 58.3% depending on dendrite) of dendritic filopodia ended next to microglial processes. This association with neuronal filopodia was true for spiny dendrites, aspiny dendrites, the relatively spine-free segments of spiny dendrites close to the cell body, and cell bodies of neurons themselves. Rarely, we observed debris within the microglial processes. In distinction to the dendritic associations of microglia, NG2-OPCs enveloped ends of axonal processes. We found one case in which an NG2-OPC process enveloped an axonal synaptic bouton and its associated dendritic spine. Moreover NG2-OPCs appeared to completely phagocytose folded pieces of axons (often with vesicles). Oligodendrocyte branches were easily distinguished from other glia because they generated myelin sheaths. The sheaths were exclusively at terminal branches of the oligodendrocytes. Interestingly, comparing two oligodendrocyte branches, one formed on average thicker myelin sheaths than the other (rank sum test, $p=0.014$). Astrocyte processes were ubiquitous in the volume branching out between neuronal processes, closely associating with inhibitory dendrites and sheathing about a third of the excitatory and inhibitory synapses. Astrocytes formed multilayered glomerular capsules at <1% of synapses. The determination of which synapses were encapsulated appeared to be based on the identity of the axon rather than the dendrite. These results suggest that serial electron microscopy can be helpful in determining the specific roles of the different glial cell types within cerebral cortex.

Title: Relevance of neuron-glia interactions to the action of oxytocin in pain processing

Authors: *J. WAHIS, B. BELLANGER, T. MADUNA, V. LELIÈVRE, P. POISBEAU, A. CHARLET;
INCI-CNRS UPR 3212, Strasbourg, France

Abstract: Oxytocin (OT) is a hypothalamic hormone and neuropeptide well known for its numerous roles in social interaction, anxiety and pain modulation, among others. Particularly, OT can modulate the local circuitry of the central amygdala (CeA) in order to decrease the fear response. Here we study the action of OT on the calcium dynamics of astrocytes and the relevance of the astrocyte-neuron interaction to the OT neuromodulatory effect in the CeA. Through calcium imaging and patch clamp experiments on horizontal slices of rat amygdala, we characterize the response of astrocytes and neurons of the CeA upon specific activation of OT-receptor and study further the cellular mechanisms involved as well as possible astrocyte to neuron gliotransmission. Through a neuropathic pain model we tested the relevance of those mechanisms *in vivo*. Taken together, our results provide insight into the mechanisms underlying OT action in the CeA and its role in pain processing.

Title: Activity dependent remodeling of ECM monitored by extracellular proteolysis of brevican

Authors: *J. B. SINGH[1,2], N. J. PANDYA[3], A. B. SMIT[3], K. W. LI[3], C. SEIDENBECHER[2], R. FRISCHKNECHT[2];
[2]Dept. Neurochemistry and Mol. Biol., [1]LIN, Magdeburg, Germany; [3]Mol. and Cell. Neurobio., CNCR, Amsterdam, Netherlands

Abstract: The chondroitin sulfate proteoglycan brevican is one of the main components of the mature extra cellular matrix (ECM). It is the smallest member of the family of lecticans. Together with other proteoglycans and glycoproteins such as tenascinR, the lecticans form a tight meshwork around neurons. It has been suggested that the ECM inhibits structural plasticity by stabilizing synaptic contacts and preventing synaptogenesis in the adult. On the other hand the ECM provides important instructive information necessary for LTP, a measure for synaptic plasticity. It has been shown that brevican and the other lecticans can undergo proteolytic cleavage, mainly by ADAMTS4 (a disintegrin and metalloprotease with thrombospondin motifs) and ADAMTS5. Here we hypothesise that proteolysis of the ECM is required to alter locally the structure of the ECM to allow for synaptic rearrangements in the adult in a restricted area and time. Interestingly, it has been reported that during the first minutes to hours after LTP induction neurons show enhanced structural plasticity. Therefore we wondered whether brevican as a representative of the ECM is particularly proteolytically cleaved during LTP. To this end we induced chemical LTP in acute hippocampal slices and performed quantitative western blotting to measure brevican cleavage, as well we as an unbiased approach by MS screening for modulation of ECM upon activity. We found a marked increase in brevican cleavage compared to control slices 15-60 min after LTP induction in both approaches. Cleavage was reduced to basal level and increase in brevican full length was observed, when a broad spectrum protease inhibitor as well specific protease inhibitors were used during the experiment. This indeed indicates that proteolytic cleavage and therefore remodelling of the ECM may be involved in learning and memory processes that require structural plasticity

Title: Mir-133b inhibits glial scar formation and promotes brain remodeling after treatment of stroke in rats with multipotent mesenchymal stromal cells

Authors: *F. WANG;
neurology research, Henry Ford Hosp., detroit, MI

Abstract: Multipotent mesenchymal stromal cells (MSCs) improve functional recovery after stroke in rats, in-part by reducing glial scar formation and promoting neurite outgrowth. MicroRNA-133b (miR-133b) has been shown to participate in stroke recovery. We hypothesize that MSCs with enhanced miR-133b will further inhibit glial scar formation and promote neurite outgrowth. In this study, six male adult rats were subjected to middle cerebral artery occlusion (MCAo) and injected intravenously with MSCs transfected with miR-133b (Real-time PCR showed miR-133b level in these MSCs increased significantly compared to naive MSCs, 60.5±10.5 fold, $p<0.01$) or naïve MSCs, at 1 day after MCAo. The function of miR-133b enriched MSC group significantly improved neurological recovery from stroke compared to the naïve MSC group ($P<0.05$). Animals were sacrificed 28 days after stroke. MiR-133b enhanced MSC treatment reduced the thickness of the glial scar wall, indicated by Vimentin staining (pixel relative thickness: miR-133b 61.16±14.22, naïve MSC 83.90±6.41; $P<0.01$). Connective tissue growth factor (CTGF) and Ras homolog gene family, member A (RhoA) are targets of miR-133b. Both CTGF and RhoA inhibit neurite outgrowth. Immunostaining showed a decreased expression of CTGF in reactive astrocytes in the scar boundary zone in the miR-133b enhanced MSC treated rats compared to the naive treated rats (positive staining area: miR-133b 0.11±0.07 %, naïve MSC 0.26±0.14%; $P<0.05$). The expression of RhoA, likewise, decreased in the miR-133b enhanced MSC treated rats (positive staining area: miR-133b 0.12±0.09%, naïve MSC 0.27±0.15%; $P<0.05$). MiR-133b regulation of neurite outgrowth via ERK1 and PI3K/Akt signaling pathway by RhoA suppression was further demonstrated by Western-blot. *In vitro*, cultured primary astrocytes were subjected to oxygen and glucose deprivation (OGD). MSCs enriched with miR-133b were co-cultured with astrocytes subjected to OGD for 24 hours. Real-time PCR showed miR-133b level was significantly increased in miR-133b treatment group compared with naïve MSC treatment group (by 4.35±0.56 fold, $p<0.05$). Correspondingly, the expression of CTGF in the miR-133b treated astrocytes significantly decreased compared to MSC group. Our data suggest that enhanced miR-133b reduces CTGF expression and thereby reduces the glial scar formation. In addition, increased miR-133b level in brain is related to reduction of RhoA expression via the ERK1 and PI3K/Akt signaling pathway, and promotes the

neurite outgrowth. Thus MSCs enriched with miR-133b by reduction of CTGF and RhoA likely contribute to improved functional recovery after stroke.

Title: Akap200 scaffolding protein controls blood-brain barrier responses to alcohol

Authors: *S. PARKHURST[1], A. LEGENDRE[1], E. KONG[2], F. W. WOLF[2,1];
[1]Univ. of California, Merced, Merced, CA; [2]Ernest Gallo Res. Ctr., Univ. of California, San Francisco, Emeryville, CA

Abstract: Alcohol is the most commonly abused drug today, yet our knowledge of its biological mechanisms and our ability to effectively treat alcoholism is lacking. The fruit fly *Drosophila* is a model for the molecular and behavioral actions of alcohol, including the development of tolerance to its sedating effects. The fly blood-brain barrier (BBB) provides a physical and chemical protection for the brain, and is composed of the perineurial glia (PG) and the subperineurial glia (SPG). The protein kinase A scaffolding protein, Akap200, increases expression following exposure to alcohol. Decreased Akap200 expression in the whole fly, in all glia, and specifically in the PG resulted in a decreased ability to develop alcohol tolerance. Acute alcohol exposure caused morphological rearrangement of the PG that was delayed when Akap200 expression was reduced in the PG; the chemical and physical BBB functions were unaffected. Ca2+/CaM signaling, that may regulate Akap200 function, was critical for BBB-dependent alcohol tolerance. Our findings implicate the glial BBB in the development of behavioral plasticity, and suggest that the barrier communicates with central brain neurons to facilitate the development of alcohol tolerance.

Title: Genome-wide approaches reveal Bexarotene controlled regulatory networks in APOE3 mice

Authors: *K. NAM[1], A. MOUNIER[1], J. SCHUG[2,3], N. F. FITZ[1], I. LEFTEROV[1], R. KOLDAMOVA[1];
[1]Envrn. and Occup. Heath, Univ. of Pittsburgh, Pittsburgh, PA; [2]Functional Genomics Core, Dept. of Genet., [3]Inst. for Diabetes, Obesity and Metabolism, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Nuclear receptors Retinoid X receptors (RXRs) are ligand-activated transcription factors that heterodimerize with other nuclear receptors to generate functional transcription factors. Previous studies showed that RXR synthetic and highly selective agonist Bexarotene improves memory in mice expressing human apolipoprotein E (APOE) - isoforms APOE3 and APOE4. Our preliminary studies demonstrate also that Bexarotene increases neuronal differentiation and adult neurogenesis in APOE4 mice (not published). To identify direct RXR targets genome-wide in APOE3 mice we applied chromatin immunoprecipitation for transcription factor binding followed by high-throughput sequencing (ChIP-seq). We demonstrate that Bexarotene treatment induced changes in the distribution of RXR binding - there was a significant shift towards RXR binding in promoter regions of annotated genes in Bexarotene treated, compared to control mice (0.4% vs 10%); second, functional annotation clustering using DAVID and IPA web tools revealed that GO categories chromatin modification and chromatin organization were significantly enriched only in Bexarotene treated APOE3 mice. Thus highly and significantly enriched clusters were transcription factor activity, axonal

guidance and neuritogenesis. As a next step, to determine how Bexarotene affects mRNA levels, and potentially gene expression in brain, we applied high-throughput mRNA-seq with RNA isolated from cortices of the same mice: IPA analysis of RNA-seq datasets showed that differentially affected categories are: learning, cognition, behavior, synaptic transmission, axon- and neurites outgrowth. Several signaling pathways important for axonal guidance and neuritogenesis were identified as significantly overlapping in ChIP-seq and RNA-seq datasets, such as Wnt/β-catenin, PI3K/AKT and CREB signaling. These data were further validated in cell culture and *in vivo* using QPCR and morphological analysis of Bexarotene promoted neuritogenesis. The results of this study suggest that Bexarotene can affect memory function through regulation of several, amongst them Wnt/β-catenin and PI3K/AKT signaling pathways involved in neuritogenesis.

Title: GRK5 deficiency renders vulnerability to cognitive deficits triggered by mild intermittent hypoxia

Authors: *W. Z. SUO[1,2,3], P. SINGH[1], W. PENG[1], Q. ZHANG[1], X. DING[1];
[1]Kansas City VA Med. Ctr., Kansas City, MO; [2]Neurol. and Physiol., Univ. of Kansas Med. Ctr., Kansas City, KS; [3]Univ. of Kansas Alzheimer’s Dis. Ctr., Kansas City, KS

Abstract: Obstructive sleep apnea (OSA) leads to sleep fragmentation and intermittent hypoxia (IH). The latter posts significantly increased health risks for cardiovascular system. In addition, recent evidence indicates that OSA may also increase the risk of suffering from cognitive impairment such as Alzheimer’s disease (AD), though the underlying mechanisms remain elusive. In parallel, our recent studies have suggested that G protein-coupled receptor kinase-5

(GRK5) deficiency accelerates AD pathogenesis most likely by selectively rendering cholinergic neurons more vulnerable to various degenerative insults, including hypoxia. To test this hypothesis, we placed young (4 months) wild type (WT) and GRK5 knockout (KO) mice in the absence and presence of mild IH (8%/21% O2 90 sec cycle for 8 hours a day) for a month. After completion of the IH treatment, the mice were transferred to behavioral room and environmentally adapted for two weeks before they were behaviorally assessed with a battery of tasks. Our results showed that the mild IH only induced marginally abnormal behavior (slightly elevated anxiety with most others unchanged) in WT mice but in the KO mice it caused significantly more behavioral deficits, ranging from weakened balancing function, elevated anxiety, slowed swimming speed, reduced spontaneous alternation score in Y maze, and worsened performances in Morris water maze and radial arm water maze that measure spatial memory. Although the pathological analyses are pending, these behavioral results support our hypothesis and suggest that GRK5 deficiency makes the mice more vulnerable to wide range of behavioral impairments, including spatial memory deficits.

Abstract: Type 2 diabetes mellitus, a pathology associated with increased blood glucose levels (hyperglycemia), has been linked to Alzheimer's disease (AD). Indeed, hyperglycemia, oxidative stress, and dysfunctional insulin signaling are common features of these two age-related diseases. Therefore, elucidate the molecular mechanisms underlying the neurodegenerative process that occurs in AD under hyperglycemia is of utmost relevance. Moreover, little is known about how the perturbation of glucose metabolism affects the formation of new neurons during adult hippocampal neurogenesis, a process that plays an important role in learning and memory. In order to evaluate whether hyperglycemia aggravates the alterations of hippocampal adult neurogenesis in AD and further impair memory, 2 month-old triple transgenic AD (3xTg-AD) mice were treated with an elevated dose of sucrose over 6 months. Non transgenic (NonTg) and 3xTg-AD mice treated with sucrose presented decreased glucose tolerance and increased levels of glycated hemoglobin, cholesterol and leptin, in comparison with the respective non-treated group. Untreated 3xTg-AD mice exhibited increased glucose tolerance, when compared to NonTg, which was associated to increased insulin levels. Interestingly, hyperglycemia had a negative effect on learning and spatial memory of 3xTg-AD mice, leading to the impairment of these cognitive functions. Furthermore, our results show that hyperglycemia potentiated cell proliferation in the subgranular zone of the dentate gyrus of the hippocampus, namely of neuroblasts, which in the case of sucrose-treated 3xTg-AD mice did not contribute to an increase in the total number of neuroblasts or immature neurons. In these mice, we also observed decreased dendrite complexity of immature neurons, when compared to untreated 3xTg-AD mice. These data suggest that hyperglycemia enhances AD pathology, contributing for the impairment in neurogenesis, defective learning and memory loss.

Abstract: It is known that high caloric diets and type 2 diabetes are risk factors for the development of dementias, particularly Alzheimer's Disease (AD). Even though AD has a high prevalence among elderly women over men, there is no clear hormonal, metabolic of physiological factor to explain such prevalence. In order to study the effects of a high caloric diet on the development of AD and how it affects males and females we exposed a murine model of AD harboring three mutations related to the amyloid beta and p-tau accumulation (3xTg-AD) to a high-fat (60% calories from fat) plus high-fructose (20% in tap water) diet (HFHF). Additionally we exposed non-transgenic mice to the same HFHF diet and after 30 days assessed the cognitive performance in object recognition and Morris water maze tasks. As a consequence of HFHF diet exposure, only 3xTg-AD male mice showed cognitive deficits as well as metabolic dysfunctions reflected on poor glucose tolerance and higher adiposity. These data suggest that an early exposure to high caloric food has a powerful impact on the acceleration or production of cognitive impairments in the 3xTg-AD male mice, indicating the possibility of a protective factor in young female 3xTg-AD.

Title: A novel administration of systemic streptozotocin leads to alterations relevant to vascular dementia and Alzheimer's disease

Authors: *A. S. MURTISHAW[1], C. F. HEANEY[2], M. M. BOLTON[2], K. D. BELMONTE[2], M. A. LANGHARDT[2], J. W. KINNEY[2];
[1]Neurosci., UNLV Neurosci. Doctoral Student, Las Vegas, NV; [2]Psychology/Neuroscience, UNLV, Las Vegas, NV

Abstract: Diabetes Mellitus (DM) has been identified as a major risk factor for developing vascular dementia (VaD) and Alzheimer's disease (AD). Among the various characteristics associated with DM, disruptions to insulin signaling have been implicated as the main factor that confers the greatest risk for these dementia-related diseases. Streptozotocin (STZ), a compound that targets and destroys insulin producing pancreatic β-cells, has been utilized to better understand DM. Additionally, the administration of STZ has been used to model sporadic AD due to its ability to alter behavior and hyperphosphorylate tau in the brain. Studies utilizing STZ often rely on a very high single dose or repeated doses of a slightly lower dose, both of which are often associated with increased mortality and renders sick animals not optimal for behavioral testing. We optimized a multiple low-dose STZ schedule, administered over the course of 15 days that led to significantly elevated blood-glucose levels and overall healthy animals following a battery of standardized behavioral tests. Starting the sixth week after the first STZ injection, animals were assessed in the open field and Novel object recognition tasks. Brains were removed and prepared for either western blotting to investigate proteins related to tau pathology and insulin signaling, specifically insulin degrading enzyme, or for immunohistochemistry to evaluate microglia activity, amyloid plaque deposition, and microinfarcts. Results indicate that our novel dosing schedule of STZ results in a viable and sustainable diabetic state and ultimately leads to alterations in learning tasks and dementia-related protein changes, with relevance to VaD, in particular that peripheral insulin disruption leads to wide-spread microglia activation throughout the brain.

Title: Sensorimotor Integration measured by a Reaching task in Neurodegenerative disease

Authors: ***M. A. SANTOS**[1], J. O'DOHERTY[2], G. RABINOVICI[1], B. L. MILLER[1], M. GORNO TEMPINI[1], P. SABES[2];
[1]Memory and Aging Ctr. UCSF, San Francisco, CA; [2]UCSF, San Francisco, CA

Abstract: Background: Sensory-motor integration refers to the integration of visual and tactile/proprioceptive sensory information for the purpose of action planning and execution. Neurodegenerative disease syndromes cause prominent deficits of sensorimotor function, yet there is limited data characterizing these deficits and its underlying mechanisms are poorly understood. While various reaching studies involving large cohorts of stroke patients have been published, similarly-sized studies in patients with neurodegenerative disease are lacking. We report the largest reaching study in patients with neurodegenerative disease to date. Objective: To characterize sensorimotor integration ability in various forms of neurodegenerative disease with the overall goal of improving clinical diagnosis. Methods: More than 60 subjects diagnosed with various neurodegenerative conditions including early onset Alzheimer's disease (EOAD), posterior cortical atrophy (PCA), cortical basal syndrome (CBS), progressive supranuclear palsy (PSP), non-fluent, logopenic, and semantic variant forms of primary progressive aphasia (nfvPPA, lvPPA, svPPA), and behavioral variant frontotemporal dementia performed a reaching task and a limb proprioception task designed to measure various aspects of sensorimotor integration. Performance was correlated with neuroimaging data using voxel based morphometry. Results: Different diagnostic groups presented partially differentiable sensory-motor integration profiles. All patient groups were different from controls in at least one measure. Overall, patients with diagnoses associated to parietal and posterior temporal atrophy such as CBS, PCA, and lvPPA showed more problems in measures that reflect sensory-motor integration for planning such as initial reaching angle. Subjects with diagnoses associated to motor and premotor cortex atrophy such as CBS, PSP, and nfvPPA generally performed worse on measures of speed reflecting motor execution. Conclusion: These results demonstrate we can detect and measure sensory-motor integration deficits in patients and that we can capture distinctive profiles across different neurodegenerative disease syndromes which may be useful for improving clinical diagnosis.

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disorder which observed amyloid plaques and neurofibrillary tangles. Appropriated medicine is not available so far. There are many animal models to imitate AD using mutant genes of presenilin and APP. However, these animal models which used mutant genes are based to familial dementia to developed young age. We proposed new animal model for AD using ibotenic acid (Ibo) and amyloid beta (Aβ) to induce neuronal cell loss. We injected ibotenic acid and Aβ into bilateral hippocampus of mouse at 6 week age. Animal behavioral test and histological analysis were shown to decline of learning, memory, neuronal cell loss and deposits of amyloid plaque in hippocampus regions. Total RNAs were used for global gene network. These results suggested that new animal model may be a useful tool to study as AD-like disease.

Abstract: Classical behavioural tasks used to test cognition in mouse models are usually low throughput and are in general very distinct from human cognitive tests. A source of variability for testing drugs in animal models of disease is the lack of automation, reproducibility and influence by experimenters in behavioural testing. The Bussey-Saksida touchscreen tasks provide a new paradigm for testing cognitive deficits in animal models of dementia and addresses most of the pitfalls above. In this study, using the 5-Choice Serial Reaction Time Task (5-CSRTT) we compared the performance of two different mouse models of familial Alzheimer's Disease (AD) (5xFAD and 3xTG-AD) and a cholinergic deficient mouse model. The AD mice present mutations driving Aβ42 overproduction and accumulation of amyloid-β-plaques. In addition the 3xTG-AD mice present mutated tau. Both male and female AD mice were tested longitudinally at 4, 7 and 10 months of age. We tested reproducibility of the tests by performing the same experiments at both the University of Western Ontario and the University of Guelph. The data was then used to create an online database of mouse performance in cognitive tests. Cholinergic-deficient mice presented attention deficits at 4 months as previously published. In both sites we observed similar attention performance in the two AD mouse lines when probed in the 5-CSRTT therefore data were pooled. Both 5xFAD males and females showed attention deficits at 7 months of age when compared to their age matched controls. Male and female 3xTG-AD mice showed deficits in attention earlier at 4.5 months of age. The 3xTG-AD mice continued to show greater attention deficits, compared to wild-type controls, at 7 and 10 months of age (170 mice in total). 5xFAD mice present higher accumulation of amyloid than the 3xTG-AD line in earlier ages, suggesting that the Tau mutation, rather than the accumulation of amyloid, may interfere with attentional performance at 4 months. This work provides an initial screening of comparative cognitive deficits in distinct mouse models of AD showing

reproducibility and robustness of results. These automated tasks lend themselves to high-throughput, and during this project we have been able to test close to 300 mice per day. These results point to the potential usefulness of the touchscreen behavioural tasks as powerful tools for drug screening in AD and other neurodegenerative diseases.

Title: The left fusiform gyrus is the crucial region of the neuroanatomical network underlying the core behavioral profile of semantic dementia

Authors: ***J. DING**[1], K. CHEN[3], Y. CHEN[2], Y. FANG[2], Q. YANG[3], Y. LV[4], N. LIN[5], Y. BI[2], Q. GUO[3], Z. HAN[2];

Abstract: Semantic dementia (SD) is a progressive cerebral atrophy disorder characterized by the loss of semantic memory in both the verbal and nonverbal domains. Given that abnormal regions or tracts are co-atrophied in SD, little is precisely understood about the regions or tracts

actually causing such semantic deficits (SD-causing regions or tracts). To address these issues, the present study investigated the relationship between the degree of cortical atrophy [i.e., the gray matter volume (GMV)] or whiter matter atrophy [i.e., mean fractional anisotropy (FA) value] and the severity of semantic deficits (i.e., the performance on three tasks: oral picture naming, picture associative matching, and word associative matching) in 19 SD individuals. We found 36 atrophic regions in the patients, and these regions primarily involved the bilateral temporal, ventral frontal, and insular cortices. Three of the atrophied regions (left fusiform gyrus, left hippocampus, and left parahippocampal gyrus) were associated with semantic impairments related to SD, and the GMVs of these regions significantly correlated to the scores on each semantic task. The left fusiform gyrus was further determined as an SD-causing region, and its GMV significantly correlated to the semantic performance scores after partialling out the GMVs of the left hippocampus and the left parahippocampal gyrus. The association of the left fusiform gyrus with semantic disruptions in SD was well sustained even when we controlled for a range of potential confounding factors (total GMV, overall cognitive state, laterality of brain damage, and non-semantic task performance). Finally, we observed that the mean FA values of the white matter tracts connecting the left fusiform gyrus with the left hippocampus and the left inferior occipital gyrus significantly correlated to the severity of semantic impairment in SD patients, when controlling for the above potential confounding factors. These results reveal the causal structural network of the left FFG as the center of semantic impairments in SD, providing direct evidence for a part of the anatomical framework of the semantic network.

Title: Alterations of learning-induced hippocampal ripples in a mouse model of Alzheimer’s disease impairs spatial memory formation

Authors: *O. NICOLE[1], S. HADZIBEGOVIC[1], J. GAJDA[2], B. BONTEMPI, PhD[1], T. BEM[2], P. MEYRAND[1];
[1]CNRS, Univ. Bordeaux, UMR-CNRS5293, Bordeaux, France; [2]Polish academy of science, Nalecz Inst. of Biocybernetics and biomedical engineering, Warsaw, Poland

Abstract: Post-learning hippocampal sharp wave-ripples (SWRs) generated during sleep or rest periods are thought to play a crucial role in information processing and memory formation. Accordingly, disrupting SWRs experimentally impairs spatial learning (Girardeau et al., Nat Neurosci 12(10): 1222-1223). While in pathological conditions, such as Alzheimer's disease (AD), abnormal hippocampal oscillations have been reported, the functional contribution of SWRs to the typically observed spatial memory impairments remains poorly understood. These memory impairments have been related to degenerative synaptic changes produced by the presence of soluble amyloid beta oligomers (Aβos) which, surprisingly, seem to spare the SWR dynamics during routine behavior. To unravel a potential effect of Aβos on SWRs in cognitively-challenged animals, we submitted vehicle- and Aβo-injected mice to spatial recognition memory testing in a modified version of the Y-maze tailored to maximizing spatial cognitive demand. After confirming the hippocampal-dependency of this task, we established its ability to detect spatial memory impairments, 15 days after a single intracerebroventricular injection of Aβos. We examined recognition memory performance either 10 minutes or 4 hours after encoding. While capable of forming short-term recognition memory, Aβ mice exhibited faster forgetting, suggesting successful encoding but an inability to adequately stabilize and retrieve previously acquired information. We then determined the signature of this Aβo treatment on hippocampal SWRs in mice without cognitive requirements or while undergoing a single spatial discrimination session. Without prior cognitive requirements, similar properties of SWRs (baseline occurrence rate, frequency, duration and power) occurring during slow wave sleep periods were observed in Aβ and control mice. In contrast, when cognitively challenged, the post-encoding and -recognition peaks in SWR occurrence rates observed in the first 40 min of recording in controls were abolished in Aβ mice, indicating impaired hippocampal processing of spatial information. Thus, our results reveal the crucial involvement of SWRs in spatial memory formation and identify the Aβ-induced impairment in SWRs dynamics as a putative disruptive mechanism responsible for the spatial memory deficits associated with AD.

Title: Novel 5-HT6 antagonist, SUVN-502 potentiates the effects of Donepezil on neurochemical and electrophysiological activity in rat hippocampus

Authors: S. DARIPELLI, G. BHYRAPUNENI, *K. MUDIGONDA, V. BENADE, G. AYYANKI, V. KAMUJU, R. PONNAMANENI, A. MANOHARAN, R. NIROGI;
Suven Life Sci., Hyderabad, India

Abstract: SUVN-502 is a potent and selective 5-HT6 antagonist being developed for the symptomatic treatment of Alzheimer's disease. SUVN-502 is orally bioavailable and has adequate brain penetration. SUVN-502 exhibited pro-cognitive properties when tested in various rodent models. When administered alone, SUVN-502 increased acetylcholine levels in brain regions involved in learning and memory, providing the neurochemical basis for the pro-cognitive effects in rodent models. Effect of SUVN-502 in combination with donepezil was evaluated using brain microdialysis for the modulation of acetylcholine, and EEG for the effects on power density of stimulation induced theta in hippocampus. Effect on the hippocampal acetylcholine was tested with SUVN-502 (3 mg/kg, p.o.) administered alone and in combination with donepezil (1 mg/kg, s.c.). Effect on the hippocampal theta activity was tested after administration of SUVN-502 (1 mg/kg, i.v.) along with donepezil (0.3 mg/kg, i.v.). Hippocampal theta activity was elicited by electrical stimulation of Nucleus Pontis Oralis in urethane anesthetized male Wistar rats. SUVN-502 alone produced moderate increase in acetylcholine levels. However, in combination with donepezil, SUVN-502 produced significant increase in hippocampal acetylcholine levels compared to donepezil alone. SUVN-502 produced significant potentiation of the donepezil evoked theta power in hippocampus. These results provide the neurochemical and neurophysiological evidence that SUVN-502 in combination with acetylcholinesterase inhibitor may be beneficial in the treatment of cognitive deficits associated with Alzheimer's disease.

Title: Alleviating effects of Fructus mume extracts on cognitive impairments in 5XFAD transgenic mice

Authors: *J.-C. PARK[1], J. MA[1], W. JEON[2], J.-S. HAN[1];
[1]Konkuk Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Oriental Med., Daejeon, Korea, Republic of

Abstract: Previous studies have demonstrated that Fructus mume (F. mume) extracts alleviated cognitive deficit in rats with chronic cerebral hypoperfusion and mice with scopolamine treatments. The present experiment was conducted to examine the effects of F. mume on cognitive impairments in the animal model for Alzheimer's disease (AD), 5XFAD transgenic mice with five familial AD mutations. The 5XFAD animal model is known to exclusively generate amyloid beta-42 and exhibit cognitive impairments. Daily administration of F. mume was started at 3 months of age and continued for 90 days. Cognitive function was evaluated in spatial memory version of Morris water maze task, object/location novelty recognition test, and contextual fear conditioning at the age of 6 months. In the behavioral tasks, 5XFAD mice with vehicle treatment showed impairments of hippocampus-dependent memory compared with those of non-Tg littermates, which was reversed by treating F. mume to 5XFAD mice. To elucidate the possible mechanisms underlying this memory improving effects of F. mume on 5XFAD mice, we examined alterations in hippocampal cholinergic function. As a result, reduced hippocampal choline acetyltransferase (ChAT) levels in 5XFAD mice were reversed by F. mume treatment, indicating that F. mume has enhancing effects on cholinergic neuronal functions. These results suggest that F. mume might have therapeutic effects on cognitive impairments in AD. Supported by a grant (K15310) from the Korea Institute of Oriental Medicine (KIOM).

Title: Neuropathological correlates of cognitive impairments in Alzheimer's disease

Authors: *F. CALON[1], C. TREMBLAY[1], A. FRANÇOIS[1], M. VANDAL[1], D. BENNETT[2]; [1]Fac Pharm. and CRCHUQ, Laval Univ., Quebec, QC, Canada; [2]Rush Alzheimer's Dis. Ctr., Chicago, IL

Abstract: The association between cognitive symptoms and post mortem neuropathological markers remain poorly defined in mild cognitive impairment (MCI) and Alzheimer's disease (AD). We therefore investigated the relationship between *ante mortem* global cognitive scores and series of key AD neuropathological markers assessed *post mortem* in the same brain cortex region from the same 36 volunteers (12 NCI, 12 MCI and 12 AD) from the Religious Order Study. Homogenates from the anterior parietal cortex were subjected to differential centrifugation procedures to generate soluble, detergent-soluble, insoluble formic acid and insoluble sarkosyl fractions. Biochemical approaches (Western immunoblots and ELISA) were performed to determine the relative levels of tau, Aβ, synaptic proteins and other AD-relevant markers. Semi-quantitive assessments of Aβ plaques, tau-laden tangles and TDP-43 inclusions were also analyzed. Overall, the strongest negative correlation coefficients were obtained for insoluble phosphorylated tau, insoluble Aβ42 and neurofibrillary tangles counts. Strong inverse associations were also established for TDP-43-positive cytoplasmic inclusion, total insoluble tau and Aβ plaque counts. The analysis of insoluble tau extracted using formic acid or sarkosyl-based procedures led to similar results. Of note, synaptophysin and septin were the two synaptic proteins positively associated with cognitive scores. No correlation was detected with soluble Aβ42 or soluble tau. In conclusion, our data collectively highlight the importance of the association between cognitive decline and the accumulation of phosphorylated tau and Aβ42 into a detergent-insoluble form. This substantiates the relevance of investigating these markers to understand the pathogenesis of AD and develop therapeutic tools.

Title: Impaired hippocampal synapse remodeling on GABAergic neurons correlates with memory deficits

Authors: *L. C. SCHMID, M. MITTAG, S. POLL, J. STEFFEN, S. REMY, M. FUHRMANN; DZNE, Bonn, Germany

Abstract: Aberrant neuronal activity and disturbed network function are important factors associated with Alzheimer's disease. Altered connectivity of inhibitory interneurons to excitatory neurons may contribute to the imbalance between excitation and inhibition and thereby destabilize the network. To analyze the effect of Aβ on network connectivity we investigated the structural plasticity of OLM interneurons in the hippocampus. OLM interneurons receive excitatory input in the stratum oriens and send axonal projections to the stratum lacunosum-moleculare where they synapse onto the distal dendrites of CA1 pyramidal neurons. Here, we analyze for the first time the structural plasticity of dendritic spines and axonal boutons of OLM interneuons in the stratum oriens and stratum lacunosum-moleculare respectively by long-term two-photon *in vivo* imaging over a period of 7 month. Dendritic spine density [0.7 +/- 0.05 μm^{-1}] was similar to that previously reported for interneurons in the cortex and significantly increased during aging while axonal bouton density [0.3 +/- 0.05 μm^{-1}] in the stratum lacunosum-moleculare stayed stable with increasing age. Throughout disease progression of APP transgenic mice (APP_{swe}/PS1dE9) dendritic spine turnover was significantly increased while the density stayed stable. Additionally, we observed a distinct loss of axonal structures. Our findings indicate that the connectivity of OLM interneurons is impaired during amyloidogenesis and might affect their role in hippocampal circuit. To further evaluate if altered spine dynamics could be relevant for learning deficits in APP transgenic mice, we analyzed the structural plasticity of spines during an associative learning task. In wild-type mice we observed an increase in gained spines during the learning phase, which were subsequently stabilized while the spine gain was absent in APP transgenic animals. This indicates that altered synaptic plasticity of dendritic spines might contribute to the learning deficit in APP transgenic mice.

Inst. of Alberta, [13]Fac. of Kinesology, Univ. of Calgary, Calgary, AB, Canada; [14]Psychiatry, Psychology & Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Identifying risk factors for preventing or delaying the onset of dementia is currently an important public health campaign. Without effective intervention or treatment, the prevalence of dementia worldwide could exceed 135-million individuals by the year 2050. Physical inactivity, and associated risk factors such as obesity and cardiovascular disease, account for the majority of known modifiable risk factors for dementia . Additionally, individuals with a low brain reserve, defined as low educational and occupational attainment, fewer mentally stimulating leisure activities and lower intelligence, were at an 85% increased risk of dementia compared with individuals with high brain reserve . The Brain in Motion study (n = 220, 53% female) is investigating the effects of an aerobic exercise intervention on brain health in inactive older adults (aged 55- 85). The primary aim of the current cross-sectional analyses was to examine the impact of lifetime and current cognitive and physical activity on cognitive performance in healthy older adults. Cognitive function was determined using a standardized neuropsychological test battery, current fitness was measured using a treadmill test to determine maximal oxygen uptake (VO2max), and current and lifetime physical and cognitive activities were assessed using self-report questionnaires. Multivariate regression and correlations were used to determine if

current or lifetime physical activity, current or lifetime cognitive activity, and current fitness predicted objective cognitive performance. All analyses controlled for age, years of education and sex. Participants had, on average, 15.96 years of education. Average VO2max for the study population was 26.13. The regressions revealed that lifetime cognitive activity, but not lifetime physical activity, was a significant positive predictor of global cognitive performance (β= 0.17, SE= .002, p= .007). Increased diversity of current cognitive activity, but not current fitness or physical activity, was a significant predictor of greater global cognitive performance (β= 0.15, SE= .009, p= .009). Post-hoc analysis revealed greater verbal memory performance was best predicted by increased diversity of current cognitive activities (β= 0.13, SE= .02, p= .04). These data suggest that current and lifetime cognitive activity are good predictors of current global cognitive functioning. These findings suggest that engagement in a range of activities that stimulate cognitive function (e.g., reading, creative arts, volunteer work) may be important for maintaining cognitive function, at least in healthy and well-educated older adults.

Title: Altered functional connectivity of prefrontal cortex underpins the abnormality of intra-individual variability in reaction time in mild cognitive impairment

Authors: *P. REN, R. WU, M. MAPSTONE, F. LIN;
Univ. of Rochester, Rochester, NY

Abstract: Background: Intra-individual variability in reaction time (IIVRT) is often considered a hallmark of cognitive dysfunction and is abnormally larger in mild cognitive impairment (MCI) compared to healthy controls (HC). Converging evidence confirms the role of the prefrontal cortex (PFC) in atypical IIVRT. New evidence showing that dopamine impacts IIVRT suggests

that the PFC may work with other regions (e.g., basal ganglia) to regulate IIVRT. In the present study, two PFC-based neural connections (i.e., the executive control network (ECN) and fronto-basal ganglia circuitry) were examined in relation to IIVRT in the early neurodegenerative process. Methods: We conducted a case-control study in 11 MCI participants and 7 age-, education-, and sex-matched HC. Four executive control tests addressing different levels of cognitive load were used to generate IIVRT. We used task-free functional magnetic resonance imaging (fMRI) to assess the PFC-involved neural connections. Results: As expected, we found greater IIVRT in the MCI group compared to HCs. In the MCI group, IIVRT was positively correlated with the degree of connectivity in the fronto-basal ganglia circuit, and negatively correlated with the ECN in the right hemisphere. Conversely, IIVRT was negatively correlated with connectivity in fronto-basal ganglia circuit, and had no correlation with the ECN in the HC group. Conclusions: The altered relationship between IIVRT and two PFC-involved neural connections in MCI may indicate an early marker of the neurodegenerative process, though further work determining the causal link is needed.

Title: Safety, tolerability and pharmacokinetics of a potent and selective 5-HT6 receptor antagonist, SUVN-502 following multiple ascending doses in healthy elderly humans, and effect of gender and food on single dose pharmacokinetics

Authors: ***R. V. NIROGI**, K. MUDIGONDA, K. PENTA, G. BHYRAPUNENI, D. AJJALA, N. MUDDANA, V. PALACHARLA, V. GOYAL, S. PANDEY, R. ABRAHAM, P. JAYARAJAN, R. KAMBHAMPATI, A. SHINDE;
Suven Life Sci., Hyderabad, India

Abstract: SUVN-502 and its active metabolite M1 of SUVN-502 are potent and selective 5-HT6 antagonists exhibiting cognitive enhancement in rodent models. SUVN-502 is being developed for the treatment of cognitive deficits associated with Alzheimer’s disease (AD). SUVN-502 was studied in a single-center, multi-faceted, phase 1 clinical trial (US IND) to evaluate its safety, tolerability, and pharmacokinetics after multiple ascending doses in healthy elderly male subjects. The effect of gender and food on SUVN-502 pharmacokinetics was also evaluated in

healthy subjects. SUVN-502 and its active metabolite M1 of SUVN-502 were quantified in plasma using a validated LC-MS/MS method. SUVN-502 was well tolerated up to the highest tested dose of 100 mg/day following single or repeated oral administration in healthy elderly male, and adult male and female subjects. There were no clinically relevant or serious adverse events. There was no significant effect of gender and food on the pharmacokinetics of SUVN-502 and M1 of SUVN-502 after single oral administration of 100 mg SUVN-502. SUVN-502 has shown a favorable safety and pharmacokinetic profile after single and repeated dose administration. SUVN-502 and M1 of SUVN-502 achieved the projected efficacy concentrations and attained steady state from the 7th day upon multiple administrations in elderly subjects. SUVN-502 is well tolerated in humans with adequate plasma exposure for efficacy, and favorable pharmacokinetics suitable for once a day oral administration.

Title: S-nitroso-proteome in individuals naturally resistant to Alzheimer’s disease

Authors: *O. ZOLOCHEVSKA[1], N. L. BJORKLUND[2], R. L. WOLTJER[4], J. E. WIKTOROWICZ[3], G. TAGLIALATELA[1];

[1]Neurol., [2]Neurosci. and Cell Biol., [3]Biochem. & Mol. Biol., UTMB, Galveston, TX; [4]OHSU, Portland, OR

Abstract: Alzheimer's Disease (AD) is an age-dependent disorder which impairs cognition and results in memory loss, progressive dementia and ultimately - death. Synaptic loss and death of neurons in AD correlate with excessive oxidative and nitrosative stress. In AD, S-Nitrosylation (SNO) is involved in regulation of function of cytoskeletal, synaptic and mitochondrial proteins. Despite the established fact of SNO involvement in AD, its pathological significance remains poorly understood. Nevertheless, certain individuals remain cognitively intact despite the accumulation of amyloid beta (Abeta) and neurofibrillary tangles (hereafter termed Non-Demented with Alzheimer's Neuropathology - NDAN). The mechanisms responsible for preservation of cognitive function in NDAN are currently unknown, and understanding them will provide targets for novel, effective therapies. We have previously reported that the post-synaptic density (PSD) of NDAN subjects is resistant to Abeta binding, thus protecting synapses and preserving cognitive ability. Therefore, we hypothesize that the PSD of NDAN subjects has a unique protein signature (both in terms of protein levels and SNO protein modifications) that protects synapses from detrimental binding of Abeta. In order to test our hypothesis, we performed proteomics analysis of PSD fractions of hippocampi of control, AD and NDAN subjects. Our results identified 31 unique proteins that differ significantly between AD and NDAN. DAVID and PANTHER were used to analyze molecular functions of identified proteins. We identified 15 cytoskeletal proteins, 2 enzyme modulators, 2 hydrolases, 2 kinases, 1 ligase, 3 proteins involved in membrane traffic, 2 oxidoreductases, one protein participating in redox signaling, two Ca2+-binding proteins and one carrier protein. In order to evaluate the S-Nitroso-proteome of PSD fractions, we performed the biotin-switch technique, followed by MALDI TOF/TOF and SNOFlo. Our results showed 34 differentially S-Nitrosylated proteins in NDAN vs AD. Using DAVID and PANTHER we found that of these 43 proteins, 14 were cytoskeletal, one adhesion and one Ca2+-binding protein, one carrier protein, 3 hydrolases, one protein involved in immune response, 4 kinases, 3 proteins participating in membrane traffic, one mRNA polyadenylation factor, 3 oxidoreductases, one redox signaling protein and one transferase. Taken together, these findings suggest that the PSD of NDAN has a unique abundance and SNO-modification protein signature that could be involved in protecting synapses from Abeta toxicity, thus possibly contributing to allowing NDAN subjects to retain cognitive ability.

Title: Impairment of intradimensional shift in an attentional set-shifting task in rats with chronic bilateral common carotid artery occlusion

Authors: *D.-H. KIM[1], B.-R. CHOI[1], W. JEON[2], J.-S. HAN[1];
[1]Konkuk Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Oriental Med., Dae Jeon, Korea, Republic of

Abstract: Studies of rats with chronic bilateral common carotid artery occlusion (BCCAo), an animal model for vascular dementia (VaD), have reported hippocampus-dependent memory impairment and associated neuropathologies. It is reported that patients with VaD also have attentional shifting dysfunction. However, no study has done to reveal neural attentional impairment and its underlying alterations in brain structures responsible for attention, using animal model of VaD. Therefore, the present study examined attentional function in rats with BCCAo, using attentional set-shifting task (ASST) that required rats to choose a food-baited pot from two possible pots. ASST included 6 consecutive sessions including simple discrimination, compound discrimination, intradimensional shifting, extradimensional shifting, and reversals. The BCCAo rats were significantly slower at learning the intradimensional set-shifting task compared to control rats. Previous studies have demonstrated that the cingulate cortex and medial prefrontal cortex are critical to intradimensional and extradimensional set-shifting, respectively. Additionally, inflammatory responses and neuronal alterations were observed in rats with chronic BCCAo. In addition, the number of OX-6 positive microglia was significantly increased in the forceps minor white matter of BCCAo rats, and glutamate decarboxylase signals co-localized with NeuN were reduced in the anterior cingulate cortex of BCCAo rats, compared to control rats. Alterations of GABAergic neurons in the anterior cingulate cortex, damage to white matter, and attentional impairments observed in BCCAo rats suggest dysfunction of brain structures that are associated with attentional impairments observed in patients with VaD. This study was supported by a grant (K15310) from the Korea Institute of Oriental Medicine (KIOM).

Title: Role of aberrant expression of neuroprotective genes in DLB and other synucleinopathy disorders

Authors: *P. C. MONTENEGRO[1], K. J. HEAD[2], B. DEHAY[3], E. BEZARD[3], J. JELINEK[4], Y. LIU[5], K. P. NEPHEW[6], J.-C. ROCHET[2];

Sch. of Med., Bloomington, IN

Abstract: Synucleinopathy disorders are characterized by the presence in post-mortem brains of Lewy body inclusions enriched with aggregated forms of the presynaptic protein alpha-synuclein (aSyn). Two examples of these diseases include dementia with Lewy bodies (DLB) and Parkinson's disease (PD). Pathogenic mechanisms underlying synucleinopathy disorders are poorly understood, and therapies targeting these diseases only temporarily relieve symptoms without slowing the underlying neurodegeneration. Here, we carried out a study aimed at determining the expression levels of a panel of candidate neuroprotective genes in post-mortem brain samples from DLB patients and age-matched controls (5 individuals in each group). mRNAs encoding the following proteins were quantified via qRT-PCR in homogenates prepared from cortex and cingulate gyrus: DJ-1, a protein with antioxidant and chaperone activities; PGC1-alpha, a master regulator of mitochondrial biogenesis and oxidative metabolism; MsrA, an antioxidant enzyme responsible for repairing oxidatively damaged proteins; and ATP13A2, a lysosomal protein involved in autophagy. In addition to yielding new insights into differential gene expression patterns in cortex versus cingulate gyrus, the data revealed differences in the expression levels of a subset of the mRNAs in DLB versus non-DLB cortical tissue. Notably, ATP13A2 mRNA levels were reduced in DLB cortex, and mRNAs encoding MsrA and PGC1-alpha showed trends towards being down-regulated. Additional studies revealed that aSyn neurotoxicity in primary midbrain cultures varies with the expression levels of each of these proteins. Collectively, our findings suggest that down-regulation of proteins involved in cellular antioxidant responses, mitochondrial function, and lysosomal autophagy contribute to

neurotoxicity in DLB and other synucleinopathies. Current efforts are aimed at mapping genome-wide epigenetic and transcriptional perturbations in DLB versus non-DLB brain tissue (our results suggest that genomic DNA is modestly hypomethylated in cortex and cingulate gyrus of DLB patients). These studies shed light on cellular pathways disrupted by aberrant gene expression in synucleinopathy disorders, and they set the stage for developing new therapeutic strategies.

Title: Functional evaluation of dementia-associated mutations

Authors: *Q. YUAN[1,2,3], N. HUSAIN[1], H. S. JE[1,3];
[1]Duke-Nus Grad. Med. School, Natl. Univers, Singapore, Singapore; [2]NUS Grad. Sch. for Integrative Sci. and Engineering, Natl. Univ. of Singapore, Singapore, Singapore; [3]Dept. of Physiology, Yong Loo Lin Sch. of Medicine, Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Triad3A/RNF216 is an E3 ubiquitin ligase that ubiquitinates and degrade the activity-regulated cytoskeletal protein (Arc), a key neuronal protein that regulates basal excitatory synaptic transmission through the endocytosis of AMPA-type of glutamate receptor. Rare, missense substitutions in TRIAD3A gene are genetically linked with familial form of dementia, but have not been functionally evaluated. Here, we identified that missense substitutions in Triad3A (R660C and R694C) fail to ubiquitinate Arc and cannot rescue decreased excitatory synaptic strength that results from the knockdown of endogenous Triad3A in neurons. Intriguingly, this loss of function effects of Triad3A mutants was due to disrupted cellular localization and their lack of Arc interactions. Taken together, our results indicate that loss-of-function mutations in Triad3A may contribute to dementia phenotype by modulating basal synaptic transmission through lack of Triad3A-dependent, Arc degradation.

Title: Chronic treatment with dimethyl sulfoxide (DMSO) affects neuronal structure and function *in vivo*

Authors: L. PENAZZI, J. LORENGEL, R. BRANDT, *L. BAKOTA;
Univ. of Osnabrück, Osnabrück, Germany

Abstract: Efficient drug delivery to the central nervous system is central for the treatment of cerebral diseases. However, a wide-range of potential drug candidates displays limited aqueous solubility, which complicates its delivery. One strategy to overcome this limitation is the systemic administration of these hydrophobic drugs in conjunction with an additive such as the aprotic chemical DMSO, which is widely used as a drug carrier. In clinical practices, DMSO is also directly used as treatment for traumatic brain injury or several forms of amyloidosis. Despite the commonly use of this solvent, the effects of DMSO on neuronal structure and activity remain poorly investigated and its potential additive effects to new drug candidates may be underestimated. Here, we addressed the question how chronic treatment with low dose of DMSO modulates synaptic plasticity in the presence or absence of a moderate level of beta-amyloid in a mouse model for presymptomatic Alzheimer’s disease (AD). To evaluate potential changes in synaptic connectivity, heterozygous APPSDL transgenic were crossed with homozygous EGFP expressing mice and dendritic spine morphology and density were evaluated in old male mice after oral self-administration of the drug. To explore effects on mice behavior, hippocampus-dependent and -independent learning performances were determined. We report that DMSO treatment significantly increases spine density on apical dendrites in the CA1 region of control animals and on basal dendrites in the CA3 region of APPSDL transgenic mice. Furthermore, we show that treatment with DMSO improves spatial memory performance and anxiety-like behavior in APPSDL transgenic animals. Therefore, we propose DMSO as a potential drug candidate for the prevention of amyloid beta-induced synaptotoxicity that contributes to cognitive and neuropathological symptoms in AD and other amyloidopathies.

Title: Braak stage relevance to cognitive impairment in nondemented elderly

Authors: *E. J. MUFSON[1], M. MALEK-AHMADI[2], K. CHEN[2];
[1]Neurolobiology, Barrow Neurologic Inst., Phoenix, AZ; [2]Banner Alzheimer's Inst., Phoenix, AZ

Abstract: Recent AD diagnostic criteria and initiation of clinical prevention trials necessitate the need to identify non-cognitively impaired (NCI) individuals in the pre-clinical disease stage. Amyloid imaging and clinical neuropathological studies reveal a significant percentage of NCI cases have levels of amyloid deposition and Braak neurofibrillary tangle stages similar to those with mild cognitive impairment (MCI) and AD. Here we determined whether composite scores from a battery of cognitive tests differentiate subjects with a premortem clinical diagnosis of NCI who upon postmortem neuropathological evaluation displayed low and high Braak scores. Data was analyzed from 123 NCI individuals (63 males; mean age 83.90±6.12 yrs.) from the Religious Order Study. Individuals were grouped based on Braak stage (Low = 0 to II, High = III to VI) with a median Braak stage of III (range of 0 to V). Group differences on several cognitive composite scores were assessed to determine if individuals with higher Braak stages differed from those with lower Braak stages. Unadjusted analyses showed that High Braak cases performed significantly worse than Low Braak subjects on tests of the Semantic Memory domain ($p = 0.01$). Adjusting for age at death, gender, and education this difference was not statistically significant ($p = 0.21$). Analyses revealed a significant education by Braak stage interaction on Semantic Memory performance ($p = 0.02$). Similar associations between Braak stage and cognitive function were found when cases were grouped based upon NFTs mainly in the transentorhinal cortex (Braak stages 0, I and II), limbic cortex (stages III and IV), and neocortex (stages V and VI). No significant differences were found for Global Cognition, Episodic

Memory, Working Memory, Perceptual Speed, and Visuospatial performance. The significant interaction between education and Braak stage suggest that factors relating to cognitive reserve may play a role in the ability to detect cognitive changes or that NFT pathology is not a necessary precondition for cognitive impairment in pre-clinical AD.

Title: 5-HT6 antagonist SUVN-502 potentiates the procognitive and neurochemical effects of combined treatment with donepezil and memantine

Authors: R. MEDAPATTI, *P. JAYARAJAN, R. ABRAHAM, G. BHYRAPUNENI, V. BENADE, G. AYYANKI, R. VENKATESHWARLU, N. MUDDANA, R. PONNAMANENI, R. NIROGI;
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Memory deficit is the most common symptom of Alzheimer’s disease. Memantine and donepezil are approved for the symptomatic treatment of cognitive deficits associated with Alzheimer’s disease (AD). Memantine added to stable donepezil in AD patients is associated with significant benefits in reducing decline in cognition, function and global status. SUVN-502 is a potent and selective 5-HT6 antagonist being developed for the symptomatic treatment of AD. We hypothesized that 5-HT6 antagonists may potentiate the therapeutic effects of memantine and donepezil. Therefore, the effect of SUVN-502 alone and in combination with memantine and donepezil was evaluated in object recognition task. The effect of the above combinations on the cholinergic neurotransmission was evaluated in the hippocampus of freely moving male Wistar rats using brain microdialysis. Co-treatment of SUVN-502, memantine and donepezil significantly potentiated the procognitive effects when compared with memantine and donepezil. Similarly co-treatment of SUVN-502 with memantine and donepezil significantly enhanced the acetylcholine levels in the hippocampus. The enhanced procognitive effects seen in the group co-treated with SUVN-502, memantine and donepezil can be attributed to the augmentation of the cholinergic neurotransmission in the brain. Thus combination of SUVN-502 with memantine and donepezil may offer a novel therapeutic strategy for the symptomatic treatment of AD.

Title: Memory dysfunction in a rat model of Alzheimer’s disease

Authors: ***C. R. GALLOWAY**[1], M. L. AIREY[2], K. RAVIPATI[2], R. M. COHEN[3], A. I. LEVEY[4], J. R. MANNS[1];
[1]Psychology, [2]Neurosci. and Behavioral Biol. Program, [3]Psychiatry, [4]Neurol., Emory Univ., Atlanta, GA

Abstract: Alzheimer’s disease (AD) is a growing health problem that affects millions of people, but current treatment options are limited. Many new candidate drug treatments have demonstrated efficacy in transgenic mouse models of AD, but ultimately fail in the clinic. One potential reason for the difficulty in translating preclinical findings into viable drug treatments for AD may be due to the differences between pathological features of human AD, such as tau pathology and cell death, and the pathology of transgenic AD mouse models that do not show these features. Recently, a transgenic rat model of Alzheimer’s disease (TgF344 rats) with human APPSwe and PS1ΔE9 mutations was developed (Cohen et al., 2013, J. Neurosci., 33: 6245-6256). Like mouse models of AD, TgF344 rats develop age-dependent build-up of amyloid pathology, such as soluble Aβ42 and plaques. Unlike mouse models of AD, TgF344 rats also develop tau pathology and profound cell death, making them a good model to probe questions about AD that may be more readily translatable to human AD. Moreover, using a rat model of

AD will increase the feasibility of using high-density *in vivo* electrophysiology to answer questions about how hippocampal dysfunction contributes to memory loss symptoms in AD. It was previously shown that TgF344 rats had intact spatial memory performance at 6 months of age but performed poorly on a spatial memory task at 16 months. In order to further understand this rat model of AD, in the current study we asked at what age between 6 and 16 months the TgF344 rats would show memory impairments, and whether spatial memory and non-spatial memory would be differentially impaired. 16 female Tg344 rats were tested monthly, beginning at 5 months of age, on a non-spatial and a spatial recognition memory task. We found that TgF344 AD rats (n=8) had impaired spatial recognition memory performance by 9-12 months of age relative to wild-type (WT; n=8) littermate controls. In contrast, TgF344 AD rats performed similarly to WT controls on the spatial memory task from 5-8 months of age and on the non-spatial recognition memory task from 5-12 months. The selective memory impairment of TgF344 AD rats from 9-12 months supports an important role of spatial memory dysfunction relatively early in the disease process. Subsequent studies will use *in vivo* electrophysiological recordings in the hippocampus to ask if TgF344 AD rats have dysfunctional neural representations of space (e.g. "place fields"), and, if so, whether systemic administration of a muscarinic acetylcholine receptor agonist might attenuate the dysfunction.

Title: Interaction between metabolic syndrome and Alzheimer's disease

Authors: *N. IVANOVA, N. WEISHAUPT, S. N. WHITEHEAD, D. F. CECHETTO; Anat. and Cell Biol., Western Univ., London, ON, Canada

Abstract: Accumulation of amyloid-β peptide and its cerebral deposition in a form of extracellular plaques are considered to be one of the major histopathological features of the Alzheimer's disease (AD). Insulin resistance and abnormal glucose metabolism, characteristics of type 2 diabetes and metabolic syndrome, has been also found to be implicated in

etiopathogenesis of AD linking these metabolic disorders with AD. Among other shared pathological mechanisms inflammation is of a great importance being one of the earliest processes contributing to cognitive decline prior to the plaque formation. Unhealthy lifestyle choice, particularly consumption of high-fat, high-sugar western type diets is a common risk factor for development of metabolic syndrome and increased incidence of clinical dementia. The existence of a common basis for these two pathologies raises the possibility of a contribution of metabolic disorders to the course of the dementia when these conditions are co-morbid, however, the underlying mechanisms of this interaction are yet to be elucidated. This study aims to investigate the co-morbid interaction between metabolic syndrome and AD and defining its role on the cognitive function in an aged co-morbid model of metabolic syndrome and AD. Male Fischer 344 wild type with intact genotype and transgenic overexpressing human β-amyloid precursor protein rats, 8.5-9 month old were maintained either on a hypercaloric western style diet with 40% energy from fat supplemented with 20% corn syrup drink or on control low-fat, low-sugar diet for 12 weeks. Metabolic changes were monitored using an intraperitoneal glucose tolerance test, blood lipid profile and insulin level analysis. Hypertension monitoring was performed using a non-invasive tail cuff method of blood pressure measurement. Spatial reference learning and memory were assessed using Morris water maze (MWM). Immunohistochemical staining was used to examine neuroinflammation and amyloid accumulation. Animals maintained on the western style diet developed significant obesity and metabolic changes. Results from the MWM demonstrated worsening cognitive performance trend in both co-morbid model of AD/metabolic syndrome and metabolic syndrome alone in the wild type animals. Immunohistochemical data have shown a greater neuroinflammation and amyloid deposition in the co-morbid model in comparison to metabolic syndrome alone. These results may be indicative of a possible mechanism of interaction between AD and metabolic syndrome.

Title: Identification and characterization of a novel $GABA_A\alpha5$ negative allosteric modulator

Authors: M. NAKANISHI[1], S. KAWAHARADA[1], N. NAKANISHI[1], K. HAZAMA[1], H. MIYATA[1], M. HIGASHINO[1], A. LEWIS[2], G. CLARK[2], M. CHAMBERS[2], K. HIRST[2], S. MAIDMENT[2], A. RAE[2], G. WISHART[2], *A. KISHI[1], T. YASUHIRO[1], S. KATSUMATA[1]; [1]ONO Pharmaceut. Co., Ltd, Osaka, Japan; [2]BioFocus, Saffron Walden, United Kingdom

Abstract: Background: $GABA_A$ receptors are pentameric membrane proteins that gate chloride ions in response to binding of γ-aminobutyric acid (GABA). $GABA_A$ ion channels containing the α5 subunit ($GABA_A$α5) are highly expressed in hippocampus, the key area for cognitive processing. $GABA_A$α5 negative allosteric modulators (NAMs) enhance cognition in rodents. Similar phenotypes are observed in animals with point mutations of $GABA_A$α5. We identified orally available $GABA_A$α5 NAMs. **Methods:** Approximately 124,000 compounds were screened in both receptor binding and FLIPR functional assay in HEK-293 cell line stably expressing $GABA_A$α5. $GABA_A$α5 NAM activities of hit compounds were confirmed in electrophysiological assay. In the lead optimization phase, compounds with high binding affinity and selective $GABA_A$α5 NAM activity were evaluated in passive avoidance test, 8-arm radial maze test and novel object recognition test in rats. Anxiogenic-like and proconvulsant effects associated with non-selective $GABA_A$ NAM activity were also evaluated in rat elevated plus maze test and mouse PTZ test, respectively. General toxicity was evaluated by a 4-day repeated oral dose toxicity study in rats. **Results:** We identified an advanced lead compound with high affinity (Ki value = 7.9 nmol/L), NAM activity (EC_{50} = 1.1 nmol/L, Emax = -50%), and selectivity for α5 (Emax for $GABA_A$α1, 2 and 3 = -2%, 5% and -6%, respectively). Receptor occupancies in rat hippocampus were 44, 53, 71 and 89% at 1, 3, 10 and 20 mg/kg (p.o., 1 h), respectively. This agent (3, 10 and 20 mg/kg, p.o., 1h) significantly reversed MK-801-induced cognitive deficit in rat passive avoidance test. This agent (10 mg/kg, p.o., 1h) significantly reversed scopolamine/MK-801-induced cognitive deficit in rat 8-arm radial maze test. Moreover, this agent (10 mg/kg, p.o., 1h) significantly enhanced cognition in normal rat novel object recognition test. In rat hippocampus slice, this agent (300 nmol/L) significantly enhanced long term potentiation. This agent did not show anxiogenic-like or proconvulsant effects. In general toxicity study, this agent (30 mg/kg, p.o.) showed no obvious toxicological findings except for slight high values of plasma total cholesterol and phospholipid. **Conclusions:** We identified a novel, selective, orally available $GABA_A$α5 NAM which enhances cognition without anxiogenic or proconvulsant side effects.

Title: ABCA7 variant and its impact on Alzheimer's disease

Authors: *J. VASQUEZ, S. ESTUS, J. SIMPSON;
Dept. of Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Genome-wide association studies (GWAS) identify single nucleotide polymorphisms (SNPs) that associate with Alzheimer's disease (AD). Adenosine triphosphate binding cassette A7 (ABCA7) reached significance within several of these studies warranting investigation into this association. Rs200538373, within ABCA7, increases risk for AD in a process predicted to involve loss-of-function. Elucidating the mechanism of action for this increased AD risk may help to target this pathway effectively with pharmacological agents. Our overarching hypothesis is that rs200538373 modulates ABCA7 expression leading to decreased phagocytic clearance of amyloid-beta (Aβ). Here, we investigate the effects of rs200538373 at the molecular level. In preliminary results, we found that the minor allele of rs200538373 is associated with the extension of exon 41 into intron 41, thereby modulating the reading frame. In our current work, we are quantifying expression of both isoforms using qPCR to discern the extent that the atypical isoform is modulated by AD status, other SNPs, or cell type differences in the samples. In addition, we will use minigenes containing each allele to determine directly whether the AD-associated SNP modulates splicing. The results of these experiments will be presented in Chicago.

Title: Amyloid β enhances typical rodent behavior while it impairs contextual memory consolidation

Authors: *K. G. SALGADO[1], F. PEÑA-ORTEGA[2], R. PRADO-ALCALÁ[2];
[1]Inst. De Neurobiologia, Queretaro, Mexico; [2]Univ. Nacional Autónoma de México, Queretaro, Mexico

Abstract: Alzheimer's disease (AD) is associated with an early hippocampal dysfunction, which is likely induced by an increase in soluble amyloid beta peptide (Aβ). This hippocampal failure contributes to the initial memory deficits observed both in patients and animal models, and possibly to the deterioration in activities of daily living (ADL). One typical rodent behavior that has been proposed as a hippocampus-dependent assessment model of ADL in mice and rats is burrowing. Despite the fact that AD transgenic mice show some evidence of reduced burrowing, it has not yet been determined whether or not Aβ can affect this typical rodent behavior and whether this alteration correlates with the well-known Aβ-induced memory impairment. Thus, the purpose of this study was to test whether or not Aβ affects burrowing while inducing hippocampus-dependent memory impairment. Surprisingly, our results show that intrahippocampal application of Aβ increases burrowing while inducing memory impairment. We consider that this Aβ-induced increase in burrowing might be associated with a mild anxiety state and conclude that Aβ-induced hippocampal dysfunction is reflected in a differential impairment of ADL and memory, through mechanisms yet to be determined.

Title: Contribution of neuroinflammation to Parkinson's disease in humanized immune system mice

Authors: *G. D. MANOCHA[1], K. L. PUIG[2], C. K. COMBS[3];
[1]Basic Sci., Univ. North Dakota, Grand Forks, ND; [2]Basic Sci., Univ. of North Dakota, Grand Forks, ND; [3]Basic Sci., Univ. of North Dakota, Grand forks, ND

Abstract: Reactive microglia have been associated with the histological changes that occur in Parkinson's disease brains and many mouse models of the disease. The presence of microgliosis during disease has been documented in many brain regions including the substantia nigra, striatum, hippocampus and various cortical areas. The rodent MPTP injection model of disease also produces striato-nigral microgliosis correlating with the loss of dopaminergic neurons. These findings support the notion that inflammatory changes contribute to cell loss during disease with the spectrum of change best characterized in rodent models. However, it is possible that immune responses in mice and humans may differ with respect to tissue or insult. In order to better profile specific inflammatory changes in the brain during human disease, we used female CD34+ humanized mice and the MPTP injection model. NSG mice engrafted with human CD34+ hematopoietic stem cells were injected with MPTP for comparison to MPTP injected C57BL/6 mice in order to quantify neuron loss, gliosis, inflammatory changes, and behavior. The mice were also treated with or without FK506 to quantify effects of immunomodulation on disease phenotype in each mouse line. MPTP injection produced the expected impairment of motor performance and tyrosine hydroxylase immunoreactivity in the substantia nigra and striatum of C57BL/6 mice with minimal effect of FK506 treatment. A similar decrease in tyrosine hydroxylase immunoreactivity and motor performance was observed in the MPTP injected CD34+ humanized mice demonstrating conservation of toxin-mediated neuron death in this line. More importantly, FK605 treatment had a dramatic effect on improving behavior performance but not tyrosine hydroxylase immunoreactivity in these mice. As expected, MPTP injection produced a significant increase in Iba-1 positive microglial staining in the striatum and substantia nigra of both mouse lines with FK506-mediated attenuation in the CD34+ humanized mice. These data demonstrate differences in the MPTP injection model of PD between female C57BL/6 and CD34+ humanized mice with a significant benefit of immunomodulation in the later.

Abstract: Parkinson's disease (PD) is the most common neurodegenerative movement disorder. Rho kinase (ROCK) was recently described as a novel molecular neuroprotective target in PD. Since alpha-synuclein (αSyn) aggregation is a major pathophysiological step in the development of PD, we aimed to evaluate the anti-aggregative potential of pharmacological ROCK inhibition using the isoquinoline derivative Fasudil, a small molecule inhibitor already approved for clinical human use. In a cell-free aggregation assay, Fasudil treatment significantly delayed αSyn aggregation and inhibited fibril formation. NMR spectroscopy revealed a direct binding of Fasudil to two tyrosin residues in the C-terminal region of αSyn. In a cell culture aggregation model using double transfection with synphilin-1 (SYPH1) and carboxy-terminally truncated αSyn (synT) in H4 human neuroglioma cells *in vitro*, the number of intracellular SYPH1/synT aggregates was significantly reduced after Fasudil treatment. Interestingly, site-directed mutagenesis against the C-terminal tyrosine residues abolished this effect. Furthermore, size-exclusion chromatography (SEC)-HPLC followed by dotblot analysis of synT indicated a shift towards smaller synT aggregates in the H4 model after Fasudil treatment. We then evaluated the impact of long-term Fasudil treatment on αSyn pathology *in vivo* using a transgenic mouse model expressing human αSyn.A53T. Fasudil treatment did not show any deleterious side effects. Motor behavior investigated by Catwalk gait analysis was significantly improved after Fasudil treatment. Additionally, Fasudil treatment improved recognition memory of αSyn.A53T mice as detected in the novel object recognition (NOR) test. Overall survival of αSyn.A53T mice treated with Fasudil was not significantly altered. Our data show that pharmacological ROCK inhibition directly alters αSyn aggregation in cell free as well as cell culture models *in vitro*, and improved motor behavior and cognition after long-term treatment in αSyn.A53T mice. This strengthens the value of Fasudil as a highly promising pharmacological candidate for disease-modifying therapies for PD.

Abstract: Heterozygous mutations of GBA1, the gene encoding glucocerebrosidase, represent the highest genetic risk factor for developing synucleinopathies such as Parkinson's disease (PD) and dementia with Lewy bodies (DLB). PD patients carrying mutated GBA1 alleles present a higher prevalence and severity of motor and non-motor symptoms, suggesting a link between the enzyme and the development of the disease. Furthermore, PD patients with or without GBA1 mutations also exhibit lower enzymatic levels of glucocerebrosidase in the central nervous system (CNS), thus implicating this lysosomal enzyme in the disease pathogenesis. However, the mechanisms by which GBA1 mutations lead to synucleinopathies remain unclear. The present studies demonstrate that reduction of glucocerebrosidase activity lead to α-synuclein accumulation and behavioral aberrations in the absence of GBA1 mutations. Partial glucocerebrosidase inhibition with CBE induced cognitive and motor deficits in the PrP-A53T-SNCA transgenic mouse accompanied by profound increase in α-synuclein. Conversely, augmenting glucocerebrosidase activity modulate synucleinopathy progression in the Thy1-SNCA mouse model of PD. Using gene therapy to increase glucocerebrosidase activity led to a decrease in proteinase K-resistant α-synuclein accumulation, amelioration of behavioral aberrations and prevention of dopaminergic loss. The data confirm that increasing glycosidase activity can modulate α-synuclein processing and reduce the progression of synucleinopathies. Collectively, these findings provide the first *in vivo* validation for augmenting

glucocerebrosidase activity in the CNS as potential therapeutic strategy for Parkinson's, regardless of the GBA1 mutation status.

Title: The role of neuronal peroxisome proliferator-activated receptors in the MPTP mouse model of Parkinson's disease

Authors: ***P. TEISMANN**[1], R. B. MOUNSEY[1], H. L. MARTIN[1], M. C. NELSON[2], R. M. EVANS[2];
[1]Univ. of Aberdeen, Aberdeen, United Kingdom; [2]Salk Inst., La Jolla, CA

Abstract: Background. Parkinson's disease (PD) is a progressive neurodegenerative disorder which can be modelled by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Neuroinflammation has long been implicated in the disease process. Activation of peroxisome proliferator-activated receptors (PPAR), namely PPARγ and PPARδ, has been shown to provide neuroprotection in PD, and the observed effect has been linked to anti-oxidant and anti-inflammatory effects of the PPARs. Objective. Herein we addressed the role of neuronal expressed PPARs in the MPTP-model of PD. Methods. Mice null for neuronal expressed PPARγ and/or PPARδ received a sub-acute regimen of MPTP (30mg/kg i.p., over 5 consecutive days). Expression of PPARγ and PPARδ was assessed by immunofluorescence. 21 days after MPTP, striatal optical density, striatal dopamine content and number of surviving dopaminergic neurons in the SNpc was assessed. Results. Presence of one or both these receptors show a trend toward protection against MPTP-induced neurodegeneration as higher dopaminergic cell immunoreactivity and striatal monoamine levels are evident. Although not significant, mice null for both receptors show the lowest levels of TH-positive cell bodies following MPTP administration (3033 ± 531 compared to wt controls: 4135 ± 766). Conclusion. This data supplements recent studies that have elected to use agonists of the receptors to regulate immune responses. The results place further importance on the activation of PPARs and the neuroprotective roles these have in inflammatory processes linked to neurodegenerative processes. But our studies show that the main protective role is played by glial rather than neuronal receptors, which will need further evaluation.

Title: Development of a leucine-rich repeat kinase 2 *in vivo* Parkinson's disease model by stereotactic intracranial injection of high-capacity adenoviral vectors

Authors: *A. KRITZINGER[1,2], T. CIOSSEK[2], B. FERGER[2], S. KOCHANEK[1];
[1]Dept. of Gene Therapy, Ulm Univ. Med. Ctr., Ulm, Germany; [2]CNS Res., Boehringer Ingelheim Pharma GmbH & Co KG, Biberach, Germany

Abstract: Mutations in the leucine-rich repeat kinase 2 (LRRK2) gene are the most common genetic cause of Parkinson's disease. The most prevalent mutation, G2019S, leads to increased kinase activity, which appears to be cytotoxic for neurons. LRRK2 animal models are of significant value for research to test therapeutic LRRK2 inhibitors counteracting the toxic impact of LRRK2_G2019S and to uncover general mechanisms underlying the development of Parkinson's disease. Only two out of five published LRRK2_G2019S transgenic rodent models, however, showed the hallmark of Parkinson's disease, which is degeneration of dopaminergic neurons (Ramonet et al., 2011; Chen et al., 2012; Li et al., 2010; Melrose et al., 2010; Zhou et al., 2011). Viral vectors are an alternative approach to introduce LRRK2_G2019S into the brain and they might be more successful in inducing neurodegeneration (Dusonchet et al., 2011; Lee et al., 2010; Tsika et al., 2015). One caveat with these viral vector based models is, however, that transgene expression decreases over time, likely due to immunologic clearance of transduced cells in response to low level expression of viral genes. We aim to develop a LRRK2_G2019S Parkinson's disease mouse model by stereotactic intracranial injection of high-capacity adenoviral vectors. This vector type lacks any viral coding sequences, thereby being an ideal tool to achieve long-term expression of delivered transgenes. We designed and generated high-capacity adenoviral vectors encoding either LRRK2_G2019S or the kinase-dead mutant LRRK2_D1994A. Since it is not known whether LRRK2_G2019S expression in neurons themselves or in surrounding glia is the trigger for neurodegeneration *in vivo*, we make use of two different promoters: the neuron-specific human synapsin promoter and the ubiquitously active chicken β-actin (CAG) promoter. To determine an optimal dose for intracranial injection resulting in efficient transduction and transgene expression without significant virus-mediated neuroinflammation, CAG-LRRK2 vectors were titrated in the mouse striatum. Immunohistochemical analysis showed that injection of 1.3E+08 vector particles lead to severe neuroinflammation accompanied by a loss of LRRK2 expression within three weeks. In contrast, we observed widespread LRRK2 expression and only mild neuroinflammation at low vectors doses between 1 and 4.3E+07 particles. After further refinement of vector dosage we will perform long-term studies on vector-injected mice. Behavioral, biochemical and immunohistochemical analyses will be employed to show if Parkinson's disease can be mimicked in this high-capacity adenoviral LRRK2-vector based mouse model.

Inst., Univ. of Bordeaux, Bordeaux, France

Abstract: Loss of function mutations in the gene ATP13A2 are associated with Kufor-Rakeb Syndrome and Neuronal Ceroid Lipofuscinosis. The former is designated as a rare inherited form of Parkinson’s disease (PD). The function of ATP13A2 is unclear but *in vitro* studies suggest that it is involved in the lysosomal degradation of proteins and in the homeostasis of manganese and zinc. We recently showed that ATP13A2-deficient (13a2) mice develop age-dependent sensorimotor deficits, and enhanced lipofuscinosis and accumulation of insoluble alpha-synuclein (aSyn) in the brain. The presynaptic protein aSyn abnormally accumulates in PD and is degraded in part through lysosomal-autophagy degradation pathways suggesting the relationship between ATP13A2 and aSyn may be important in PD. In order to better understand the function of ATP13A2 and its interaction with aSyn we developed double mutant mice that are ATP13A2 deficient (13a2) and overexpress human wildtype aSyn (aSyn). Female and male wildtype (WT), 13a2, aSyn, and 13a2-aSyn mice were tested on a battery of sensorimotor and non-motor tests including the challenging beam traversal test, spontaneous and locomotor activity, nest building, gait, object recognition, and elevated plus maze. Sensorimotor tests were performed at 2, 4, and 6 months (m) of age, while object recognition and elevated plus maze were performed at 2 and 6

months. At 2m of age female 13a2-aSyn mice displayed significant impairments on the challenging beam compared to WT mice while 13a2 and aSyn mice did not differ from WT. In addition, the impairment was progressive with 13a2-aSyn at 6m making significantly more errors compared to 13a2-aSyn at 2m. Similarly, 13a2-aSyn mice displayed increased locomotor activity at 2m compared to WT while 13a2 and aSyn mice did not differ from WT. An effect of the double mutation was also observed in the elevated plus maze. At 6m 13a2-aSyn mice spent significantly more time in the open arm compared to WT while 13a2 and aSyn did not differ from WT. These results indicate that loss of ATP13A2 function accelerates the behavioral phenotype in aSyn mice. Analysis of autophagy markers, aSyn, neuronal integrity, and microglial response are currently ongoing.

Title: Complementary phenotypic characterization of two genetically modified animal models of Parkinson’s disease: Line 61 and Line D

Authors: *S. RAMBOZ, K. CIRILLO, R. SPRINGER, M. MAZZELLA, M. WINDISCH, K. WALKER;
Psychogenics Inc., Tarrytown, NY

Abstract: Numerous genetic and pharmacological animal models have been generated to mimic different aspects of Parkinson’s disease, a neurodegenerative disorder estimated to affect more than 1% of the over-65 population. Parkinson’s disease is associated with the loss of nigral dopaminergic cells leading to a decline in dopamine levels. Due to this observation, depletion of nigral dopaminergic cells using lesion models have been developed and used to investigate the basis of symptomatic treatment. In the last couple of years, PsychoGenics has established and validated lesions models of MPTP and 6OHDA which are broadly used to assess neuroprotective drug treatments. Like any model, the lesions have a down side, provoking a very rapid loss of dopaminergic neurons, which would have taken decades in human. Slow cell loss and dopamine depletion would allow some compensatory mechanisms to take place, which might be not

present in the lesion models. Recently, PsychoGenics licensed a well described and validated genetically modified α-synuclein mouse line from Prof. Masliah's laboratory at UCSD: Line 61. This line is α-synuclein transgenic mouse model expressing the human α-synuclein cDNA under the murine Thy-1 promoter . Line 61 presents most of the characteristics of parkinsonism symptoms, including lack of coordination at 4 months, cognition deficit at 4.5 months, increased of total activity in open field by 7 months, hypolocomotion by 14 months and presence of α-synuclein positive aggregates. By 9 months of age, accumulation of phosphorylated Serine 129 residues in striatum and substantia nigra which might modulate the formation of protein aggregation likes inclusion bodies and fibrils. We are assessing the line 61 animal model using PsychoGenics proprietary technologies (SmartCube®, PhenoCube® and NeuroCube®) to retrieve early onset phenotype and establish high throughput preclinical readouts.

Title: Dysregulated macroautophagy and mitochondrial dynamics in pd with glucocerebrosidase mutations

Authors: *H. LI[1], A. HAM[2], M. CHENG[2], Y. QUAN[2], S.-H. KUO[2], G. TANG[2];
[2]Dept. of Neurol., [1]Columbia Univ. Med. Ctr., New York City, NY

Abstract: Glucocerebrosidase (GBA) is a lysosomal hydrolase. While homozygous GBA mutations result in Gaucher disease (GD), a prototypic lysosomal storage disorder, heterozygous GBA mutations are associated with α -synuclein aggregation disorders ("synucleinopathies"), including Parkinson's disease (PD) and dementia with Lewy bodies (DLB). Both homozygous and heterozygous GBA mutations produce an approximately 20-fold increase in the risk for PD. Recent studies provide mechanistic links between the GBA mutations and PD, including α -synuclein aggregation, lysosome and mitochondrial dysfunction. In the present study, we have examined fibroblasts from 8 controls and 8 GBA mutant PD (GBA-PD) patients for autophagy signaling and mitochondrial function/dynamics. In GBA-PD patients, GBA protein level is decreased by 30%, and the GBA enzyme activity is reduced by 45.5 %. Autophagy is suppressed in GBA-PD fibroblasts, as indicated by a decrease in LC3-II and an increase in P62 protein.

Consequently, we find an accumulation of mitochondria mass which is manifested by increased protein levels of Tom20 and porin, two mitochondrial membrane protein. Consistently, we find that mitochondria membrane potential decreases slightly and mitochondria reactive oxygen species accumulate in GBA-PD fibroblasts. We also detect an increase in protein levels of Mfn2 and Opa1 in GBA-PD patient fibroblasts, as well as GBA L444P heterozygous mouse brain, suggesting altered balance in mitochondria fission and fusion in response to GBA mutations. These observations indicate that GBA deficiency can interrupt autophagy pathway and lead to impaired energy and free radical homeostasis.

Title: Loss of striatal mitochondrial mitoNEET leads to a Parkinson’s disease phenotype in mice

Authors: *W. J. GELDENHUYS[1], L. LIN[1], P. SADANA[1], M. A. SMITH[1], G. N. WILSON[1], S. D. CRISH[1], D. M. INMAN[1], H. M. YONUTAS[2], P. G. SULLIVAN[2], A. S. DARVESH[1]; [1]Northeast Ohio Med. Univ., Rootstown, OH; [2]Univ. of Kentucky, Lexington, KY

Abstract: Parkinson’s disease (PD) is an age-associated neurodegenerative disease which affects the dopaminergic neurons in the substantia nigra. The loss of the neurotransmitter dopamine (DA) leads to the characteristic movement symptoms seen in PD. Mitochondrial dysfunction is thought to contribute to the pathology of the neuronal cell death in PD. Here we describe the effect of loss of the mitochondrial membrane protein mitoNEET in a novel PD model. We found that mice null for mitoNEET showed a significant decrease in DA as well as tyrosine hydroxylase levels in the striatum. Mitophagy was significantly affected in the mice null for mitoNEET with markers such as LC3 and P62 greatly reduced. Additionally we found significant increases in protein misfolding as seen from Congo Red histology of striatal brain section in five month old mice. Compared to mice with the transgenic strain FVB/NJ-Tg(Slc6a3-PARK2*Q311X)AXwy/J, where the mice express the mutant human parkin gene (PARK2) carrying the Q311X truncation associated with Turkish early-onset PD, mice null for mitoNEET

showed increased levels of reactive oxygen species in the striatum. Behavioral analysis using a battery of tests showed that mice null for mitoNEET had shorter stride lengths and were more prone to fall during a rota-rod assay. In conclusion, our data here indicates that mitochondrial dysfunction in the mitoNEET null mice contributes to a PD phenotype in the mice. Support: Michael J. Fox Foundation

Abstract: Mutations in the GBA1 gene encoding the lysosomal enzyme glucocerebrosidase (GBA) are an important risk factor for Parkinson’s disease. Altered GBA activity promotes alpha-synuclein accumulation and elevated levels of alpha-synuclein compromise GBA enzymatic function, thus supporting a pathogenic mechanism in PD. Because knock-out of GBA1 in the whole central nervous system in mouse induces massive neurodegeneration associated with early death, we sought to generate a mouse model of dopaminergic GBA deficiency to investigate the long-term consequences of compromised GBA function. Mice

expressing Cre recombinase under the control of the dopamine transporter promoter (DAT) were crossed with mice where GBA1 is flanked with two loxP sites between exons 9 and 11 in order to obtain animals with a selective disruption of GBA in dopaminergic neurons. DAT-GBA KO mice were assessed for motor function (pole test, challenging beam task), striatal neurochemistry, nigral lysosomal function, alpha-synuclein accumulation and number of dopaminergic neurons. DAT-GBA KO mice did not display motor impairments up to 12 month old. Lysosomal activity (beta-hexosaminidase, alkaline phosphatase, and cathepsin D) was unaffected in 4 month-old DAT-GBA KO followed with increased activity at 14 months. HPLC analysis of striatal levels of dopamine (DA) and metabolites revealed normal DA tissue content in DAT-GBA KO mice at 8 months, although there was a trend for reduced DOPAC levels and DA turnover. Histopathology revealed no significant effect of GBA deficiency in mice aged 8 months regarding alpha-synuclein accumulation and stereological counts of tyrosine hydroxylase-positive neurons in the substantia nigra. Whether nigral GBA deficiency affects dopaminergic neurodegeneration induced by viral-mediated overexpression of alpha-synuclein is currently being tested. Together, these results suggest that dopaminergic GBA deficiency in young to mature mice does not lead to detrimental effects on motor function and dopaminergic neurons in those young to mature animals.

Abstract: Heterozygous mutations in the GBA1 gene, which encodes for lysosomal glucocerebrosidase (GCase), have been identified as the most common genetic risk factor for Parkinson's disease (PD). Decreased GCase activity has been reported in PD patients, in both genetic as well as in sporadic cases and emerging experimental evidence suggests a correlation between this decreased activity and accumulation of alpha-synuclein (aSyn). These strong genetic and pathological links make GCase an attractive target for PD drug development. As such, The Michael J. Fox Foundation (MJFF) has made robust investments to address key questions to effectively translate GCase therapeutically for PD patients. First, are GBA1 mutations relevant to sporadic Parkinson's and could a therapeutic directed against GBA1-mediated Parkinson's be efficacious for general PD population? To address this challenge, MJFF has funded biomarker studies in samples from sporadic patients to determine how GCase levels/activity and lipid substrates relate to aSyn burden and disease severity. Also, MJFF initiated recruitment of 250 GBA1 (125 affected and 125 unaffected) mutation carriers to the Parkinson's Progression Markers Initiative to identify GBA1-related biomarkers and inform our understanding of the natural history of PD. Second, the hypothesis that reduced GCase activity is causative of PD via aSyn accumulation needs to be confirmed. To address this issue, MJFF has funded generation of animal models and tools that would aid in studying the reciprocal relationship between GCase and aSyn, and for testing efficacy. The GBA1 D409V knock in mouse model developed in collaboration with MJFF's Industry Tools Consortium shows a gene dose-dependent reduction in GCase activity and a corresponding increase in substrate accumulation. MJFF is further characterizing this model by crossing it with an aSyn transgenic mouse to determine if loss of GBA1 function affects aSyn induced pathology and related phenotypes. Third, it remains unclear what is the most optimal approach to target GCase therapeutically. To this end, MJFF has funded diverse programs to increase GCase activity to possibly slow disease progression and "reverse" synuclein-related pathological manifestations of the disease. This includes therapeutic programs which increase stabilization and lysosomal translocation of GCase or direct activation of GCase, which would increase the levels of functional enzyme in lysosomes. MJFF's vision is to apply a holistic strategy to address research and therapeutic challenges to enable accelerated development of GBA1-targeting therapeutics and optimally informed clinical trials.

Title: The effect of aging on catecholamines and purines levels in the basal ganglia of mice carrying the A53T and A30P alpha-synuclein mutations

Authors: A. K. PANI, D. B. LESTER, A. KORFF, *Y. JIAO, R. J. SMEYNE;
Developmental Neurobio., St.Jude Children's Res. Hosp., Memphis, TN

Abstract: The risk of developing Parkinson's disease increases with age. Although Parkinson's disease causation is multifactor in nature, a number of genes have been implicated in its genesis including the gene encoding alpha-synuclein (SNCA). Mutations in SNCA lead to an autosomal dominant form of parkinsonism, and the two most common mutations are A53T and A30P. Although there are many documented effects of these mutations, their effect on purine and catecholamine levels in the basal ganglia during aging have not been documented. Understanding how these levels change during aging is important since adenosine is known to be involved in modulation of the ATP pools (energy within the cell). Adenosine also acts as a non-classical inhibitory neurotransmitter and neuromodulator, that has been shown to act on catecholamine's, especially on dopamine levels and dopamine synthesis and turnover; two critical factors that underlie many of the motor symptoms in Parkinson's disease. Within the brain, purinergic levels are the combination of the additive actions of adenosine formation and breakdown; and thus are only a snapshot of total content of adenosine. The formation of adenosine is controlled by the enzymatic activity of intracellular and extracellular AMP-selective 5' nucleotidases that catalyze the breakdown of ADP and AMP. To determine if there are age-related alterations in these purine pools, we used the liquid- chromatographic techniques with an electrochemical detector to examine adenosine, ATP, ADP and AMP levels simultaneously, in the basal ganglia of wild-type mice as well as mice carrying mutations in the alpha-synuclein gene (A53T and A30P and SNCA-/-) at 4, 12, 18 and/or 24 months. The evaluation of striatal adenosine levels shows significant changes between WT and alpha-synuclein at each age examined. ATP alterations are seen in 4-month mice, while ADP changes are only seen at 24 months. No significant differences were observed in striatal AMP at any age. In the SN, adenosine levels shows significant changes between WT and alpha-synuclein at 12 and 24 months, while ATP changes are seen at 12 months, ADP changes are seen at 4, 12 and 24 months and AMP changes are seen at 12 and 24 months. The age-related alterations to purinergic contents will be compared with aminergic levels in the basal ganglia of mice carrying the A53T and A30P alpha-synuclein mutations.

Title: The accelerating rotarod is a more sensitive test for detecting dopamine-related loss of motor function than automated gait analysis

Authors: *D. ANDERSSON, M. RONILD, J. FULLERTON STØIER;
Neurodegeneration, H. Lundbeck A/S, Valby, Denmark

Abstract: The MitoPark (+/DAT-cre, TfamloxP/TfamloxP) mouse model is a progressive model of dopamine (DA) loss brought about by the conditional knock-out of the mitochondrial transcription factor A (Tfam). This transgene results in a gradual loss of DA neurons, resulting in a motor phenotype that develops gradually. In this study, we have evaluated the motor function of these mice by means of the accelerating rotarod test and the CatWalk, an automated gait analysis system (Noldus, Wageningen, The Netherlands). We repeatedly (once a week) tested Mitopark mice and littermate control mice (carrying one floxed copy of Tfam) in the two assays from a relatively early age (when motor function was similar in the two groups) and onwards until MitoPark mice developed a clear deficit in the respective assay. In parallel, we also evaluated the striatal dopamine content at various ages in order to create a timeline of DA loss. In addition, we were also able to completely reverse the deficits in the respective assays via treatment with the DA precursor L-3,4-dihydroxyphenylalanine (L-DOPA), demonstrating the DA-dependence of the respective phenotypes. Our results indicate that the rotarod deficit starts developing at around 10-11 weeks of age, when striatal DA levels are at around 30% of that in the littermate control mice. In contrast, the gait deficits as measured by CatWalk appear at a more advanced age (approximately 14-15 weeks), when DA levels are projected to be around 15-20%. In summary, the results of the current study indicate that while automated gait analysis allows for a more detailed investigation of the nature of gait deficits, measuring maximal motor performance via the accelerating rotarod constitutes a more sensitive method for detecting motor deficits related to loss of striatal DA levels.

Title: Sex and genotype specific differences in inflammation and degeneration of the substantia-nigral dopamine system in a multi-hit model of Parkinson's disease

Authors: ***S. BELLEVUE**, Z. DWYER, C. RUDYK, M. CHAIQUIN, S. HAYLEY; Carleton Univ., Ottawa, ON, Canada

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disorder, affecting more that 1% of the population over the age of 60. PD is characterized by the progressive loss of dopamine (DA) producing neurons in the substantia nigra pars compacta (SNc). This results in motor deficits such as bradykinesia, altered gait and trembling, as well as other non-motor symptoms. According to the multi-hit hypothesis, PD is precipitated by exposure to an array of risk factors, including environmental toxins, inflammatory insults, and genetic vulnerabilities over many years. Interestingly, males display increased rates of incidence and severity of PD symptoms. The objective of our current research is to assess sex and genotype specific differences in inflammation and neurodegeneration using a multi-hit PD mouse model. To achieve this, both male and female adult wild-type mice and adult mice containing the G2019S mutation in the leucine-rich-repeat kinase 2 (LRRK2) gene, the most common genetic anomaly found in PD patients, were exposed to inflammatory insult, lipopolysaccharide (LPS) and environmental toxin, paraquat (PQ). Specifically, animals were primed with a single peripheral LPS treatment, followed by six peripheral treatments with PQ spanned over 21 days. During this time, motor behaviours were assessed using catwalk, rotarod, and micromax apparatuses. DA degeneration and inflammation in the SNc, and blood-brain-barrier permeability were assessed using immunohistological assays. It was found that the LPS-PQ challenge caused sex and genotype specific degeneration and inflammation of the SNc-DA system, and disruptions in blood-brain-barrier permeability. Moreover, this disruption was accompanied by deficits in motor behaviour. These findings uniquely characterize the role sex and the G2019S-

LRRK2 mutation plays in PD pathology and further supports the multiple-hit model of PD etiology.

Abstract: Cholinergic interneurons have been implicated as key players in the pathogenesis of movement disorders. In synucleinopathies, the accumulation and aggregation of the alpha-synuclein protein in neurons of the basal ganglia network is critical for disease progression. Here we describe a mouse model overexpressing human wild-type alpha-synuclein in a subpopulation of striatal cholinergic interneurons that display bradykinesia and increased stereotypic behavior. We observed a 25% decrease in the number of cholinergic interneurons in the striatum and a concomitant reduction of ChAT expression in transgenic mice, but normal levels of extracellular dopamine, dopamine metabolites and synthesizing enzymes. Furthermore, remaining ChAT-positive interneurons that co-expressed alpha-synuclein showed a markedly reduced cell diameter compared to unaffected ChAT neurons. The resulting disruption of the striatal acetylcholine/dopamine balance in favor of dopamine induced an adaptive downregulation of D1 and D2 receptors (D1R and D2R), as well as upregulation of the muscarinic acetylcholine receptor M4 in transgenic mice, as shown in behavioral pharmacology and biochemical experiments. Interestingly, stereotypic movements induced by the D2R antagonist haloperidol were less pronounced and the anxiolytic effect of D1R agonists SKF81297 and apomorphine was completely reversed in transgenic animals, underlining the specificity of receptor subtypes and circuits involved in these behaviors. We conclude that pathological alpha-synuclein expression in cholinergic interneurons is sufficient to induce motor dysfunction and disruption of basal ganglia

synaptic integration through adaptive changes in receptor expression. Thus, our transgenic mice provide a useful model to test new therapeutic strategies for the treatment of synucleinopathies.

Abstract: Aggregation of misfolded proteins is a common feature of many neurodegenerative diseases (Jucker & Walker, Nature, 2013). Parkinson's disease (PD) is characterized by intracellular deposits of aggregated α-synuclein in the form of Lewy bodies and Lewy neurites, which appear in a stereotypical manner in the brains of PD patients (Goedert et al, Nature Reviews Neurology, 2013). The mechanism underlying the formation and spreading of α-synuclein pathology is still puzzling. Inoculation studies, where α-synuclein lesions are induced in susceptible hosts, suggest that α-synuclein behaves in a prion-like protein by templated misfolding of soluble α-synuclein into insoluble aggregates (Luk et al, PNAS, 2009). In the first part of our study we aimed to further characterize this phenomenon using different α-synuclein transgenic (tg) mouse lines that all develop α-synuclein lesions with aging followed by premature death. We found that α-synuclein aggregates among the lines are not only morphologically different but also exhibit differential proteinase K sensitivities. Furthermore, by using conformation-sensitive dyes, distinct morphological properties of α-synuclein aggregates in the various mouse lines were found. To further investigate these findings, we inoculated tg

hosts with brain-derived extracts from terminally ill tg donors. We found an acceleration of end-stage α-synucleinopathy with a significantly reduced life span. In summary, we show that the α-synuclein protein exhibits strain-like features and a cell-to-cell propagation reminiscent of prions. However, more studies appear necessary to characterize these different aggregates and how they might affect disease onset and propagation.

Title: LRRK2 plays a role in substantia nigra dopaminergic cell loss in an environmental toxin model of Parkinson's disease

Authors: ***C. A. RUDYK**, Z. DWYER, S. E. BELLEVUE, S. P. HAYLEY;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Parkinson’s disease (PD) is a chronic progressive neurodegenerative disorder characterized by the presence of motor and non-motor behavioural deficits. Much attention has focused on the commonly used pesticide, paraquat (PQ), as an environmental risk factor for the development of PD. Animal models using PQ have been shown to recapitulate many of the hallmark pathological features of the disease. Additionally, neuroinflammatory and oxidative processes are critically important for PQ-induced degeneration of the substantia nigra pars compacta (SNc) dopamine (DA) neurons. Indeed, priming SNc neurons with the inflammatory agent, lipopolysaccharide (LPS), influences the impact of later exposure to the pesticide. The leucine-rich repeat kinase 2 (LRRK2), a kinase mutated in both inherited and sporadic PD cases, has been shown to modulate neuroinflammatory processes. Findings demonstrate that LRRK2 regulates neuroinflammation and its ablation attenuates the microglia proinflammatory response. However, whether or not LRRK2 plays a role in LPS primed PQ-induced brain and behavioral

changes has not yet been characterized. Accordingly, we investigated the effect of LPS-PQ exposure in male LRRK2 knockout (KO) and wild-type (WT) mice on motor, degenerative, and inflammatory outcomes. Results showed that LPS infusion into the SNc sensitized DA neurons to the neurodegenerative effects of a series of paraquat injections commencing 2 days later as well as increased microglial response in WT but not KO mice. Moreover, these alterations were accompanied by motor behavioural disturbances. These findings suggest that LRRK2 is critically involved in PQ induced inflammatory cascades induced by LPS-PQ exposure.

Title: Exploiting the relationship between parkin and DMT1 to generate a novel "gene-environmental" mouse model of Parkinson's disease

Authors: ***B. H. CHAI**[1], C. ZHANG[1], A. Y. K. TAI[2], E. T. E. HONG[1], T. SOONG[2], K. LIM[1,2,3];
[1]Res., Natl. Neurosci. Inst., Singapore, Singapore; [2]Dept. of Physiol., Natl. Univ. of Singapore, Singapore, Singapore; [3]Duke-NUS Grad. Med. Sch., Singapore, Singapore

Abstract: Parkinson disease (PD) is a prevalent neurodegenerative disorder characterized by motor deficit as a consequence of damage to the nigrostriatal dopaminergic pathway. The disease remains incurable and the lack of a representative preclinical animal model has hampered efforts for drug discovery. Although the etiology of PD is unclear, exposure to divalent metals such as iron and manganese has consistently been implicated by epidemiological studies to be a significant risk factor for the disease. Under normal circumstances, cellular iron and manganese uptake is regulated by the Divalent Metal Transporter 1 (DMT1). Accordingly, alterations in DMT1 levels may underlie the abnormal accumulation of metal ions and thereby disease pathogenesis. Indeed, DMT1 expression has been demonstrated to be significantly elevated in the *substantia nigra* of PD patients compared to age-matched controls. Interestingly, parkin, a ubiquitin ligase associated with recessive parkinsonism, has separately been demonstrated to protect against metal-induced toxicity. Consistent with this, we found that the expression of

parkin is markedly enhanced in transgenic mice over-expressing DMT1, which likely explains their lack of observable phenotype. Accordingly, we have generated here a novel PD mouse model based on the transgenic overexpression of DMT1 against a parkin null background. Surprisingly, the double mutant mice display no significant nigrostriatal dopaminergic loss or overt locomotion defects in the absence or presence of long-term iron or manganese-enriched diet (fed over a period of 9-12 months) relative to control mice. However, these mutant mice do exhibit greater susceptibility towards 6-hydroxydopamine-induced dopaminergic neurotoxicty, and display enhanced rotational deficits following apomorphine administration as a result. Together, these findings suggests that multiple hits are required for the pathogenesis of PD to occur, which may help explain the lack of robust parkinsonism in virtually all the genetic mouse models of PD generated thus far.

Abstract: Loss-of-function mutations in the progranulin (PGRN) gene have been causally associated with a significant number of neurodegenerative diseases including frontotemporal dementia (FTD), amyotrophic lateral sclerosis (ALS), Alzheimer's disease (AD) and Parkinson's disease (PD). An insufficient level of PGRN leading to unrestrained inflammation is thought to contribute, in part, to the pathogenesis of these diseases. Whether dysregulated PGRN expression underlies the pathogenesis of PD and contributes to the loss of nigrostriatal dopaminergic neurons is as yet, unknown. Here we show that PGRN is expressed by midbrain dopaminergic neurons in mice and humans. Compared to the wild type mice PGRN deficient mice showed progressive age-dependent loss of nigrostriatal dopaminergic neurons as assessed by stereological cell counts of tyrosine hydroxylase and Nissl positive neurons in substantia nigra. In addition, PGRN-deficient mice showed augmented age-dependent accumulation of ubiquitin, alpha-synuclein, and TAR DNA binding protein-43, as well as activation of microglia and astrocytes in the substantia nigra. These neuropathological changes were associated with increased production of pro-inflammatory cytokines and chemokines but not mitochondrial dysfunction in the ventral midbrain of aged PGRN-deficient mice. Our data suggest that PGRN-deficiency could lead to the development of PD associated neuropathology due to exaggerated inflammation and aging. Therapeutic strategies to induce PGRN expression could serve as a promising approach to block neurodegeneration in PD.

Abstract: Introduction. Schizophrenia is a highly disabling disease, which would involve an imbalance in the dopaminergic neurotransmission and a glutamatergic hypofunction. The information processing appears to be deficient in schizophrenia. Prepulse inhibition (PPI), which measures the inhibition of a motor response by a weak sensory event, is considered particularly useful to understand the biology of information processing in schizophrenia patients. Drugs that facilitate dopaminergic neurotransmission such as amphetamine induce PPI disruption in human and rodents. Clinical and neurobiological findings suggest that the endocannabinoid system and cannabinoids may be implicated in the pathophysiology and treatment of schizophrenia. Cannabidiol (CBD), a non-psychotomimetic constituent of the Cannabis sativa plant, has also been reported to have potential as an antipsychotic. Objective. Our aim was to investigate if CBD pretreatment was able to prevent PPI disruption induced by amphetamine. Since one possible mechanism of CBD action is the facilitation of endocannabinoid mediated neurotransmission through anandamide, we tested the effects of an anandamide hydrolysis inhibitor (URB597) in the amphetamine induced PPI disruption. Methods. Male Swiss mice were treated with CBD systemic or intra-accumbens, or URB597 (systemic) prior to amphetamine and were exposed to PPI test. The PPI test consist of 64 trials irregularly divided into pulse (P, white noise, 105 dB), prepulse (PP; pure tone; 7kHz; 80, 85 or 90 dB), prepulse + pulse (PP+P) and no-stimuli with white background noise level of 64 dB - %PPI=[100-(PP+P/P)*100]. The PPI results were analyzed by mixed-design ANOVA with treatments (treatment 1, vehicle or CBD; treatment 2, saline or amphetamine) as the main independent factors, and prepulse intensity (80, 85, and 90 dB) as the repeated factor. Data from URB597 were analyzed by repeated measures with treatment as between-subject factors and prepulse intensity as a within subject factor. Duncan´s post hoc test ($p<0.05$) was used to specify differences. Results. Amphetamine (10 mg/kg) disrupted PPI while CBD (15-60 mg/kg) or URB597 (0.1-1 mg/kg) administered alone had no effect. Pretreatment with CBD attenuated the amphetamine disruptive effects on PPI test after systemic or intra-accumbens administration. Similar effects were also found with the inhibitor of anandamide hydrolysis. Conclusion. These results corroborate findings indicating that CBD induces antipsychotic like effects. In addition, they pointed to the nucleus accumbens as a possible site of these effects. The increase of anandamide availability may be enrolled in the CBD effects.

Title: Nitric oxide modulation effects in the reserpine-induced oral abnormal involuntary movements in rats

Authors: *M. BORTOLANZA, A. ISSY, K. BARIOTTO, C. A. DA-SILVA, E. A. DEL-BEL; Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: In patients with Parkinson’s disease L-DOPA-induced abnormal involuntary movement (dyskinesia) is an inevitable complication associated with long-term treatment. Rodents treated with reserpine develop spontaneous oral dyskinesia, usually described as vacuous chewing movements (VCM) and tongue protrusion (TP). In contrast to L-DOPA induced dyskinesia reserpine-induced oral dyskinesia develops rapidly reaching a maximal level within 3 days at a dose of 1 mg/kg per day. They are different with respect to the underlying disease, but they both share similarities. It is believed that a deregulation occurs at striatal dopaminergic receptors or related to non-dopaminergic neurotransmitters systems playing a role in the development and persistence of the mechanisms causing dyskinesia. Our group described that L-DOPA-induced dyskinesia in hemiparkinsonian rodents could be attenuated with nitric oxide synthase inhibitors. The aim of this study was to extend our findings to another experimental condition of pharmacologically induced oral dyskinesia. Thus, the present study investigated the nitric oxide system modulation on oral dyskinesia induced by reserpine. Male Wistar rats received either vehicle or reserpine (1mg/kg/day, s.c.) during two days, with 24h of interval, preceded by saline or the nitric oxide inhibitor NG-nitro-l-arginine-methyl ester (L-NAME; 10 or 50mg/kg/day, i.p.), or the nitric oxide donor sodium nitroprusside (SNP; 2 or 4mg/kg/day, i.p.). Rats were placed individually in glass cages containing a mirror at the wall to permit the evaluation of the VCM and TP. Animals were recorded during 5 min, after 1 min habituation. Data were analyzed with one-way ANOVA. Duncan´s post hoc test ($p<0.05$) was used to specify individual effects. Reserpine treatment elicits an increased number of abnormal involuntary oral movements in rats and reduced the locomotor activity. L-NAME at two different

doses significantly reduced reserpine-induced oral movements. SNP treatment showed no significant effects. These results corroborate and extend findings indicating that nitric oxide inhibitors are able to attenuate the pharmacological induced oral dyskinesia. This approach may allow the use of a simple rodent model to provide an initial assessment of whether potential adjunctive therapies to L-DOPA might have actions to reduce motor complications associated with L-DOPA therapy (dyskinesia). Given the simplicity of this model, acute systemic drug administration, compared with other models of dyskinesia (repeated L-DOPA-treatment in the 6-OHDA-lesioned rat) a potential utility in providing an initial indication of therapeutic benefit is great.

Title: Cannabidiol modulates L-DOPA induced dyskinesia via CB1 receptor

Authors: *M. S. PEREIRA[1], C. SILVA[2], F. GUIMARÃES[3], E. DEL BEL[2];
[2]FORP, [3]FMRP, [1]Univ. De São Paulo, Ribeirão Preto, Brazil

Abstract: The cannabinoid system is emerging as an important modulator of basal ganglia functions. Pharmacologic manipulation of this system represents a promising therapy to alleviate L-DOPA-induced dyskinesias (LID). Our aim is to verify if the major non-psychoactive cannabis constituent cannabidiol (CBD) modulates LID in hemiparkinsonian mice. C57BL/6 mice with a striatal 6-hydroxydopamine-induced lesion received L-DOPA (25 mg/kg + benserazide 10 mg/kg i.p.) for 21 days and develop dyskinesia characterized by axial, limb, locomotor and orofacial abnormal involuntary movements (AIMS). After that, mice received CBD (15, 30 or 60 mg/kg i.p.) 30 minutes prior to L-DOPA for 3 days. To analyze a possible involvement of the transient receptor potential vanilloid 1 receptors (TRPV-1) in CBD effects, the TRPV-1 antagonist capsazepine (1 or 5 mg/kg; 45 minutes prior to L-DOPA) was administered in association with CBD (30 mg/kg) or vehicle. We also treated animals with arachdonoyl-serotonin (AA5HT; 5 mg/kg i.p., 30 minutes prior to L-DOPA), an inhibitor of the fatty acid amide hydrolase (FAAH) and potent TRPV-1 blocker, in the hemiparkinsonian mice. For dyskinesia analysis, mice were videotaped and scored based on the protocol described by Pavon et al. (2006). CBD *per se* did

not influence axial, limbic and orofacial or locomotor AIMs in any of the doses (AIMS: CBD15: 30.38 ± 6.31 vs. 27.81 ± 6.40; CBD30: 34.63 ± 4,82 vs. 29.75 ± 5.13; CBD60: 34.63 ± 4.82 vs. 33.25 ± 6.40, $p > .05$); Locomotor: CBD 15: 2.56 ± 1.09 vs. 1.31 ± 0.60; CBD 30: 1.81 ± 0.72 vs. 0.93 ± 0.39; CBD 60: 1.91 ± 0.82 vs. 1.93 ± 0.67, $p > .05$). Capsazepine also did not reduce axial, limbic and orofacial AIMs at the dose of 1 mg/kg (34.56 ± 5.33 vs. 36.94 ± 5.68; $p > .05$) or 5 mg/kg (33.31 ± 5.89 vs. 28.63 ± 5.40, $p > .05$), as it was unable to change the locomotor AIMs (1mg: 1.37 ± 0.41 vs. 2.62 ± 0.52; 5mg: 1.62 ± 0.47 vs. 1.00 ± 0.43, $p > 0.05$). However, capsazepine associated with CBD significantly reduced axial, limbic and orofacial AIMs at both doses (1mg + CBD = 34.56 ± 5.33 vs. 15.88 ± 5.16; 5mg + CBD =33.31 ± 5.89 vs. 15.69 ± 5.70, $p < .01$) without altering locomotor AIMs (1g + CBD: 1.37 ± 0.41 vs. 0.87 ± 0.30; 5mg + CBD: 1.62 ± 0.47 vs. 0.81 ± 0.32, $p > .05$). Similarly, AA5HT significantly decreased axial, limbic and orofacial AIMs (31.88 ± 5.72 vs. 19.13 ± 5.26, $p < .01$) but did not alter locomotor AIMs (1.25 ± 0.48 vs. 1.56 ± 0.31, $p > .05$). Our data indicates that CBD when associated with CPZ decreases the manifestations of LID. Since CBD inhibits FAAH but activates TRPV1 receptors, our results, together with the effects of AA5HT, suggest that CB1 activation by anandamide associated with the blockade of TRPV-1 can be a possible treatment for L-DOPA-induced dyskinesia.

Title: Role of dorsostriatal D3 receptors in motivational processes: implication for neuropsychiatric symptoms in Parkinson’s disease

Authors: M. FAVIER, C. CARCENAC, G. DRUI, S. BOULET, M. SAVASTA, *S. CARNICELLA;
Grenoble Inst. Des Neurosciences - Inserm U836, LA Tronche Cedex, France

Abstract: We recently developed a rodent model reproducing the major motivational and affective impairments described in Parkinson's disease (PD), by using partial and bilateral 6-hydroxydopamine (6-OHDA) lesions of the substantia nigra pars compacta (SNc) (Drui et al., Mol Psychiatry, 2014). We further showed that the motivational deficits related to PD neuropsychiatric symptoms, observed in SNc-lesioned animals, can be fully reversed by specific activation of dopaminergic (DA) D3 receptors (D3R) (Carnicella et al., Transl Psychiatry, 2014). In the present study, using quantitative autoradiography, we demonstrated that D3R are specifically down-regulated in the dorsal striatum of 6-OHDA-lesioned rats. By combining intracerebral infusion of a selective D3R (SB-277011A) or D2R (L-741,626) antagonist into the dorsal striatum of non-lesioned animals with the use of instrumental and non-instrumental behavioral tasks, we showed next that blockade of D3R, but not D2R neurotransmission reproduce the motivational impairments seen in our lesion-based model. Moreover, we observed that the behavioral deficits related to dorsostriatal D3R inhibition was specifically implicated in the maintenance of instrumental behaviors. Interestingly, infusion of SB-277011A into the nucleus accumbens also modified the motivational state of the animals, but this effect was rather linked to deficits in the invigoration of reward-seeking behaviors. Our findings unravel an unsuspected involvement of dorsostriatal D3R in motivational processes and suggest complementary psychobiological roles of D3R in dorsal and ventral striatum. In addition, this study strengthens the idea that targeting D3R neurotransmission may be a valuable strategy for the treatment of PD-related neuropsychiatric symptoms.

Title: Functional connectivity changes following deep brain stimulation in the subthalamic nucleus measured with FDG-PET

Authors: E. KORDYS[1], N. APETZ[2], F. JUNG[2], B. NEUMAIER[1], A. DRZEZGA[3], L. TIMMERMANN[2], *H. ENDEPOLS[1];

Abstract: Deep brain stimulation in the subthalamic nucleus (DBS-STN) is a successful therapeutic approach to treat motor symptoms of Parkinson's disease. Because functional network changes underlying DBS-STN are not fully understood, we combined DBS-STN with functional [18F]FDG-PET in a rat hemiparkinson model. Parkinson-like symptoms were induced by injecting 6-hydroxydopamine (6-OHDA) unilaterally into the medial forebrain bundle. Automated gait analysis and [18F]FDOPA-PET confirmed motor impact and dopaminergic lesion, respectively. For DBS-STN an electrode was inserted through a chronically implanted guide cannula aiming at the ipsilesional STN. Two weeks after 6-OHDA injection, [18F]FDG (2 mCi) was injected intraperitoneally, and immediately after injection awake and freely moving rats (n=5) underwent one of three randomized stimulation conditions for 40 minutes: 1) DBS-STN with a pulse rate of 130 Hz. 2) OFF-stimulation. 3) Without electrode (control). 60 min after FDG injection, animals were anesthetized and a brain scan was acquired in a small animal PET scanner (Focus 220, Siemens). This procedure was repeated with the other stimulation conditions on different days. Ipsilesional DBS-STN increased metabolic activity compared to control in the ipsilateral striatum and septum in all animals. During OFF-stimulation contralateral hippocampal activity was lower than during control, indicating a mechanical effect of the electrode. Depending on the exact electrode location, FDG uptake increased during DBS-STN in the ipsilateral SNr, amygdala, piriform cortex, and ventral subiculum. Intra-individual difference images (DBS-STN minus OFF-stimulation) were used for a seed-based correlative analysis. The seed placed in the ipsilateral striatum revealed functional connections during stimulation to motor-related areas including the contralateral striatum, globus pallidus, M1, and cerebellum. Our study shows that DBS-STN changes functional connectivity in the basal ganglia network, particularly within key areas related to pathologic motor symptoms in a rat model of Parkinson's disease.

Title: A novel mouse model of Parkinson's disease: Diamide, a potent thiol oxidant, causes degeneration of dopaminergic neurons and Parkinsonism phenotype in mice

Authors: *A. RAY, M. KAMBALI, V. RAVINDRANATH;
Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Single unilateral administration of diamide, a potent thiol oxidant, into substantia nigra (SN) of mice leads to emergence of locomotor deficits and degeneration of dopaminergic neurons in the SN pars compacta (SNpc). Diamide-injected mice showed hemiparkinsonian behavior, measured as spontaneous contralateral rotations, poor grip strength and impaired locomotion on rotarod. Tyrosine hydroxylase immunostaining revealed significant loss of dopaminergic neurons in SNpc and their striatal fibers in the ipsilateral but not contralateral sides. We also saw an increase in Fluoro-Jade C labeling and loss of NeuN staining, indicative of neurodegeneration. Importantly, diamide injection led to ipsilateral aggregation of α-synuclein in SNpc neurons, a hallmark of PD pathology, not often discerned in animal models of PD. Upon investigating putative mechanism(s) involved in the degenerative process, we observed loss of the major non-protein thiol glutathione, which is essential for maintaining protein thiol homeostasis. Concomitant with loss of glutathione, we observed activation of the redox-sensitive ASK1-p38 MAPK death signaling pathway in ipsilateral but not contralateral ventral midbrain. In Neuro-2a cells, diamide activated ASK1-p38 cascade through oxidation of the thiol disulfide oxidoreductase thioredoxin 1, leading to cell death, which was abolished by ASK1 knockdown. Since diamide selectively disrupts protein thiol homeostasis, we can now attempt to understand the molecular determinants of the selective vulnerability of dopaminergic neurons to such perturbations. Identifying the precise role of dysregulation of protein thiol homeostasis in neurodegeneration, especially early in disease, will not only facilitate identification of death signaling cascades, but potentially aid in developing disease-modifying strategies for PD.

Title: Levodopa chronic treatment promotes reinforcing properties of pramipexole in an alpha-synuclein rat model of Parkinson's disease: linking behavior to transcriptional modifications

Authors: *S. LOIODICE[1,2], P. WINLOW[2], S. DREMIER[2], A. HAFIDI[1], A. NOGUIERA DA COSTA[2], F. DURIF[1];
[1]Univ. D'Auvergne EA7280 Npsy-Sydo, Clermont-Ferrand, France; [2]Non-Clinical Develop., UCB Biopharma SPRL, Braine-l'alleud, Belgium

Abstract: Parkinson Disease (PD) is characterized by a progressive dopaminergic (DA) cell loss in the Substantia Nigra pars compacta (SNc) inducing motor disorders which can be reversed by DA replacement therapies (DRT). About 10% of patients develop medication overuse, a disorder called dopamine dysregulation syndrome (DDS). Based on similarities between DA hypersensitization in drug addiction and PD, we hypothesized that DDS is due to a synergic effect of nigrostriatal lesion and repeated administration of DRT. Our objective is to specify the physiopathology of this addictive disorder. We performed a bilateral lesion of the SNc in rat (n=96) using an AAV-mediated strategy enabling the overexpression of the a-synuclein (a-syn) protein. Five weeks after surgery, animals were chronically treated with L-Dopa/benserazide during 3 weeks. Motor assessment was performed on week 8 by a rotarod test. Reinforcing properties of pramipexole (ppx) were assessed using a conditioned place preference (CPP) test. Brains were sampled for immunohistochemistry, microarray (genome-wide expression) and qPCR analysis. A-syn overexpression induced a SNc lesion (about 70% of DA cell loss) accompanied by significant motor coordination impairment that was reversed by L-dopa. Repeated administration of L-Dopa enhanced the reinforcing properties of ppx in the CPP test (1.4 fold increase of time spent in drug paired side after conditioning). This enhancement was increased when animals were SNc-lesioned (1.6 fold increase of time spent in drug paired side after conditioning) indicating that PD context and chronic DA stimulation may promote the reinforcing properties of ppx in a synergistic manner. Moreover, the molecular analysis highlighted a panel of 7 genes that were significantly modulated. With qPCR analysis, we confirmed an increase in expression of Oxt (associated to modulation of the DA pathway) in dorsal striatum of SNc lesioned animals receiving L-dopa. We also revealed that L-dopa induced expression of Egr2 and Grm5 (within lesioned animals). These results suggest that expression of the ppx rewarding properties could have been promoted by neuroplasticity events already described in dyskinesia and drug abuse contexts. The results obtained suggest that DDS is not only a side effect of DRT. It may be considered that DA hypersensitization related to PD is increased by repeated DA stimulation. To the best of our knowledge, this is the first study where

a transcriptional profile of DDS emphasizes the role of a neuroplasticity phenomenon associated to DDS and suggesting that over medication of DRT in PD occurs in a specific sensitized context.

Abstract: LRRK2 is a large cytoplasmic protein linked to an autosomal dominant form of Parkinson’s disease (PD). It contains multiple functional domains, including a kinase and GTPase domain, but the mechanism by which these mutations lead to disease remain unclear. Studies increasingly highlight the importance of autophagy in the biology of PD. Here we show that LRRK2 and its disease-associated mutations form a complex with HDAC6, a histone deacetylase known to regulate quality control autophagy (1). We further show that

phosphorylation of HDAC6 is enhanced in brains from patients with sporadic PD. We pursued this putative link further, and show that LRRK2 and its mutations stimulate tubulin deacetylation. Given the strong involvement of HDAC6 with autophagy and its tight regulation with LRRK2, we investigated whether LRRK2 regulates autophagy through this interaction with HDAC6. RNAi experiments reveal that LRRK2 harboring disease-associated mutations exhibits increased dependence on HDAC6 for regulation of autophagy. Similarly, overexpression experiments reveal the same close regulation of HDAC6 with the LRRK2 mutants. HDAC6 was also able to rescue neurite retraction in G2019S transfected SH-SY5Ys. These studies identify a key role for HDAC6 in LRRK2 biology. Disease linked LRRK2 mutations reduce the ability of LRRK2 to stimulate autophagic flux. These results highlight a novel mechanism for regulation of mutant LRRK2 deficits through HDAC6, and identify a pathway by which mutations in LRRK2 could mediate Parkinson's disease.

Abstract: Leucine-rich repeat kinase 2 (LRRK2) mutations are the most common cause of genetic Parkinson's disease (PD), accounting for 1-2% of all cases and up to 40% in some ethnic

groups. Several mutations in LRRK2 increase kinase activity and have been shown to be neurotoxic, hence the interest in the discovery and development of drugs that inhibit the kinase activity of LRRK2 to slow the progression of PD. To this end, Fuji et al. (2015) recently undertook and reported the results of toxicology studies of two LRRK2 kinase inhibitors (GNE-7915 and GNE-0877) in non-human primates (NHPs). Abnormal accumulations of lamellar bodies in type II pneumocytes were seen with both inhibitors after 7- and/or 29 days of daily dosing. The present study was undertaken with two major aims: (a) to confirm that the lung effect was not chemotype-specific and therefore mediated by inhibition of LRRK2 kinase activity, by testing LRRK2 kinase inhibitors of very distinct structural classes (PFE-360 and MLi-2), and (b) to assess the reversibility of the lung finding by evaluating NHP lungs after 2 weeks off dosing of GNE-7915. PFE-360 and MLi-2 were administered to cohorts at two dose levels for two weeks. GNE-7915 was administered at one dose level for two weeks as positive control, with one cohort evaluated after a 2-week dose-free period. The low doses of PFE-360 and MLi-2 targeted kinase inhibition similar to that reported for the GNE-7915 dose, and the high doses targeted 10x kinase inhibition. All three LRRK2 kinase inhibitors reduced pSer935 in the lungs by >90% at all doses tested (at Cmax). However, the same mild type II pneumocyte change was only observed at the high doses of PFE-360 and MLi-2. GNE-7915 also induced the effect as expected; importantly, absence of the lung change was seen after two weeks off dosing. Overall, these data indicate that the lung pathology is an on-target effect of LRRK2 kinase inhibition, but reversible. Encouragingly, we also observed that it was possible to inhibit brain LRRK2 kinase activity with the lower doses of PFE-360 and MLi-2 without producing the lung effect. Currently, we are investigating whether the abnormal lung morphology is associated with pulmonary functional deficits as this information is essential in assessing respiratory system risk and in informing the monitoring of this potential lung safety liability in patients.

Title: Histological and clinical pathology in LRRK2-related mouse and rat models

Authors: *T. N. MARTINEZ[1], M. A. S. BAPTISTA[1], M. A. GREELEY[2], M. T. HERBERTH[2], D. KOVARIK[1], A. MARTIG[1], K. D. DAVE[1], M. A. FRASIER[1], B. FISKE[1], T. SHERER[1]; [1]Res. Programs, The Michael J. Fox Fndn. For Parkinson's Res., New York, NY; [2]WIL Res., Ashland, OH

Abstract: Several mutations in the gene leucine-rich repeat kinase 2 (LRRK2) are associated with autosomal-dominant late-onset Parkinson's disease (PD). The common G2019S mutation in the kinase domain increases LRRK2 kinase activity and may explain LRRK2-related PD pathology. Thus, inhibition of LRRK2 kinase activity is an attractive target for developing novel therapeutic approaches for PD patients. As part of a broad effort to determine the impact of loss of LRRK2 function, which may be concomitant to pharmacological inhibition of LRRK2 kinase activity, we undertook a rigorous study of histological and clinical pathology readouts in LRRK2-related mouse and rat models. We previously reported progressive kidney pathology (cytoplasmic vacuolation, hyaline droplets, and pigment accumulation) and mild lung pathology (observed only with advanced age and by electron microscopy analysis) associated with loss of LRRK2 in Long Evans rats at several ages (Baptista, M.A. et al., PLOS One, 2013). Here we summarize recent pathology findings in LRRK2-/- and LRRK2+/+ C57Bl/6 mice at several ages, LRRK2 gene dosage effects in LRRK2-/-, LRRK2+/- and LRRK2+/+ rats, and potential LRRK1 genetic interaction in LRRK1/2 double knockout versus wild type rats. The progressive kidney pathology findings in LRRK2-/- mice generally recapitulated previous observations in LRRK2-/- rat models albeit with some species differences, including an apparent earlier onset in mice compared to rats. In addition, lung pathology (cytoplasmic vacuolation in Type II pneumocytes) was more severe in LRRK2-/- mice than in LRRK2-/- rats and observable using light microscopy. In the rat studies, we observed evidence of a LRRK2 gene-dosage effect for kidney pathology and apparent exacerbation of LRRK2-related kidney pathology with loss of LRRK1. However, studies to examine potential LRRK2 gene dosage effects or LRRK1 interactions were not conducted in mice. These results may inform follow-up pathology and toxicology studies aimed at therapeutic strategies to modulate LRRK2 levels or kinase activity.

Abstract: Parkinson's disease (PD) is a progressive disorder of the central nervous system leading to dopaminergic neuron loss. Although commonly sporadic, mutations in *PARK8*, encoding the Leucine-Rich Repeat Kinase 2 protein (LRRK2), have been associated with late onset autosomal dominant genetic forms of PD. The most common mutation of LRRK2, G2019S, leads to an increase in its kinase activity in transfected cells or transgenic knock-in mice. In cell cultures, this gain of function is directly related to neurotoxicity. LRRK2 is expressed in different tissues and notably in human peripheral blood mononuclear cells (hPBMC). Different sites of phosphorylation and autophosphorylation have been described including serine 935 (Ser935) which is correlated to the LRRK2 activity. We evaluated the effect of a new LRRK2 kinase inhibitor, ODS2005294 (IPSEN-ONCODESIGN compound), on LRRK2 phosphorylation on Ser935 after *ex vivo* incubation on fresh blood collected from PD patients with G2019S mutation (n = 11), and their first degree asymptomatic relatives carrying (n = 13) or not carrying (n = 10) the same mutation. Blood samples were collected in five centers in France and immediately incubated with ODS2005294 during 1h at 30µM (equivalent to 180 nM of free compound). Signals of pSer935-LRRK2 and LRRK2 were measured on hPBMC lysates by using a Homogeneous Time Resolved Fluorescence (HTRF) immunoassay. This technology based on a transfer of energy between two fluorophores fixed on antibodies was specifically

developed for this study and compared to western blots. Our data show a significant 64% (p value <0.001) decrease in pSer935-LRRK2 and 58% (p value < 0.001) for the ratio pSer935-LRRK2/LRRK2 in PBMCs for patients and relatives after LRRK2 inhibitor exposure as compared to vehicle. Similar results were found in parallel by Western blot. Altogether, we showed that ODS2005294 is able to inhibit the phosphorylation on the serine 935 of LRRK2 in hPMBC from subjects with PD with G2019S, as well as from their asymptomatic relatives with or without G2019S mutation. We were able to monitor this effect by a HTRF immunoassay suitable for a future use in clinical study.

Title: Modulation of LRRK2 kinase activity by a fragment of its COR domain

Authors: *A. SCHAFFNER[1], X. LI[2], Y. GOMEZ[3], I. UBARRETXENA[3], Z. YUE[2]; [2]Dept. of Neurol., [3]Dept. of Structural Biol., [1]Icahn Sch. of Med. At Mt. Sinai, New York, NY

Abstract: Mutations in the Leucine-Rich Repeat Kinase (LRRK2) gene have been linked to an autosomal-dominant form of Parkinson’s disease (PD). Early studies in primary neurons show that the toxic effects caused by pathogenic LRRK2 mutations are dependent on a functioning kinase domain. Therefore, a number of LRRK2 kinase inhibitors have been reported for therapeutic purposes, though none have succeeded in entering the phase of clinical trials. Beyond its kinase domain, LRRK2 is an active GTPase, contains multiple protein-interacting domains, and is known to form dimers in solution. However, there is little information on the full-length structure of LRRK2 and how its various functions are related. This complexity has motivated us to explore alternative mechanisms for therapeutic intervention. Here we report the study of the COR domain, which is the sequential link between the kinase and GTPase domains and may provide cis regulation of the two enzymatic activities. While previous work showed that the ROC-COR tandem domain could reduce LRRK2 kinase activity *in vitro*, we find that the COR domain alone can modulate LRRK2 kinase activity. We have mapped the inhibitory function to a fragment of COR domain. Furthermore, we find that the fragment of COR forms a dimer in solution. Through biochemical and biophysical analysis, structural modeling and cellular functional assays, we will uncover the precise mechanism by which this modulation of kinase activity occurs. Our study is expected to provide insight into how LRRK2 activity is regulated,

which in turn will assist in the identification of novel therapeutic strategies targeting LRRK2-associated PD.

Title: LRRK2 mediation of alpha-synuclein aggregation

Authors: ***Y. VOSKOBIYNYK**, L. A. VOLPICELLI-DALEY, A. B. WEST;
Dept. of Neurol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Lewy bodies and Lewy neurite inclusions principally comprised of alpha-synuclein are the primary characteristic of late onset Parkinson disease (PD) pathology. Mutations in leucine-rich kinase 2 (LRRK2) are the most common known genetic cause of dominantly inherited PD. Previous studies in model systems have demonstrated a link between LRRK2 and alpha-synuclein in neurodegenerative pathways, although the mechanisms underlying this link are not yet clear. Our goals are to first determine if LRRK2 activity enhances the formation of alpha-synuclein inclusions, and then determine if potential therapeutics that target LRRK2 inhibit alpha-synuclein inclusion formation. We focus efforts in primary neurons cultured from LRRK2 transgenic and knockout rodents that develop Lewy pathology induced by the administration of synthetic alpha-synuclein pre-formed fibrils (PFFs). To attribute changes in susceptibility to alpha-synuclein pathology directly to LRRK2, we further utilize highly potent and selective LRRK2 inhibitors to block LRRK2 kinase activity as well as antisense oligonucleotides to acutely block LRRK2 expression. Our findings are expected to contribute to understanding the efficacy of LRRK2 targeting as a therapeutic approach to ameliorate PD pathophysiology.

Title: Elevated Ser(p)-1292 LRRK2 in exosomes from Parkinson's disease subjects

Authors: ***K. B. FRASER**[1], R. ALCALAY[2], M. MOEHLE[1], D. STANDAERT[1], A. WEST[1]; [1]Neurol., Univ. of Alabama At Birmingham, Birmingham, AL; [2]Columbia Univ., New York, NY

Abstract: Leucine-rich repeat kinase 2 (LRRK2) mutations are the most common autosomal-dominant cause of Parkinson disease (PD). The penetrance of the most prevalent pathogenic LRRK2 mutation, G2019S, is incomplete, and the effects of the G2019S mutation on LRRK2 kinase activity have not been demonstrated in clinical samples. We evaluated a novel biomarker for LRRK2 kinase activity, Ser(P)-1292 LRRK2, in cell lines and human subjects with and without the G2019S LRRK2 mutation. Ser(P)-1292 LRRK2 was enriched in the kinase-active dimer isoform of LRRK2 protein, and all pathogenic LRRK2 mutations tested increased Ser(P)-1292 LRRK2 levels in transfected cell lines. In human urinary exosomes, G2019S carriers with PD had increased Ser(P)-1292 LRRK2 while asymptomatic G2019S carriers had lower levels. Increased Ser(P)-1292 LRRK2 levels in G2019S LRRK2 carriers with PD support a kinase-activation hypothesis for the mutation. We further evaluated the Ser(P)-1292 LRRK2 marker in urinary exosomes as a biomarker in idiopathic PD cases in a cross-sectional study at the University of Alabama at Birmingham Movement Disorder Program and found there to be a significant increase in Ser(P)-1292 LRRK2 in idiopathic PD cases versus healthy age and gender matched controls. We also observed a correlation between this marker and PD severity. Further studies are required in longitudinal cohorts to evaluate the potential of Ser(P)-1292 LRRK2 levels in the diagnosis and prognosis of PD.

Title: The role of LRRK2 in inflammaging and Parkinson's disease

Authors: *E. M. KLINE, D. A. COOK, G. T. KANNARKAT, J. CHANG, J.-K. LEE, J. M. BOSS, M. G. TANSEY;
Emory Univ., Atlanta, GA

Abstract: As individuals age, they become more susceptible to infections and the development of serious life-threatening diseases such as cancer, Alzheimer's and Parkinson's disease (PD). The immune system functions to prevent and fight infection as well as repair damaged tissues. Over time, a phenomenon known as immunosenescence occurs, where immune function becomes dysregulated leading to both a persistent low level inflammation and an increased susceptibility to development of disease. Leucine rich repeat kinase 2 (LRRK2) is a protein highly expressed in immune cells that has been reported as a negative regulator of nuclear factor of activated T cells (NFAT), a transcription factor essential to proper T cell function and activation. The *lrrk2* locus is associated with many immunological diseases, including Parkinson's disease, Crohn's disease, and increased risk for *Mycobacterium leprae* infection, indicating that it plays an important role in proper immune function. As reported in the literature, we have confirmed that LRRK2 is expressed in cells of the immune system (CD4+ and CD8+ T cells, CD14+ monocytes, and CD19+ B cells). In addition, we have established that there are time dependent changes in LRRK2 within T cells subsets upon activation. The relative expression levels in individual subsets of immune cells are not currently known. It is also not known how LRRK2 expression changes with age. We have found that at baseline, there is greater LRRK2 expression in T cells of subjects with PD. Following stimulation, LRRK2 expression levels increase in both monocytes and T cells, with no differences between PD patients and age-matched, healthy control subjects. We have also found that during T cell proliferation, subjects with PD have greater upregulation of LRRK2 compared to healthy

controls. By determining the role LRRK2 plays in modulating immune function, we will reveal opportunities to develop new therapies to treat or slow progression of age-related diseases involving immune cell dysfunction.

Title: LRRK2 small molecule inhibitors block α-synuclein-mediated dopaminergic neurodegeneration

Authors: *H. ABDELMOTILIB[1], J. P. DAHER[2], X. HU[1], P. GALATSIS[3], W. D. HIRST[3], A. B. WEST[1];
[1]Neurol., Univ. of Alabama At Birmingham, Birmingham, AL; [2]Sch. of medical sciences, Neurosci. research, Univ. of New South Wales, Sydney, Australia; [3]Pfizer neuroscience and pain research unit, Cambridge, MA

Abstract: Mutations in the leucine-rich repeat kinase 2 (LRRK2) gene can cause late-onset Parkinson's disease (PD). These mutations cluster within the catalytic core of LRRK2. Recent work has demonstrated that many of the pathogenic LRRK2 mutations result in an increase in LRRK2 kinase activity. LRRK2 is therefore a potential therapeutic target for small molecule kinase inhibitors. We can demonstrate that inhibition of LRRK2 kinase activity by a potent and selective orally-available LRRK2 kinase inhibitor, PF-06447475, significantly attenuates α-synuclein-induced dopaminergic neurodegeneration in a rAAV2-α-synuclein rat model. We extend these findings through utilization of a second class of LRRK2 small molecule inhibitors structurally distinct from PF-06447475 but with similar or superior potency and drug properties. These inhibitors are being used to delineate dose-responsiveness and timing of delivery with respect to α-synuclein induced neurodegeneration. Results from these studies may be useful for the design of additional pre-clinical studies and ultimately clinical trials for LRRK2-targeting therapeutics.

Title: LRRK2 mediates myeloid cell chemotactic responses

Authors: ***M. S. MOEHLE**[1], J. P. L. DAHER[1], T. D. HULL[2], R. BODDU[3], H. A. ABDELMOTILIB[1], J. A. MOBLEY[2], G. T. KANNARKAT[4], M. G. TANSEY[4], A. B. WEST[1];

[1]Neurol., [2]Surgery, [3]Med., Univ. of Alabama At Birmingham, Birmingham, AL; [4]Physiol., Emory Univ., Atlanta, GA

Abstract: The *Leucine rich repeat kinase 2* (*LRRK2*) gene is genetically and biochemically linked to several diseases that involve innate immunity. LRRK2 protein is highly expressed in cells of the immune system, most notably in myeloid cells capable of mounting potent pro-inflammatory responses. We and others have shown that knockdown of LRRK2 protein results in reduced pro-inflammatory responses and fewer myeloid cells recruited to the brain after insult. To study the effect of LRRK2 pathogenic mutations that cause Parkinson's disease on myeloid cell function, we utilized rats expressing G2019S LRRK2 from a human bacterial-artificial chromosome. G2019S-LRRK2 expression caused an exaggerated pro-inflammatory response and subsequent neurodegeneration after lipopolysaccharide injections in the substantia nigra, with a marked increase in recruitment of CD68 myeloid cells to the site of injection. While G2019S LRRK2 expression did not affect cytokine or chemokine release or phagocytosis, myeloid cells expressing G2019S LRRK2 showed enhanced chemotaxis both *in vitro* in two-chamber assays as well as *in vivo* in response to thioglycollate injections in the peritoneum. The G2019S mutation enhanced the association between LRRK2 and actin-regulatory proteins that control chemotaxis, and this interaction and the enhanced chemotaxis can be blocked by LRRK2 kinase inhibitors. In order to better understand how LRRK2 kinase activity may modulate actin-regulatory networks important for chemotaxis, we employed an unbiased SILAC based whole-phosphoproteomic approach in primary macrophage cells. Differential phosphorylation of actin-regulatory protein complexes may explain the effect of LRRK2 kinase inhibitors on myeloid cell chemotaxis. Taken together, these results suggest that the primary mechanism of G2019S LRRK2 with respect to myeloid cell function in disease may be related to exaggerated chemotactic responses through up-regulation of actin-mediated cell motility.

Title: Lrrk2 autophosphorylation enhances gtpase activity

Authors: *Z. LIU[1], L. DELUCAS[2], W. ANDREW[3];
[2]Optometry, [3]Neurol., [1]Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: The leucine rich repeat kinase 2 (LRRK2) protein possesses both GTPase and kinase activities, with mutations in either enzymatic domain resulting in late-onset Parkinson disease (PD). GTPase proteins are critical upstream modulators of many protein kinases, but in LRRK2, the kinase domain autophosphorylates several amino acids within its own GTPase domain (known as ROC) which might regulate the GTPase activity. Pathogenic mutations up-regulate autophosphorylation of the ROC domain. Despite predictions using the crystal structure of ROC that suggests phosphorylation of the nucleotide pocket would block nucleotide binding, we find that autophosphorylated ROC has normal nucleotide binding properties. Despite normal off-rates of nucleotide, the GTPase activity of autophosphorylated ROC is stimulated compared to non-phosphorylated ROC. ROC dimerization has been implicated in GTPase activity, and we found that autophosphorylation of ROC promotes the formation of GDP-bound protein dimers. However, we found equivalent GTPase activity associated with monomeric and ROC dimers, suggesting the increased GTPase activity in autophosphrylated ROC is not due to ROC dimerization. Molecular modeling predictions based on the local effects of phosphorylation show that the addition of phosphates, particularly to the p-loop residues, may enhance GTP hydrolysis through promoting the catalytic action of bound magnesium. Mining the phospho-proteome database revealed that phosphorylation in equivalent p-loops occurs in many other well-known GTPases including members of the Rab and Rho superfamilies. Therefore phosphorylation might be a common mechanism in regulation of GTPase activity. The unique configuration and biochemistry of LRRK2 has uncovered a novel mechanism for kinase-mediated control of GTPase activity that warrants further exploration in both LRRK2 and other GTPases.

Title: Identification and Characterization of a novel LRRK2 kinase inhibitor: ODS2005294

Authors: *B. SPINNEWYN[1], C. BERTHET[2], G. MAUTINO[1], O. LAVERGNE[1], P. BLOM[2], J. HOFLACK[2];
[1]IPSEN, Les ULIS, France; [2]Oncodesign, Dijon, France

Abstract: Leucine-rich repeat kinase 2 (LRRK2) has been identified as a potential target for disease-modifying therapy in Parkinson's disease (PD) because mutations in its catalytic core have been associated with both autosomal-dominant and late-onset sporadic PD. Most described LRRK2 mutations and notably the well characterized G2019S, enhance kinase activity suggesting that small molecule LRRK2 kinase inhibitors may serve as potential therapeutic agents Our strategy was to design and develop LRRK2 kinase inhibitors crossing the blood-brain barrier (BBB) using the Nanocyclix® technology based on small macrocycles that readily cross the BBB. One of our lead compounds, ODS2005294 was shown to exert potent inhibition on LRRK2 *in vitro* (IC_{50} = 9 nM and K_i = 0.6 nM), with cellular activity (IC_{50}) of 79 and 52 nM on hWt and hG2019S transfected cells, respectively. Of 386 profiled kinases, only 7 demonstrated more than 50% inhibition at 0.1µM of ODS2005294. *In vivo*, ODS2005294 administered by oral route was cleared rapidly from plasma and demonstrated good brain penetration (total Brain/Plasma ratio = 4.4). In CD1 or BAC transgenic mice expressing human LRRK2 protein (Wt or G2019S mutation) robust concentration-dependent knockdown of pLRRK2 in brain and peripheral tissues (kidney and PBMC) was observed (from 15 to 100 mg/kg), based on p Ser935 levels and measured compound concentrations. Based on its encouraging *in vitro* and *in vivo* profile, ODS was progressed further to early *in vitro* and *in vivo* toxicological studies. This compound provides a starting point for developing a candidate that could ultimately be used to address the therapeutic benefit of inhibiting LRRK2 in Parkinson's patients harboring the LRRK2 G2019S mutation.

Title: The protective R1398H LRRK2 variant affects GTPase activity and canonical Wnt signalling

Authors: *D. C. BERWICK[1,2], J. NIXON-ABELL[1,3], S. GRANNO[1], V. A. SPAIN[1], C. BLACKSTONE[3], K. HARVEY[1];
[1]UCL Sch. of Pharm., Univ. Col. London, London, United Kingdom; [2]Life, Hlth. and Chem. Sci., The Open Univ., Milton Keynes, United Kingdom; [3]Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Hereditary mutations in *LRRK2* are a common cause of Parkinson's disease (PD), yet how these mutations act, and indeed the basic function of LRRK2 protein, is disputed. A further *LRRK2* single nucleotide polymorphism, encoding an R1398H amino acid substitution within the LRRK2 Roc domain, has been reported and is suggested to confer protection from PD. Despite this tantalising possibility, the LRRK2 R1398H variant remains almost entirely unstudied in cellular and *in vitro* assays. Here, we present evidence that R1398H affects LRRK2 function in the opposite manner to pathogenic mutants. In contrast to PD-causing mutations within the LRRK2 Roc and COR domains, LRRK2 R1398H displays elevated GTPase activity. Remarkably, and in contrast to pathogenic mutations throughout LRRK2, R1398H enhances canonical Wnt signalling. Providing a mechanistic explanation for these observations, we use molecular modelling to show that arginine-1398 lies in close spatial proximity to PD-causing mutations in the Roc and COR domains, and is likely to affect intramolecular Roc-COR domain interactions. Taken together, our data suggest that the protective and pathogenic effects of LRRK2 mutants may be mediated by increased and decreased canonical Wnt activity, respectively; and that R1398H is indeed a *bona fide* protective mutation. In light of the neuroprotective role of Wnt signalling, our data could have important implications for the treatment of PD.

Title: Nicotine improves abnormal mitochondrial morphology but not turnover in Parkin loss-of-function *Drosophila* dopaminergic neurons that modulate motor behavior

Authors: *L. M. BUHLMAN[1], J. CACKCOVIC[1], G. B. CALL[2], S. GUTIERREZ[1];
[1]Biomed. Sci., [2]Arizona Col. of Med., Midwestern Univ., Glendale, AZ

Abstract: Parkinson's disease (PD) is characterized by a selective degeneration of dopaminergic neurons in the substantia nigra *pars compacta*. Mitochondrial pathology is heavily implicated in both sporadic and familial forms of PD, including Autosomal Recessive Juvenile Parkinsonism (ARJP), which is often caused by mutations in the *PARK2* gene. Parkin, the cytosolic ubiquitin ligase product of *PARK2*, has been shown to promote the turnover of mitochondrial import proteins and respiratory chain enzymes. Homozygous $park^{25}$ mutant *Drosophila* have decreased mitochondrial function that selectively affects dopaminergic (DA) neurons. Decreases in mitochondrial function initiate network fragmentation and mitophagy, a quality control mechanism in which mitochondrial networks become fragmented, and poorly functioning organelles are digested by lysosomes. Using 3D image processing in heterozygous Parkin loss-of-function *Drosophila melanogaster* that express a mitochondrially-targeted GFP in Tyrosine hydroxylase-producing cells, we have shown that mitochondria are fragmented and lost in dopaminergic neuronal clusters that are functionally homologous to the mammalian substantia nigra *pars compacta*. In order to explore whether the mechanism by which nicotine administration selectively improves heterozygous Parkin loss-of-function phenotypes in *Drosophila*, we measured mitochondrial network morphology and volume in mutant flies raised on nicotine food and found that nicotine affects mitochondrial morphology, but does not prevent loss of mitochondrial network. Interestingly, mitochondrial network volume was decreased in control flies raised on nicotine food; this result provides insight to the potential mechanism by which nicotine reduces lifespan, climbing and flight capabilities in control flies. Our results shed light on the mechanisms of Parkin loss-of-function pathology, propose that nicotine may improve the mutant phenotype via effects on mitochondrial function, and further substantiate the use of *Drosophila* as a model of ARJP.

Title: Lack of dopaminergic neuron degeneration in the substantia nigra pars compacta of non-human primates with chronic manganese exposure

Authors: *K. K. GONZALES[1], J. MCGLOTHAN[1], K. H. STANSFIELD[1], J. S. SCHNEIDER[2], T. R. GUILARTE[1];

Abstract: Movement abnormalities caused by chronic manganese (Mn) intoxication clinically resemble but are not identical to those in idiopathic Parkinson's disease (iPD), a disorder linked to the progressive, large-scale degeneration of dopaminergic neurons in the substantia nigra pars compacta (SNpc). Clinical evidence from individuals with Mn-induced parkinsonism has revealed functional dopaminergic terminals in the striatum, along with an unresponsiveness to the anti-parkinsonian dopaminergic drug levodopa (Perl & Olanow, 2007). In agreement, pre-clinical data from our laboratory has shown markedly impaired dopamine release from intact nigrostriatal dopaminergic axon terminals in Mn-exposed monkeys (Guilarte, 2006, 2008). However, in-depth pathological studies as performed in iPD patients and parkinsonian animal models are still needed for Mn-induced parkinsonism. We used a non-human primate model of Mn-induced neurotoxicity to determine if Mn-induced parkinsonism involves degeneration of SNpc dopaminergic neurons. We collected serial sections (1:8) from the entire rostrocaudal extent of the dopaminergic midbrain for unbiased stereological cell counts of tyrosine hydroxylase (TH)-immunoreactive neurons using the optical fractionator principle (Visiopharm). Preceding stereological quantification, we performed a pilot study (n=3 animals; 3 sections per animal; 489 neurons) that revealed optimal antibody penetration throughout the tissue sections (25 μm thickness after processing) and a low coefficient of error (0.023) indicating sufficient precision. Our findings from stereological analyses demonstrate that the total number of TH-positive neurons (N) in the SNpc did not significantly differ between the control (n=4) and Mn-exposed groups (n=5) (t-test; $p = 0.07$), representing the first stereological quantification of TH-positive SNpc cell numbers in Mn neurotoxicity. Follow-up studies will investigate TH-positive neuron numbers in the ventral tegmental area and retrorubral fields, as well as in the precise functional regions of the SNpc. These collective findings suggest that the motor signs of Mn-induced parkinsonism are unrelated to dopaminergic nigral cell loss. Thus, the underlying

pathophysiology of movement disturbances associated with Mn intoxication is different than those present in iPD.

Title: Disruption of Parkin integrity by caspase or calpain-cleavage induced by proteasomal or mitochondrial impairment and its prevention by cAMP: relevance to Parkinson's disease

Authors: A. STOLL[1], T. JEAN-LOUIS[3], H. WANG[1], Q. HUANG[1], P. ROCKWELL[1], *M. E. FIGUEIREDO-PEREIRA[2];
[1]Biol. Sci., [2]Hunter Col. CUNY, New York, NY; [3]Biol. Sci., Hunter Col. CUNY, The Grad. Center, CUNY, New York, NY

Abstract: The mechanisms by which Parkin dysfunction contributes to Parkinson disease are poorly delineated. As mitochondrial and proteasomal impairment and inflammation are linked to PD, we investigated the effects of mitochondrial (oligomycin, Oligo) or proteasomal (Epoxomicin, Epox) inhibitors or the product of inflammation prostaglandin J2 (PGJ2), on Parkin integrity in rat midbrain and cortical cultures. Treatments with PGJ2 and Epox induced caspase-cleavage of Parkin while those with Oligo led to calpain-cleavage. Parkin cleavage by caspase was previously shown to be triggered by stress-conditions. However, as far as we know, Parkin cleavage by calpain has not been reported. Upon calpain cleavage, Parkin migrates as a doublet with a slightly larger size than the caspase-mediated fragment. Full length (FL)-Parkin

was localized in the cytosolic, mitochondrial and nuclear fractions. Calpain or caspase-cleaved Parkin were mostly detected in the mitochondrial fraction. We postulate that liberation of the Ubl domain of Parkin by caspase or calpain cleavage facilitates its recruitment to mitochondria. The freed UbL could bind to proteasomes and inhibit their activity. Pre-treatment with the phosphatase inhibitor okadaic acid prior to Oligo treatment, stabilized a higher molecular weight form of FL-Parkin and reduced Parkin cleavage by calpain. This suggests that stabilizing phosphorylation of FL-Parkin with phosphatase inhibitors decreases its susceptibility to calpain-cleavage. Raising intracellular cAMP with PACAP27 (pituitary adenylate cyclase activating peptide) to preserve Parkin integrity prevented its cleavage by caspase but not calpain. Stabilizing intracellular ATP levels with cyclocreatine moderately mitigated Oligo induced calpain cleavage of Parkin. In conclusion, stabilizing FL-Parkin could provide a novel therapeutic strategy for treating PD.

Abstract: Parkinson's disease (PD) is one of the most common neurodegenerative disorders. The major motor features of PD are the result of the loss of dopamine neurons in the substantia nigra pars compacta (SNpc) of the midbrain. Despite extensive experimental effort, the cause of neuronal degeneration in PD is not fully understood. Mitochondrial dysfunction, oxidative stress, abnormal protein handling, excitotoxicity, and apoptotic and inflammatory processes have been implicated in the cascade of events leading to loss of dopaminergic neurons in the SNpc. A growing body of evidence show that mutations in the glucocerebrosidase (*GBA*) gene, which encodes the lysosomal enzyme that is deficient in Gaucher's disease (GD), are important and common risk factors for PD. However, the mechanisms by these mutations predispose to cell death remain unclear. Fibroblasts share the genetic complexity of neurons and represent an easily accessible source of proliferating cells, making them a unique patient-specific cellular model of different neurodegenerative diseases. To study the role of heterozygous GBA mutations in the pathology of PD, we generated fibroblast lines from skin biopsies of five PD patients with heterozygous GBA mutation carriers (N370S and L444P) and four controls. We found that both GBA mutations present significantly reduced level of GCase protein and enzyme activity as well as an altered autophagy flux and lysosomal function due to an accumulation of misfolded proteins in endoplasmic reticulum.

Title: Identification of transglutaminase 2 as a novel substrate of PINK1 and its physiological consequence of Lewy body formation in Parkinson's disease

Authors: B. MIN[1], S. LEE[1], H. RHIM[3], *K. C. CHUNG[2];
[1]Dept. Systems Biology, Coll. Life Sci. Biotechnol., Yonsei Univ., Seoul 120-749, Korea, Republic of; [2]Yonsei Univ., Seoul, Korea, Republic of; [3]Ctr. for Neuroscience, Brain Sci. Institute, Korea Inst. of Sci. and Technol. (KIST), Seoul 136-791, Korea, Republic of

Abstract: Parkinson's disease (PD) is the most prominent and progressive movement disorder. PINK1 gene mutations cause one form of autosomal recessive early-onset PD. PINK1 encodes a serine/threonine protein kinase which protects cells from stress-induced mitochondrial dysfunction. Transglutaminase 2 (TG2) is an intracellular protein cross-linking enzyme that has an important role in Lewy body formation during PD pathogenesis. This study identifies PINK1 as a novel TG2 binding partner and shows that PINK1 stabilizes the half-life of TG2 via inhibition of TG2 ubiquitination and subsequent proteasomal degradation. PINK1 affects TG2 stability in a kinase-dependent manner. In addition, PINK1 directly phosphorylates TG2 in carbonyl cyanide m-chlorophenyl hydrazine-induced mitochondrial damaged states, thereby enhancing TG2 accumulation and intracellular protein cross-linking products. This study further confirms the functional link between upstream PINK1 and downstream TG2 in *Drosophila* melanogaster. These data suggest that PINK1 positively regulates TG2 activity, which may be closely associated with aggresome formation in neuronal cells.

Title: An evolutionarily conserved RAB7L1-LRRK2 pathway regulates lysosome integrity and neurite morphology

Authors: *T. KUWAHARA[1,2], K. INOUE[2], T. IWATSUBO[1], A. ABELIOVICH[2];
[1]Univ. Tokyo Grad Sch. Med., Tokyo, Japan; [2]Dept Pathology, Cell Biol. and Neurol., Columbia Univ., New York, NY

Abstract: Mutations in leucine-rich repeat kinase 2 (LRRK2) are the major genetic cause of Parkinson's disease (PD). We previously identified RAB7-like variant 1 (RAB7L1) as an

interactor of LRRK2: RAB7L1 and LRRK2 cooperatively modulates neurite morphology, intracellular trafficking and PD risk. However, the detailed physiological and genetic relationships between LRRK2 and RAB7L1 are still unclear. Here we provide evidence that LRRK2 and RAB7L1 normally serve essential cellular roles in the maintenance of lysosome function and neurite morphology in diverse organisms. Mice deficient in either RAB7L1 or LRRK2 display prominent age-associated lysosomal defects in kidney proximal tubule cells, in the absence of frank CNS pathology. *C. elegans* mutants deficient in orthologues of LRRK2 or RAB7L1 harbor lysosome and axon morphologic abnormalities in neurons. We further identified a retromer and a lysosomal adaptor protein complex that link RAB7L1/LRRK2 dysfunction to lysosomal and neurite abnormalities. These data underscore the evolutionarily conserved role of RAB7L1-LRRK2 pathway in diverse cellular contexts.

Title: Differential kinase function between dimeric/oligomeric and monomeric LRRK2 species isolated from size exclusion chromatography fractions

Authors: M. LEANDROU[1], K. MELACHROINOU[1], A. MEMOU[1], L. STEFANIS[1,2], *H. J. RIDEOUT[1];
[1]Biomed. Res. Foundation, Acad. of Athens, Athens, Greece; [2]2nd Dept. of Neurol., Univ. of Athens Med. Sch., Athens, Greece

Abstract: The ROCO/RIP kinase protein LRRK2, mutations in which are causally linked to Parkinson’s disease (PD), exists in a broad range of monomeric to highly oligomeric species regulated by a multitude of factors. Multiple groups have reported that mutations associated with PD can enhance the formation of cytoplasmic skein-like filaments, which have been suggested to be highly oligomeric. This phenomenon is linked to the phosphorylation status of a cluster of Ser

residues located in the N-terminal region of the protein; and subsequently, the binding of 14-3-3 to LRRK2. The significance of this redistribution of LRRK2 to highly oligomeric species is not fully understood; nor is the impact of oligomerization on the function or activity of LRRK2. Multiple lines of evidence suggest that the dimeric conformation of LRRK2 possesses greater kinase activity, however it is not clear whether this distinction is unique to membrane-localized LRRK2, or in other compartments as well. Wild type LRRK2 displays a broad range of elution between low and high molecular weight fractions by size exclusion chromatography (SEC). We detect a significant shift in elution towards higher molecular weight fractions in most of the pathogenic PD mutations in LRRK2. Mutations localized within the kinase domain enhance phosphorylation of a peptide substrate in discrete fractions, as opposed to a global increase in activity across all fractions where LRRK2 is detected. However, SEC alone cannot discriminate between truly dimeric or oligomeric species of LRRK2 and monomeric LRRK2 that is bound to a large protein complex. We have developed a technique to selectively label and purify functionally active dimeric/oligomeric LRRK2 species from mammalian cells. With this approach we can not only quantify dimeric or oligomeric LRRK2 eluted from SEC-derived fractions; but also we can also directly compare multiple features of LRRK2 kinase activity within each sub-pool of LRRK2 species. This platform can also be exploited to screen for LRRK2 kinase inhibitors with a selective affinity for certain LRRK2 conformations or species.

Title: Post-transcriptional regulation of α-synuclein by lrrk2 through interactions with micrornas in Parkinson’s disease

Authors: *J. BOON;
Pharmacol., Boston Univ. Sch. of Med., Boston, MA

Abstract: Recent studies have suggested that specific RNA transcript isoforms of α-synuclein with an extended 3’ untranslated region (UTR) are selectively linked to Parkinson’s pathology,

relative to α-synuclein with short 3'UTR. 3'UTR is a target region for RNA binding proteins and microRNAs, which lead to regulation of translation. LRRK2 is the most commonly mutated gene in Parkinson's Disease and studies have shown that it has a role in translation. In this study, we hypothesize that the expression and toxicity of α-synuclein are regulated by LRRK2 post-transcriptionally through interactions with microRNAs. Our data shows that LRRK2 modulates α-synuclein translation. In HEK293FT cells, co-expression of α-synuclein with either long or short 3' UTR and wild-type LRRK2 lead to a significant increase in α-synuclein expression relative to without LRRK2 as measured by florescence level of the GFP-tagged α-synuclein and there is a greater increase in the condition with short relative to long 3'UTR. In primary culture neurons, α-synuclein transcript isoform with short 3'UTR has higher expression level relative to isoform with long 3'UTR in the presence of LRRK2 as well. In addition, in conditions of α-synuclein with short 3'UTR together with LRRK2, neurons demonstrate a broader distribution of α-synuclein, along with a greater number of α-synuclein containing puncta along the processes. This data suggests a differential effect of LRRK2 on α-synuclein with either short or long 3'UTR's expression and distribution. Also, by co-staining with Mitotracker dye, our data shows co-localization of α-synuclein with mitochondria along the processes of primary culture neurons. Next, we investigated whether regulation of α-synuclein expression by LRRK2 require the binding of microRNAs. The short 3'UTR sequence of α-synuclein has a binding site for miR-7 and the long 3'UTR has binding sites for both miR-7 and miR-153. We performed site-directed mutagenesis where we mutated the binding site for miR-7 on the short 3'UTR and that for miR-7 or miR-153 on the long 3'UTR, so these microRNAs can no longer bind. Deletion of the miR-7 site abolished all effects of LRRK2 on expression of α-synuclein with short or long 3'UTR. In contrast, deleting the miR-153 site resulted in a moderate decrement in the expression of the long 3'UTR α-synuclein. We further investigate whether the kinase domain of LRRK2 is involved in the observed differences. We employed LRRK2-specific kinase inhibitor, LRRK2-IN-1, and our data shows that inhibition of the kinase domain of LRRK2 decreases the level of α-synuclein protein expression. For future studies, we will measure direct effects of LRRK2 on microRNAs productions.

Title: The kinin system in the 6-hydroxy-dopamine model of Parkinson´s disease

Authors: *L. M. DATI, L. R. G. BRITTO;
Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Parkinson´s disease (PD) involves loss of dopaminergic neurons of the substantia nigra, which produces marked motor and cognitive disorders. PD has been studied with several approaches, including animal models such as the 6-OH-dopamine intrastriatal injection. There is evidence on the possible participation of neurotransmitters and receptors in the development of neurodegeneration and neuroprotection processes. For example, kinins, through their actions on B1 and/or B2 receptors, may be involved with neuroprotection. In this study, we sought to investigate a possible participation of the kinins in the pathophysiology of PD-like condition in the mouse, by means of immunohistochemistry, Western blotting, pharmacological approaches and the use of a B2 knockout mouse. Tyrosine-hydroxylase immunolabeling in wild-type mice (C57BL/6) was reduced by about 50% both in the striatum and the substantia nigra on the side ipsilateral to the 6-OH-dopamine injection in relation to the contralateral side, injected with saline. After toxin injections in the B2 knockout mouse, we observed a much smaller reduction of tyrosine-hydroxylase protein expression (ca. 10%; $p<0.001$). A very similar effect was observed with the use of intrastriatal HOE-140 (100 nM), a specific antagonist of the B2 receptor. Intrastriatal administration of bradykinin (10 μM) also produced a smaller reduction of tyrosine hydroxylase in the striatum (ca. 30%; $p<0.05$) but a slightly higher drop in the substantia nigra (ca. 60%; $p<0.05$) in relation to untreated PD-like animals. Immunolabeling for an astrocyte marker, glial fibrillary acidic protein (GFAP), was reduced in the striatum of B2 knockout mouse injected with the toxin in relation to wild-type injected mice (ca. 30%; $p<0.05$). Bradykinin-treated PD mice exhibited very small GFAP increases (ca. 15%; $p<0.05$ vs untreated mice), but HOE-140 produced unconsistent data in regard to astrocytic activation. These results indicate a possible participation of the kinin system in the pathophysiology of PD, which remains to be further characterized.

Title: Characterizing the role of prolyl oligopeptidase in mouse nigrostriatal dopaminergic and GABAergic systems

Authors: *U. JULKU, R. SVARCBAHS, M. SAVOLAINEN, S. TIILIKAINEN, T. MYÖHÄNEN;
Div. of Pharmacol. and Pharmacotherapy, Univ. of Helsinki, University of Helsinki, Finland

Abstract: Aplha-synuclein (aSyn) is the main component of the Lewy bodies, a histopathological finding of Parkinson's disease (PD). Prolyl oligopeptidase (PREP) is a serine protease that accelerates aggregation of aSyn *in vitro*, and PREP enzyme inhibitors have shown to block the aggregation process *in vitro* and in cellular models, and also enhance the clearance of aSyn aggregates in transgenic mice models. In addition, PREP is shown to be colocalized with aSyn in the post mortem PD brain. However, although PREP has several known substrates, the physiological and pathological roles have remained unclear. PREP inhibitors have caused some alterations in dopamine (DA) and metabolite levels in the striatum and substantia nigra, and PREP localizes GABAergic neurons of nigrostriatal tract and in some extent in DAergic neurons, but the functions of PREP in nigrostriatal pathway are unclear. Moreover, aSyn is shown to have physiological functions in DA release and storage in nigrostriatal pahtway. The aim of the study was to to characterize the role of PREP in nigrostriatal DAergic and in GABAergic systems of C57Bl/6 and PREP knock-out mouse, and the effects of PREP overexpression by AAV-hPREP or PREP inhibition (small molecule inhibitor KYP-2047) on these systems by using microdialysis and HPLC analysis. Single injection or 5-day treatment by KYP-2047 did not have effect on concentration of DA, its metabolites, glutamate or GABA in tissues of striatum and substantia nigra or extracellular concentration of DA and GABA in striatum measured by microdialysis in young C57Bl/6 mice. Overexpression of PREP in nigrostriatal tract by nigral AAV-hPREP injection did not have effect on extracellular concentrations of DA and DOPAC in striatum but increased HVA and 5-HIAA at 5 weeks as measured by microdialysis. There was also statistically significant difference in d-amphetaminesulphate induced DA release. AAV-hPREP seems to decrease locomotor activity slightly at 4 weeks post-injection but the difference is not statistically signigficant. Lack of PREP did not have effect on baseline level of striatal extracellular DA or its metabolites in microdialysis study in PREP knock-out mice but d-

amphetaminesulphate induced DA release was lowered when PREP expression was restored by nigral AAV-hPREP injection. Results suggest that PREP and PREP inhibitor do not affect basal DA and GABA release directly but overexpression of PREP causes alterations on induced dopamine release and baseline levels of HVA and 5-HIAA. This suggests that of PREP could contribute to release of neurotransmitters in nigrostriatal pathway but the mechanisms needs to be studied further.

Title: Classification of Parkinson's disease genotypes in *Drosophila* using spatiotemporal profiling of vision

Authors: *A. R. WADE[1], R. J. H. WEST[2], C. J. H. ELLIOTT[2];
[1]Univ. of York, Heslington, United Kingdom; [2]Biol., Univ. of York, York, United Kingdom

Abstract: Electrophysiological studies have demonstrated altered contrast processing in Parkinson's Disease (PD) patients. Here we asked whether multivariate data extracted from steady-state visually-evoked potentials (SSVEPs) in *Drosophila* could be used to identify different PD mutations. Flies from four control lines were compared to three early-onset PD mutations (PINK1, DJ-1α and DJ-1β) and one mutation in the fly LRRK2 orthologue (dLRRK). Results from supervised machine learning indicate that this is a promising technique for rapid phenotyping of PD-related mutations in an animal model. Methods: Stimuli were dynamic, contrast reversing grating stimuli, spanning 64 spatiotemporal frequency combinations (8 spatial x 8 temporal frequencies). We recorded the second harmonic of the SSVEP generated by the contrast reversal across all combinations using a single-channel ERG electrode. A supervised linear classifier combined with an iterative dimensionality reduction algorithm was used to estimate classification accuracy for a) Each pair of genotypes, b) PD vs Control genotypes and c)

Each individual genotype within the entire set. Statistical significance was computed using a bootstrap procedure and a leave-one-out procedure. Data from 180 flies are presented. Results The patterns of neuronal responses differed between genotypes. Wild-type and early-onset PD flies formed separate clusters in the high-dimensional data space and the late-onset mutation was an outlier. This clustering was preserved in a multidimensional scaling analysis. Neuronal responses in early-onset PD flies were, in general, stronger than in wild-types and multivariate pattern analysis assigned flies to PD or non-PD genotypes with an accuracy >85%. Conclusion There are reliable and significant differences in the evoked visual responses of flies carrying different PD-related mutations. These differences can be used to assign flies to the correct genotype with high accuracy. As well as aiding in the use of *Drosophila* to study the mechanisms of PD and in drug discovery, we propose that machine learning algorithms may also be useful in increasing the diagnostic specificity of human electrophysiological measurements.

Title: Levodopa-induced motor behavior alterations in *Drosophila* larvae

Authors: A. DERGAN, J. STANTON, R. GOUGH, B. DIEDERICH, *B. A. CHASE;
Dept Biol, Univ. Nebraska-Omaha, Omaha, NE

Abstract: Dyskinesias associated with dopamine-replacement therapy pose therapeutic challenges for individuals with Parkinson’s Disease. A better understanding of their physiological basis holds promise for more effective management of these anomalous motor behaviors. Not all patients receiving dopamine-replacement therapy develop dyskinesias, suggesting the hypothesis that the degree of dyskinesia development is a quantitative trait that can be influenced by genetic variants. Since motor behavior in a wide range of animals is influenced by dopaminergic function, observations from model organisms can provide meaningful insights with human application. Therefore, we are taking an unbiased approach to identify *Drosophila* quantitative trait loci (QTL) that influence the motor responses to levodopa treatment. We present data showing the viability of this approach. Motor behavior was assayed

in third-instar larvae fed L-dopa in 3% sucrose for 15 minutes. Quantitative analysis of locomotory behavior following levodopa treatment identifies motor behaviors that are differentially responsive to levodopa. Larvae fed 0.58 mM L-dopa in 3% sucrose, compared to controls fed only sucrose, show increases in contractions per minute ($t(84) = -8.499$, $p < .001$) and turns per minute ($t(81) = -9.952$, $p < .001$), and a modest decrease in bends per minute ($t(82) = 2.039$, $p = .045$). L-dopa also induces two novel uncoordinated behaviors: “stagger”, an anterior lateral tilt immediately before or during a contractile motion, and a “horizontal tail flip”, a posterior lateral bend during a contractile motion. Since wild strains of *Drosophila* show substantial genetic variation, we are currently evaluating variation in these responses among such strains as a prelude to identifying responsible QTLs.

Title: Potential role of FosB and ΔFosB in the differential long-term regulation of parkin expression in central dopaminergic neurons in response to acute neurotoxicant exposure

Authors: *J. PATTERSON[1], K. LOOKINGLAND[2], J. L. GOUDREAU[3];
[2]Pharmacol. and Toxicology, [3]Dept. of Neurol., [1]Michigan State Univ., East Lansing, MI

Abstract: A characteristic of Parkinson disease (PD) is the progressive loss of nigrostriatal dopamine (NSDA) neurons. In mice, these neurons can be preferentially damaged through exposure to the neurotoxicant 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Another population of DA neurons that respond to MPTP, but are able to recover is the tuberoinfundibular DA (TIDA) neurons whose recovery is correlated with an increase in parkin mRNA and protein. Parkin is a product of the PARK2 gene, which is linked to autosomal recessive or juvenile PD. Parkin has multiple functions in neurons and is predicted to protect against the neurotoxic effects of MPTP. Differential expression of transcription factors that regulate the parkin promoter could explain the differential susceptibility of DA neurons. The parkin promoter is bi-directional consisting of an approximately 200 bp segment of DNA that

regulates the expression of the PARK2 gene as well as parkin co-regulated gene. Potential transcription factors of parkin were identified using TFSEARCH and PROMO. One predicted transcription factor of parkin is Activator Protein 1 (AP-1), which is a heterodimer composed of proteins from the Fos, Jun, and ATF families. In the present study the temporal expression of FosB and ΔFosB were measured after acute neurotoxicant administration. Male C57BL/6j were injected with 20 mg/kg MPTP (sc) and decapitated at 4, 6, 8, 12, or 24 h post-injection. Control mice were injected with saline (10 mL/kg; sc) and killed 24 later. Brains were frozen, sectioned, regions containing the cell bodies of the TIDA (arcuate nucleus; ARC) and NSDA (substantia nigra; SN) neurons were dissected and processed for Western blot analysis. The results reveal that expression of FosB and ΔFosB correlates with parkin, increasing in the ARC and not in the SN. As ΔFosB is a highly stable truncated form of FosB, both FosB/ΔFosB and parkin were measured 1, 3, and 7 days after a single injection of 20 mg/kg MPTP (sc). Elevated ΔFosB and parkin protein levels were observed over all seven days in the ARC, but did not change in the SN. These results reveal that expression of FosB and ΔFosB correlate with the differential expression of parkin, increase prior to parkin, and are predicted to bind the parkin promoter sequence, which suggests that FosB and ΔFosB may act to regulate parkin expression in response to neurotoxicant exposure.

Title: Identification of neuro-protective genes during the progression of dopaminergic cell loss in zebrafish

Authors: *S. L. WALKER[1], S.-C. CHEN[2], W.-H. YUNG[3], Y. KE[3];
[2]Sung Hing Inst. of Advanced Engin., [3]Sch. of Biomed. Sci., [1]The Chinese Univ. of Hong Kong, Shatin, Hong Kong, Hong Kong

Abstract: The neurodegenerative disorder Parkinson's disease (PD) is among the most debilitating diseases currently afflicting the aging population. Extensive studies into the onset and progression of Parkinson's disease have elucidated multiple genes affected during dopaminergic cell loss. However, the extent of networks involved in the progression of PD is still largely undefined. This limits testing of potential therapeutic gene targets to a handful of gene candidates. As a means to identify potential gene networks involved in neural protection, we utilized temporal microarray data during various neuronal ablation paradigms from the zebrafish model. Here we identified multiple genes potentially involved in neural protection, some of which are currently being targeted in the literature as important neuro-protective factors, during dopaminergic neuronal cell death. In this study we tested the potential role of Glutathione Reductase (GSR), Major Vault Protein (MVP), ZGC:174888, and other candidates during dopaminergic neuronal cell death in the zebrafish model. Following treatment with 6-OHDA, a chemical which induces dopaminergic neuronal cell death, the extents of dopaminergic cell loss and delay in motility were assessed. Gene expression was either silenced using morpholinos and/or chemical inhibitors or overexpressed using chemical activators to define their roles in neuronal cell death and cell survival. *In vivo* time-lapse imaging in conjunction with behavioral studies were utilized to establish the extent of neural cell death and protection of normal behavioral patterns during dopaminergic cell loss.

Title: Neurogenesis in hippocampus induced by administration of L-dopa/melatonin in the hemi-Parkinsonian rat

Authors: A. SANCHEZ-SORIA[1], M. MORENO[2], A. GUTIERREZ-VALDEZ[2], M. AVILA-COSTA[2], J. RAMOS-JIMENEZ[3], *V. ANAYA-MARTINEZ[2];

Abstract: Parkinson disease (PD) is a neurodegenerative disorder of unknown etiology characterized by the loss of dopaminergic neurons in the substantia nigra compacta (SNc), conventional therapy with L-Dopa produces adverse effects after the prolonged period of administration probably due to the generation of free radicals. Melatonin has endogenous antioxidant actions. Previously we concluded that the co-administration of some antioxidants like melatonin with L-Dopa, helps to reverse some alterations induced by L-Dopa treatment and could promote the generation of new dopaminergic neurons in the SNc probably by reducing the oxidative environment. The hippocampus, a nucleus involved in memory processes, have a neurogenic area the dentate gyrus; this nucleus receive dopaminergic innervation from SNc neurons, and the neurogenic capacity is reduced in tissue of people who had PD. This study examines the ability of melatonin (10 mg/kg)/ L-DOPA (7.5 mg/kg) to increase neurogenesis in the hippocampus of the rats with Parkinson's disease model compared to a group with L-DOPA (7.5 mg/kg), a group with melatonin and a control group (sham lesion). During the month of drug treatment they received the injections of neurogenic marker, the BrdU. The neurogenesis in the hippocampus was judged by the counting of neurons with the colocalization of the markers antiBrdU and antiNeuN (neuronal marker). Our data show that the injection of 6-OHDA reduces the presence of BrdU/TH positive, and that the administration of L-dopa and/or melatonin reverses this effect. These results indicate that melatonin can modulate the survival of new neurons in the adult hippocampus.

Title: Rab7 induces clearance of alpha-synuclein aggregates

Authors: *B. H. FALKENBURGER, E. DINTER, T. SARIDAKI, M. NIPPOLD, L. FENSKY, L. DIEDERICHS, A. VOIGT, J. SCHULZ;
RWTH Univ. Aachen, Aachen, Germany

Abstract: Parkinson's disease is characterized and likely caused by aggregates of the protein alpha-synuclein. Using GFP-labelled alpha-synuclein we have previously shown that cells can in principle remove these aggregates. Here we describe the effects of the small GTPase Rab7, which is primarily known for regulating trafficking of late endosomes. We found that Rab7 decorates vesicles containing alpha-synuclein aggregates, and that Rab7 overexpression reduces the number of cells with aggregates (60% of cells without aggregates instead of 40%). Most strongly reduced is the number of cells with aggresomes, supporting their role in clearance of protein aggregates. In time-lapse microscopy we confirmed that aggregates disappear more often with Rab7 overexpression (17% instead of <5% of cells with aggregates). A reduction of alpha-synuclein by Rab7 was validated by analyzing alpha-synuclein content using immunoblots (40% reduction). Rab7 overexpression also reduced alpha-synuclein induced cell death as mesured by trypan blue staining. In a fly model of Parkinson's disease created by overexpressing alpha-synuclein in neurons, Rab7 rescued the locomotor deficit these flies display in the climbing assay. Taken together, Rab7 strongly increases cellular clearance of alpha-synclein aggregates, leads to fewer cells with aggregates, reduces alpha-synuclein amounts and toxicity, and is beneficial in a fly model of Parkinson's diseas. Activating Rab7 or its effectors could therefore be a new therapeutic strategy for Parkinson's disease.

Abstract: It has been suggested that effects of MSCs in CNS regenerative medicine are mediated by their secretome. Indeed, our lab as previously shown that the secretome of MSCs from different sources increased neurogenesis and cell survival, inhibits apoptosis and has numerous neuroprotective actions in different pathological conditions. More recently, we have found that the use of dynamic culturing conditions, using computer-controlled bioreactors, can further modulate the MSC secretome thereby generating a more potent neurotrophic factor cocktail. Having this in mind, in this present work we aimed to (1) Perform a proteomic analysis of MSCs secretome, (2) assess the effects of MSCs secretome (in the form of conditioned media (CM)) on the proliferation, survival and differentiation of human neural progenitors (hNPCs) *in vitro* and *in vivo* on the resident cells of the dentate gyrus (DG) of adult rat hippocampus, and (3) Study the potential role of the sole use of the secretome as a therapeutic tool in Parkinson's Disease (PD) regenerative medicine. Results revealed that MSCs CM induced higher levels of neuronal differentiation (MAP-2+ and DCX+ positive cells) of hNPCs *in vitro*. *In vivo*, when injected into the DG of the hippocampus, was able to increase the levels of cell proliferation (Ki-67+ cells) as well as the number of newborn neurons (DCX+ cells) and astrocytes (GFAP+ cells). Additionally, when this MSC secretome was injected into a PD model, it was possible to observe that the secretome potentiated the recovery of dopaminergic neurons (increasing TH+ staining both in the SNc and Striatum), thereby leading to a recovery in the parkinsonian rats' motor performance outcomes. Finally, proteomic characterization of MSCs secretome (through LC-MS/MS and Bioplex assays) revealed the presence of important neuroregulatory molecules, namely PEDF, Cys C, GDN, Galectin-1, IGF-1 and GDNF. The present data shows the modulatory role of MSCs secretome in brain repair, further indicating that cell free therapies based in it could represent the basis of future strategies in PD regenerative medicine.

Title: NEDD4-mediated HSF1 degradation underlies α-synucleinopathy

Authors: *F.-F. LIAO[1], E. KIM[1,2], H. CAI[2];
[1]Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Transgenics Section and 4Bioinformatics Core, Lab. of Neurogenetics,, Natl. Inst. on Aging, Bethesda, MD, 20892, USA, Bethesda, MD

Abstract: Impairment of molecular chaperones and the ubiquitin ligases and proteasome system (UPS) have been implicated in several neurodegenerative diseases, including Alzheimer's (AD) and Parkinson's (PD), which are characterized by accumulation of abnormal protein aggregates. Induction of heat-shock proteins (HSP), such as via Hsp90 inhibition, is being investigated as a treatment option for these proteinopathic diseases, which depends on the activation of heat shock factor 1 (HSF1). Heat shock transcription factor 1 (HSF1), a master stress-protective transcription factor, activates genes encoding protein chaperones (e.g., iHsp70) and anti-apoptotic proteins. Compelling evidence suggests that increasing HSF1 activity may be a promising therapeutic approach for neurodegenerative diseases that are all characterized by protein misfolding and aggregation. Indeed, overexpression of iHsp70 or chronically activated HSF1 has been found to be beneficial in experimental models of all major neurodegenerative diseases. However, whether and how HSF1 is dysregulated during neurodegeneration has not been studied. HSF1 regulation is extremely complex, involving both transcription and posttranscription, as well as several posttranslational modifications (e.g., phosphorylation, acetylation, and sumoylation). It should be stressed that these regulatory mechanisms are studied almost exclusively in non-neuronal cell types (i.e., cancer). Aberrant accumulation of α-synuclein (α-syn)-positive Lewy bodies have been found in brains of AD and PD and are associated with accelerated cognitive dysfunction. In primary forebrain neuronal culture model, we discovered that mutant A53T α-syn induced drastic HSF1 protein degradation via UPS, which involves the HECT domain E3 ligase, Nedd4. Markedly reduced HSF1 was also found in the tyrosine hydroxylase (TH)-positive neurons in the substantia nigra (SNc) region of pre-symptomatic A53T α-syn transgenic mice. We found that Nedd4 can be transcriptionally upregulated by A53T α-syn and SIRT1 activity is tightly linked with the intracellular level of HSF1. Furthermore, the Lys 80 residue located in the DNA-binding domain of HSF1 is critical for the protein's stability which depends on its acetylation status and the interplay between acetylation and ubiquitination. Since we discovered HSF1 protein degradation in other proteinopathy conditions such as G93A SOD and mutant Htt, we speculate that HSF1 protein degradation, and perhaps its inactivation as a transcriptional factor (repression), represents a common molecular mechanism underlying neurodegeneration.

Title: Roles of ERα, ERβ and GPER1 receptors in neuroprotective and anti-inflammatory effects of 17β-estradiol in the murine enteric system in a MPTP model of Parkinson's disease

Authors: A.-A. POIRIER[1], M. CÔTÉ[1], M. BOURQUE[1], M. MORISSETTE[1], T. DI PAOLO[1,3], *D. SOULET[2,4];
[1]CHUQ Res. Ctr., Quebec City, QC, Canada; [2]Neurosci., CHUQ Res. Ctr., Quebec, QC, Canada; [3]Laval University, Pharm. Fac., Quebec City, QC, Canada; [4]Psychiatry and Neurosci., Laval University, Med. Fac., Quebec City, QC, Canada

Abstract: Motor symptoms in Parkinson's disease (PD) are often preceded by non-motor symptoms related to dysfunctions of the autonomic nervous system such as constipation, defecatory problems and delayed gastric emptying. These gastrointestinal impairments are associated with the alteration of dopaminergic (DA) neurons in the myenteric plexus (MP) of the gut. Studies in our laboratory have demonstrated the immunomodulatory effect of female sex hormones to treat neurodegeneration in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse model of enteric nervous system degeneration in PD. We also uncovered the implication of the G protein-coupled estrogen receptor 1 (GPER1) in this phenomenon. In order to better understand the role of the estrogen receptors ERα, ERβ and GPER1 in neuroprotection and immune modulation in the MP, adult C57BL/6 male mice received, daily for 10 days, 2 injections of different combinations of the following products: 17β-estradiol (1 µg), G1 (5 µg) GPER1 agonist, G15 (10 µg) GPER1 antagonist, PPT (1 µg), ERα agonist, DPN (3 µg), ERβ agonist and ICI 182,780 (25µg) ERα/β antagonist. On day five, 4 injections of saline or MPTP (4.75 mg/kg) were administered. On day ten, mice were killed, the ileum was fixed and microdissected to isolate the MP. Cuprolinic blue staining and immunohistochemistry with antibodies against tyrosine hydroxylase (TH) and ionized calcium-binding adapter molecule 1 (Iba-1) were performed for stereological counting of total neurons, DA neurons (TH+) and macrophages (Iba-1+). We observed a loss of about 85% TH+ neurons in MPTP mice and maintenance of control levels following 17β-estradiol and G1 treatments, demonstrating the

important implication of GPER1. The ERα/β specific agonists, PPT and DPN, only partially prevented the DA loss resulting from MPTP intoxication. There was no difference in total neurons counts between groups, suggesting that neuronal loss was specific to TH+ neurons. Moreover, we observed an increase of approximately 55% in the number of macrophages in MPTP mice, but maintenance of control levels with 17β-estradiol and G1 treatments, demonstrating a significant anti-inflammatory effect of the drug in MPTP animals. When administered along with the antagonist G15, 17β-estradiol did not lower the number of macrophages, indicating the important implication of GPER1. Overall, the present results suggest that estrogen therapy may help prevent the loss of DA neurons and infiltration of macrophages in the MP in a MPTP mouse model of Parkinson's disease, mainly involving GPER1 and, to a lesser extent, ERα/β. This suggests a potential therapeutic avenue of immunomodulation for the human condition.

Title: Endogenous Nociceptin/Orphanin FQ is neurotoxic for nigral dopamine neurons

Authors: *L. ARCURI[1], S. BIDO[1], R. VIARO[2], F. LONGO[1], M. CALCAGNO[1], P.-O. FERNAGUT[3], G. CALÒ[1], E. BEZARD[3], M. MORARI[1];
[1]Med. Sci., [2]Biomed. and Specialty Surgical Sci., Univ. of Ferrara, Ferrara, Italy; [3]Inst. des Maladies Neurodégénératives, Univ. de Bordeaux, Bordeaux, France

Abstract: Indirect evidence that nociceptin/orphanin FQ (N/OFQ) and its receptor (NOP) might contribute to the degeneration of nigral dopamine (DA) neurons associated with experimental parkinsonism has been presented. Indeed, N/OFQ knockout mice were found to be partially resistant to the neurotoxic effect of MPTP (Marti et al, J Neurosci 25: 9591, 2005). However,

N/OFQ is obtained by cleavage of a larger precursor, which codes for other two peptides, namely nocistatin and N/OFQ II, which might also play a role in MPTP-induced neurodegeneration. Therefore, to unequivocally prove the neurotoxic role of N/OFQ we undertook a genetic and pharmacological approach, using NOP receptor knockout (NOP-/-) mice, and the small molecule NOP-selective receptor antagonist SB-612111. Stereological unbiased methods were used to estimate the total number of DA neurons in acute (4x25 mg/Kg, i.p., 90 min apart) and subacute (25 mg/Kg, i.p., once daily for 7 days) MPTP mouse models of PD. NOP-/- mice showed a 50% greater amount of nigral DA neurons spared in response to acute MPTP compared to controls. Consistently, SB-612111, administered (10 mg/Kg, twice daily, i.p.) from 4 days before the onset of MPTP treatment, and for additional 6 days (10 days overall) prevented the loss of nigral DA neurons and DA axonal terminals in the striatum caused by subacute MPTP in naïve mice. To investigate whether N/OFQ is directly neurotoxic to DA neurons, we cultured SH-SY5Y cells in the presence of 6-OHDA and N/OFQ or the selective NOP receptor agonist UFP-112. 6-OHDA showed a strong neurotoxic effect on cell viability, which was exacerbated by N/OFQ and UFP-112. Two NOP receptor antagonists (UFP-101 and SB-612111) prevented the effect of UFP-112, confirming that this effect was mediated by the NOP receptor. These results show that endogenous N/OFQ contributes to DA neuron loss associated with MPTP treatment in mice, suggesting that NOP receptor antagonists might have neuroprotective potential. A study testing SB-612111 in the synuclein-AAV rat model is ongoing, to more convincingly prove that endogenous N/OFQ contributes to neurodegeneration associated with Parkinson's disease.

Title: Exercise promotes alterations in Hif1a and Hif2a levels in the SN, which play different roles in the survival of DA neurons in exercise (Hif1a) and standard (Hif2a) conditions

Authors: M. SMEYNE, Y. JIAO, L. OAKLEY, *R. J. SMEYNE;
Dept Dev Neurobiol, St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Neuroprotection in the brain, and specifically the substantia nigra pars compacta (SNpc), is likely the result of the combination of a number of factors whose end result is the maintenance of metabolic and oxidative homeostasis. Exercise reduces the risk of developing disorders such as Parkinson's disease (PD), Alzheimer's disease and stroke, as well as providing neuroprotection in experimental models of these disorders. Voluntary wheel running provides partial to full protection to dopaminergic (DA) neurons of the SNpc in a mouse model of parkinsonism, dependent on both the number of daily wheel revolutions and length of time which they run. The role of the transcription factor hypoxia inducible factor (HIF) in this exercise-induced neuroprotection has been investigated. HIF is important in sensing cellular oxygen levels and initiating adaptive mechanisms in the event of hypoxia or oxidative stress. HIF functions as a heterodimer consisting of an inducible isoform (HIF1a, HIF2a, HIF3a) and a constitutive isoform (HIF1b, identical to the aryl hydrocarbon receptor nuclear translocator (ARNT)). Hif1a induces genes encoding proteins known to be important in the regulation of metabolism, autophagy, erythropoiesis, and vascular development and angiogenesis. Hif2a (Epas1) is necessary for mitochondrial homeostasis, expression of antioxidant enzymes, control of tyrosine hydroxylase expression, and vascular remodeling. Acute hypoxia induces increased HIF 1a in the brain, but with chronic exposure to low oxygen HIF levels return to baseline. We have previously reported that running exercise induces hypoxia in DA neurons as well as the modulation of Hif1a and Epas1 expression. Additionally, reduction of Hif1a or Epas1 in postnatal neurons has differential effects on DA neuron number in the SNpc. Conditional knockout (CKO) of Hif1a results in lower DA neuron number with exercise or exercise plus 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) treatment, while Epas1 CKO mice show lower DA neuron number in standard housing conditions (SH) that is rescued with 3 months of exercise. The downstream signaling regulated by Hif1a and Epas1 in exercise and standard conditions is currently being explored to gain further understanding of the roles of Hif1a and Epas1 in the survival and maintenance of SNpc DA neurons.

Title: The role of cerebral dopamine neurotrophic factor in zebrafish

Authors: *Y.-C. CHEN, S. SEMENOVA, P. PANULA;
Univ. of Helsinki, Helsinki, Finland

Abstract: Cerebral dopamine neurotrophic factor (CDNF) with potential therapeutic applications for the treatment of Parkinson's disease (PD) belongs to the evolutionary-conserved novel CDNF/ MANF family. CDNF not only restores the loss of dopaminergic neurons in PD animal models, but also protects cortical neurons against ischemic stroke. However, the molecular mechanisms of CDNF during development or disease pathology are still largely unfolded. In this study, using zebrafish we report that cdnf mRNA was mainly found in brain, myotomes and ears during embryonic development by *in situ* hybridization and detectable in adult organs including the brain, eyes, kidney and liver by qPCR. We also generated two cdnf -knockout fish strains with a one-nucleotide insertion and a sixteen-nucleotide deletion on exon 2 of cdnf gene by the CRISPR/Cas9 method. These indel mutations introduced a premature stop codon causing malfunctioned proteins. The larval cdnf -/- mutants did not show apparent gross phenotype nor was the locomotor behavior impaired although a significant reduction of cdnf mRNA was detected in cdnf +/- and cdnf -/- larvae in comparison of wild-type siblings. Notably, a dramatic increase of the tyrosine hydroxylase 2 transcripts, one of the teleost counterparts of mammalian tyrosine hydroxylase, was discovered when larvae lacked cdnf expression. Notch1a, tyrosine hydroxylase 1 and histidine decarboxylase transcripts showed no significant changes. The new zebrafish genetic models, cdnf -/- mutants may provide a powerful tool for understanding the biological functions of this neurotrophic factor.

Abstract: Monoacylglycerol lipase (MAGL) is the principal enzyme for 2-arachidonylglycerol (2-AG) metabolism and an important player in the endocannabinoid system. Here, we investigate the effects of two commercially available MAGL inhibitors KML29 and JZL184 in comparison with the cyclooxygenase 2 (COX2) inhibitor rofecoxib in an animal model of Parkinson's disease (PD) 6-Hydroxydopamine (6-OHDA) (3.5 µg/1 µl) was administered in the left striatum in male C57BL/6JRj mice. KML29, JZL184 and rofecoxib (30 mg/kg/day p.o.) were administered daily for one week starting one day before 6-OHDA surgery. Rotarod measurement was performed at day 7. Post mortem, striatal dopamine depletion and nigral tyrosine hydroxylase positive (TH+) cell loss were evaluated. Furthermore, the effect of MAGL inhibition on mechanistic biomarkers was assessed. 6-OHDA led to a 70 % dopamine depletion in the striatum and 40% loss of TH + neurons in the substantia nigra. The neuroprotective effect of KML29 was indicated by attenuation of dopamine depletion by 50 % and TH+ neuron loss by 30 %. Motor behavior was impaired by 6-OHDA but not restored by MAGL inhibition. Overall, the effects of JZL184 and rofecoxib treatment were less pronounced. The MAGL inhibitors increased 2-AG levels and decreased arachidonic acid and prostaglandins in the brain. Rofecoxib was able to decrease prostaglandins but had no effect on 2-AG and arachidonic acid levels. In conclusion, administration of the MAGL inhibitor KML29 further strengthens the concept of targeting the endocannabinoid system as a valuable therapeutic concept in PD.

Title: Intramuscular administration of C-terminal fragment of tetanus toxin modulates Nrf2 expression and prevents locomotor damage in rats with MPP+

Authors: *D. JUÁREZ TORRES[1], A. CANDALIJA[2], I. MARTÍNEZ-GARCÍA[3], J. AGUILERA[2], F. LUNA[4], L. MARTÍNEZ MENDIETA[1,5], I. D. LIMÓN[1];

Abstract: Parkinson's disease has been linked to different celular mechanisms which of them, produce neurodegeneration in the substancia nigra pars compacta (SNpc). Mainly, deregulation of protein control, excitotoxicity, mitochondrial deficit and oxidative stress are common markers and have been proposed like triggers of celular death. However, oxidative stress (OS) is one of the most prevalent events and its regulation, has been demonstrated could prevent the celular damage. So far, the intracelular regulation of OS has been characterised trough by Nrf2 transcription factor, which lead to synthesis of antioxidant and trophic proteins. Since there, the use of molecules which activate Nrf2 have been a new target for models of neuroprotection. Neurotrophins, can activate MAPK/IP3K pathway which could lead to Nrf2 activation and in our laboratory we have used a molecule like-neurotrophin, it is the case of C-terminal fragment of tetanus toxin that has been demonstrated prevents the damage in hemiparkinsonian rats. The aim of this work, was evaluated the effect of the administration of C-terminal fragment of tetanus toxin about Nrf2 expression in rats with MPP+ and a possible effect overt the motor asymmetry. Male Wistar rats were used and 3 previous days to stereotaxical surgery were administrated with Hc-TeTx (20 μg/kg) or vehicle intramuscular via. One day before of surgery, one group of animals were evaluated in cylinder test and after, that animals were evaluated 3 days posterior to surgery and other group of animals were euthanised at the same time, to evaluated Nrf2, 3-NT and tyrosine hydroxilase (TH) expression trough immunohistochemistry. Results shown that the rats administrated with Hc-TeTx previous to MPP+ deposition, prevents the locomotor activity asymmetry respect to rats only with MPP+. In the case of immunohistochemistry, Hc-TeTx caused that loss of TH in SNpc of rats were lesser than the the MPP+ group, besides the nitration of proteins has a different pattern of expression with a probable effect of anti apoptotic and a positive regulation of OS. Finally, 3 days after of the MPP+ lesion, the Nrf2 expression in rats with Hc-TeTx decreased the levels of this protein in SNpc, the correlation between the potential positive locomotor effect, probably is due a regulation of Nrf2, because although the MPP+ increased Nrf2 expression, the locomotor activity was impaired whereas Hc-TeTx improves the behaviour. In conclusion Hc-TeTx could act as protective molecule that modulates OS trough Nrf2 expression in the model of dopaminergic lesion with MPP+.

Title: Role of microRNA-155 in alpha-synuclein induced inflammatory response in a model of Parkinson's disease

Authors: *A. D. THOME, A. S. HARMS, L. A. VOLPICELLI-DALEY, D. G. STANDAERT; Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Parkinson disease (PD) is a neurodegenerative disorder characterized by loss of dopamine neurons in the substantia nigra pars compacta (SNpc) and aggregates of the protein alpha-synuclein (α-syn). Increasing evidence points to inflammation as a chief mediator of injury, however the role of α-syn in triggering and sustaining this inflammation remains unknown. Neuro-inflammatory responses have shown to be dynamically regulated by short, non-coding sequences called microRNAs (miRs). MiRs regulate messenger RNAs in a post-transcriptional fashion by binding to specific 3' untranslated regions resulting in repression or degradation of the transcript. We used an *in vivo* mouse model in which human α-syn is overexpressed by an AAV2 viral vector in mice (AAV2-SYN), resulting in elevated cytokine expression, reactive microgliosis, and progressive dopamine cell loss. At two weeks and four weeks after SNc AAV injection, we isolated miRNAs from the substantia nigra (injected and contralateral sides) and studied miRNA expression using a Qiagen PCR array containing probes for 84 microRNAs involved in either pro-inflammatory or anti-inflammatory regulation. We found that four of the microRNAs showed enhanced expression and two were reduced at two weeks post transduction. Among those which were increased was miR-155, which has been previously identified in other neurodegenerative diseases such as multiple sclerosis, amyotrophic lateral sclerosis, and Alzheimer disease. MiR-155 is known to target inflammatory pathways to up-regulate IL-1, IL-6, and TNF-α and regulates anti-inflammatory pathways in reducing IL-10, Arg 1, IL-13R, and TGF-βR pathway proteins. We confirmed the increase in miR-155 using qPCR, which demonstrated a 1.55 ± 0.09 ($p=0.01$) fold increase of miRNA-155 at 2 weeks post transduction and a trend toward increase at 4 weeks (1.28 ± 0.28). In 4 week mouse brain tissue, we observed decreases in MHCII expression and IgG deposition in miR-155 knockout mice compared to their WT counterparts in the SNpc. We hypothesize that this enhanced miR-155 expression promotes and sustains the inflammatory environment associated with over-expression of human α-syn which eventually leads to dopaminergic cell loss in the SNpc. These data and future experiments may point to microRNA-155 as a target for novel therapeutic treatments for

Abstract: Augmentation of cellular antioxidant capacity either by pro¬viding exogenous anti¬oxidants or by enhancing it endo¬genously has been the most in¬tensely in¬ves¬tigated approach in Parkinson's disease (PD) therapies. One of the strategies involves activating the nuclear-factor-E2-related factor 2 (Nrf2)/anti¬oxidant re¬sponse element (ARE) sig¬nal¬ing pathway, which regu¬lates ex-pression of anti-oxi¬dative, anti-in¬flam¬matory, and cyto¬pro¬tective genes. Tecfidera is an oral formulation of dimethyl¬fumarate (DMF) that is currently approved in USA as a treatment for Multiple sclerosis. Fumaric acid esters such as dimethyl and mono-methyl ¬fumarate (DMF and MMF) have been shown to exert

neuro¬pro¬tective effects by activating the Nrf2/ARE sig¬nal¬ing pathway. In this study we investigated *in vivo* pharma¬cokinetics of DMF and its mode of action to block 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) toxicity, as¬so¬ci¬ated oxi¬dative damage, neuroin¬flam¬mation and mitochondrial dysfunction in mice. We found that administration of dimethylfumarate and its active metabolite mono-methyl¬fumarate activates Nrf2 pathway *in vitro* using Neh2-luciferase reporter, and when orally administered in an OKD48-luciferase transgenic mice *in vivo*. Both dimethyl and mono-methyl¬fumarate at (10, 25, 50, and 100mg/kg) exhibited dose de¬pen¬dent neuroprotective effect against acute MPTP neuro-toxicity assessed by stereological cell counts of total and tyrosine hydroxy¬lase positive neu¬rons in sub¬stanti¬a nigra and by measuring striatal levels of catecholamines in wild type but not in Nrf2 null mice. Dimethyl¬fumarate prevented MPTP-induced oxi¬dative damage and inflammation assessed by 3-nitrotyrosine content, CD68 immuno¬reactivity and ex¬pression of pro-in¬flam¬matory cyto¬kines respectively in the ventral midbrains. Both dimethyl and mono-methylfumarate increased mRNA of nuclear and mitochondrial genes associated with mitochondrial function in wild type mouse embryonic fibroblasts (MEFs) but not in Nrf2 null MEFs. Our results suggest that fumaric acid esters exhibit neuroprotective effect against nigrostriatal dopaminergic neuro-toxicity owing to their Nrf2 dependent anti-oxidant, and anti-inflammatory activity and by facilitating mitochondrial biogenesis. Given that oxidative damage, neuroinflammation and mitochondrial dysfunction are all implicated in PD pathogenesis, our results provide strong pre-clinical evidence in favor of repurposing dimethylfumarate as a novel PD therapeutic.

Title: Temporal dynamics of 20S and 26S proteasome activities in brain regions containing differentially susceptible central dopaminergic neurons following acute neurotoxicant administration

Authors: *T. LANSDELL[1], K. J. LOOKINGLAND[2], J. L. GOUDREAU[3];
[1]Pharmacol. and Toxicology, Michigan State Universsity, East Lansing, MI; [2]Pharmacol. and Toxicology, [3]Neurol., Michigan State Univ., East Lansing, MI

Abstract: Parkinson disease is a chronic neurodegenerative disease characterized by significant loss of nigrostriatal dopamine (NSDA) neurons. While NSDA neurons originating in the substantia nigra (SN) are susceptible to degeneration, tuberoinfundibular dopamine (TIDA) neurons in the arcuate nucleus (ARC) are spared. This pattern of DA neuronal susceptibility can be simulated following exposure to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). MPTP inhibits mitochondrial complex I resulting in the generation of protein damaging reactive oxygen species. Oxidative damage to proteins can produce conformational changes which may result in alteration of native protein function and toxic aggregate formation. The proteasome is a highly dynamic complex that exists in an equilibrium between the 20S and 26S catalytically active forms. Degradation of oxidatively damaged proteins occurs primarily through a ubiquitin- and ATP-independent mechanism involving the more abundant 20S core proteasome particle. The 26S proteasome is composed of the 20S catalytic core and 19S regulatory subunits, and specifically degrades ubiquitinated proteins in an ATP-dependent mechanism. The purpose of this study was to characterize the time course effects of MPTP on 20S and 26S proteasome activities in brain regions containing axon terminals of NSDA (striatum; ST) and TIDA (median eminence; ME) neurons. The underlying hypothesis of this study is that differences in 20S/26S proteasome dynamics may underlie susceptibility of these DA neurons to toxicant exposure. Proteasome activity was measured using chymotryptic-like substrate (Suc-LLVY-AMC) in tissue collected 4, 6, 8, 12 or 24 h after MPTP (20 mg/kg; sc) or vehicle. 26S Proteasome activity in ST synaptosomes was increased 4 h after MPTP and then diminished over time, whereas 20S proteasome activity decreased 4 h following MPTP and then increased over time. In congruence with enhanced 26S activity, expression of the catalytic β5 subunit in the SN was significantly increased after MPTP exposure. In contrast, 26S proteasome activity in the ME was not altered either 4 or 24 h following MPTP. The maintenance of 26S activity in the ME correlated with an increase in expression of β5 catalytic subunit in the ARC after MPTP. Differential proteasome dynamics between the ST and ME following neurotoxicant exposure suggests that effective modulation of the proteasome may be a determining factor in the susceptibility of central DA neurons to acute toxicant exposure.

Title: Hydroxytyrosol inhibits MAO-B and improves dopaminergic functional recovery after MPP+ administration in rats

Authors: *G. A. PÉREZ-BARRÓN[1], A. MONROY-NOYOLA[1], M. RUBIO-OSORNIO[2], S. MONTES[2], S. GARCÍA-JIMENEZ[1];
[1]Lab. 11, Facultad de Farmacia, Univ. Autónoma Del Estado De Morelos, Cuernavaca, Mexico; [2]Inst. Nacional de Neurología y Neurocirugía, Mexico city, Mexico

Abstract: Parkinson's disease is a neurological syndrome of unknown etiology, environmental organic molecules such as the metabolite 1-methyl-4-phenylpyridinium (MPP+) which induce a selective toxicity towards dopaminergic neurons in the nigrostriatal pathway. Another hypothesis in this disease is the loss of dopaminergic neurons by an increase in the catabolism of dopamine across the monoamine oxidase (MAO) enzyme that produced reactive oxidant species. *In vivo* studies have demonstrated that hydroxytyrosol (HT) is a potent antioxidant in the central nervous system. In the present study, Wistar male rats were administered a single dose of 1.5 mg/Kg of HT intravenously. Five minutes later, the animals received a intrastriatal stereotaxic micro-injection of 10 µg MPP+ dissolved in 8µL of sterile saline solution. Six days later, all animals were treated with apomorfine at a dose of 1 mg/Kg by subcutaneous injection for the behavioral evaluation through counting ipsilateral rotations during 1 hour. Rats were sacrificed by decapitation and the striatum region was dissected for the quantification of catecholamines and MAO activities. The results show that pretreatment with HT diminished significantly ($p< 0.05$) the number of ipsilateral rotations (70%). This behavioral recovery was corroborated by the 78% preservation of the levels of striatal dopamine ($p < 0.05$) and an inhibition of 20% and 60% of the MAO-A and B activity respectively ($p < 0.05$). These results demonstrate the neuroprotective effect of HT in the MPP+ Parkinson´s disease model in rats, possibly due to the inhibition of MAO-B meanly.

Title: Comparative effect of novel incretin analogues in an *in vitro* model of Parkinson's disease

Authors: *J. JALEWA, M. K. SHARMA, C. HOLSCHER;
Lancaster Univ., Lancaster, United Kingdom

Abstract: There is no viable treatment available for Parkinson's disease till date that could potentially prevent or treat this dreadful motor impairment disorder. Interestingly, several Exendin-4 (Byetta) studies have shown neuroprotective/neurorestorative properties in the pre-clinical and clinical studies of Parkinson's disease. Incretin hormone analogues were originally developed to treat type 2 diabetes, but recent research have shown their neuroprotective properties. Incretins can cross blood brain barrier and activate neurogenesis and synaptogenesis and growth factor signalling in neurons in the CNS. A range of novel long-lasting analogues for glucagon-like-peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP) that are resistant to protease cleavage have been developed, which exhibit superior receptor activation properties, elongated half-life and are protected from renal clearance due to the acetylation that helps bind to the blood proteins. We have previously shown very promising effect of Liraglutide (Victoza) on SH-SY5Y cells against methyl glyoxal oxidative stress. In this study, we tested novel incretin analogues on the dopaminergic SH-SY5Y neuroblastoma cells against mitochondrial complex I inhibitor, Rotenone (a pesticide) toxicity. Here, we report for the first time comparative effect of six different incretin analogues (Liraglutide, Oxyntomodulin, Dual agonist, dAla-2GIP Glupal, Val-8 GLP-1 Glupal and Exenatide. Post-treatment with 1nM, 10nM and 100nM incretin analogues for 12hrs increased the cell viability (XTT assay) of SH-SY5Y cells when tested against 1μM and 10μM Rotenone stress for 12hrs. In addition, the involvement of PI3K signalling in the comparative neuroprotective effect of these incretin analogues will be detailed. Further results will be unrevealed at the meeting.

Title: Neuroprotective effect of 4R, a tobacco cembranoid on 6-hydroxydopamine-induced Parkinson's disease in rat

Authors: *J. HAO[1], J. HU[1], P. A. FERCHMIN[2], V. A. ETEROVIC[2];
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Dept. of Biochem., Univ. Central del Caribe, Bayamon, Puerto Rico

Abstract: The *in vivo* experiments of the present study have shown that (1*S*,2*E*,4*R*,6*R*,-7*E*,11*E*)-2,7,11-cembratriene-4,6-diol (4R), a cyclic diterpenoid found in leaves of *Nicotiana* species, decreased the depletion of tyrosine hydroxylase (TH) positive cells in striatum and substantia nigra (SN) in 6-OHDA-induced PD model in rat. Compared to the contralateral side, there was a significant depletion of TH-positive cells in the right (the lesion) side of striatum and right side of substantia nigra (SN). In the vehicle (DMSO) controls, the TH density was 51.9%±5.7 and 23.6%±14.7 of the density observed in the left not lesion contralateral. However, 6 or 12 mg/kg 4R significantly mitigated TH depletion in both striatum and SN in the lesion side. TH expression was 70.3±11.3% and 62.8±25.8% of the left, not lesion side striatum and SN respectively after 6mg/kg 4R treatment. TH expression was 80.1±11% and 79.3±15% of the control side striatum and SN respectively after 12mg/kg 4R treatment. The behavioral deficit was significantly improved after 4R treatment as shown by the performance in the cylinder test and corner test. The 4R-injected subjects were approaching the expected baseline score of 0.5. The scores of the corner test were 0.63, 0.62, 0.51, 0.50 in the 6 mg/kg 4R-treatment groups at 1, 2, 3 and 4 weeks after the injection of 6-OHDA respectively. The scores of the DMSO group they were 0.69, 0.8, 0.81, 0.87 at 1, 2, 3 and 4 weeks after the injection of 6-OHDA respectively. The scores of the cylinder test were 0.48, 0.46, 0.47, 0.49 in the 6 mg/kg 4R-treatment groups at 1, 2, 3 and 4 weeks after the injection of 6-OHDA respectively. In contrast, the scores of the DMSO were 0.36, 0.31, 0.22, 0.22 in DMSO groups at 1, 2, 3 and 4 weeks after injection of 6-OHDA respectively. Similar results were observed in the 12mg/kg 4R-treatment groups. *In vitro* 4R protected the differentiated neuro-2a cells (a neuronal cell line) from 6-OHDA-induced cytotoxicity, and this protection was associated with restoration of the anti-apoptotic proteins, p-Akt and Hax-1, expression and decrease of the cellular levels of cleaved caspase-3. Furthermore, 4R also inhibited inflammatory responses in brain-derived endothelial cells induced by TNF-α, which were shown to reduced the level of p65, a NF-kB subunit, VACM-1 expression, and the percentage of monocytes adhered to endothelial cells. In conclusion, the present study demonstrates that 4R has a protective effect on 6-OHDA-induced PD model in rat. In addition,

4R inhibited inflammation and restored Akt and Hax-1 functions, which are most likely involved in the mechanisms of 4R protection against 6-OHDA-induced injury.

Title: Substantia nigra activation as a mechanism of neuroprotection in a progressive mouse model of Parkinson's disease

Authors: *R. HOOD[1], C. MOORE[2], P. M. FULLER[3], C. K. MESHUL[1,2];
[1]Behavioral Neuroscience, Oregon Hlth. & Sci. U, Portland, OR; [2]Portland VA Med. Ctr., Portland, OR; [3]Dept. of Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Parkinson's disease (PD) is a common neurodegenerative disorder, affecting 7-10 million people worldwide. Through a progressive loss of dopaminergic cells in the substantia nigra pars compacta (SNpc), signaling in the basal ganglia becomes dysfunctional, leading to declining motor and cognitive function. Targeting specific dysregulated regions in the basal ganglia may help to potentially protect SNpc cells from further loss. Imaging studies of PD patients demonstrate an alteration in motor cortex (MC) activation when compared to healthy control patients, and repetitive transcranial magnetic stimulation targeting the MC attenuates motor impairments in PD patients. These results suggest the MC is viable as a novel therapeutic target. We have previously shown that unilateral Vgat (the gene encoding the vesicular GABA transporter VGAT) deletion in the MC of Vgatflox/flox mice injected with AAV-Cre-GFP is completely bilaterally protective against a progressive PD model utilizing 4 weeks of an increasing dose of 1-methyl-2-phenyl-1,2,3,6-tetrahydropyridine (MPTP), 5 d/wk injected i.p., at doses of 8, 16, 24, and 32 mg/kg/d. Since VGAT is required for GABAergic function, we believe targeting GABAergic interneurons with focal AAV-Cre-GFP injections prevents inhibitory GABAergic signaling in the MC, and this disinhibtion exerts a neuroprotective effect in our model. What is not known, however, is the mechanism by which this neuroprotection occurs. Since the MC strongly innervates the dopamine-depleted striatum, we hypothesized that MC disinhibition would activate the corticostriatal pathway. Based on post-embed immunogold

labeling for glutamate, there is no detectable change in glutamate in striatal nerve terminals originating from the cortex either after MPTP or in Cre-injected Vgatflox/flox animals. Therefore, though the majority of MC projections are corticostriatal projections, we believe the mechanism of protection is not through activation of the corticostriatal pathway. Cytochrome oxidase (CO) was used as a marker of cellular activity and showed no significant difference in labeling between any treatment groups in the striatum. However, CO labeling in the SN was significantly decreased in wt mice given MPTP, and this decrease was attenuated in the Vgatflox/flox+MPTP mice. It is possible that the mechanism of protection occurs through activation of the SN. Anterograde labeling studies reveal bilateral projections from the motor cortex to both the STN and the SN, suggesting that the hyperdirect pathway may indirectly be activating the SN, or the corticonigral pathway could be directly activated, leading to protection from MPTP lesions.

Title: Inactivation of calcineurin/cyclophilin D by Cyclosporin A as a neurorestorative target in a progressive MPTP animal model of PD

Authors: M. J. CHURCHILL[1], M. D. SCONCE[1], C. MOORE[1], M. DECRESSAC[2], *C. K. MESHUL[1,3];
[1]Neurocytology Lab/Bldg 101, Room 520, VA Med. Ctr., Portland, OR; [2]Telethon Inst. of Genet. and Med., Pozzuoli, Italy; [3]Behavioral Neurosci., OHSU, Portland, OR

Abstract: In Parkinson’s disease (PD), there is an increased inflammatory response as the disease progresses (Tufekci et al., 2012). The focus on targeting the inflammatory response has been the use of non-steroidal anti-inflammatory drugs; however, meta-analyses have shown inconclusive results (Samii et al., 2012). Animal data in a PD model suggests that cyclosporin A (CsA) has neuroprotective properties (Matsuura et al., 1999). In a human clinical fetal transplant study, when cyclosporin A was withdrawn from treatment, the UPDRS score increased (Olanow et al., 2003). CsA has two targets which are calcineurin, a regulator of inflammatory proteins and

the mitochondrial pore modulator, cyclophilin D. Specifically the focus of the effects of CsA upon calcineurin/cyclophilin were examined in the nigrostriatal dopamine (DA) pathway. CsA is first and foremost an anti-inflammatory drug as it inactivates calcineurin, preventing dephosphorylation of nuclear factor of activated T-cells (NFAT) and preventing component 3 of NFAT (i.e., NFATc3) from starting transcription of pro-inflammatory proteins, such as interleukin 2. A second target of CsA is cyclophilin D, which regulates the opening of the mitochondrial permeability transition pore (Doczi et al., 2011) preventing the release of cytochrome C, and thereby blocking apoptosis. We have developed a model of progressive loss of nigrostriatal DA over a 4-week time period by increasing the weekly dosing of MPTP (Goldberg et al., 2011), resulting in a 50-70% loss of DA. Using a more clinically relevant neurorestoration animal model of PD, CsA treatment (20 mg/kg/d, 7d/wk) was initiated following the 4 weeks of MPTP administration. Motor/strength testing revealed a significant 16% increase in grip strength, (i.e., unable to release from the bar) following MPTP ($p = .0004$), which was restored back to the control levels by CsA treatment. There was a 60% loss of tyrosine hydroxylase (TH) expression within the dorsal lateral striatum following MPTP, which recovered to only a 30% loss with CsA treatment. After MPTP, there was a 47% decrease in the number of TH-labeled neurons within the substantia nigra pars compacta compared to the controls, while CsA treatment resulted in only a 39% loss of TH-labeled neurons. Within the striatum, there was a significant increase of nearly 200% in the levels of SCG 10 (indicative of regenerating axons) in the MPTP/CsA group compared to the MPTP only ($p = .01$) and the vehicle group ($p = .008$). Overall, using a neurorestoration model of PD, our data suggests that CsA facilitates sprouting of striatal axons, resulting in improved motor function.

Title: Inhibition of Cdk5/p25 hyperactivity by a truncated peptide (TP5), derived from P35, a Cdk5 activator, provides neuroprotection in the MPTP model of Parkinson's disease

Authors: *B. BALACHANDRAN KRISHNAMMA, N. D. AMIN, S. SKUNTZ, V. SHUKLA, J. STEINER, P. GRANT, H. C. PANT;
Building 49, Room 2A35, 49 Convent Drive, MSC 4479, NIH, Bethesda, MD

Abstract: Parkinson's disease (PD) is a chronic neurodegenerative disorder characterized by the loss of dopamine neurons in the substantia nigra, decreased striatal dopamine levels, and consequent extrapyramidal motor dysfunction. Recent evidence indicates that cyclin-dependent kinase 5 (Cdk5) is inappropriately activated in several neurodegenerative conditions including PD. To date, strategies to inhibit Cdk5 activity have not been successful in selectively targeting aberrant activity without affecting normal Cdk5 activity. Previously, we reported that TP5 peptide has neuroprotective effects in animal models of Alzheimer's disease. Here, we show that TP5 selective inhibition of Cdk5/p25 hyperactivation *in vivo*, rescues nigrostriatal dopaminergic neurodegeneration caused in the MPTP induced animal model of PD. TP5 peptide treatment also blocked dopamine depletion in the striatum and improved in gait dysfunction after MPTP administration. The neuroprotective effect of TP5 peptide is also associated with marked reduction in neuroinflamation and apoptosis. The findings reported here showing selective inhibition of Cdk5/p25 hyperactivation by TP5 peptide, identify the kinase as a potential therapeutic target to reduce neurodegeneration in Parkinson's disease.

Title: Plasma and brain levels of several steroids following progesterone treatment in neuroprotection of MPTP-treated male mice

Authors: *M. BOURQUE[1], M. MORISSETTE[1], S. AL SWEIDI[1], D. CARUSO[2], R. C. MELCANGI[2], T. DI PAOLO[1,3];

Abstract: Steroids exert neuroprotective effects and neurodegeneratives diseases affect the level of neuroactive steroids. However, little is know about the changes induced by neuroactive steroid treatment when neurons are damaged. The aim of this study was to measure and compare plasma and brain levels of several neuroactive steroids in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated male mice following neuroprotection with progesterone (PROG) treatment. Mice received 4 injections of MPTP (6.5 mg/kg) and were treated with progesterone (8 or 16 mg/kg) during 6 days. Data obtained showed that among pregnenolone, PROG and its derivatives, only dihydroprogesterone (DHP) and isopregnanolone were increased in plasma of MPTP-treated mice. PROG treatments showed in plasma a dose-dependent increase in PROG levels; assessment of PROG metabolites revealed that both doses of PROG administered decreased DHP levels as compared to MPTP mice, while only the highest dose of PROG decreased isopregnanolone levels. Tetrahydroprogesterone levels were not affected in MPTP-treated male mice, and with PROG treatment. In brain tissue, the levels of all these neuroactive steroids were unchanged in MPTP-treated male mice, however treatment with PROG at the highest dose increase pregnenolone, PROG, DHP, isopregnanolone and tetrahydroprogesterone levels. Interestingly, PROG treatment at 8 mg/kg decreased pregnenolone levels and increased PROG and tetrahydroprogesterone levels in brain tissue. Significant positive correlations were observed between plasma and brain levels of PROG and a significant negative correlation was found between plasma and brain levels of isopregnanolone. The levels of testosterone metabolites dihydrotestosterone (DHT), 3α-diol and 3β-diol were decreased in the plasma of MPTP-treated mice, while no change was observed for dehydroepiandrosterone (DHEA) and testosterone. By contrast, in brain tissue, only DHT levels were increased. Treatment with PROG at 8 mg/kg decreased brain levels of DHT as compared to MPTP mice, while after treatment with the highest dose, an increase was observed. Brain levels of DHEA and 3β-diol were not modified in MPTP-treated mice, but PROG treatment at a dose of 16 mg/kg decreased the levels of these two steroids. Significant positive correlations were observed between plasma and brain levels of DHEA, as well as between plasma and brain levels of testosterone; a significant negative correlation was found between plasma and brain DHT levels. Our results shown that changes in brain steroids levels following a neuroprotective PROG treatment do not necessarily reflected the changes observed in plasma levels.

Title: Neurorescue effects of Progesterone on dopaminergic neurons in the MPTP mouse model of Parkinson's disease

Authors: *N. LITIM[1,2], M. MORISSETTE[1], T. DI PAOLO[1,2];
[1]Neurosci. Res. Unit, Ctr. De Recherche Du CHU De Q, Quebec, QC, Canada; [2]Fac. of Pharm., Laval Univ., Quebec City, QC, Canada

Abstract: Parkinson disease (PD) is a neurodegenerative disease characterized by a loss of dopaminergic neurons in the nigrostriatal pathway. Several studies have reported the neuroprotective effect of estradiol while the efficacy of the ovarian steroid progesterone to prevent the loss of dopaminergic neurons is less documented. Previous studies have shown that treatment with low dose of progesterone has neuroprotective effects on striatal dopamine (DA) in mice lesioned with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) when administered before the toxin. However, the rescue and restorative potentials of this compound on the integrity of dopaminergic neurons remains to be investigated. In this study, we hypothesized that brain DA can be restored by progesterone when administered 24 h or even 5 days after the lesion with MPTP. Male mice received 4 injections of MPTP (8 mg/kg) and were treated with progesterone (once daily at 8 mg/kg) 24 h or 5 days after the lesion with MPTP during 5 days. The striatal levels of DA and its metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) were quantified by HPLC. Specific binding to the dopamine transporter (DAT) and vesicular monoamine transporter 2 (VMAT2) was measured by autoradiography. The MPTP lesion decreased striatal DA concentrations while serotonin concentrations remained unchanged. MPTP mice treated with progesterone 24 h after the lesion had higher concentrations of DA, DOPAC and HVA than vehicle-treated MPTP mice, whereas this effect was not observed in mice treated with progesterone 5 days after MPTP compared to the vehicle-treated MPTP mice. Progesterone administered 24 h after the lesion partially prevented the striatal increase of HVA/DA ratio induced by MPTP. Autoradiography of striatal DAT and VMAT2 showed that treatment with progesterone 24 h after MPTP decreased the effect of the toxin in the striatum while no protection was observed when progesterone was administered 5 days after the toxin. These results suggest that the ovarian steroid progesterone at the dose of 8 mg/kg has the capacity to promote the recovery of dopaminergic neurons when administered 24 h after the MPTP lesion in male mice whereas no restorative effect 5 days post lesion was observed.

Title: Impact of aging on recombinant adeno-associated and lentiviral vector-mediated transduction of the rat nigrostriatal and striatonigral system

Authors: *N. POLINSKI, L. CONGDON, L. FISCHER, F. P. MANFREDSSON, M. BENSKEY, C. J. KEMP, N. C. KUHN, A. COLE-STRAUSS, K. STEECE-COLLIER, K. L. PAUMIER, J. W. LIPTON, C. E. SORTWELL;
Translational Sci. and Mol. Med., Michigan State Univ., Grand Rapids, MI

Abstract: Clinical trials are currently examining the efficacy of viral vector-mediated gene delivery for treating age-related neurodegenerative diseases such as Parkinson's disease (PD). While viral vector strategies have been successful in preclinical studies, to date, human clinical trials have disappointed. This may be partially due to the fact that preclinical studies fail to account for aging as an important covariate even though aging is the primary risk factor for PD, with the majority of idiopathic cases occurring in people over the age of 65. Previously, we found that gene transfer utilizing recombinant adeno-associated virus serotype 2/5 (rAAV2/5) results in decreased transduction efficiency in the aged (20 month) rat nigrostriatal system as compared to the young adult (3 month) rat (PMID: 25457558). Specifically, injection of rAAV2/5 expressing green fluorescent protein (GFP) to the substantia nigra (SN) of aged rats resulted in: 1) ~60% fewer cells expressing detectable GFP, 2) ~50% less striatal protein, and 3) 4-fold lower mRNA expression than identical injections into the young adult rat SN. These results were generalizable over rat strain, duration of expression, and location sampled in the nigrostriatal system. In the present series of experiments, we investigated whether the phenomenon of deficient transduction in the aged nigrostriatal system is generalizable to other vector constructs and other circuitry. To examine this, we compared the transduction efficiency

of rAAV2/5, rAAV2/2, rAAV2/9, or lentivirus (LV) expressing GFP in young (3 month) or aged (20 month) male Fischer 344 rats following injections into either the SN or the striatum, the structure most often targeted in PD gene therapy clinical trials. Four weeks after injection in the SN, three of the four vector constructs (rAAV2/5, rAAV2/2, and LV) were less efficient in transducing the aged nigrostriatal system as assessed via GFP immunoassay in the striatum. In contrast, rAAV2/9 GFP injection into the SN resulted in equivalent protein expression in the striatum of young adult and aged rats. Similarly, four weeks following injection into the striatum, all three rAAV serotypes were deficient in transducing the striatonigral system as assessed via GFP immunoassay in the SN pars reticulata. These results demonstrate that the aged brain is less amenable to viral vector-mediated gene transfer. As aging-related deficits in transduction have the potential to impact current and future gene therapy trials, identification of the mechanism of the deficiency will be required for efficient protein delivery in future gene therapy clinical trials for age-related neurodegenerative diseases.

Title: Pharmacological rescue of Parkinson’s disease symptoms in *Drosophila* larvae

Authors: ***D. LEE**[1], E. PODOLSKY[2], J. BLOSSER[2];
[2]Dept. of Biol. Sci., [1]Ohio Univ., Athens, OH

Abstract: Parkinson’s disease (PD) is a devastating motor system disorder. However, its treatments, including the ‘gold standard’ drug L-DOPA, remain inadequate. In order to advance PD treatments and understanding of the disease, it is necessary to develop a better animal model that is fast and sufficiently mimic the pathology of human PD. The fruit fly *Drosophila melanogaster* has been widely used as a model for human diseases including PD, primarily due to its genetic similarity with mammals and the sophisticate genetic tools available to study disease mechanisms as well as potential therapies. Prior studies have demonstrated *Drosophila*

larvae to be a useful PD model, showing two key features: locomotion deficits and loss of dopaminergic (DA) neurons (Varga et al, 2014). This larval model can also be very useful in quickly screening drugs as well as probing their mechanisms due to its rapid onset of PD symptoms, which takes less than 4 days. In this study, therefore, we have extended this model to screen and better understand PD treatments. Both genetic and neurotoxin PD models (i.e., α-Synuclein (A53T) and rotenone, respectively) were used to quantify the symptomatic improvement in locomotion speed, turning rate, and pause time after treatment with potential PD drugs. First, the fly larvae were exposed to L-DOPA to determine whether they show similar symptomatic relief. When L-DOPA (100μM) was added to the food, both α-Synuclein (A53T) and rotenone-treated larvae showed significant improvements in the locomotion, demonstrating the usefulness of the fly larval model to study the rescue of PD symptoms. The next goal was to demonstrate how this model could be used to test previously understudied new drugs. For this purpose, the citrus flavonoid nobiletin was chosen for its previously demonstrated potential therapeutic benefit in various neural diseases including PD (Yabuki et al., 2014). Nobiletin (10μM) effectively rescued motor deficits in two larval PD models. Further, it was found that nobiletin's rescue effects were achieved through activation of D2 autoreceptors as there was no rescue in the larvae expressing D2 receptor RNAi selectively in DA neurons. We are currently examining the number of DA neurons rescued by L-DOPA and nobiletin. Taken together, our fly larval PD model can be a very useful model to rapidly and more effectively screen potential PD drugs and also to study their rescue mechanisms.

Title: Brain somatic mutations in MTOR cause focal cortical dysplasia type II leading to intractable epilepsy

Authors: J. LIM[1], W.-I. KIM[1], H.-C. KANG[3], D. KIM[2], D. KIM[3], *J. LEE[1];
[1]Grad. Sch. of Med. Sci. and Engin., [2]Biol. Sci., KAIST, Daejeon, Korea, Republic of; [3]Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Focal cortical dysplasia type II (FCDII) is a sporadic developmental malformation of the cerebral cortex characterized by dysmorphic neurons, dyslamination and medically refractory epilepsy. It has been hypothesized that FCD is caused by somatic mutations in affected regions. Here, we used deep whole-exome sequencing (read depth, 412-668×) validated by site-specific amplicon sequencing (100-347,499×) in paired brain-blood DNA from four subjects with FCDII and uncovered a de novo brain somatic mutation, mechanistic target of rapamycin (MTOR) c.7280T>C (p.Leu2427Pro) in two subjects. Deep sequencing of the MTOR gene in an additional 73 subjects with FCDII using hybrid capture and PCR amplicon sequencing identified eight different somatic missense mutations found in multiple brain tissue samples of ten subjects. The identified mutations accounted for 15.6% of all subjects with FCDII studied (12 of 77). The identified mutations induced the hyperactivation of mTOR kinase. Focal cortical expression of mutant MTOR by *in utero* electroporation in mice was sufficient to disrupt neuronal migration and cause spontaneous seizures and cytomegalic neurons. Inhibition of mTOR with rapamycin suppressed cytomegalic neurons and epileptic seizures. This study provides, to our knowledge, the first evidence that brain somatic activating mutations in MTOR cause FCD and identifies mTOR as a treatment target for intractable epilepsy in FCD.

Abstract: Epileptic encephalopathies (EEs) are a devastating group of severe childhood onset epilepsies with medication resistant seizures and poor developmental outcomes. EEs have strong genetic contributions and are associated primarily with *de novo* mutations in many genes, including $GABA_A$ receptor subunit genes (*GABRs*). Recently, we performed next generation sequencing on patients with a range of EE phenotypes and identified six novel *de novo GABRG2* mutations (A106T, I107T, P282S, R323Q, R323W and F343L). To gain insight into the molecular basis for how these mutations contribute to EEs, we explored and compared the effects of the mutations on the properties of recombinant α1β2γ2L $GABA_A$ receptors transiently expressed in HEK293T cells. Using a combination of flow cytometry, immunoblotting, confocal imaging and patch clamp recording, we found that these *GABRG2* mutations impaired $GABA_A$ receptor biogenesis and/or channel function to different extents. Compared with wild-type α1β2γ2L receptors, $GABA_A$ receptors containing different mutant γ2 subunits had reduced cell surface expression with altered subunit stoichiometry or decreased GABA evoked whole-cell current amplitudes but with different levels of reduction. While a causal role of these mutations cannot be directly established from these results, the functional analysis together with the genetic information suggests that these *GABRG2* mutations may at least be genetic risk factors of EE or could be the major contributors to the affected cases. Our study further expands the *GABRG2* phenotypic spectrum and supports growing evidence that defects in GABAergic neurotransmission participate in the pathogenesis of genetic epilepsies including EE.

Abstract: Sudden unexpected death in epilepsy (SUDEP) is the leading cause of epilepsy-related mortality, but its genetic etiology is largely unknown and likely complex involving multiple genes. The *Kcna1* gene encodes Kv1.1 potassium channels that act to dampen neuronal excitability whereas the *Scn2a* gene encodes Nav1.2 sodium channels important for action potential conduction. We investigated the ability of subclinical *Scn2a*-null heterozygosity to act as a protective genetic modifier of epilepsy and premature death in the *Kcna1*-null mouse model of SUDEP. We tested the hypothesis that subclinical *Scn2a* heterozygosity reduces SUDEP incidence in *Kcna1*-null mice by suppressing neurocardiac dysfunction associated with the absence of Kv1.1 channels. SUDEP-prone *Kcna1*-null mice exhibited about a 50% increase in lifespan when heterozygous for the *Scn2a*-null allele, that is $Scn2a^{+/-}$, $Kcna1^{-/-}$. In simultaneous video electroencephalography (EEG)- electrocardiography (ECG) recordings, *Scn2a* heterozygosity did not eliminate seizures in $Kcna1^{-/-}$ mice, but seizure burden was partially reduced due to a significant reduction in seizure durations. Analysis of beat-to-beat heart rate variability (HRV) revealed that $Kcna1^{-/-}$ and $Scn2a^{+/-}$, $Kcna1^{-/-}$ mice exhibit similarly high RMSSD (Root Mean Square of the Successive Differences), suggesting the functional interactions between the two mutations do not involve significant alteration of parasympathetic tone. To measure the association of brain and heart activity in more detail, EEG-ECG interaction dynamics were analyzed by dividing EEG-ECG recordings into 10-s segments and estimating the following variables: 1) brain connectivity across channels at traditional EEG bands (coherence C(band)); 2) complexity of EEG and ECG signals (Shannon's Entropy - ENTR); and 3) heart rate variability (the median (M) and Inter Quartile Range (IQR) of the R peak amplitudes and length of RR intervals from QRS complexes in ECG). The degree of association of the extracted EEG-ECG features over the whole record was then evaluated using the phi coefficient. Analysis of EEG-ECG interaction dynamics revealed a significantly higher degree of association between brain and cardiac activity in double mutant mice compared to $Kcna1^{-/-}$ animals for several different measures, suggesting that *Scn2a*-null heterozygosity reduces SUDEP risk by altering neural control of the heart. These findings expand our understanding of the complex genetic interactions underlying SUDEP and identify EEG-ECG association as a potential new biomarker of SUDEP susceptibility.

Title: Identification of seizure susceptibility loci using the Collaborative Cross

Authors: *M. BI[1], R. RAM[2], G. MORAHAN[2], L. M. ITTNER[1,3];
[1]Dementia Res. Unit, The Univ. of New South Wales, Sydney, Australia; [2]Ctr. for Diabetes Res., Harry Perkins Inst. of Med. Res., Perth, Australia; [3]Neurosci. Res. Australia, Sydney, Australia

Abstract: AIM: The Collaborative Cross (CC) was originally designed to facilitate rapid mapping of genes in mice using hundreds of recombinant inbred strains derived from eight diverse inbred founder strains. Seizure disorders are complex trait and have been studied for many years, however only a few strongly penetrant candidate genes have been discovered. Recently, identification of mutations on multiple backgrounds has revealed the impact of some lesser penetrant or modifier genes that impact on epileptic seizure severity, latency and form. METHOD: We induced epileptic seizures by intra-peritoneal injection of pentylenetetrazol (PTZ) into 6 to 8 week old CC mice and 4 of the initial founder strains. After injection, each mouse was monitored for 10 minutes. Between 8 to 10 male mice were used for each. Seizure severity was scored using a modified seizure scale (0 – no visible effect; 1 – freezing or immobility; 2 – isolated limb clonus; 3 – generalised clonus; 4 – generalised tonic clonic seizure) and the latency taken to reach each stage was recorded. RESULTS: The CC mice showed highly variable response to PTZ-induced epileptic seizures with some showing high resistance to PTZ challenge whilst others displayed rapid progression to severe seizures. Using QTL analysis, we have identified susceptibility loci and narrowed down target missense mutations for further investigation. CONCLUSION: The CC is a suitable and useful tool for mapping complex traits. Here we have mapped loci for susceptibility to PTZ-induced epileptic seizures in mice. Given the common mechanism of excitotoxicity between seizure disorders, stroke and neurodegenerative disorders such as Alzheimer's disease, we believe the candidates described here may play roles in other neurological conditions where excitotoxicity is implicated.

Abstract: Epilepsy is a neurological condition characterized by recurrent epileptic seizures Epilepsy is a common and disabling neurologic disorder which affects about 1% of the population. Seizures are the result of abnormal electrical activity in the brain and can be profoundly disabling, affecting work, social activity and increasing risk of harm. Specific genetic anomalies or non-genetic factors could lead to epilepsies, but in various cases the underlying cause is unknown. Novel technologies, such as array comparative genomic hybridization (array-CGH), may reveal the copy number variants (CNVs), established as significant risk factor for epilepsies. This study carried out by using high density whole genome Agilent sure print G3 Hmn CGH 2x 400K array-CGH with blood DNA samples from a cohort of forty two epilepic patients to search for novel CNVs associated with epilepsy. We found novel deletion and duplication using microarray data analysis software PARTEK and the novelty of CNVs was checked by using Database of Genomic Variants. Microdeletion of 14q31.1 was observed in four patients including two from the same family with loss of NRXN3 gene; microdeletion of 15q12 with loss of GABRG3 gene, and microduplication of 20q13.33 in three patients with loss of gene group CHRNA4, KCNQ2, EEF1A2 and PPDPF were also found. These CNV findings were confirmed by using real-time quantitative PCR (qPCR). We have described, for the first time, numerous potential CNVs/genes implicated in epilepsy in the Saudi population. The study

presents a better description of the genetic variations in epilepsy, and would eventually enable us to provide a foundation for understanding the critical genome regions which might be involved in the development of epilepsy.

Title: Computational models of ictogenesis

Authors: ***T. JACOB**[1], W. SWIERCZ[2], K. STALEY[1];
[1]Neurol., Massachusetts Gen. Hospital/Harvard Med. Sch., Charlestown, MA; [2]Kiva Systems, Reading, MA

Abstract: Seizures are so called because we don't know when they will occur, despite many decades of investigation. This situation may have arisen because the relevant parameters are not yet accessible experimentally. To investigate ictogenesis more generally, we created a computational model of the CA3 hippocampal region. The model has a layer of 100 x 100 pyramidal cells, interspersed with a 15 x 15 array of interneurons. We tested two models of spiking neurons - the MacGregor model and the Izhikevich model. Every neuron is connected to a neighborhood of surrounding neurons, using several different strategies for synaptic connectivity. Synapses were designed to undergo activity-dependent short-term depression and

recovery. The initial number of releasable glutamate vesicles in each presynaptic terminal was normally distributed. The amount of glutamate released at a synapse depends on: 1) probability of release of a glutamate vesicle and 2) the number of releasable glutamate vesicles currently available at the synapse. Both spontaneous release and activity dependent release of glutamate are supported by the model. In this work, we are investigating 1) the role that synaptic connectivity strategies play in seizure threshold 2) how the initial distribution of releasable glutamate may play a role in the transition from bursting to ictal like activity. Our initial findings were that a critical level of variance in the availability of releasable glutamate was ictogenic. We are currently completely rebuilding the network in order to replicate this work and ascertain the robustness of our startling initial results.

Title: Statistical and computational modeling of meso- and mircoscale human seizure activity

Authors: *G. M. FIDDYMENT[1], O. AHMED[3], L.-E. MARTINET[2], U. EDEN[2], S. CASH[4], M. KRAMER[2];

Abstract: Epilepsy is an often debilitating brain disorder, affecting approximately 50 million people worldwide. For a third of these patients, seizures remain poorly controlled despite intensive medical management. To advance the clinical treatment of epilepsy requires a more detailed understanding of the physiology that drives focal initiation and subsequent seizure

spread. Here we describe procedures that link: (I) voltage data from clinical epilepsy patients, (ii) statistical modeling, and (iii) biophysical modeling to advance our understanding of human epilepsy. The data consist of recordings from small patches of cortex using the NeuroPort microelectrode array. These recordings capture both the collective activity of the local field potential (LFP) and the spiking activity of individual neurons. To analyze the data, we build complementary models that characterize how (1) general spatiotemporal features and (2) specific mechanisms contribute to seizure activity. Using descriptive statistics, we show that ictal discharges (IDs) in the LFP comprise two distinct types: large and small amplitude IDs. We then fit statistical models describing the propagation of large and small amplitude IDs across cortex. Models show that large amplitude discharges switch in dominant rhythm from 3-4 Hz to 1-2 Hz and, often, become spatially organized approaching seizure termination. Small amplitude discharges exhibit strong 10 Hz rhythmic activity, but much less spatial organization over the same period. These results suggest that the late stage of seizure is marked by the emergence of different mechanisms, compared to early in the seizure, to support the different dynamics. Additionally, we develop a data assimilation procedure that links observed spike train activity to biophysical parameters. We simulate data from a Hodgkin-Huxley-type model neuron and show that, given only a spike train, the data assimilation procedure accurately recovers hidden model parameters. These methods represent a powerful, data-driven approach to directly investigate the mesoscale dynamics of human seizures.

Title: Neuronal field dynamics interact across spatial scales during propagation of human seizures

Authors: *L.-E. MARTINET[1], G. FIDDYMENT[1], O. J. AHMED[2], E. N. ESKANDAR[3], S. S. CASH[4], M. A. KRAMER[1];
[1]Dept. of Mathematics and Statistics, Boston Univ., Boston, MA; [2]Dept. of Neurosci., Brown Univ., Providence, RI; [3]Dept. of Neurosurg., [4]Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Epilepsy is a complex multiscale disease, extending spatially from microscopic synapses to macroscopic behavioral manifestations. Seizures - the hallmark of epilepsy - exhibit multiscale spatiotemporal dynamics that remain incompletely understood. Here we study the properties of focal seizures using a unique data set of multiscale recordings from microscopic (NeuroPort, 10x10 grid, 0.4 mm spacing) and macroscopic (8x8 grid, 10 mm spacing) subdural electrode arrays implanted in patients with pharmacoresistant epilepsy. We find voltage waves propagating along the brain surface in the local field potential (LFP), as well as in the invasive electroencephalogram (ECoG) recordings. We analyze the spatio-temporal properties of these travelling waves using descriptive statistics including amplitude, speed, orientation and rate within each recording scale. Preliminary results suggest that these statistics change toward the end of the seizure, indicating more spatial and temporal organization of the neural population within scales as well as between scales. Beyond descriptive analysis, we also employ a statistical modeling framework to detail different aspects of the multi-scale dynamics before, during and after seizures: the influence of one channel on itself (self-history dependence), the influence from other channels at the same spatial scale (intrascale relationships), and the influence from channels at other spatial scales (interscale relationships). We hypothesize that the coupling between LFP and ECoG evolves during seizures, with local circuit activity at the microscopic scale being influenced by macroscopic ictal propagation. A deeper understanding of ictal spatio-temporal dynamics within and across scales may have clinical implications, such as the

development of tailored surgical interventions or improved guidance for stimulation induced seizure interruption.

Title: Local hubs of the functional modular structure serve as an indicator of the epileptic zone: an iEEG study

Authors: *B. FILE[1], T. NÁNÁSI[2], B. TÓTH[2], M. MOLNÁR[2], C. J. STAM[3], A. HILLEBRAND[3], I. ULBERT[2], L. ENTZ[4], L. ERőSS[4], D. FABÓ[5];

Neurosciences, Budapest, Hungary

Abstract: According to a recent theory, the generation and propagation of the seizure is the consequence of abnormal brain networks, rather than the effect of an isolated pacemaker region. Graph theoretical measurements could be applied on the network of functionally connected brain regions in order to identify the epileptogenic zone (EZ) and examine the neurobiological mechanisms during seizures. The structure of the functional network in the healthy brain can be modelled with a “small-world” topology by a highly modular structure. Previous studies suggested that the epileptic seizures are characterized by a shift toward a more lattice like (ordered) network topology by disconnection of the long range connections. The current study is aimed to investigate the functional modular changes linked to epilepsy. 6 epilepsy surgery patients interictal and ictal intracranial EEG (iEEG) recordings were analyzed. EZs were determined by expert clinicians. After the intervention 5 of the 6 patients were rendered seizure free. Functional brain networks were investigated based on the measurement of phase synchronization (phase lag index; PLI) in gamma (30-45 Hz) frequency band. The functional

networks were partitioned into spatially nonoverlapping groups of nodes. The functional role of each node is characterized by the level of “within- module” connectivity and “between- module” connectivity. Local ”hubs” corresponded to the nodes with a high level of “within- module” and a low level of “between- module” connectivity. The neuronal network changed during seizure activity accompanied by the loss of long range connections and the extensive development of local synchronization. During seizures, the neuronal network moved in the direction of a more ordered, configuration compared to the interictal “small-world” like network organization. Analysing the interictal modular topology resulted that the most prominent local hubs tended to colocalize with the EZ identified by clinicians in the good outcome patients, and located outside of the EZ in the bad outcome patient. In line with previous results we demonstrated that ictal functional networks have a more ordered configuration than interictal ones. In this study we localized the EZ with the local ”hubness” as the topological indicator of the disconnection of long-range connections and strengthening of local connections. The high level of local ”hubness” has a promising clinical relevance as a marker of the EZ even in interictal recordings. The results support and supplement the growing number of evidence, that functional network analysis could be an efficient clinical tool for EZ localization.

Title: Expanding the taxonomy of seizure dynamics

Authors: J. SCOTT[1], Y. BHAGAT[2], C. BERNARD[3], V. JIRSA[3], *W. C. STACEY[2]; [1]Biomed. Engin., [2]Neurol., Univ. of Michigan, Ann Arbor, MI; [3]Aix Marseille Univ., Marseille, France

Abstract: Recent work has shown that focal seizures exhibit a set of general conserved dynamics. We recently developed a mathematical model of seizure dynamics based upon the features of seizure onset and termination[1]. This model was based upon identifying the various types of global behavioral shifts, or bifurcations, that occur going into and out of seizures. In that

initial work, a combination of theoretical and experimental data found that most seizures displayed behavior typical of a specific pair of bifurcations. These two bifurcations impose certain constraints on the seizure dynamics, such as predicting a shift in DC offset at seizure onset and a logarithmic scaling of spike rates near seizure termination. These findings were validated experimentally across brain regions, syndromes, and even across species (humans, mice, rats, zebrafish, etc), suggesting that seizures with vastly different pathophysiologies share fundamental and conserved dynamics. The study also found, however, that in different human patients a small number of recorded seizures (< 20%) displayed behavior suggestive of other types of bifurcations. In this study, we analyzed more than 150 seizures across more than 75 patients to identify the types and prevalence of other types of seizure dynamics at seizure offset. We employ curve-fitting techniques to these data and demonstrate several additional seizure offset behaviors - exponential increase of firing rates (power law scaling), linear change of firing rates (linear scaling), and disorganized firing rates - all of which occur less frequently than the logarithmic scaling described above. Preliminary modeling also shows these different behavioral shifts to be well-represented by bifurcations not described in our original work. These data will be instrumental in developing an expanded taxonomy of seizure dynamics, aiding in the further characterization and prediction of behaviors of various seizure types. [1] Jirsa, V. Univ., Newcastle upon Tyne, United Kingdom; [5]Arizona State Univ., Tempe, AZ; [6]Icahn Sch. of Med. at Mount Sinai, New York, NY; [7]Weill Cornell Med. Col., New York, NY

Abstract: The vast majority of seizures terminate naturally, yet almost nothing is known about how this happens, particularly in human epilepsy. We investigate the electrophysiology of spontaneous seizures during the period leading up to seizure termination using microelectrode arrays and electrocorticography in patients undergoing monitoring for surgical treatment of medically refractory epilepsy. We found that, universally, there were steady increases in large-scale synchronization of low-frequency (<50 Hz) local field potentials and in the rate of multiunit firing. Simultaneously there was a gradual decrease in multiunit synchronization in the ictal core, reflected in both microelectrodes and clinical subdural electrodes by significant, progressive decreases in high-gamma power and frequency. We also found evidence that the narrow ictal wavefront initiates discharges of traveling waves into the territory of the seizure core. We present a simple mean field computational model demonstrating that these and related temporal dynamics of human seizure recordings can be explained as a consequence of decreasing excitatory input, as from a more distal or weakening ictal wavefront. Together these results describe an evolving, self-organized structure of human seizures that does not require the often-held assumption of long-range cellular interaction. These results shed new light on our understanding of the structure of human seizure generation, propagation, and termination, and may provide a useful framework to aid in accurate seizure localization for targeted epilepsy therapies.

Title: Cognitive activation can suppress epileptic afterdischarges

Authors: *R. P. LESSER[1], H. J. LESSER[2], P. F. MORRISON[3], W. R. S. WEBBER[1]; [1]Johns Hopkins Hosp, Baltimore, MD; [2]Clin. Trials Unit, Univ. of Pennsylvania, Philadelphia, PA; [3]Neurol., Maine Med. Ctr., Portland, ME

Abstract: We report findings in patients who had subdural electrodes implanted for clinical purposes prior to surgical resections. In these patients we performed cortical stimulation to help localize functional areas prior to the resections. Stimulation at times produced afterdischarges (AD), an unwanted side effect which interferes with the clinical testing and which can result in clinical seizures. (We have previously showed that additional brief pulses of stimulation (BPS) could abort AD, but did so only about half the time; Lesser et al. Neurology 53:2073-2081, 1999). Patients were tested in their hospital rooms, in the Epilepsy Monitoring Unit at John Hopkins. They were awake and comfortable, lying in bed with the head of the bed elevated. We recorded electrocorticographic activity (EcoG) continually. When BPS did not terminate AD, we presented patients with cognitive tasks (subtraction from 2 digit number, spelling word backwards). We found that, although BPS had been unsuccessful, AD could be aborted by the cognitive tasks used on some but not all trials. The tasks were perceived by the patients to be effortful: alertness or attention alone was insufficient to abort AD. Cognitive effort can abort AD occurring throughout the brain regions tested, regardless of whether the regions are thought important for carrying out these cognitive tasks. The cognitive tasks most likely activate a widespread brain network needed to solve the presented problems, with this network not limited to the region with AD. The interaction of this spatially widespread network with the more localized network with AD determines whether AD would be aborted.

Title: Brain state predicts success or failure of cognitive effort in suppressing epileptic after discharges

Authors: *S. E. MULDOON[1,2], J. COSTANTINI[1], R. P. LESSER[3], W. R. S. WEBBER[3], D. S. BASSETT[1];
[1]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA; [2]US Army Res. Lab., Aberdeen Proving Ground, MD; [3]Johns Hopkins Med. Institutions, Baltimore, MD

Abstract: Cognitive activation can play a role in shifting brain states, but little is known about its effects on pathological brain dynamics in disorders such as epilepsy. Here, we study the role of cognitive activation in suppressing after discharges (AD) in epileptic patients. Electrocorticographic (ECoG) recordings were obtained from patients who had subdural electrodes implanted for localization purposes as a part of efforts to treat their medically intractable epilepsy with surgical resections. During this evaluation, electrical stimulation was performed to help localize motor, sensory, language, and other functional areas. An unwanted effect of stimulation can be the occurrence of afterdischarges (AD), electrical patterns that closely resemble epileptic seizures. In some cases we noted that AD were suppressed by cognitive tasks such as answering a simple math question. We therefore ask how the cognitive effort alters the functional structure of the brain, and whether the initial brain state predicts the success or failure of the cognitive effort in stopping and/or modifying the AD. We quantify brain states using measures of functional network structure derived from ECoG recordings obtained before and after math questions were asked. We observe that answering the math question induces frequency dependent changes in the functional structure that vary depending on whether or not AD terminated. Additionally, we observe that the spatial properties of the community structure present in the initial brain state are correlated with the success of cognitive effort to stop AD. These results indicate that an individual's brain state may tune the success of therapeutic interventions to mitigate epileptiform activity.

Title: Phase analysis of network dynamics in human electrocorticography: a potential adjunct to visual inspection for seizure detection

Authors: *K. J. O'NEILL, III[1], K. ASHMONT[1], P. ADELSON[1,2], B. GREGER[1];
[1]Sch. of Biol. Hlth. Sci. and Engin., Arizona State Univ., Tempe, AZ; [2]Barrow Neurolog. Inst. at Phoenix Children's Hosp., Phoenix, AZ

Abstract: One in 26 individuals in the United States will be diagnosed with a seizure disorder at some point in their lives. Of these, 22.5% will be medically intractable, and may seek surgical intervention for palliation or cure. If there is a lack of lateralization or localization, electrocorticography (ECoG) has been used to define the seizure focus. Following focal resection, 50-70% of patients remain seizure free at one year. The current gold standard for seizure focus localization is visual inspection of video and ECoG recordings by an epileptologist. This is a time consuming and subjective process. Quantitative analyses could help reduce the time associated with the review process and introduce objective measures of the complex and dynamic neural processes associated with seizure related electrographic events. We hypothesize that analysis of the phase relationships across ECoG electrodes could serve as a useful adjunct to visual inspection. Given a signal x(t) and its Hilbert transform x'(t), the instantaneous phase $\phi(t)$ of the signal may be calculated by: $\phi(t)=\arctan(x'(t)/x(t))$. Two signals are phase-locked if their instantaneous phase difference $\Delta\phi(t)=\phi1(t)-\phi2(t)$ is concentrated around a specific value ϕlock. The phase lag index (PLI) is a measure of coupling between two electrodes that are separated in space. The PLI is calculated from differences in the instantaneous phase of each signal (Stam, et al. 2007). An asymmetry in the distribution of instantaneous phase difference between two signals requires that one signal consistently lags in time behind the other. PLI is calculated as: $PLI=|\langle sign(\Delta\phi(t))\rangle|$. When PLI=1, the signals are perfectly phase locked at $\phi lock=\langle\Delta\phi(t)\rangle$. When PLI=0, the signals are non-coupled. PLI can be used to characterize the nature of the phase relationship between two signals, and evaluate functional connectivity and network dynamics. Following analysis of the ECoG data from 3 patients containing 12 seizures, we observed that the average PLI values fluctuate about a baseline value during non-ictal periods, but displayed a notable increase from the mean during ictal events. For some seizures, there appeared to be a measurable increase in coupling prior within the first few minutes to the clinically determined seizure onset times. These results suggest that PLI could assist in seizure detection by directing epileptologists' attention during inspection of ECoG recordings, and could ultimately lead to improved patient care.

Title: Ketogenic diet induces changes in purine-dopamine neuronal system interactions

Authors: J. G. RUBIN, M. L. DYER, *W. H. CHURCH;
Chemistry/Neuroscience Program, Trinity Col., Hartford, CT

Abstract: Previous research from this lab has indicated that a three-week ketogenic diet (KD) increases dopaminergic activity in the motor and somatosensory cortex areas of adult mice. Adenosine has been implicated in the therapeutic effect of the KD and the purine system is known to modulate dopaminergic activity. This study evaluated whether the changes seen in dopaminergic activity were associated with changes in purine neurochemistry. Samples from the previous study were analyzed using a high performance liquid chromatography (HPLC) method for the quantification of adenosine, hypoxanthine, xanthine, and inosine. No alteration in tissue levels of these purinergic compounds was found in the KD treatment group when compared to the control diet group. Cortical adenosine tissue levels and ß-hydroxybutyrate (BHB) blood levels were negatively correlated in the KD treatment group but not in the control diet group. A negative correlation was also observed between the adenosine metabolites (xanthine, hypoxantine and inosine) and BHB blood levels in the KD treatment group. Cortical dopaminergic activity (as measured by the DOPAC+HVA/DA ratio) and adenosine tissue levels were negatively correlated in the control diet group ($r=-0.70$, $p=0.054$). No such correlation was found in the the KD treatment group. These findings support previous literature regarding interaction between the dopaminergic and purinergic neuronal systems and suggest a possible ketogenic diet-induced change in the purinergic modulation of cortical dopaminergic activity in mice.

Title: Functional synaptic connectivity during development of hippocampal neuronal networks *in vitro*

Authors: *J. SURESH[1], A. BHANSALI[2], J. MARKS[3], J. WANG[4], A. K. TRYBA[4], W. VAN DRONGELEN[4];
[1]Dept of Pediatrics, The Univ. of Chicago, Chicago, IL; [2]Section of Neurosurg., Univ. of Chicago, Chicago, IL; [3]Pediatrics, Univ. of Chicago, University of Chicago, IL; [4]Pediatrics, Univ. of Chicago, Chicago, IL

Abstract: Dissociated rat hippocampal cell cultures develop unique network activity patterns at different maturation stages in-vitro. An important component of this network behavior is determined by synaptogenesis. In a previous study, we quantified anatomical synaptogenesis by counting synapses at four critical stages of maturation - 5, 8, 14 and 20 days *in vitro* (DIV). We are now interested in determining the development of functional synaptic connectivity at these stages. To accomplish this, we made whole cell patch clamp recordings of pairs of connected neurons to determine the strength of synaptic connectivity. We computed spike-triggered averages (STA) of postsynaptic activity triggered by action potentials in the presynaptic neuron. We compared the area under the curve (AUC) for STAs during spontaneous and evoked synaptic activity to quantify synaptic connectivity at different maturation stages. Evoked activity was achieved by current injections leading to bursts in the presynaptic neuron. Preliminary results show that at 5 DIV, there is no spontaneous spiking as evidenced by sub-threshold membrane potential values. However current injections in the presynaptic neuron were able to trigger spikes in the postsynaptic neuron. By 8 DIV, there is significant amount of spontaneous spiking activity and the AUC of STA during evoked activity is larger compared to that at 5 DIV. However comparison of AUC during spontaneous and evoked activity within this stage shows no clear differences. At 14 DIV, in addition to spiking and bursting activity, there are also periods of sustained depolarization, characteristic of paroxysmal depolarization shifts (PDS). There is a clear increase in the AUC during spontaneous and evoked activity compared to 8DIV. Moreover, there is a relative increase in AUC for evoked activity when compared to spontaneous activity at this maturation stage. At 20 DIV, there is a further increase in the AUC of STAs during spontaneous and evoked activity compared to 14 DIV. The relationship between these findings and emergent network activity patterns, as well as histology of maturing in-vitro cell cultures will be discussed.

Title: Protective effect of erythropoietin, but not that of Epotris, on cognitive function is compromised in rats subjected to status epilepticus when raised in enriched environment

Authors: *L. BEZIN[1,3], M. OGIER[2,3], J. BODENNEC[1,3], S. PANKRATOVA[4], V. BEREZIN[4], A. BELMEGUENAI[1,3];

Abstract: Cognitive impairment is a condition frequently associated with pediatric epilepsy that can severely affect the quality of life of children with epilepsy and their family. Therefore, there is an urge to find therapeutical and alternative interventions aimed at preventing or reducing the decline of cognitive functions. In rats raised in conventional environment (CE), we showed that recombinant erythropoietin (Epo) treatment (5,000 IU/kg daily for 5 consecutive days) following pilocarpine-induced status epilepticus (SE) at weaning prevented alteration of spatial memory and synaptic plasticity. Housing rats in an environmental enrichment (EE) alone just after SE produced the same effects as Epo alone. However, the amplitude of LTP in rats subjected to SE and raised in EE did not reach the magnitude measured in healthy rats raised in EE. We therefore tested the hypothesis that the combination of Epo and EE after SE may help to reach this goal. Unexpectedly, we observed that this combination totally abolished the beneficial effects of either Epo or EE alone in rats subjected to SE. We then tested whether this detrimental combination could be avoided by using Epotris, a non-erythropoietic derivative of Epo. We showed that Epotris exerted neuroprotective effects on LTP and spatial learning after SE in rats raised in CE, and that these effects were not compromised when rats were raised in EE. However, Epotris in combination with EE was not able to restore the amplitude of LTP measured in healthy rats raised in EE. Our results thus showed that the protective effects of Epotris are independent of the quality of the living environment, and suggest that non-erythropoietic derivatives of Epo may be preferred over recombinant or native Epo to protect learning and memory following severe brain injury such as occurs after SE.

Abstract: The Cyclin-dependent kinase-like 5 (CDKL5) gene encodes for a serine-threonine kinase sharing homology to Mitogen-activated kinases (MAPKs) and Cyclin-dependent kinases (CDKs). Recently, mutations in the CDKL5 gene have been identified in the patients with severe neurodevelopmental disorders accompanied by intractable epilepsies, i.e. West syndrome or atypical Rett syndrome, suggesting its critical role in neurodevelopment. However, the molecular functions or pathomechanisms caused by its mutations are largely unknown. Aiming to solve these problems, we have taken multidimensional strategies, combining an unbiased interactome approach and a targeted loss-of-function (LOF) approach. For the interactome approach, we

performed the yeast two-hybrid screening and identified several CDKL5 interacting proteins. For the LOF approach, we have generated the Cdkl5 knockout mouse and analyzed the neurological phenotypes. The combination of these approaches suggested us possible mechanisms of CDKL5 regulating neural functions during development.

Title: Effect of pinealectomy on experimental absence seizures

Authors: *A. DE FUSCO[1], S. MOYANOVA[1], I. SANTOLINI[1], R. CELLI[1], M. MADONNA[2], C. SCHWARZER[3], F. NICOLETTI[1,4], J. TCHEKALAROVA[5], R. T. Abstract: Melatonin, an endogenous hormone with neurotransmitter properties that regulates the circadian rhythms is mainly produced by the pineal gland. Melatonin has been shown to positively modulate seizures and depressive-like comorbidity in the kainate model of epilepsy (Tchekalarova et al., 2013; Petkova et al., 2014). We investigated the effects of removal of the pineal gland on pentylenetetrazole (PTZ)-induced absence-like seizures. Acute subcutaneous injections of PTZ (21 mg/kg b.w.) resulted in bilateral synchronous spike and wave discharges (SWDs) and associated behavioral arrest, vibrissae twitching and facial myoclonus. Rats were maintained in 12 hours light-12 hours dark conditions. We evaluated the effect of PTZ in pinealectomized- and sham-operated Wistar rats on EEG during dark and light phases. We took into consideration the biological peak of melatonin secretion and we injected PTZ four hours after beginning of the dark phase. Another group of Wistar rats was treated with PTZ at matched time points during the light phase. EEG analysis showed that pinealectomized rats have increased susceptibility to PTZ-induced absence seizures with about two-fold greater number of SWDs compared to sham-operated rats, both in dark and light phases. The results demonstrate that modification of the melatoninergic system influences the brain thalamo-cortical network,

which is responsible for the development of absence epilepsy, and suggest a protective role of the endogenous melatonin against PTZ-induced absence-like seizures. Tchekalarova et al., Epilepsy Behav. 2013 Apr;27(1):174-87. Petkova et al., Epilepsy Behav. 2014 Feb;31:198-208.

Title: Modulation of intracellular ATP influences seizure activity via the activity-dependent release of adenosine

Authors: ***J. HALL**, B. G. FRENGUELLI;
Life Sci., Univ. of Warwick, Coventry, United Kingdom

Abstract: The purine nucleoside adenosine is involved in the regulation of both normal physiological processes, such as the modulation of neuronal excitability, and in the pathophysiology of neurological conditions such as epilepsy. Adenosine, via its inhibitory A_1 receptor raises the threshold for seizure activity and its release during seizures results in the attenuation and termination of the seizure. Adenosine has thus been described as an endogenous anticonvulsant. However, brain injury causes a rapid decline in cellular ATP levels, which can be long lasting. Given that ATP represents the primary reservoir for adenosine, this has implications for the availability of adenosine after brain injury and the propensity to both seizures in the acute post-injury period, and the initiation of post-traumatic epileptogenesis. We have previously shown that the provision of ribose (1 mM) and adenine (50 μM; "RibAde") in the incubation medium of acutely-prepared hippocampal slices can restore tissue ATP levels to those found *in vivo*[1]. We have also shown that this translates into greater adenosine release in response to physiological and pathological stimuli[1,2]. We have now tested whether RibAde can influence seizure activity, and, as a comparator, used creatine (1 mM), which, via its conversion to phosphocreatine, serves as a buffer against ATP metabolism and reduces adenosine release[2]. Hippocampal slices exposed to nominally Mg^{2+}-free aCSF and 4-AP (50 μM) showed regular

bursts of seizure activity and associated adenosine release, as measured with adenosine biosensors. Three-hour pretreatment of slices with RibAde resulted in greater seizure-induced adenosine release compared to control and creatine slices. In addition, RibAde reduced the frequency of spiking and seizure intensity as well as increased the time between seizures. In contrast, seizure intensity was increased in creatine-treated slices and the time between seizures was reduced compared to RibAde. These studies provide evidence for the value of using RibAde to increase ATP levels in the injured brain. Given the prior safe use of ribose and adenine in humans, RibAde may be a means to improve brain recovery after injury and thus mitigate against the mortality and morbidity associated with such insults. 1) zur Nedden, S., et.al., 2011, J Neurosci, 31, 6221-34. 2) zur Nedden, S., et.al., 2014, J Neurochem 128: 111-24

Title: Stimulation-based endpoints for assessing seizurogenic activity with multiwell microelectrode array technology

Authors: *D. C. MILLARD, A. M. NICOLINI, C. A. ARROWOOD, J. D. ROSS;
Axion Biosystems, Atlanta, GA

Abstract: The lack of advancement in anti-epileptic drugs (AEDs) over the last 30 years, along with the continued need for improved proconvulsant screening in drug safety, motivates the need for new assays of seizurogenic neural activity. Previous work has established an *in vitro* approach for detecting and quantifying seizurogenic activity using multiwell microelectrode array (MEA) technology, providing a predictive and high-throughput avenue for the evaluation of the efficacy of AEDs and the proconvulsant risk of other drug candidates. However, incorporation of electrical and optogenetic stimulation to directly evoke neural activity may lead to improved sensitivity for *in vitro* seizurogenic assays. Here, we present an assay of seizurogenic activity based upon the Axion BioSystems Maestro multi-well MEA system. We

used previously published metrics for the detection of burst spiking events and the quantification of synchronization across a neural population, triggered on external stimuli. Data are included from rat cryopreserved cortical neurons, in response to pharmacological manipulation with AEDs (i.e. Carbamazepine, Phenytoin, Tiagabine) and reference compounds with known proconvulsant risk (i.e. 4-Aminopyradine, Strychnine, Pentylenetetrazole, Picrotoxin). Our results support the combined use of evoked and spontaneous neural activity, collected using multi-well MEA technology, for the high throughput evaluation of complex neuronal networks *in vitro* to inform the development of AEDs, while also quantifying the proconvulsant risk of candidate pharmaceuticals in a pre-clinical setting.

Title: Properties of 4-aminopyradine induced epileptiform activity: multichannel electrophysiology and optical coherence tomography *in vitro*

Authors: *T. L. MYERS, O. C. GONZALEZ, M. M. EBERLE, D. BINDER, H. PARK, M. BAZHENOV;
Univ. of California, Riverside, Riverside, CA

Abstract: 4-aminopyradine (4AP) blocks the I_A channel, an outward voltage-gated potassium current that may trigger epileptiform activity. While precise mechanisms for seizure initiation are still unknown, 4AP is a well-established model for epilepsy for both *in vitro* and *in vivo* studies. Here, we studied the effects of varying 4AP concentrations on the mouse hippocampus activity *in vitro* using simultaneous multi-electrode array (MEA) recordings and optical coherence

tomography (OCT). We observed distinct synchronous firing patterns following bath application of 4AP. Lower concentration (25 – 75 uM) generated continuous synchronous epileptiform activity at lower frequencies (0.1 – 0.2 Hz) and amplitudes (0.3 – 0.4 mV). Bath applications of 100 – 200 uM 4AP led to the development of higher amplitude (0.5 – 0.6 mV) and frequency (0.3 – 0.5 Hz) burst-firing of the hippocampal network. Spatiotemporal analysis revealed that increases in 4AP concentration elicited more focal epileptiform activity as compared to more diffuse activity at lower concentrations. *In vivo* studies found that 4AP induced seizure in mouse cortex can be optically detected using OCT. However, it remained unclear to what extent the changes of the optical signal depend on the increased blood flow through the tissue during seizure. Here, we found decreases in the OCT measured attenuation coefficient, which temporally aligned with the onset of the 4AP induced epileptiform activity in the hippocampus. Overall, we show distinct spatiotemporal dynamics for 4AP induced activity in a concentration dependent manner, and revealed that these forms of neuronal activity can be optically detected *in vitro.* This refutes the hypothesis that the entirety of the optical signal detected *in vivo* 4AP induced seizures are due to changes in blood flow, and that there is a component that may reveal changes in cell swelling associated with intense electrical activity during seizure.

Title: Propagating spikes are associated with the emergence of neocortical high-frequency oscillations remote from the epileptic focus in the mouse-model of temporal lobe epilepsy

Authors: *L. SHEYBANI[1,2], F. PITTAU[3], G. BIROT[3], S. VULLIEMOZ[3], M. SEECK[3], K. L. SCHALLER[4], C. M. MICHEL[2], C. QUAIRIAUX[2];
[1]Fundamental Neurosci., Fac. of Medicine, Univ. of Geneva, Geneve, Switzerland; [2]Fundamental Neuroscience, Fac. of Medicine, Univ. of Geneva, Functional Brain Mapping laboratory, Geneva, Switzerland; [3]Clin. Neuroscience, Univ. Hosp. of Geneva, Neurol. Clin.,

Geneva, Switzerland; [4]Clin. Neuroscience, Univ. Hosp. of Geneva, Neurosurg. Clin., Geneva, Switzerland

Abstract: In focal epilepsies, the epileptic focus may affect the activity of remote brain regions leading to the progressive development of an epileptic network. Fast ripples (FRs, 200-550 Hz), a subpopulation of high-frequency oscillations (HFOs, 80-550 Hz), are believed to be a marker of epileptogenic brain areas and have been used in humans and animal models of epilepsy to locate epileptic foci. We hypothesize that FRs could hence be used to locate normal brain regions progressively recruited within the epileptic network. We studied the expression of FRs outside of the initial epileptic focus in the kainate mouse-model of hippocampal sclerosis. In a first step, a total of 23 adult mice were recorded with 32 surface electrodes prior (internal controls) to injection of kainate in the left hippocampus (LH), then at day 7, 14 and 28 after injection. Surface recordings allowed us to map the epileptic network and to identify brain regions expressing FRs using a newly developed automated detector of FRs. The epileptic network was characterized by propagating spikes (PrS) starting from the hippocampus and propagating to all contacts in < 20 msec. Their occurrence increased throughout the disease. While prior to kainate injection physiological FRs could be observed mainly over the barrel fields, they then appeared massively over the LH over time and also progressively over the right hippocampus and neocortical frontal areas. Those FRs recorded after injection had properties different than the physiological FRs, i.e. longer duration and lower intrinsic frequency. Importantly, outside of the LH, neocortical FRs were tightly coupled with the occurrence of PrS: the further away from the LH FRs were recorded, the higher their chance to be associated with PrS. Furthermore, the presence of a FR during a PrS was associated with a higher amplitude of the PrS; if the FR occurs over frontal areas, its amplitude was even higher. This was then confirmed using intracerebral recordings. 9 of these mice were recorded with 4 x 16 electrodes in the left motor and cingulate cortices and both hippocampi revealing that the onset of frontal FRs appeared during a preferential phase of the local-field potential, within the frequency band of PrS. In conclusion, we show for the first time that in addition to the generally accepted notion that pathological FRs are strictly found in the seizure-onset zone, neocortical FRs can occur in non-injured neocortical areas and can be triggered by epileptic spikes. This is of utmost importance, as FRs are dysfunctional activities ordinarily seen in epileptogenic tissues.

Title: Modulation of EEG by hyperventilation in an animal model of absence seizures

Authors: *K. A. SALVATI, N. N. KUMAR, M. P. BEENHAKKER;
Dept. of Pharmacol., Univ. of Virginia, Charlottesville, VA

Abstract: Absence epilepsy is a non-convulsive generalized seizure disorder characterized by a sudden arrest of consciousness and 3-5Hz spike-and-wave discharges (SWDs) in electroencephalography (EEG) recordings (Crunelli and Leresche, 2002). Absence seizure generation involves reciprocal circuitry between neurons of the thalamus and cortex. Voluntary hyperventilation reliably triggers SWDs in the EEG of absence patients and, therefore, is used to clinically diagnose this childhood form of epilepsy (Penry and Dreifuss, 1969; Adams and Leuders, 1981). The mechanism(s) fully elucidating how induced-hyperventilation precipitates SWDs remains unknown, despite the knowledge of such a link for over four decades (North et al., 1990; Wirrell et al., 1981). Many studies demonstrate that hyperventilation and the associated change in brain pH modulate neuronal excitability (Dulla et al., 2005) and epileptic activity (Miley, and Forster, 1977). Neurons sensitive to brain pH are known as central respiratory chemoreceptors (Guyenet et al., 2010). Collectively, these neurons modulate their activity through pH-sensitive ion channels and G-protein coupled receptors (GPCRs) (Guyenet et al., 2010). Two GPCRs, OGR1 and GPR4, are proposed to mediate neuronal activity in the brain (Schneider et al., 2012; Huang et al., 2007). We set out to determine whether hyperventilation alters SWDs in the EEG of two rodent models of absence epilepsy: the DBA/2J mouse and the WAG/Rij rat. To do so, we pharmacologically induced hyperventilation *in vivo* (Cotten, 2013) and measured ensuing SWD activity. Preliminary data from these experiments indicates that SWD frequency and duration increases following i.p. injection in both our rodent models compared to vehicle injection. Our preliminary EEG studies motivated our hypothesis that pH-sensitive neurons in the thalamus trigger hyperventilation-induced SWDs. To begin testing this hypothesis, we first set out to characterize the level of expression of OGR1 and GPR4 in the thalamus. We used multi-label fluorescence *in situ* hybridization to assess expression. Our data shows that GPR4, but not OGR1, mRNA is abundant in the thalamus. Moreover, GPR4 mRNA is localized to excitatory ($VGLUT2^{+}$) cells within the thalamus. Our future experiments will assess how these putative pH-sensitive neurons are modulated by hyperventilation-induced changes in brain pH.

Title: Manipulating the medial entorhinal cortex via dreadd receptors in a mouse model of temporal lobe epilepsy

Authors: *B. S. BARKER, J. A. HOUNSHELL, R. P. GAYKEMA, M. K. PATEL;
Univ. of Virginia, Charlottesville, VA

Abstract: Manipulating the Medial Entorhinal Cortex via DREADD Receptors in a Mouse Model of Temporal Lobe Epilepsy Temporal lobe epilepsy (TLE) is the most common form of adult epilepsy involving the limbic structures of the temporal lobe. In TLE, surviving medial entorhinal cortex (mEC) neurons become intrinsically hyper excitable, leading to excessive excitatory input into the hippocampus. Increased mEC-hippocampal innervation is believed to play a significant role in the initiation and propagation of seizures in TLE. The ability to manipulate specific regions of the brain via activation of excitatory (G_q) or inhibitory (G_i) designer receptors exclusively activated by a designer drugs (DREADD) using Clozapine N-Oxide (CNO) is a powerful tool that enables us to selectively study the role of the mEC in TLE. In the kindling model of epilepsy, motor seizures are induced via an electrical stimulation of the hippocampus at a pre-determined intensity known as an after discharge threshold (ADT). In mice expressing the G_i DREADD receptor, inactivating the mEC with 5 mg/kg CNO resulted in a dramatic increase in the ADT compared to control mice. To further test the role of the mEC in TLE, we examined the effects of activating the mEC in spontaneous seizing mice produced by the continuous hippocampal stimulation (CHS) protocol. Activating the mEC in CHS mice expressing the G_q receptor with CNO (3 mg/kg) produced an increase in seizure frequency compared to animals given saline. Activation of the mEC in control, non-epileptic mice expressing the G_q receptor with CNO (3 mg/kg) had no effect. This study validates the crucial role of the mEC in initiation and propagation of seizures in temporal lobe epilepsy.

Title: Changes in functional imaging of DBA/1 mouse brain in seizure-induced respiratory arrest

Authors: *S. KOMMAJOSYULA[1], M. E. RANDALL[2], T. J. BROZOSKI[3], B. ODINTSOV[4], C. L. FAINGOLD[2];
[2]Pharmacol., [3]Div. of Otolaryngology, [1]Southern Illinois Univ. Sch. of Med., Springfield, IL;
[4]Biomed. Imaging Center, Beckman Inst., Univ. of Illinois, Urbana-Champaign, IL

Abstract: Introduction: Sudden unexpected death in epilepsy (SUDEP) accounts for 8-17% of total epileptic deaths. Generalized seizures and respiratory dysfunction are major proposed mechanisms of human SUDEP. DBA/1 mice are a SUDEP model that is susceptible to generalized audiogenic seizures (AGSz), resulting in seizure-induced respiratory arrest (S-IRA). Magnetic resonance imaging (MRI) studies of SUDEP patients observed atrophy in specific brainstem structures, implicating them in the neuronal network for SUDEP (Mueller et al., Neuroimage Clin 2014; 5: 208-16). Therefore, we evaluated changes in brain activity using manganese-enhanced MRI (MEMRI) to map the neuronal network of DBA/1 mice and compare it with the human network. Methods: Manganese chloride (80 mg/kg) was injected SC 10 hr prior to AGSz induction in 3 groups of DBA/1 mice: (1) mice that exhibited AGSz with S-IRA; (2) mice that exhibited AGSz without S-IRA [NS-IRA, induced with 45 mg/kg (i.p.) fluoxetine]; and (3) mice that were not exposed to sound or AGSz (controls). Immediately after AGSz, the mice were anesthetized and their brains fixed. The fixed brains were scanned *in situ* with a 14.1T Varian microimagerc consisting of a vertical bore magnet (89mm) and a 600 MHz Varian Unity/Inova NMR spectrometer. A high image quality spin-echo-multi-slice protocol was employed for the T1 mapping. TIFF images were analyzed using Image J (ver. 1.49h), and a mixed-factor ANOVA (SPSS ver22). Results: The MEMRI data indicate a significant ($p<0.001$) overall increase in the neuronal activity of the NS-IRA group vs S-IRA and control DBA/1 group 110.24±0.72 vs 104.34±0.70 and 103.26±0.61. Detailed analysis revealed significant ($p<0.05$) increases in activity at Kölliker-Fuse nuc. (123.6±4.4 vs 103.4±1.7), pontine raphe nuc. (126.1±6 vs 104.2±1.8), and inferior colliculus (IC) (111.5±2.7 vs 102.1±0.6) at AP -5.3 (Franklin and Paxinos Mouse Stereotaxic Atlas, 1997); dorsomedial periaqueductal gray (PAG) activity was also significantly elevated (113.6±1.6 vs 100.7±1.7) at AP -3.4, in the NS-IRA compared to S-IRA group, suggesting action of fluoxetine at these regions in preventing S-IRA. Discussion: These results indicate that the neuronal network for AGSz and S-IRA in DBA/1 mice include several nuclei that have been implicated in other AGSz models. This network also contains structures which exhibited atrophy in neuroimaging studies in human SUDEP, including PAG, IC, and raphe nuclei (Mueller et al., 2014). The similarities of these neuroimaging data to

human MRI studies supports increased relevance of the DBA/1 mouse model to human SUDEP. (Support: Epilepsy Foundation, CURE)

Title: Seizure-like events in the olfactory cortex of the isolated guinea-pig brain are initiated by extracellular potassium changes

Authors: *L. M. UVA, M. CHIKHLADZE, S. SACCUCCI, M. MORBIN, M. DE CURTIS; Fondazione Inst. Neurologico C. Besta, Milano, Italy

Abstract: The olfactory region has been described as an epileptogenic structure. In a previous paper (Uva et al., 2013) we showed that arterial application of the potassium channel blocker 4-aminopyridine (4AP; 50μM) in the isolated guinea-pig brain maintained *in vitro* induces different and independent seizure patterns in the olfactory and limbic regions. Field potentials (FPs) recordings in piriform cortex (PC) at 3-400μm in depth showed that epileptiform activity starts with runs of fast activity around 30Hz, followed by a rapid positive component (phase 1), a second negative component with fast activity superimposed (up to 60Hz) and 10hz activity (phase 2) before the transition to spikes (phase 3). Simultaneous extra and intracellular recordings demonstrated that seizures-like events (SLEs) correlate with depolarization of superficial layer neurons of the PC, whereas deep layers neurons are poorly involved. The aim of this study is the investigation of the mechanisms underlying the SLE onset. We arterially applied 4AP to the isolated guinea-pig brain maintained *in vitro* and recorded SLE activity with glass pipettes inserted at the surface of the cortex and at 3-400μm in depth, or with a 16-channel linear silicon probes (50 contact separation) to monitor the change of FPs components in depth. We observed a large and slow negative potential in the most superficial positions at SLE onset suggesting ionic shifts. We then monitored K^+ changes simultaneously in two or three different

depth positions in PC (from surface to 750µm in depth) with ion-sensitive electrodes. Data showed that SLE onset correlates with a rapid increase of K^+ at the surface of the PC (K^+ peak during phase 2 of SLE) and slower increase in deeper layers (K^+ peak during phase 3 of SLE). Experiments performed in guinea-pig PC-slices cut parallel to the surface (500µm thick) and including only the most superficial portion of the cortex confirmed the ability of superficial layer to generate K^+ increases. This K^+ shift could explain 1) the neuronal firing abolishment in layer II during phase 2 that gradually restored before seizure end (Uva et al., 2013), 2) the abolishment of the response evoked by lateral olfactory tract (LOT) stimulation during SLE, 3) the scarse involvement of layer III cells. To identify the source of the superficial K^+ shift we looked at morphology of PC Ia layer, containing LOT axons, at the electron microscopy. The absence of myelin observed in layer Ia could facilitate the large release of K^+ from LOT axons during 4AP-induced activity, contributing to K^+ rapid increase at SLE onset. The next step is the study of layer Ia astrocytes, that could decrease their K^+ buffering capability after 4AP application.

Abstract: A growing body of evidence suggests a potential role for the α2δ subunit of voltage-gated Ca2+ channels (VGCCs) in the pathophysiology of non convulsive epilepsy. The mutant mouse ducky, which carries a mutation in the gene encoding for the α2δ-2 protein, is characterized by absence seizures and ataxia. In addition, gabapentin and pregabalin, which bind to, and negatively modulate α2δ-1 and α2δ-2 proteins may precipitate absence seizures in humans. α2δ subunit is a key player of both trafficking and current amplitude and kinetics of high-voltage activated (HVA) Ca2+ channels, indeed it has been shown that Ca(v)2.3 channels are critical for oscillatory burst discharges in the thalamic reticular nucleus (nRT) neurons and for the expression of absence epilepsy (Zaman et al., 2011). Although ducky mice show absence epilepsy, there is no evidence of which anatomical area of the thalamo-cortical network ignites the development of absence seizures in these mice. At least α2δ-1 has functions that lie beyond the regulation of VGCCs by functioning as a high affinity receptor for the developmental protein thrombospondins (TSPs). Interaction between TSPs and α2δ-1 appears to be instrumental for the formation of new excitatory synapses in the CNS (Eroglu et al., 2009). This prompted us to study whether changes in the expression of TSPs are associated with absence epilepsy in experimental animal models and humans. We used WAG/Rij rats, which develop spontaneous absence seizures after 2-3 months of age. The transcript of TSP-1 was largely reduced in the ventrobasal thalamus of both pre-symptomatic and symptomatic WAG/Rij rats, as compared to age-matched non-epileptic control rats. This reduction was region-specific because it was not observed in the somatosensory or primary motor cortex of WAG/Rij rats. We speculate that a reduced production of TSP-1 with an ensuing defect in synaptogenesis in the ventrobasal thalamus contributes to the pathophysiology of absence epilepsy at least in WAG/Rij rats. We are currently extending the study to other rodent models of absence epilepsy and we are also searching for polymorphic variants in the gene encoding for TSP-1 and α2δ-1 protein in a large cohort of european patients with primary absence epilepsy. Title: Challenging the dogma: ethosuximide reduces natural and pentobarbital-induced spindles and non-REM sleep

Authors: L. J. BARUCHIN, M. VENZI, G. DI GIOVANNI, *V. CRUNELLI;
Cardiff Univ., Cardiff, United Kingdom

Abstract: The occurrence of absence seizures (ASs), non-convulsive seizures characterized by EEG spike-and-wave discharges (SWDs) concomitant with impairment of consciousness, is strictly dependent on the patient arousal state, i.e. they most commonly emerge during quiet wakefulness but are relatively rare during active wakefulness and non-REM (NREM) sleep. Ethosuximide (ETX), a gold-standard anti-absence drug, is effective in 50% of patients under mono-therapy and abolishes ASs in all well-established experimental AS models. Thus, it is generally believed that ETX ability to block ASs is a necessary feature to validate new AS models. Indeed, in some instances, this pharmacological validation (i.e. the predictive validity) has become prevalent in defining a new model, often disregarding careful characterization of the EEG and behaviour (i.e. the face validity). This postulate is based on two assumptions: 1) ETX effect is specific to SWDs, i.e. ETX does not affect other brain oscillations; 2) ETX effect is specific to the mechanism of AS generation and is not mediated by other effects, such as changes in the arousal/sleep states, which could indirectly modulate SWD expression. Further complication arises from the fact that one hypothesis of the generation of SWDs is that they represent 'perverted' sleep spindles (0.5-3 sec oscillations with a frequency, 7-14 Hz, similar to experimental SWDs). In order to clarify these issues, we investigated the effect of ETX on natural and pentobarbital (PB)-induced spindles and NREM sleep in freely-moving Wistar rats implanted with fronto-parietal EEG and neck EMG electrodes. ETX (150 mg/kg i.p.) halved the time spent in NREM sleep, from 28±2% in saline pretreated and 56±2% in PB-pretreated rats to 11±1%($p<0.01$) and 28±6% ($p<0.01$; n=8 rats), respectively. Similarly, the number of spindles recorded over a two-hour period was decreased following ETX injection from 81±19 and 194±32 in saline- and PB-pretreated rats to 26±9 ($p<0.05$) and 73±18($p<0.01$), respectively. ETX also increased the spindle peak-to-peak amplitude, attenuated the increase of spindle frequency induced by PB, and shortened spindle duration from 963±18msec to 840±26msec in saline pretreated rats. A lower dose of ETX (50 mg/kg i.p.) produced smaller reductions than the higher dose on spindle and NREM sleep parameters but decreased spindle peak-to-peak amplitude. These results show that ETX has a strong effect on NREM sleep and sleep spindles, two thalamocortical-dependent brain activities. Current work is directly comparing ETX effects on SWDs, NREM sleep and spindles in AS models.

Title: Glial waves during seizures - coupled or uncoupled with neurovascular activity?

Authors: *H. MA[1,2], A. G. S. DANIEL[1], P. LAFFONT[1,3], M. ZHAO[1,2], T. H. SCHWARTZ[1,2]; [1]Dept Neurolog. Surgery, [2]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY; [3]The Browning Sch., New York, NY

Abstract: Background: Neuronal and glial activity are thought to coordinate regional blood flow through a complex sequence of events. During normal sensory processing, these events appear to be coupled in space and time. Using a 4-AP injection into rat cerebral cortex and simultaneous voltage sensitive and intrinsic signal (IS) wide-field imaging, we have previously shown that ictal events are coupled in space, but not time, with perfusion. Although glia are a key component in neurovascular coupling, wide-field imaging of glial waves during seizures has not been investigated. Methods: Using calcium dyes, either OGB-1, which can be filtered to image glia (1Hz), or the calcium dye Rhod-2, which stains only astrocytes, along with IS and local field potentials, we were able to measure each compartment of the neurovascular unit through a wide area of *in vivo* rat neocortex during seizure onset and evolution. Results: A clear glial wave which began focally and spread across the cortex occurred simultaneous with each ictal event. However, glial waves propagated 43% further (4.3±1.3 mm) than CBV changes (3.0 ± 1.0 mm, t-test, p=0.0013). Despite widely varying seizure durations (10-70s, 43.5±17.6 s), the duration of astrocytic activation remained more constant (10-40s, 23.6±6.5 s) and did not significantly correlate with the duration of the seizures (n = 25 seizures from 4 rats, r = 0.28, p = 0.18). The hemodynamic change, on the other hand, lasted longer than both the astrocytic and neuronal activity in all trials (54.5±17.7 s, p <0.01). Moreover, glial waves were significantly delayed in onset compared with hemodynamic waves (2.4±1.1 s versus 0.8±1.0s respectively, p<0.01). Our results suggest that during ictal events, each compartment in the neurovascular unit displays a unique spatiotemporal onset and evolution. Conclusions: Although clearly coupled in a macro-global scale i.e. similar number of events in a similar region of cortex, they are uncoupled on a micro-detailed scale. In spite of rapidly propagating multidirectional subthreshold neuronal waves of varying duration, glial activity is characterized by a more homogeneous slowly propagating wave that extends well beyond the limits of the neuronal or perfusion changes,

having a more constant predictable duration. These results call into question the putative essential role of astrocytes in ictal neurovascular coupling.

Title: Two distinct ictal onset patterns in hippocampal CA1 subfield *in vitro*: A potential therapeutic role for oxytocin in controlling seizures

Authors: *D. SUBRAMANIAN[1], E. N. PRALONG[2], R. T. DANIEL[2], A. G. CHACKO[1], R. STOOP[3], K. S. BABU[1];
[1]Dept. of Neurolog. Sci., Christian Med. Col., Vellore, India; [2]Clin. Neurosciences, [3]Psychiatry, Univ. Hosp. of Lausanne, Lausanne, Switzerland

Abstract: Pharmacological interventions in temporal lobe epilepsy have been notoriously unsuccessful up to now. Although effective in the beginning of the treatment, drug resistance often develops and previously successful drugs do not further work. The development of new pharmacological treatments is importantly guided by epileptiform mechanisms that are identified in *in vitro* slice models, but that may not necessarily reflect the precise human epileptic pathology. We here show in horizontal slices of the hippocampus prepared from 4-8 weeks old wistar rats, a new transitional mechanism of epileptiform activity in CA1 which was initially driven by glutamatergic inputs from the CA3, but then developed independently based upon GABAergic synaptic transmission. Thus, within thirty minutes after incubation in artificial cerebrospinal fluid containing 8.5 mM KCl and 1.2 mM CaCl2, we found the development in the CA1 of ictal-like epileptiform discharges with duration of 112 ± 3 sec, appearing every 186±4 sec and that could be blocked by AMPA and NMDA receptor antagonists. Around sixty minutes after incubation, a new type of activity appeared in the CA1 region, consisting of shorter

duration bursts (3.9±0.2 sec) in the gamma frequency range. Anatomical isolation of the CA1 from the CA3 abolished the long-duration ictal-like discharges in the CA1, allowing the short duration bursts to appear at shorter intervals of 53 ±1 s. Their activity was not affected by AMPA nor NMDA receptor antagonists but was effectively blocked by the GABA(A) receptor antagonist bicuculline. In addition, they were also significantly suppressed by the NKCC1 blocker bumetanide (20 μM) suggesting a change in chloride equilibrium potential to underlie their generation. Interestingly, the oxytocin agonist [Thr4, Gly7] oxytocin (TGOT, 0.4 μM), recently shown able to correct changes in the Cl- equilibrium potential, also suppressed the ictal-like discharges in these isolated CA1 mini-slices. Taken together, our findings reveal two different mechanisms of ictal onset in hippocampal CA1 region, one driven by glutamatergic input from CA3 and a second developed independently in CA1 by inhibitory neurons. This sequence of events reveals potential reasons why previous GABAergic enhancers may not function adequately in epileptiform tissue as they would enhance rather than decrease ictal activity. At the same time they provide a rationale and new model for testing efficacy of new anti-epileptic treatments such as oxytocin.

Title: Functional connectivity analysis of epileptic neural networks with inhibition

Authors: *K. P. LILLIS[1,2], K. J. STALEY[1,2];
[1]Neurol., Harvard Med. Sch., Charlestown, MA; [2]Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Fundamental insights into the dynamics of neural networks are being gleaned from graph analytic approaches. Simulations of various network topologies have shown that small

world networks (in which a few cells, from a predominantly locally-connected network, have long range connections) are a highly efficient architecture for communicating information. In experimental studies, however, anatomical connectivity of neuronal networks is seldom known. Instead, “functional connectivity” can be measured by quantifying correlated activity among recorded cells. Studies of functional connectivity have largely focused on identifying clusters of positively coupled cells (i.e. excitatory connections). Biological neuronal networks include inhibitory interneurons, which inhibit postsynaptic targets and thereby restructure functional network connectivity in a time and activity-dependent manner. Here we use windowed analysis of calcium imaging data to characterize the transitions in functional network architecture in hippocampal organotypic slice cultures, which are spontaneously epileptic, and cycle through interictal, pre-ictal, ictal, and post-ictal states. We found 1) Small-world network topology transiently emerges in CA1 pyramidal cells during epochs associated with pre-ictal disinhibition. 2) In whole-slice calcium imaging experiments in which interneurons are distinguished by flourescent tags, we computed the peak absolute value of cross-correlation between all pairs of neurons imaged and defined negative peaks as inhibitory. Preliminary data indicate that, during interictal states of relative inactivity, interneurons are most commonly negatively correlated to principal neurons (I-E), whereas principal cells tended to be positively correlated with other principal cells (E-E). We can now use this approach to characterize both short-term dynamical changes in functional inhibitory networks preceding seizure onset, and the longer-term reorganization of inhibitory circuits during post-traumatic epileptogenesis.

Title: Optogenetic mapping of functional connectivity in freely-moving mice via insertable wrapping electrode array beneath the skull (iWEABS)

Authors: *A. PARK[1], S. LEE[2], C. LEE[3], J. KIM[1], H. LEE[2], S.-B. PAIK[3], K. LEE[2], D. KIM[1]; [1]Biol. Sci., [2]Materials Sci. and Engin., [3]Bio and Brain Engin., KAIST (Korea Advanced Inst. of Sci. and Tec, Daejeon, Korea, Republic of

Abstract: Mapping the wide-ranging neuronal interactions across cortical areas during behaviors has been challenging. Although flexible electrode array covering the cortical surface have recently emerged as a solution, it requires the removal of the skull leading to gross damages to the brain. Here, we developed an insertable wrapping electrode array beneath the skull (iWEABS), an electrocorticogram (ECoG) system optimized for recording activity from sizable cortical areas in freely-moving mice. The iWEABS is designed to be inserted through a small cranial window and stably attached on the cortical surface in mice. Using the iWEABS system, we measured global cortical activities in freely-moving states. Furthermore, we reveal that the iWEABS system is highly compatible with the optogenetic mapping of cortical interactions during absence seizures. Therefore, the iWEABS system can be a standard method for the study of expansive functional connectivity in mice.

Title: Differential dominant negative suppression of gabrg2 nonsense epilepsy mutations and the protein structural basis

Authors: *J.-Q. KANG[1], J. WANG[2], D. SHEN[1], G. XIA[4], W. SHEN[4], D. XU[3], R. MACDONALD[4];
[1]Dept Neurol., Vanderbilt Univ., Nashville, TN; [2]Dept. of Computer Sci. and Christopher Bond life Sci. Ctr., [3]Univ. of Missouri, Columbia, MO; [4]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Mutations in GABAA receptor subunit genes (GABRs) are frequently associated with epilepsy, and nonsense mutations in GABRG2 are associated with various kinds of epilepsy syndromes including febrile seizures, childhood absence epilepsy, generalized tonic clonic seizures and the most severe form epileptic encephalopathy like Dravet syndrome. The molecular basis for the phenotypic heterogeneity of these truncation mutations is not clear. In this study, we focused on three nonsense mutations in GABRG2 (GABRG2(R136X), GABRG2(Q390X) and GABRG2(W429X)) associated with epilepsies of different severities. With structural modeling, flow cytometry and biochemical approaches in combination with lifted whole cell patch clamp recordings, we demonstrated that the truncation mutations all had absent to minimal surface expression of the mutant subunit and unchanged or reduced wild-type partnering subunits expression. The GABA evoked- current amplitudes from cells cotransfected with α1β2γ2(R136X), α1β2γ2(Q390X) and α1β2γ2(W429X) subunits were reduced compared to the currents from α1β2γ2 subunits but with different level of reduction. The different mutant subunits had different steady state levels of mutant protein expression. The structural modeling and structure-based analysis indicated that the wild-type γ2 subunit surface was naturally hydrophobic, which is suitable to be buried in membrane The different γ2 subunits adopted different conformations, and the hydrophobicity scores were different among these misfolded subunits. In the docking study, the mutant γ2(Q390X) subunits formed protein specific or nonspecific stable protein dimers with themselves or other proteins while γ2(R136X) subunits could not form dimers with other partnering subunits but could dimerize with themselves. The γ2(W429X) subunits also dimerized with themselves but the protein conformation was similar to the wild-type γ2 subunit protein.

Title: Modeling SCN8A mutant epilepsy in patient-derived cortical and peripheral neurons

Authors: *A. M. TIDBALL[1], L. LOPEZ-SANTIAGO[2], X. DU[1], K. GLANOWSKA[1], L. ISOM[2], J. M. PARENT[1];
[1]Neurol., [2]Pharmacol., Univ. of Michigan, Ann Arbor, MI

Abstract: De novo mutations are major contributors to the development of childhood epileptic encephalopathies (CEEs) such as Dravet syndrome, infantile spasms, and Lennox-Gastaut syndrome (LGS) (Carvill et al 2013; O'Brien et al 2013; Epi4K Consortium 2013). CEEs comprise some of the most severe and pharmaco-resistant classes of epilepsy (Chiron and Dulac 2011). Mutations in the SCN8A gene have recently been shown to be causative for cases of infantile spasm, LGS, and CEE (Veeramah et al 2012; O'Brien et al 2013). CEEs often lead to intellectual and physical disabilities in later life as well as high rates of SUDEP (Sudden Unexpected Death in Epilepsy). These mutations have been shown to result in both gain-of-function and loss-of-function mutations (Veeramah et al 2012; Blanchard et al 2015). The goal of this research project is to use patient-derived cells to characterize electrophysiology alterations caused by SCN8A mutations associated with early-onset epilepsy and develop a novel platform for identifying effective pharmacological agents for this debilitating disease. SCN8A, which encodes for the voltage-gated sodium channel is expressed in both the PNS and CNS, where it is the most abundant Nav channel. We have identified two CEE patients with missense mutations in SCN8A (Arg1872>Leu and Val1592>Leu). Fibroblasts from the patients' skin biopsies were reprogrammed into induced pluripotent stem cells (iPSCs). These iPSCs have subsequently been differentiated by two different protocols into neurons expressing cortical excitatory and peripheral markers respectively. These cells are being used to first deduce the effect the Nav1.6 mutations have on electrophysiological properties of the neurons, particularly sodium current density and persistent sodium current. We hypothesize that these mutations will increase both of these measures leading to hyperexcitability of the neurons as has been shown in the majority of other SCN8A mutations in mouse models and heterologous systems. We have also used a multielectrode array platform (Axion Biosystems) to measure spontaneous activity. Cortical neurons from three patient lines all show increased spontaneous activity and burst activity compared to one human iPSC-derived neuronal control line. Future studies will involve culturing cortical and peripheral neurons, as well as cardiac myocytes, on MEAs to test known antiepileptic drugs and screen drug libraries for amelioration of hyperexcitable phenotypes. This work will shed light on SCN8A CEE seizure and SUDEP mechanisms and should provide lead compounds for clinical testing.

Title: Kinetic models of Slack channel function confirm cooperative gating in Slack-associated epilepsy mutations

Authors: *I. H. QURAISHI[1], J. KRONENGOLD[2], L. K. KACZMAREK[2,3];
[1]Dept. of Neurol., [2]Dept. of Pharmacol., [3]Dept. of Cell. and Mol. Physiol., Yale Univ., New Haven, CT

Abstract: Mutations in Slack (KCNT1) Na^+-activated K^+ channels lead to a spectrum of childhood epilepsy syndromes including malignant migrating partial seizures of infancy and autosomal dominant nocturnal frontal lobe epilepsy. These mutations increase Slack current amplitude at the whole cell level, as has been demonstrated in oocytes expressing the mutant channels. At the single channel level, only minor changes in gating of the mutants are observed in patches containing a low (1-3) number of channels. In contrast, in clusters of 4 or more channels, the open probability is very much greater than that of wild type channels. The distribution of open and closed states in such clusters deviates very strongly from the binomial expectation of independently gating channels. To confirm cooperativity in such clusters, we developed a nonlinear kinetic model of Slack channel gating. We compared the predictions of the model for open times and opening and closing latencies with data obtained in experimental channel recordings. For these comparisons, multichannel patch recordings were selected which appeared to have cooperativity based on comparison of channel opening histograms to recordings in patches with fewer channels. We first made a model with independent gating of channels in a cluster. The overall increase in channel opening in clusters could readily be fit by simply assuming that opening rate of the channels in a cluster was increased over that of single channels. This independently gating model however completely failed to predict conditional opening and closing latencies. In the second model, the kinetic parameters were dependent on the number of neighboring open channels. This cooperative gating model provided a much closer fit to the observed data. The dependence of the opening rate constant on the number of open channels was best fit by a saturable function. These results offer further evidence that the dysfunction in epilepsy-causing Slack mutations are depends on interactions between

neighboring channels. Inter-channel interactions could therefore be a potential therapeutic target in Slack-associated epilepsies.

Title: Neuronal network dysfunctions at the early stage of epileptogenesis in a genetic model of absence epilepsy

Authors: *G. JARRE, D. RUDRAUF, A. DEPAULIS, I. GUILLEMAIN;
Grenoble-Institut Des Neurosciences, Grenoble Cedex 09, France

Abstract: Epilepsies are characterized by recurrent seizures caused by a hyper-synchronicity and hyper-excitability of neuronal networks. Although the dynamics of these networks have often been studied in epilepsy, little is known about the epileptogenic process, i.e. epileptogenesis, in which recurring epileptic discharges progressively emerge. In genetic epilepsies, this process often takes place during brain maturation as in absence epilepsy, a childhood syndrome characterized by non-convulsive generalized seizures. In the Genetic Absence Epilepsy Rat from Strasbourg (GAERS), spontaneous seizures are characterized by spike-and-wave discharges (SWD) on the EEG and are initiated in the somatosensory cortex (SSC). We recently recorded spontaneous abnormal oscillations after the 15th post natal day (P15) which preceded the first SWD occurring at P25. Intracellular recordings during the epileptogenesis process suggest a strengthening of the synaptic activity in the network, potentially reflecting underlying network dysfunctions. Here, we aimed at understanding how the SSC's neuronal networks contribute to the emergence of SWD early on during epileptogenesis. We used *in vivo* two-photon calcium imaging in GAERS and age-matched control Wistar rats pups (P15-P19), under slight sedation (neurolept-analgesia), in order to simultaneously record calcium activity from multiple neurons in layer 2-3 of the SSC. We found that, GAERS SSC neurons were already hyperactive, with more frequent and longer calcium onsets than in controls. Analysis of functional connectivity within the network based on normalized pairwise correlation between neurons demonstrated a higher percentage of functionally connected neurons in GAERS vs controls. Overall, the values

of the correlations appeared smaller in GAERS, but they decreased as a function of between-neuron distance significantly more slowly in GAERS than in controls (over about 200µm vs 100µm). Such connectivity pattern remained unaltered after normalizing neuronal activity in GAERS pups using an acute injection of ethosuximide, an anti-absence drug. This supported the hypothesis that the dysfunction was related to an abnormal intrinsic connectivity rather than a neuronal hyperactivity per se. Altogether, these findings suggest the existence of a functional anomaly of the SSC neuronal network at the early stage of absence epileptogenesis, before SWD onset. In follow up analysis, based on multidimensional clustering techniques, clusters of neurons sharing similar activities could be quantified and characterized in order to better understand the physiopathology of absence epilepsy in the GAERS model.

Title: The human GluN2A mutation P552R enhances NMDA receptor function and promotes neurotoxicity

Authors: *S. F. TRAYNELIS[1], K. K. OGDEN[1], W. CHEN[1], A. TANKOVIC[1], E. AIZENMAN[2], K. B. HANSEN[3], H. YUAN[1];
[1]Dept Pharmacol, Emory Univ. Sch. of Med., Atlanta, GA; [2]Dept. Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [3]Biomed. / Pharmaceut. Sci., Univ. of Montana, Missoula, MT

Abstract: NMDA receptors mediate a slow, Ca2+ permeable component of excitatory synaptic transmission in the central nervous system. Overactivation of these receptors can be harmful due to swelling, which is secondary to influx of Na+, and excessive accumulation of intracellular Ca2+. Recently, mutations in the genes encoding NMDA receptor subunits have been identified in a number of cases of developmental delay and epilepsy, with mutations in the GRIN2A gene encoding the GluN2A subunit being most common. Here we describe a mutation in GRIN2A that leads to an amino acid change in the pre-M1 gating region (GluN2A-P552R), and was identified in a patient with developmental delay and epilepsy (de Ligt et al., N Engl J Med 367:1921-1929, 2012). We evaluated the functional effects of this mutation on recombinant GluN1/GluN2A receptors, and found that the potency of both glutamate (EC50 WT 3.3 uM, P552R 0.37 uM, n=9-13 oocytes) and glycine (EC50 WT 1.2 uM, P552R 0.06 uM, n=10 oocytes) increased ~10-fold without a change in open probability (n=12-17 oocytes). The time course of the response to rapid application of glutamate was dramatically slowed, with the 10-90% rise time increased 50-fold from 10 to 576 ms, and the weighted time constant describing the deactivation time course following rapid removal of glutamate increased from 45 to 794 ms (n=5-6 cells). As a result of these changes, charge transfer in response to brief synaptic-like exposure to glutamate increased more than 20-fold, raising the possibility that this mutation leads to neurotoxicity. To assess this possibility, we transfected rat cortical neuronal cultures with GFP, GFP+wild-type GluN2A, or GFP+GluN2A-P552R at 21 days *in vitro*. Our preliminary results suggest that neuronal morphology was unchanged between GFP and GFP+GluN2A-transfected neurons, however transfection of GFP+GluN2A-P552R produced extensive swelling within the dendrites. Quantification of co-transfected luciferase suggested mutant GluN2A-P552R increased neuronal death. These data are consistent with the idea that activation of GluN2A-P552R could compromise neuronal health, and may contribute to the neuropathology observed in this patient. These results also suggest that the pre-M1 helix contributes to the process of channel gating.

Title: Age-dependency of trauma-induced epilepsy in mice

Authors: *S. SOLTANI[1], J. SEIGNEUR[2], S. CHAUVETTE[2], I. TIMOFEEV[1];
[1]Psychiatry and neurosciences, CRIUSMQ, Univ. Laval, Québec, QC, Canada; [2]CRIUSMQ, Québec, QC, Canada

Abstract: Traumatic brain injury is a major risk factor for epileptogenesis. Cortical trauma leads to paroxysmal activity within 24 hours in up to 80% of patients and stops within a 48-hour period. Trauma-induced epileptogenesis (TIE) starts from that point and has unknown mechanisms leading to network reorganization and epilepsy. Because mechanisms of TIE are unknown, there is no treatment to prevent epileptogenesis. Understanding and preventing TIE will prevent epilepsy. We hypothesized that a partial deafferentation leads to a drop in excitability of the affected area. Brain then employs a variety of mechanisms to upregulate neuronal excitability (axonal sprouting, synaptic upregulation of excitatory and down-regulation of inhibitory synapses, alteration of intrinsic neuronal currents, ...). A reliable model of TIE is cortical deafferentation (undercut) and our group recently proposed that TIE is age-dependent because cats of unknown age developed epilepsy in about 70% of cases, while young cats did not. We aimed to verify this hypothesis of age-dependency in mice. We hypothesized that a 'plastic' brain (young animals) would restore excitability to a normal level. In a 'less plastic brain' (adult or old animals) this increase in excitability would be poorly controlled and lead to the development of epilepsy. The methodologies included aseptic surgeries, chronic electrographic recordings, and cortical undercut. We performed undercut in the somatosensory area in wild-type (C57BL/6) mice of different ages (young and old) under isoflurane anesthesia. Mice were implanted with LFP electrodes in different cortical areas and EMG to identify behavioral states. The electrographic activities of these mice were recorded continuously for at least two months or until they developed epilepsy. Almost all animals generated acute seizures of variable morphology within the first 10 hours after the lesion. In young animals, only isolated interictal spikes, but not seizures were recorded afterwards. In the following weeks, all old mice revealed recurrent seizure activities of different types. The most common type was 8-16 Hz spindle-like oscillations in the frontal cortex accompanied with an increase in the muscle tone and either body freezing or rhythmic contractions. In some animals, lower frequency (3-6 Hz) seizures were generalized and accompanied by behavioral freezing and low muscle tone or by rhythmic muscle and body contractions. The low frequency (1.5-3 Hz) seizures were accompanied with rhythmic muscle contractions. We conclude that TIE is age-dependent and it is likely due to an uncontrolled up-regulation of excitability in adult animals.

Title: FTY720 preserves blood-brain barrier integrity and restricts brain edema in rats subjected to subarachnoid hemorrhage

Authors: B. CHANGYALEKET[1], F. ZHAI[1], A. MUHAMMAD[2], C. PAISANSATHAN[1], D. PELLIGRINO[1], *H.-L. XU[1], F. TESTAI[2];

Abstract: Our recent study indicated that, in rats subjected to subarachnoid hemorrhage (SAH), the treatment with FTY720, a sphingosine 1-phosphate receptor modulator, was associated with a restriction of neuroinflammatory reaction, preserved cerebrovascular dilating function, and improved neurological outcome. The blood-brain barrier (BBB) disruption that leads to consequent edema formation has been recognized as one of the major contributors to SAH-related early brain injury. The core objective of the present study was to test the hypothesis that the neuroprotective effect of FTY720 is, at least partially, derived from its action on preserving BBB and restricting brain edema. The experiments were guided by 2 specific aims testing (1) effect of FTY720 on SAH-induced loss of BBB integrity; and (2) effect of FTY720 on SAH-associated brain edema. SAH was established using a rat anterior cerebral artery perforation model. Animals were randomized into three groups: (1) sham surgical control; (2) SAH rats treated with vehicle solution; and (3) SAH rats treated with FTY720. FTY720 was applied via an intraperitoneal route at 3h post SAH. Brain samples were collected at 48 h post SAH to determine BBB integrity and brain edema. BBB integrity was evaluated based on the cortical distribution of Evan's blue (EB) and the immunochemistry stain of tight junction proteins (ZO-1 and occludin). Brain edema was expressed as brain water content using the weight/dry method. Compared to sham surgical group, the permeability of BBB to EB was elevated significantly in the vehicle-treated SAH animals (12.96±3.14 μg/g tissue, vs 3.20±2.12 μg/g tissue in the sham

surgical group). FTY720 markedly restricted EB interstitial accumulation (6.96±2.83 μg/g tissue). Immunochemistry staining revealed that both ZO-1 and occludin were strongly expressed and heavily concentrated along with the cerebral microvessels in sham group. This expression pattern, however, was diminished at 48 h post-SAH. FTY720 partially restored the expression of these proteins. SAH was accompanied by a severe brain edema (SAH: 82.50±0.94%, vs sham: 79.38±0.37%), which was normalized by the presence of FTY720 (79.63±0.72 %). These results suggest that the attenuation of SAH-associated BBB disruption and brain edema accounts for the neuroprotective effect of FTY720.

Title: Attenuation of methamphetamine-induced neurotoxicity by dl-3-n-butylphthalide in sh-sy5y neuroblastoma cell line

Authors: J. ZHAO[1], *H. (. XIONG[2], J. LIU[2], Y. LIU[1], X. ZHANG[1], H. LI[1], H. LIU[2]; [1]Dept. of Neurol., Taian City Central Hosp., Taian, China; [2]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Methamphetamine (Meth) is a highly addictive drug and its abuse is associated with neural cell injury and loss. Currently, there are no efficacious therapies to treat Meth-induced neuronal injury as the mechanisms underlying Meth-associated neuronal injury are poorly understood. Thus, research in elucidating the mechanisms and identifying potential therapeutic interventions is imperative. In the present study, we investigated how Meth causes neural cell injury and tested protective effects of DL-3-n-Butylphthalide (NBP), a synthetic compound based on L-3-n-Butylphthalide which was isolated from seeds of Apium graveolens, in SH-SY5Y Neuroblastoma cell Line. Treatment of SH-SY5Y cells with Meth produced a reduction of cell viability in a dose-dependent manner as detected by PI staining and MTT assay. The Meth-induced reduction of cell viability was significantly attenuated by pretreatment of SH-SY5Y cells with NBP. Western blotting studies revealed that Meth reduced cell viability by upregulation of cleaved-caspase-3 and NBP partially reversed the Meth-associated upregulation of cleaved-caspase-3, resulting in neuroprotective activity, indicating that NBP attenuates Meth-

induced neural cell injury by down-regulation of Meth-associated caspase 3 activation. Our results suggest that NBP could be a potential therapeutic agent for Meth-induced neural cell injury.

Title: Blueberries affect neuroinflammation and cognition differentially depending on individual cognitive baseline status

Authors: N. THANGTHAENG, M. G. MILLER, S. M. POULOSE, D. F. BIELINSKI, D. R. FISHER, *B. SHUKITT-HALE;
USDA, ARS, Human Nutrit Res. Ctr. On Aging, Boston, MA

Abstract: Aging and neurodegenerative diseases are thought to be the results of prolonged effects of oxidative stress and inflammation. Previously, we have shown that daily supplementation of blueberries (BBs) was able to reverse age-related deficits in behavioral and neuronal function in aged rats. However, it is unclear whether BB will be more beneficial to one subset of the population compared to another, or if the beneficial effects are a global phenomenon where everyone benefits equally. Because there are various degrees of age-related cognitive decline and inflammation status observed in the general population, it is possible that daily BB supplementation would have differential effects dependent on baseline cognitive performance. To examine the effect of individual differences on the efficacy of dietary BB, aged rats (17 mo old) were assessed for cognitive status via the radial arm water maze (RAWM) and divided into good, average, and poor performers based on reference (RM) and working memory (WM) errors. Half of the rats in each cognitive group were then fed a control or a 2% BB diet for 8 weeks, before being re-tested in RAWM. Serum samples were collected pre-diet and at the end of the study to assess inflammation. The control-fed good performers committed more WM and RM errors in the post-test than pre-test ($p<0.05$), while the BB-fed good performers showed no change. Latency in the RAWM was significantly ($p<0.05$) reduced in the BB-fed poor

performers from pre- to post-test. A subsequent *in vitro* study using the serum showed that cognitive performance is associated with innate anti-inflammation capability, and BB supplementation further enhanced this capability. Behavioral findings reflect the individual rat's neuroinflammation status. Based on these findings, daily consumption of BB may reverse some age-related deficits in cognition, as well as preserve function among those with intact cognitive ability, especially in those with increased inflammation and poor cognitive status.

Title: Aging and walnut-rich diet supplementation affects the expression of immediate-early genes in critical brain regions

Authors: S. M. POULOSE[1], *D. F. BIELINSKI[1], J. W. CROTT[2], A. J. ROE[1], N. THANGTHAENG[1], B. SHUKITT-HALE[1];
[1]Neurosci. & Aging Lab., [2]Vitamins and Carcinogenesis, USDA Human Nutr. Res. Ctr, Tufts Univ., Boston, MA

Abstract: Emerging evidence indicates a direct link between age-associated changes in epigenetic mechanisms and onset of neurodegenerative diseases, and that these genomic modulations are directly affected by diet. Diets deficient in folate, choline and methionine, or the trace elements zinc and selenium, are reported to induce DNA hypomethylation and are linked to aberrant gene transcription. In a cognitively healthy adult, transcription of immediate-early genes (IEGs) is essential in memory formation and synaptic plasticity. In the current study, we investigated the effect of walnut diets, which are rich in polyunsaturated fatty acids and nutrients such as folate, selenium, magnesium and polyphenolics, on epigenetic mechanisms in critical regions of the brain. Young (3 months, n=30, 10/group) and old (19 months, n=45, 15/group) male Fischer 344 rats were supplemented with control (0%), 6% or 9% walnut diets for 10

weeks. All animals were tested on the radial arm water maze (RAWM) which measures spatial learning and memory. Age-related deficits in cognitive behavior were exhibited in the RAWM. The 9% walnut diet improved performance in the RAWM in both young and old rats. In hippocampus, target gene expression using the comparative CT (ΔΔCT) method revealed that differential regulation of IEG signaling exists for the different walnut treatments. Significant aging effects were observed for the expression of BDNF, ARC, EGR1 and AKT1 genes. The most significant difference between 6% and 9% WN was their effect on the RELN and EGR1 genes. BDNF increased among old animals fed with WN diet. In frontal cortex, expressions of target genes were affected by both age as well as diet. Significant increases in the transcript levels of zif268 or EGR among the 9% WN group could be a factor for the improved memory in that group. Benefits observed with regard to reference memory among animals fed with the 9% walnut diet could possibly be linked to the higher transcript levels of EGR1 in the frontal cortex, which is involved in cognition, long-term memory, and learning.

Title: Effects of strawberry supplementation on mobility and cognition in older adults

Authors: M. G. MILLER, *N. THANGTHAENG, T. M. SCOTT, B. SHUKITT-HALE; Neurosci. and Aging, Jean Mayer USDA Human Nutr. Res. Ctr. On Aging At Tufts Univ., Boston, MA

Abstract: During aging, functional changes in the central and peripheral nervous system can alter mobility and cognition - in some cases leading to early cognitive decline, disability, or injurious falls among older adults. Previously, we have shown that two months of dietary supplementation with berry fruit can reverse several parameters of brain aging, as well as age-related motor and cognitive deficits, when fed to aged rats (19 months old). The present study investigated the effects of 3 months of dietary supplementation with strawberry (12g twice a day, equivalent to approx. 2 cups/day fresh strawberry) or a seemingly identical, isocaloric placebo powder on healthy older men and women (60-75 years old). Participants completed a battery of balance, gait, and cognitive tasks at day 0, 45, and 90 of supplementation. Dietary supplementation with strawberry attenuated some aspects of declining mobility and cognition in older adults. Including berry fruit in the diet of healthy older adults may therefore be one means of combating age-related functional declines.

Title: Effect of progesterone treatment in streptozotocin-induced diabetic neuropathy

Authors: *S. YOUSUF[1], F. ATIF[1], M. C. PRUNTY[2], J. WANG[1], D. G. STEIN[1];
[1]Emergency Med., Emory Univ., Atlanta, GA; [2]Univ. of Missouri-Columbia, Columbia, MO

Abstract: Diabetic neuropathy (DN) is the common name for nerve damage caused by diabetes mellitus. The diabetic brain has been little studied and its possible dysfunctions remain to be identified. Progesterone (PROG) is a neurosteroid with well-established neuroprotective properties. We investigated the effect of PROG on DN-induced changes in brain function. DN was induced in male Sprague Dawley rats by intraperitoneal administration of streptozotocin (STZ) (60 mg/kg, b.w.) for 5 weeks. The animals were divided into sham control (Sham, n=8); streptozotocin (STZ, n=8) -treated and STZ+PROG (STZ+PROG, 8 mg/kg for 17 days with tapering, n=8) -treated groups. PROG treatment was started after hyperglycemia was confirmed

3 days after administering STZ. Body weight and blood sugar were evaluated weekly for 5 weeks. At the end of week 5, spontaneous locomotor activity of the animals was assessed. Various markers for angiogenesis (vascular endothelial growth factor (VEGF)), inflammation (IL-6) and injury (CD11b, NG2, IL-6, COX2 and matrix metalloproteinaise-2 (MMP-2)) were evaluated in brain, spinal cord and sciatic nerve tissues. We examined changes in intraepidermal nerve fibers (IENFs) by using the antibody PGP 9 in the foot pads to evaluate whether PROG has any effect on nerve fiber regeneration. PROG treatment did not lead to any significant improvement in body weight by the end of 5 weeks. Blood glucose values were found to be significantly ($p<0.05$) decreased in the PROG-treated group at the end of week 5 compared to the STZ group. The STZ group covered significantly ($p<0.05$) more distance than sham or the PROG+STZ group, a finding we attribute to hyperactivity due to diabetes. Reduced PGP9 and IENF densities were found in the STZ group compared to sham, whereas PROG treatments led to an increase in IENF densities. Significant changes were seen in the STZ group in expression of VEGF, CD11b, NG2, IL-6, COX2 and MMP-2. PROG treatment reduced these changes, thereby limiting further DN damage. Based on our findings, we conclude that PROG might represent a safe and effective therapeutic for DN treatment. **Keywords:** Progesterone, Diabetic Neuropathy, IENF, Behavior

Title: Neuroprotective effect of valproic acid in a neonate rat hypoxia model

Authors: *J. M. ORTEGA IBARRA, SR[1], S. J. LÓPEZ PÉREZ[2];
[2]cell and molecular biology, [1]Univ. De Guadalajara, Zapopan, Mexico

Abstract: During neonate period the brain is particularly sensible to hypoxia. Neonate rats exposed to hypoxia showed apoptosis, neuronal projections loss and high extracellular glutamate. Valproic acid (VA) has been shown neuroprotection in experimental models of hypoxia. The goal of this study was to estimate the density of brain cells in 20 and 30 days old rats (DOR) subjected to hypoxia in the neonatal period, which received a daily dose of VPA until sacrifice. Sections of prefrontal cortex (PFC), dorsal striatum (DS), sustantia nigra pars compacta

(SNpc) and ventral tegmental area (VTA) were processed by immunohistochemistry whit NeuN/TH or GFAP antibodies. In hypoxic 20 DOR, a diminution of $NeuN^+$ cells in PFC was found (2131 ± 103 vs. 2338 ± 43 CTL vs hypoxia groups respectively), but higher cell number in the VA groups (2537 ± 81 vs CTL). In SNpc we found less TH^+ neurons in hypoxic animals vs CTL (215 ± 43 vs 242 ± 37 respectively) and higher cell count in VA group (331 ± 35 vs CTL). There were no differences in $NeuN^+/TH^+$ cells in DS and ATV. With respect to $GFAP^+$ cells in hypoxic PFC, a high amount than CTL was found (433 ± 18 vs. 348 ± 31 respectively), whereas the VA group did not show difference (227± 15 vs CTL). In the DS, hypoxia induced an increase, whereas AV treatment has the same level of CTL (443 ± 18, 223± 15 and 235 ± 31 respectively). SNpc from hypoxic animals also had more $GFAP^+$ cells than CTL (509 ± 13 vs 391 ± 42 respectively), and the VA treatment was associated with a smaller cells number (223 ± 15 vs CTL). In PFC of **30 DOR**, a decreased number of $NEuN^+$ cells was found (2336 ± 40 vs. 2175 ± 46 CTL vs hypoxia respectively) and an increase in the VA treated groups (2527 ± 37 vs. CTL). In the SNcp, TH^+ cells in hypoxic group were less than in CTL group (228 ± 35 vs 392 ± 24 respectively), whit a higher cell number in the VA treated group (414 ± 61 vs CTL). VTA of hypoxic group showed less TH^+ cells that CTL group (154 ± 35 vs. 224 ± 35 respectively); the VA treatment did not show differences with CTL. In SD no significant difference was found in $NEuN^+$ cells count neither whit hypoxia nor VA. About $GFAP^+$ cells in 30 DOR, SNpc showed more cells in hypoxic group than CTL (632 ± 31 vs 463 ± 57 respectively), and a diminution in the VA group (287± 6 vs CTL). In DS and VTA did not found any difference. Altogether these results indicates that hypoxia had a general deleterious effect on the density of the cell types analyzed heren and VA treatment attenuates cell loss and appears to prevent astrocytes proliferation, suggesting a neuroprotective effect in this neonatal hypoxia model. Title: Protective role of folic acid against glutamate-induced excitotoxicity in hippocampal slices is dependent on PI3K/AKT/GSK-3B/B-catenin pathway and inhibition of iNOS

Authors: ***M. MORETTI**[1], J. BUDNI[2], S. MOLZ[3], T. DAL-CIM[2], M. D. MARTÍN-DE-SAAVEDRA[4], J. EGEA[4], M. G. LÓPEZ[4], C. I. TASCA[2], A. L. S. RODRIGUES[2];

Abstract: Introduction and objectives: Folic acid (folate) is a water-soluble vitamin important for neurological function. Since excitotoxicity induced by glutamate is a pathological event associated with different diseases, we investigated the putative protective role of folic acid on glutamate-induced hippocampal slices damage in rats as well as the intracellular signaling pathways involved in such effect. Methods: Hippocampal slices were isolated from adult male Wistar rats and incubated 1 h with 1 mM glutamate. When present, folic acid (1, 10 and 100 μM) was preincubated for 30 min. LY294002 (PI3K inhibitor, 30 μM) was added to the incubation medium 15 min before folic acid and maintained during the folic acid preincubation period. After glutamate incubation, slices were maintained in fresh culture medium without glutamate for an additional 6 h period. D-[3H]-aspartate release was determined through scintillation counting and cell viability was measured as MTT reduction. The phosphorylation of GSK-3β (Ser 9) and the immunocontent of β-catenin and iNOS were evaluated using western blot. Results: Hippocampal slices treated with folic acid (100 μM) had a significant reduction of cell death and D-[3H]-aspartate release induced by glutamate. The administration of LY294002h abolished the protective effects of folic acid against glutamate-induced cell damage and D-[3H]aspartate release. Six hours after glutamate insult, folic acid induced phosphorylation of GSK-3β and β-catenin expression in hippocampal slices of rats. In addition, glutamate-treated hippocampal slices exhibited increased iNOS immunocontent, an effect that was reversed by folic acid preincubation. Conclusions: The results of this study show that folic acid can protect hippocampal slices against glutamate-induced excitotoxicity through a mechanism that involves PI3K/Akt/GSK-3β/β-catenin pathway and inhibition of iNOS.

Title: Binge ethanol exposure increases the Kruppel-like factor 11-monoamine oxidase (MAO) pathway in rats: Examining the use of MAO inhibitors to prevent ethanol-induced brain injury

Authors: *J. W. DUNCAN[1], X. ZHANG[1], S. JOHNSON[1], C. UDEMGBA[1], N. WANG[1], S. HARRIS[1], X. OU[1], C. STOCKMEIER[1,3], J. WANG[1,2];

[3]Psychiatry, Case Western Reserve Univ., Cleveland, OH

Abstract: Alcohol misuse can result in devastating effects to the brain and behavior and is a major cause of morbidity worldwide. Binge drinking, in particular, induces several neurotoxic consequences, including oxidative stress and neurodegeneration. Because of these deleterious effects, drugs which prevent ethanol-induced detriment to brain could be very beneficial. We have observed an ethanol-responsive effect of the pro-apoptotic, Sp1-like transcription factor, Kruppel-like factor 11 (KLF11), and its transcriptional target, Monoamine Oxidase-B (MAO-B), in rodents exposed to a chronic ethanol model. Here, we examined whether the KLF11-MAO pathway is also upregulated in a binge ethanol rodent model and, further, whether administration of new generation Monoamine Oxidase Inhibitors (MAOIs) yielded some neuroprotective effects against ethanol as have been demonstrated in other neurodegenerative rodent models. Sprague-Dawley rats were administered N-propargylamine-containing MAOIs (Selegiline, Rasagiline, or M30) and fed ethanol by intragastric gavage following a modified 4-day Majchrowicz binge model. Binge ethanol rats demonstrated an increase in KLF11, both MAO isoforms, catalase, and caspase-3 expression compared to control rats. Moreover, Rasagiline and M30 significantly reduced the ethanol-mediated increase of KLF11, and M30 increased catalase expression in both control and binge ethanol rats. These results suggest an active ethanol-induced cell death mechanism involving the KLF11-MAO pathway in binge ethanol-treated rats and demonstrates some neuroprotective enhancement afforded by MAOI drug therapy. Further investigation of new generation MAOIs to improve ethanol-related brain injury outcomes is warranted. In addition, examining whether the pharmacotherapeutic effects of MAOIs persist during withdrawal of high concentrations of ethanol, as seen in alcohol poisoning, is of great interest due to its clinical relevance.

Title: Rosmarinic acid and carnosic acid display overlapping and distinct neuroprotective effects in cultured cerebellar granule neurons

Authors: *F. I. TARAM[1], E. IGNOWSKI[2], D. LINSEMAN[2];
[1]Biol., [2]Univ. of Denver, Denver, CO

Abstract: Neurodegeneration in the brain and spinal cord underlies many devastating diseases, such as amyotrophic lateral sclerosis (ALS), Alzheimer's disease, and Parkinson's disease. All of these disorders are characterized by the progressive loss of neurons in specific regions of the brain and/or spinal cord due to apoptosis, necrosis, or other forms of cell death. Oxidative and nitrosative stress, along with excitotoxicity and caspase activation, have been implicated as major pathways leading to cell death. Nutraceuticals (natural products) have been shown to have neuroprotective effects in a variety of *in vitro* and *in vivo* disease models. The two nutraceuticals under investigation in this study are rosmarinic acid and carnosic acid, compounds found at substantial concentrations in the herb rosemary. Here, the ability of these compounds to attenuate damage to cultured cerebellar granule neurons (CGNs) was observed and compared. Rosmarinic acid and carnosic acid both significantly reduced cell death induced by the nitric oxide donor, sodium nitroprusside. Rosmarinic acid but not carnosic acid, notably protected neurons against glutamate-induced excitotoxicity. Finally, carnosic acid displayed a unique ability to protect CGNs from caspase-dependent, intrinsic apoptosis induced by removal of serum and depolarizing extracellular potassium (5K apoptotic condition). Carnosic acid protected CGNs from 5K-induced apoptosis through a MAPK-independent but PI3K-dependent pathway. These results demonstrate that carnosic acid and rosmarinic acid have both overlapping and distinct neuroprotective effects on a range of stressors implicated in neurodegeneration. Thus, these nutraceuticals may act in either a complementary or possibly synergistic manner to protect susceptible neuronal populations in various disease states.

Title: Zinc modulates autophagy flux via regulation of cathepsins activity and expression

Authors: *K. KIM, S. KANG, R. MEHMOOD, Y. KIM;
Sejong Univ., Seoul, Korea, Republic of

Abstract: Recent studies have suggested that intracellular free zinc regulates autophagy and autophagic cell death in cultured neurons and astrocytes. Increase of intracellular zinc by zinc ionophore, clioquinol, or neurosteroids such as allopregnanolone and progesterone activated autophagy showing the increase of LC3-II conversion and reduction of mutant huntingtin (mtHtt) aggregates. In addition, oxidative stress-induced autophagic cell death was mediated by release of intracellular zinc, which induced lysosomal membrane permeabilization (LMP) and resultant cell death. In the present study, we examined whether an increase of extracellular zinc activates autophagy flux and which molecules are involved in zinc-mediated autophagy activation. First, we found that p62 protein levels were attenuated by zinc, suggesting the increase of autophagy flux. Furthermore, blockade of autophagy flux by chloroquine or NH4Cl was also reduced by zinc. Accumulation of autophagic vesicles and p62 proteins by chloroquine was significantly diminished by zinc. Since we saw that impairment of autophagy flux in neurodegenerative diseases is related to the reduction of cathepsin B activity, we next examined whether cathepsin activity or expression may be modulated by zinc. One hour later after zinc treatment at sublethal dose, cathepsin B activity was noticeably increased in cortical neuronal cultures. In addition, mRNA and protein levels of cathepsin B, cathepsin L, and cathepsin D were also increased from 6 hr after zinc treatment. Consistent with this, mtHtt aggregates in GFP-mtHttQ74-transfected HEK cells were substantially decreased by zinc treatment. Thus, the modulation of free zinc has a potential as therapeutics for neurodegenerative disease in which abnormal protein aggregates are involved.

Title: The protective role of erythropoietin on the histological changes in ca1 region of the hippocampus of diabetic mice

Authors: *M. A. OTHMAN[1,3], E. K. RAJAB[4], A. H. AL-ANSARI[2];
[2]Physiol., [1]Arabian Gulf Univ. Col. of Med., Manama, Bahrain; [3]Histology, Assiut Univ. Fac. of Med., Assiut, Egypt; [4]Physiotherapy, Ahlia Univ. Col. of Med. and Hlth. Sci., Manama, Bahrain

Abstract: Background: Diabetes mellitus is one of the most common metabolic disorders in humans. It is highly involved in some neurological deficits, including the CNS. This is in the form of cognitive and memory impairments. These changes could be associated with degenerative changes in the hippocampus. Finding alternative treatment for diabetic complications is a challenge for clinical neurology nowadays. Erythropoietin (EPO) is a hormone secreted mainly by the kidney and it classically stimulates erythrogenesis. A neuroprotective role for EPO has been reported in some CNS injuries like stroke and spinal cord injury. This effect is supposed to result partially from its enhancement of neurogenesis and prevention of cell death. The aim of this study was to determine whether EPO can ameliorate the degenerative effects of diabetes-induced histological changes of the CA1 region of the hippocampus. Materials and Methods: Eighteen male BALB/c mice (7 weeks old) were divided into three groups of 6 animals each. Group I: the control group, injected sodium citrate intraperitoneally (IP) every other day for 6 weeks. Group II: injected streptozotocin in sodium citrate (IP) for 5 days. Group III: injected streptozotocin in sodium citrate (IP) for 5 days and after 6 weeks injected EPO (IP) every other day for 6 weeks. After sacrificing the animals, the brain was obtained from the three assigned groups and processed for light microscopic evaluation of CA1 region of the hippocampus. Results: In the diabetic mice, the CA1 region of the hippocampus appeared to have some degenerative changes. These changes were in the form of cell loss and shrinkage and darkening of the nuclei of other cells. After administration of EPO there was improvement in the neurogenesis and also in the nuclear shape of the cells of the CA1 region of the hippocampus of diabetic mice. Conclusion: Diabetes resulted in histological degenerative changes in the CA1 region of the hippocampus. These changes were ameliorated by the administration of EPO which may be useful in the treatment of diabetic neuropathy.

Title: Oral administration of AQ is neuroprotective in an acute slice model of oxygen-glucose deprivation

Authors: *E. L. ADAMS, V. L. EHLERS, N. B. FETTINGER, S. C. MICHELS, J. R. MOYER, Jr;
Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Stroke is a leading cause of death among adults over the age of 65 in the United States (Go et al., 2013). Due to the lack of treatments for this disease, a need for novel neurotherapeutics prevails. A hallmark of ischemic stroke is excessive calcium (Ca2+) influx into cells, triggering cytotoxic signaling cascades leading up to and including cell death (Choi et al., 2009). By binding excess Ca2+, it may be possible to reduce neuronal cell death and improve outcomes for stroke victims. Our lab has recently shown that an intrahippocampal infusion of the Ca2+-binding protein (CaBP) apoaequorin (AQ) is neuroprotective in an *in vitro* model of ischemia called oxygen-glucose deprivation (OGD; Detert et al., 2013). Because it was observed that cytokine mRNA expression was altered following AQ infusion, a neuroimmunomodulatory mechanism may contribute to the observed neuroprotection. The current study tests the hypothesis that oral administration of AQ is neuroprotective in our *in vitro* OGD model. In order to study the effects of daily administration of AQ on neuroprotection, rats in the experimental groups began to receive 48 mg/kg AQ added to their peanut butter (PB) either 1h, 1d, 2d, or 7d prior to carrying out the *in vitro* OGD experiments. All control rats were fed ½ tsp PB for 9 days. On the last day, brains were extracted and hemisected. One hemisphere was subjected to *in vitro* OGD, while the other hemisphere was micro-dissected and dorsal hippocampus processed for protein analyses (e.g., AQ, IL-10, TNF-α, and β-actin). It was found that oral administration of AQ was significantly neuroprotective following 1 hour, 1 day, or 2 days of oral administration ($p < .05$). A neuroprotective effect was observed following 7 days of oral administration but this effect was not statistically significant, suggesting the need for more experiments at longer time points. These neuroprotective effects were paralleled by a significant 25% increase in IL-10 protein expression at the 1h time point ($p < .05$). TNF-α protein expression gradually increased over time from 1h until 7 days, at which point a significant 64% increase in TNF-α protein was observed as compared to control animals ($p < .05$). These results suggest that neuroprotection by oral administration of AQ may be in part due to modulation of cytokine expression.

Title: Docosahexanoic acid protection under lipotoxicity: role of pi3k/akt pathway

Authors: *M. DESCORBETH, M. DE LEON;
Ctr. for Hlth. Disparities and Mol. Medecine, Loma Limda Univ., Loma Linda, CA

Abstract: Lipotoxicity induced by an overload of saturated fatty acids results in cells and tissue damage and can play an important role during traumatic and hypoxia/ischemic injuries in nerve tissues. In contrast, docosahexaenoic acid (DHA), an n-3 polyunsaturated fatty acids, has been shown to have neuroprotective roles. We have shown that Palmitic Acid, a saturated fatty acid, induces apoptotic cells death through an increase of oxidative stress, ER stress and mitochondria

dysfunction in Schwann cells as well as in neuronal cells. In this study, we investigated the protective effect of DHA against PA-induced lipotoxicity (PA-LTx) in primary Schwann cells (pSC) and the involvement of the PI3K/AKT pathway. Primary Schwann cells were cultured in EG (5.5 mM glucose) and HG (17 mM glucose) environments for 5 days and followed by treatment with PA:BSA (300 μM: 150 μM) in the presence or absence of DHA (50-200 μM) for up to 48 hrs. Cell viability was determined by crystal violet staining, nuclear morphology was examined using Hoechst staining and protein expressions were measured by Western blots. Overload of PA decreased cell viability and induced apoptosis as demonstrated by the increased number of chromatin condensations in pSC under euglycemic (EG) and high glucose (HG) conditions. Co-treatment of DHA (50 μM) with PA restored the cell viability and eliminated the chromatin condensation in both EG and HG conditions. Next, post-treatment experiments were performed. We found that the protective effects of DHA decreased dramatically if it was added 12 hrs after exposure to PA; however, significant protection was observed when the DHA was added within 6 hrs. Further, we found that PA decreases AKT phosphorylation in pSC in a time-dependent manner, however in the presence of DHA, the p-AKT levels were restored towards the control level. Thereafter, selected PI3K/AKT inhibitors were used to investigate the implication of the PI3K/AKT pathways in DHA protection of pSC from PA-LTx. Our data show that LY294002 and BMK120, but not Wortmannin, significantly decreased the protective effect of DHA under PA-LTx, shown by decreasing AKT phosphorylation, decreasing the cells viability and increasing the chromatin condensation in EG and HG conditions. In conclusion, our results demonstrate that DHA protects Schwann cells from PA-LTx and that the PI3K/AKT is involved in the protective effect of DHA.

Title: Vitamin-D3 upregulation of synaptic proteins, activity- dependent neuroprotective protein and bcl-xL may provide neuroprotection to cortical neurons

Authors: S. KANG[1], K. BLACKBURN[1], D. SLAWSKI[3], *J. K. MORRIS[2];
[1]Neurosci. Program, [2]Dept. of Biol., Baldwin Wallace Univ., Berea, OH; [3]Col. of Med. and Life Sci., The Univ. of Toledo, Toledo, OH

Abstract: Vitamin-D_3 is a multi-function agent that has been well studied in bone and calcium metabolism. Deficiencies in vitamin D have been linked to neuropsychiatric and neurodegenerative disorders such as schizophrenia, Parkinson's disease, or Alzheimer's disease due to alterations in brain neurochemistry. Previously vitamin D was demonstrated to protect cortical neurons treated with anesthetic doses of the ketamine, NMDA antagonist, induced apoptotic cell death in the neonatal rat neurons. Neuroprotective effects of vitamin D may include: increased calcium binding proteins, increased neurotrophic factors such as GDNF, NGF, regulation of iNOS (nitric oxide synthase), as well as, decrease in L-type calcium channels. In order to determine the neuroprotective effects of vitamin D, we analyzed the somatosensory cortex, and cingulate cortex for an increase in neurons expressing calcium binding protein (CBP, calretinin, calbindin, or parvalbumin), in tissues exposed to vitamin-D_3, ketamine or a combination. The vitamin-D_3 (0.5 μg/kg) did not significantly increase the number of cells expressing CBP, except for a significant increase (237.71%) in calretinin-positive neurons in the cingulate cortex. Activity-dependent neuroprotective protein (ADNP), Bcl-X_L, PSD-95, and synaptophysin were all increased in the cortex in rats injected with vitamin D while, bax and bcl-2 were decreased in cortical tissue exposed to an anesthetic dose of ketamine (20 mg/kg). The increase in bax correlated with increased caspase-3 positive neurons following an anesthetic dose of ketamine. Thus vitamin-D_3 may enhance neuron cell health as demonstrated through increased synaptogenesis (PSD-95 and synaptophysin), alteration in pro-apoptotic factor, bax, and increased production of anti-apoptotic factor, bcl-x_L.

Title: Gene expression is modulated by pleiotrophin absence in the hippocampus of knockout mice

Authors: *A. E. ROJAS-MAYORQUIN[1], C. GONZÁLEZ-CASTILLO[2], C. GUZMÁN-BRAMBILA[3], M. PALLÀS[4], D. ORTUÑO-SAHAGÚN[2];
[1]Inst. de Neurociencias, [2]Inst. de Investigación en Ciencias Biomédicas (IICB), CUCS, Univ. de Guadalajara, Guadalajara, Mexico; [3]División de Biotecnología y Salud, Escuela de Medicina, Tecnológico de Monterrey, Campus Guadajara, Mexico; [4]CIBERNED, IBUB, Univ. de Barcelona, Barcelona, Spain

Abstract: Pleiotrophin (PTN) is a secreted growth factor associated with the extracellular matrix. It is expressed in several tissues, where its signals are generally related with cell proliferation, growth, and differentiation by acting through different receptors. In Central Nervous System (CNS), PTN exerts post-developmental neurotrophic and -protective effects, and additionally has been involved in neurodegenerative diseases and neural disorders. Its expression increases after cerebral lesion or damage, and in some degenerative diseases such as in patients with Parkinson disease. Specifically in the hippocampus, PTN-deficient mice exhibit a lowered threshold for induction of LTP, which is attenuated in mice overexpressing PTN, involving PTN functioning in learning and memory and exerting post-developmental neurotrophic and -protective effects. However, molecular evidence is scarce regarding the complex signaling system involved in PTN modulatory activity. Thus, to address this aspect, we analyzed the gene expression profile by means of microarrays of 22,000 genes in the hippocampus from mice lacking PTN (PTN-/-). Microarray analysis showed that 102 genes are differentially expressed (z-score >3.0) in PTN-null mice. For group analysis, we selected only genes that range from a median z-score over (or under) 3.0. Of these, a total of 41 identified genes (40%) are of unknown function, which indicates that PTN deficiency elicits an unmapped response. The genes known to have increased are mainly related with neuroprotection, cell differentiation and proliferation, and transcriptional regulation. Conversely, genes that diminished PTN expression are mainly related with cytoskeleton, cell cycle regulation, neural development, ion transport, and signal transduction. Eight genes that modify its expression (increasing or decreasing) in hippocampus of knockout (KO) mice also modify its expression *in vitro* after silencing PTN by siRNA. Therefore, our results indicate that absence of PTN affects the expression of genes related with neuroprotection (Mgst3 and Estrogen receptor 1) and cell differentiation (Caspase 6, Nestin, and Odz4), both *in vivo* and *in vitro*. Consequently, it leads us to propose that PTN function as a neuromodulatory peptide in the CNS. The outcome of this analysis constitutes a strong starting point in the identification and study of groups of genes involved in compensatory mechanisms activated by the absence of PTN, providing a model for analyzing some aspects of neurodegenerative diseases.

Abstract: The brain exhibits a higher demand for oxygen and glucose than any other tissue of human body. During ATP production, reactive oxygen species (ROS) are unavoidably generated. The accumulation of ROS leads to dysfunction of various subcellular organelles. Oxidative stress has been linked to the development of many neurodegenerative conditions. Glutamate-induced oxidative stress is a known cause of pathological cell death in neurons. This process is initiated by the depletion of antioxidant glutathione (GSH) synthesis by blocking cysteine uptake, and is followed by an accumulation of ROS. Buthionine sulfoximine (BSO), an inhibitor of gamma-glutamylcysteine synthetase, also blocks GSH synthesis by inhibiting the rate-limiting synthetic step. Geissoschizine methyl ether (GM) is an indole alkaloid found in Uncaria Hook, and has been identified as the active component responsible for the anti-aggressive effects of the Uncaria Hook-containing traditional Japanese medicine, Yokukansan. In this study, we examined the protective effect of GM on oxidative stress-mediated cytotoxicity. GM prevented glutamate-induced cytotoxicity in HT-22 neuronal cell line even with a 9 hr treatment delay. GM blocked glutamate-induced intracellular ROS and mitochondrial superoxide accumulation without preventing GSH depletion. We found that GM profoundly deceased mitochondrial respiration and increased glycolysis. We suspect that inhibition of mitochondrial respiration by GM may contribute to preventing glutamate-induced ROS accumulation. Moreover, GM protected cells from both glutamate and BSO toxicity in the immature rat primary cortical neurons. This study is the first to demonstrate the protective effect of GM on oxidative stress-mediated cytotoxicity in both transformed neuronal cell line and primary cortical neurons. These significant data may

provide a clinically-relevant argument for using GM against acute neuron-compromising conditions.

Title: B-hydroxybutyrate protects against glucose deprivation-induced neuronal death by the stimulation of the autophagic flux

Authors: ***L. CAMBEROS LUNA**, C. GERÓNIMO-OLVERA, T. MONTIEL, R. RINCÓN-HEREDIA, L. MASSIEU;
Neuropatología Molecular. Lab. AL-302, Inst. De Fisiología Celular, UNAM, Ciudad de México, Mexico

Abstract: Ketone Bodies (KB), acetoacetate (AcAc) and b-hydroxybutyrate (BHB) are formed as an end product of lipid catabolism in the liver and can be used as metabolic fuel in certain conditions such as prolonged fasting, the ketogenic diet, breastfeeding and severe hypoglycemia. Increasing evidence supports the neuroprotective action of KB in models of neurodegenerative disorders, epilepsy, hypoglycemia, excitotoxicity and ischemia. The mechanisms of protection of KB are not completely understood but several studies have suggested that the improvement of energy metabolism is one of the major factors involved in KB protective action. In the present study we have investigated whether the D isomer of BHB (D-BHB) prevents neuronal death induced by glucose deprivation (GD) in cortical neurons, through the modulation of autophagy. Autophagy is a lysosomal-dependent degradation process activated during nutritional stress, that digest damaged proteins and organelles providing energy for cell survival. Primary cultures of cortical neurons obtained from rat E17 embryos, were exposed at 8 DIV to GD followed by different times of GR either with or without D-BHB. We used viability assays (MTT reduction and lactic dehydrogenase release to culture media) western blot, immunocytochemistry and confocal microscopy, to investigate the effect of D-BHB on autophagy and neuronal death. Immunoblot results indicate that during GD the levels of the autophagic markers p62 and LC3-II

(the lipidated form of the microtubule associated protein light chain 3) increase, as well as the number of autophagic vesicles, according to LC3 immunocytochemistry and confocal microscopy for the the autophagosome marker Cyto-ID. During glucose reperfusion (GR) autophagosomes and the levels of LC3-II and p62 decrease, suggesting autophagic degradation. Cultures exposed to GD in the presence of D-BHB show a lower increase in LC3-II and p62 during GD and a faster decrease in autophagic markers during GR. Results suggest that D-BHB stimulates the autophagic flux improving neuronal survival. This study was supported by IN204213 PAPPIT grant to LM.

Title: PGC-1α gene delivery in the brain reduces Aβ generation, prevents neuronal loss and improves spatial and reference memory in a mouse model of Alzheimer’s disease

Authors: *L. KATSOURI, Y. M. LIM, A. M. BIRCH, N. MIRZAEI, N. D. MAZARAKIS, M. SASTRE;
Imperial Col., London, United Kingdom

Abstract: The PPARγ co-activator 1alpha (PGC-1α) is a transcriptional regulator that is involved in mitochondrial biogenesis and in the control of genes regulating oxidative stress and inflammation. We have found that the brains of Alzheimer's disease (AD) patients have decreased PGC-1α compared to healthy controls and that overexpression of PGC-1α increases the neurotrophic soluble APPα and reduces Aβ generation, thus implying that PGC-1α overexpression could be protective against AD. The aim of this study was to investigate whether PGC-1α can be used as a therapeutic target for AD by overexpressing it in the neurons of a transgenic mouse model of AD. For this purpose, we used an HIV-based lentiviral vector system and we subcloned the human PGC-1α cDNA in the lentiviral transfer genome downstream of the

human cytomegalovirus immediate early gene enhancer promoter (CMV). The vectors were pseudotyped with the rabies virus glycoprotein (RVG). Lentiviral vectors expressing either eGFP or PGC-1α were delivered by stereotaxic injection bilaterally in the frontal cortex and the hippocampus of eight month old female wild-type and AD transgenic mice (APP23). At this age there is no plaque formation in the APP23 mice, resembling a preclinical AD stage. Behavioral performances on the object location and object recognition tasks at four months post-surgery showed that the APP23 mice that received the PGC-1α vector have improved spatial and reference memory compared to the control group. Protein and immunohistochemical analysis revealed a significant decrease in total plaque numbers and Aβ load in animals injected with PGC-1α as well as a reduction in proinflammatory cytokines. Most strikingly, PGC-1α overexpression in the brain prevented neuronal loss in the cortex and the CA3 area of the hippocampus. These effects coincided with increased synaptophysin and PSD-95 expression and enhanced brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) mRNA levels, supporting a neuroprotective role for PGC-1α in this AD mouse model. Our data suggest that PGC-1α gene therapy could be a strong therapeutic candidate in AD.

Title: The primary function of the hypocretinergic system is to promote survival in health and disease states

Authors: *M. H. CHASE[1,2,3], M. XI[1,2], S. FUNG[1,2], J. ZHANG[1], S. SAMPOGNA[1]; [1]Websciences Intl., Los Angeles, CA; [2]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [3]UCLA Sch. of Med., Los Angeles, CA

Abstract: Wakefulness and motor activity are produced by the Reticular Activating System (RAS) in the brainstem. Wakefulness and motor activity are also promoted by the hypocretinergic system (HS) in the lateral hypothalamus. Is there a difference in these waking and motor behaviors? The answer is: Yes. Whereas the RAS responds to most alerting stimuli

and induces a generalized increase in motor activity, only survival-related stimuli activate the HS, which produces wakefulness, specific survival-related motor behaviors and a variety of related directives. Accordingly, we propose that the primary function of the HS is to promote survival-related behaviors and related responses that include cellular and subcellular processes. We have previously reported that hypocretinergic neurons discharge selectively during the pursuit of a food reward or during the exploration of a novel environment. Conversely, using antisense to disrupt hypocretinergic actions, we determined that there is a dramatic decrease in exploratory behaviors and a lack of reactivity to external threats. We have also found that the HS control extends to a variety of peripheral functions involving the pancreas, the adrenal gland and other organs. The maintenance of cellular and subcellular activities is also critical to survival. In this regard, we found that hypocretin suppresses apnea-induced hyperexcitability and subsequent neurotoxic changes in hippocampal neurons. Consistent with these electrophysiological findings, our morphological analyses reveal that hypocretin significantly reduces apnea-induced apoptosis (neurodegeneration). We also postulate that the survival directives of the HS include the amelioration of disease processes. To examine this hypothesis, hypocretin and vehicle solution were administered intraperitoneally (daily for 14 days) to control mice without cancer and mice with colon cancer. The animals were subsequently sacrificed and the colon in all groups of animals was examined with H&E staining. Remarkably, cancer mice that were treated with hypocretin exhibited normal colon epithelia. Hyperplasic/neoplasiac changes continued to be present in the epithelia of the colon of cancer mice treated with vehicle solution. No changes were found in the colon of control mice treated with hypocretin and vehicle solution. These data support our hypothesis that the primary function of the HS is to promote all aspects of the organism's survival, extending from behavioral to cellular and subcellular activities. Moreover, we propose that these directives of the HS are promulgated during health as well as disease states.

Title: Proteinase-activated receptor 2 (PAR2) and neuroprotection: Characterising novel activators in a CNS preparation

Authors: *S. MOUDIO;
Strathclyde Univ., GLASGOW, United Kingdom

Abstract: Proteinase-activated receptor 2 (PAR2), a subtype of GPCRs linked with inflammation, has recently received increasing interest due to their potential neuroprotective role in CNS diseases. Investigating the role and properties of PAR2 in CNS was previously made difficult by the limited selectivity and potency of PAR2 activators. Recently however, novel PAR2 activators with high potency and good stability have been developed allowing further investigation. Here, we characterise them for the first time in a CNS preparation. PAR2 activation has previously been shown to increase intracellular Ca^{2+} levels in both neurons and astrocytes. In the present study, we have utilised the recently developed PAR2 activators, GB110 and AC264613 as well as a proposed PAR2 antagonist, GB88 to determine their effects on intracellular Ca^{2+} levels in rat primary hippocampal cultures (12-15 DIV). In agreement with previous studies, our results demonstrate that activating PAR2 causes an increase of in intracellular Ca^{2+} levels in both neurons and astrocytes with GB110 (100μM) and AC264613 (100μM) resulting in an increase of 139 ±5% (n=35, $P<0.05$) and 77 ±3% (n=22, $P<0.05$) respectively in neurons and of 187 ±6% (n=26, $P<0.05$) and 92 ±3% (n=31, $P<0.05$) in astrocytes. In contrast, GB88 (100μM) produced a small but significant decrease in intracellular Ca^{2+} levels in both neurons 10 ±2% (n=37, $P<0.05$) and astrocytes 17 ±2% (n=33, $P<0.05$). To investigate further the underlying mechanisms behind PAR2 activation, we performed internalisation studies using PAR2-YFP transfected tSA201 cells. PAR2 internalisation was evident following exposure to all PAR2 compounds that elevated intracellular Ca^{2+} levels, including GB88 suggesting that it may actually be a biased agonist. Moreover, to assess the specificity of these PAR2 activators, we applied them to PAR1 and PAR4 transfected tSA201 cells with no internalisation being observed. Building on our previous work revealing the neuroprotective effects of PAR2 activation, we are currently testing the hypothesis that these novel PAR2 activators are neuroprotective against the *in vitro* kainate induced model of neurotoxicity in hippocampal organotypic slices cultures. Determining the potential of PAR2 as a novel therapeutic for CNS disorders may provide new options for a large range of CNS diseases.

Title: Spermidine prevents staurosporine-induced neuronal cell death by inhibiting caspase-mediated Beclin 1 cleavage

Authors: *Y. YANG[1], Y. ZHANG[1], S. CHEN[2], X. LIN[1], Y. SONG[1], C. LI[1];

Abstract: Spermidine is a natural polyamine that opposes age-related beneficial effects. However, the mechanism of spermidine-mediated neuroprotection remains unclear. In this study, we determined the effects of spermidine against staurosporine (STS)-induced PC12 cell death. Our findings demonstrated that STS resulted in cell apoptosis which could be efficiently reversed by the addition of caspase inhibitor z-VAD-fmk. STS-triggered cell apoptosis was accompanied with enhanced autophagic activity and Beclin 1 (the key autophagy modulator) cleavage. Administration of spermidine alone or in combination with z-VAD-fmk relieved STS-induced cell injury. Moreover, STS caused partial nuclear translocation of Beclin 1, which could be suppressed by spermidine. PC12 cells were overexpressed with full length, N- or C-terminal fragment of Beclin 1. Neither full length nor N-terminal Beclin 1 fragment affected cell survival. However, overexpression of C-terminal Beclin 1 fragment led to cell shrink, neurite loss, and caspase 3 activation in cells. Additionally, PC12 cells were transfected with Beclin 1 wide type (WT), or plasmids with site mutations (D121/124A, D146/149A, or D121/124/146/149A). D146/149A but not D121/124A resisted to STS-induced nuclear translocation of Beclin 1 and cell damage. Our results suggest that STS-induced caspase 3 activation and subsequent Beclin 1 cleavage, possibly at the site of D146/149, in PC12 cells. Addition of spermidine protected against cell injury by suppressing caspase-mediated Beclin 1 cleavage. These findings provide valuable insights for clarifying the crosstalk between autophagy and apoptosis within Beclin 1 interactome during neuronal cell death, and also provide basic evidences for understanding the mechanism of spermidine-mediated neuroprotection.

Title: Investigating the disease-modifying efficacy of voluntary exercise in experimental Multiple Sclerosis

Authors: A. GENTILE[1,2], S. BULLITTA[1], D. FRESEGNA[1,2], A. MUSELLA[1], F. DE VITO[1,2], *G. GRASSELLI[3], G. MANDOLESI[1], D. CENTONZE[2,4];

Abstract: Multiple Sclerosis (MS) is a neuroinflammatory disease and the most common cause of disability among young adults. Current therapeutic approaches are based on immunomodulants or immunosuppressants, able to provide functional recovery. Both clinical and preclinical data strongly suggest the beneficial effect of rehabilitative therapies for progressive multiple sclerosis (MS) patients, but the mechanisms involved are still poorly understood. In recent years a link between inflammation and synaptic alteration in several brain areas, like the cerebellum, has been highlighted in the experimental autoimmune encephalomyelitis (EAE), animal model of MS. In particular, we have recently shown that the pro-inflammatory cytokine interleukin 1-beta (IL1-beta), released by T-lymphocytes, has a crucial role in triggering cerebellar synaptic defects. Interestingly, symptoms linked to cerebellar dysfunction in MS seem to be responsive to motor training. We asked whether exercise could attenuate peripheral and central inflammatory reaction, thereby leading to amelioration of cerebellar pathology in the EAE model. To this aim, MOG35-55 EAE was induced in 8-week female C57BL6/N mice: the day of the immunization mice were randomly assigned to standard and wheel-equipped cages (voluntary exercise protocol). Daily clinical score analysis revealed significant reduction in disease-related disability in exercised-EAE mice. Also, grip strength test showed increased neuromuscular function in exercised-EAE mice. At the peak of the acute phase (21 days post immunization-21 dpi), mice were sacrificed and cerebella and spleens were isolated for biochemical analysis. First, we measured the levels of IL1-beta released by peripheral T-lymphocytes isolated from the spleens of exercised and non-exercised EAE mice: we found that exercise reduced consistently the amount of IL1-beta released by EAE-specific T-lymphocytes. As a measure of central inflammation we checked astrogliosis, by western blot analysis for glial fibrillary acidic protein (GFAP) in cerebellar extracts of both experimental

groups: GFAP protein levels were significantly reduced in exercised-EAE mice. Overall these data, although preliminary, provide evidence for an anti-inflammatory effect of voluntary exercise with a potential impact on cerebellar alteration of neurotransmission, corroborating the hypothesis that physical exercise is able to interfere with MS/EAE pathological mechanisms.

Title: Serotonin as a scavenger of hypochlorous acid in the brain

Authors: ***T. M. JEITNER**[1], M. KALOGIANNIS[2], E. J. DELIKATNY[3];
[1]New York Med. Col., Valhalla, NY; [2]Winthrop Univ. Hosp., Mineola, NY; [3]Radiology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Hypochlorous acid (HOCl) is a powerful two-electron oxidant produced in the brains of Alzheimer Disease, Parkinson Disease or cerebral stroke patients. At present there are no effective antioxidant therapies for the treatment of neurodegenerative diseases. HOCl reacts with neurotransmitters to produce products of varying toxicity (Jeitner et al. (2015) BBA 1852: 937). The aim of these studies was to assess the scavenging of HOCl by serotonin. HOCl altered the UV-visible and 1H-NMR spectra of serotonin indicative of chlorination of the nitrogen atoms. These reactions led to the polymerization and aggregation of chlorinated serotonin. HOCl scavenging was assessed by monitoring the oxidation of 2-thio-5-nitrobenzoate by HOCl. Serotonin prevented this reaction. Each molecule of serotonin scavenged more than one molecule of HOCl. Indeed, scavenging was more effective at ratios of HOCl to serotonin ≥ 1:1. This behavior was also exhibited in the protection of cells from the toxicity of HOCl by serotonin. Cellular alpha-ketoglutarate dehydrogenase complex activity was similarly protected from HOCl-mediated inactivation by serotonin. HOCl and serotonin are readily increased in the brain by the administration of LPS and selective serotonin-reuptake inhibitors, respectively.

Administration of selective serotonin-reuptake inhibitors to LPS-treated mice prevented the chlorination of cerebral proteins by HOCl, as well as sickness behavior induced by LPS. These demonstrations suggest serotonin may an effective scavenger of HOCl in the diseased brain.

Title: Effects of treatment with white grape juice on inflammatory cytokines on rats exposed to carbon tetrachloride

Authors: *C. S. FUNCHAL[1], A. ABUJAMRA[2], F. MACHADO[2], M. WOHLENBERG[2], N. MEDEIROS[2], V. ELSNER[2], C. DANI[2];
[1]Ctr. Universitário Metodista, Porto Alegre, Brazil; [2]Ctr. Universitário Metodista -IPA, Porto Alegre, Brazil

Abstract: Grape juice is considered a source of phenolic compounds which act as antioxidating agents and, therefore, are beneficial to those who consume them. The anti-inflammatory potential of white grape juice, however, has not yet been evaluated. The purpose of this work was to evaluate the effect of organic and conventional white grape juice on the inflammatory cytokines interleukin 1 beta (IL-1β) and interleukin 6 (IL-6) in the cerebral cortex, liver, and serum of adult rats submitted to an experimental model of hepatic encephalopathy. Forty male Wistar rats aged 90 days were treated daily, once a day, orally by gavage, with organic or conventional white grape juice during 14 days, at a dose of 7 μL/g of body weight. On the 15th day, rats received a single dose (3.0mL/Kg of body weight) of carbon tetrachloride (CCl4). Four hours later, rats were euthanized and dissected for organ harvesting and blood collection. Blood serum and cellular lisates of cerebral cortex and liver were utilized for a sandwich ELISA with

antibodies against IL-1β and IL-6. Multivariate analysis of variance (MANOVA) followed by the Tukey HSD post-hoc test was utilized to obtain the results presented herein. Rats exposed to CCl4 demonstrated a significantly higher concentration of IL-1β and IL-6 in blood serum and tissues when compared to control rats. Rats which received organic white grape juice for two weeks previously to CCl4 exposure demonstrated blood serum and tissue concentrations of IL-1β and IL-6 similar to control rats, preventing an increase in IL-1β and IL-6. These results suggest that white grape juice prevented the proinflammatory effects of CCl4, and therefore should be investigated more extensively as a potential anti-inflammatory therapy for various diseases.

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disease causing a progressive dementia that affects approximately 1/6th of people in the US age 75 and above. Despite intensive research in the past decades, the underlying mechanisms of AD remain elusive. Genetic, histological, and brain imaging data suggest that oligodendrocytes and myelination may play important roles in AD pathology. Despite intriguing reports and enticing preliminary data, a molecular-level characterization of modifications in oligodendrocytes and myelination in AD has not yet been established. Our previous study showed that myelination/oligodendrocyte-enriched gene networks were enriched for AD GWAS hits and contained the amyloid-production related genes PSEN1 and BACE1. Towards this end, we have analyzed public human brain

transcriptome data at different stages of cognitive decline using a network-based approach to interrogate the molecular structure of AD pathogenesis. Our results suggest that the myelination networks are highly dysregulated at the early stage of AD. We systematically validated five key drivers of the myelination networks using several mouse models in which these key drivers were perturbed. Using RNA-seq of samples isolated from the same brain regions that were analyzed in the human cohort, we were able to confirm in mice the key findings from the human analysis. Our results provide novel insights into the mechanisms underlying the dysregulation of oligodendrocytes and myelin in AD, and unlock potential novel molecular targets for AD in oligodendrocytes.

Title: Modulation of nitric oxide synthase I transcription by tau and alpha-synuclein

Authors: ***T. K. RIFE**, D. M. JALIL, A. L. DEAL, T. A. WEAVER, M. M. HUTH;
Biol., James Madison Univ., Harrisonburg, VA

Abstract: Transcriptional regulation of Nitric Oxide Synthase I (NOS1), an enzyme which produces nitric oxide (NO), plays a role in sleep regulation, one's ability to learn and remember, synaptic plasticity, and brain development. Additionally, excessive expression of NOS1 plays a role in many neurodegenerative diseases like Parkinson's Disease, Alzheimer's Disease, and stroke. Hence, it is vitally important to understand how NOS1 is transcriptionally regulated. NOS1 has twelve different first exons that are each controlled by a unique promoter (1a - 1l). The 1f promoter has a dinucleotide polymorphism ($(TG)_nTA(TG)_n$) located upstream of the TATA box. Genotyping shows that shorter dinucleotide polymorphisms are associated with Alzheimer's and Parkinson's Disease and that shorter repeats have decreased transcriptional expression compared to larger repeats. Purine-pyrimadine dinucleotide repeats have been shown to form alternative DNA structures like Z-DNA. Moreover, tau and alpha-synuclein, proteins

that are misregulated in Alzheimer's and Parkinson's Disease respectively, have been shown to bind to and stabilize alternative DNA structures. Therefore, we hypothesize that tau and alpha-synuclein might be involved in regulating transcription of the 1f promoter by interacting with its repeat. Human Sk-n-Mc neuroblastoma cells, which normally express high amounts of tau and low amounts of alpha-synuclein were used to test this hypothesis. A tau siRNA was utilized to knock down tau protein in the cells. Alpha-synuclein expression was increased in the cells by transfecting them with an alpha-synuclein expression plasmid. Reporter genes directed by NOS1 1f promoter regions with and without the dinucleotide polymorphism were transfected into the cells along with the tau siRNA, alpha-synuclein expression plasmid or appropriate controls. Reporter genes containing short polymorphisms were increased two-fold following tau knockdown but no change in activity was observed in constructs that did not contain the dinucleotide polymorphism. Alpha-synuclein over-expression caused a two-fold decrease in reporter gene expression when a short dinucleotide repeat was present. These findings suggest that tau and alpha-synuclein may modulate NOS1 expression through interaction with a dinucleotide polymorphism associated with disease development. Preliminary data also suggest that tau and alpha-synuclein can affect the longer repeats differently than shorter repeats. Further studies are being done to understand the nature of tau and alpha-synuclein's effects on NOS1's 1f promoter.

Title: Role of HMGB1 inhibitor Glycyrrhizin in diabetic complications

Authors: *M. CHATTOPADHYAY, M. GONZALEZ, K. PENNINGTON, S. NARGIS, V. THAKUR;
Ctr. of Excellence in Diabetes and Obesity, Texas Tech. Univ. Hlth. Sci. Ctr., El Paso, TX

Abstract: The increases in number of diabetic patients have become an epidemic worldwide which greatly affects the quality of life of the patients. Diabetic neuropathy and diabetic nephropathy are very common complications among all diabetes patients. Recent evidence suggests that the inflammatory pathway plays a crucial role in the development of these complications. Unfortunately, available medical treatment is relatively ineffective due to side its effects. We have investigated the role of a number of neuropeptides and inflammatory mediators in the peripheral nervous system and in the diabetic kidney. High mobility group box 1 (HMGB1) protein is a novel biomarker of inflammation and we have recently shown that HMGB1 is up-regulated in the peripheral nervous system and kidney. This study is designed to investigate whether blocking HMGB1 by natural inhibitor, Glycyrrhizin, can reduce the progression of the development of one or both these complications. We have also demonstrated that interruption of inflammation would ameliorate the expression of certain neuropeptides in the dorsal root ganglia and kidney of diabetic animals. Successful completion of this study may serve an effective means to alleviate inflammation that is associated with certain complications in diabetes. Zucker diabetic fatty (ZDF) rats, an established model for spontaneously diabetic rats were used for Type 2 animal model. Animals with blood glucose level ~300 mg/dl was included as diabetic. We have determined whether there is a direct association between the expression of inflammatory markers, HMGB1, TNFα and IL-1β, and release of the peptide neurotransmitters, calcitonin gene related peptide (CGRP), substance P (SP) and Pituitary adenylate cyclase-activating polypeptide (PACAP) in the peripheral nervous system and kidney of the diabetic animals, by immunohistochemistry and Western blot analysis. This study demonstrates whether HMGB1-mediated inflammation is responsible for peripheral neuropathy in diabetes and whether similar or different peptide neurotransmitters are involved in the diabetic nephropathy in Type 2 diabetic animals. Successful completion of this study may provide a more useful and efficient way to treat this debilitating problem.

Title: Temperature modulates stress response of neurons to repetative low-force mechanical impacts

Authors: D. C. KLINE[1,2], C. BEST-POPESCU[1,2], *P. SENGUPTA[1,2,3];
[2]Dept. of Bioengineering, [3]Beckman Inst. for Advanced Sci. and Technol., [1]Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Low-impact force induced concussions cause brain injury in contact sport athletes and civilians. These injuries are not treated seriously and are often ignored as "little bumps on the head". However, in recent years, increasing scientific evidence has emerged implicating recurrent, low-force mechanical impact (LFMI) -induced concussions with long-term disability and persistent damage to the central nervous system (CNS). The immediate consequences of LFMI include a cascade of subcellular events that alter the equilibrium state of the neuronal network, ultimately leading to a breakdown in neuronal communication and neurodegeneration. It would greatly help victims of LFMI if somehow this stress response of neurons could be attenuated immediately after the injury. As most physiological processes have been shown to be temperature sensitive, modulation of temperature is expected to have a significant effect on LFMI-induced injury. In fact, experimental animal research has shown that both whole-body hypothermia and selective head cooling have neuroprotective effects in a variety of CNS injury models. Alternatively, raising brain temperature by a couple of degrees above normothermia worsens outcome in a variety of injury models. In addition, therapeutic hypothermia, defined as clinically reduced deep brain structure temperature to 33-34°C, is standard of care to treat patients resuscitated after cardiac arrest, because it leads to improved neurologic outcome and decreased overall morbidity and mortality. The aim of the current study was to determine the time dependent effects of hypothermia on neuronal inflammation and network signaling in an *in vitro* repetitive LFMI neuronal injury model. For experiments, disassociated cultures of primary mouse cortical neurons were used. These neurons form networks *in vitro*. A custom-built mechanical impactor was used to deliver recurrent impacts to these networks with high precision. To ensure that a solitary impact did not create any measurable effects, a sub-threshold impact force was used for all experiments. The degree of LFMI-induced inflammation was quantified by determining interleukin-1β levels in these networks, at multiple time points and following an increasing number of impacts. The networks were treated post-impact with immediate and delayed hypothermic conditions and ensuing inflammation levels were determined. Our results demonstrate that treatment with hypothermic conditions protects neurons from injury significantly by lowering levels of inflammation. These findings have direct implications in terms of effective neuroprotective treatment design and damage prevention strategies.

Title: Sex differences in response to traffic-related air pollution exposure: male sensitivity to obesity and depressive behavior

Authors: *N. C. WOODWARD, A. CROW, Y. ZHANG, A. SAFFARI, C. SIOUTAS, H. ALLAYEE, C. FINCH, T. MORGAN;
USC, Los Angeles, CA

Abstract: Traffic-related air pollution (TRP) has a well-documented effect on cardiovascular function and mortality (Pope et al 2004). Moreover, recent studies show effects of TRP as both an obesogen and a cause of cognitive impairment (Perera et al. 2012; Sun et al. 2009; Volk et al. 2011). Our objective is to analyze the developmental impact of nanoscale particulate matter (nPM), a subfraction of TRP, on postnatal weight gain, insulin sensitivity, and behavioral-cognitive deficits. The nPM was eluted from Teflon filters, reaerosolized, and delivered to mice utilizing a novel system, which allowed exposure from conception to adulthood (Morgan et al. 2011). The exposure schedule was 3 days a week, for 5 hours per day, at a concentration of 324 ug/m3 of nPM. C57BL/6J were exposed for the duration of gestation, and the offspring were exposed from birth until 14 weeks of age. At four weeks of age the mice were put on high fat diets (45% kcal/fat), and remained on the diet until time of euthanasia. Males exposed to nPM and fed either the regular chow (6.4% kcal/fat) or high fat diet gained more weight than controls exposed to filtered room air. Their greater weight gain was observed from 4 weeks to 9 weeks of age, when the differences stabilized. In contrast, female weight was not altered by nPM exposure or diet. Males were given an intraperitoneal glucose tolerance test at 13 weeks of age. Males on both high fat diet and nPM exposure showed impaired blood glucose regulation. In behavioral tests at 12 weeks of age, males performed worse in the Porsolt forced swim test, which measures depressive symptoms. Males exposed to nPM had decreased latency to their first period of immobility, and increased total time spent immobile, corroborating findings from a prenatal only exposure in our lab (Davis et al. 2013). Females showed no changes in forced swim. In the open field test, a measure of anxiety, females exposed to nPM had an increase in total distance traveled, while the males showed no differences. No change was detected for the novel object

recognition test or elevated plus maze for either sex. Gestation and early development are critical periods in determining lifelong health, and environmental insults during this period can have disproportionate effects. This study demonstrates the impact of TRP exposure on weight gain, and cognitive functioning. Diet induced obesity is associated with neuroinflammation, which can contribute to age related cognitive decline (Jayaraman et al. 2014).These results highlight substantial sex differences in effects, with females less responsive to nPM effects on weight and depressive symptoms.

Title: White matter substrates of limited visual working memory capacity in schizophrenia

Authors: ***M. LAZAR**, D. MALASPINA, O. GONEN;
New York Univ. Sch. of Med., New York, NY

Abstract: *Background: Working memory (WM), which plays an essential role in many higher-order cognitive processes, has a limited capacity of only several objects. Our previous work has shown that, in healthy adults, 59% of inter-individual variability in the visual WM capacity is explained by variations in axonal density of the white matter pathways connecting brain regions involved in WM, with another 12% explained by variations in the global diffusion properties of the extra-axonal space. The goal of this study was to evaluate the relationship between visual WM capacity and white matter microstructural properties in schizophrenia (SZ), a disorder with known WM capacity limitations. Methods: 19 healthy controls (HC) and 16 right-handed male SZ patients ages 30 to 55 years old participated in the study. Visual WM capacity was measured using the Symbol Span test from WMS-IV. The Diffusional Kurtosis Imaging (DKI) approach was employed to estimate 1)Axonal Water Fraction (f_{axon}), a metric reflective of axonal density and caliber, 2) Intra-axonal Diffusivity (D_{axon}), which describe overall organization of the intra-axonal millieu and 3) Axial (AD_{extra}) and 4) Radial (RD_{extra}) extra-axonal diffusivities, which*

reflect the size, number, and organization extracellular structures such as oligodendrocytes, astrocytes, or microglial cells. RD_{extra} may also reflect axonal packing and, thus, dysmyelination, and was found to be impaired in SZ. DKI data were acquired and employed to derive three-dimensional maps of f_{axon}, D_{axon}, $AD_{extra,}$ and RD_{extra}. Tract specific and global (whole brain) mean DKI metrics were obtained from these maps. Results: No significant relationships between white matter DKI metrics and visual WM capacity were found at the tract level in the SZ group. Multiple regression identified some similar relationships to the ones found in the HC group (with f_{axon} of left inferior longitudinal fasciculus and global AD_{extra}). However, relationships to f_{axon} of left inferior longitudinal fasciculus and right cingulum were no longer present, with other axonal density contributions detected only at the global level (through the global f_{axon}). A significant contribution was detected for the RD_{extra} of the right cingulum. The overall model explained 55% of the inter-individual variations in visual WM capacity in the SZ group. Conclusion: In schizophrenia, only some of the relationships between visual WM capacity and white matter microstructural properties found in the healthy brain are maintained with atypical microstructural features reflective of dysmyelination appearing to be involved.

Title: Rapid oxidative and inflammatory effects of acute traffic-derived nanoscale particulate matter exposure on olfactory gateways to the brain

Authors: *H. CHENG, C. E. FINCH, T. E. MORGAN;
USC, Los Angeles, CA

Abstract: Urban traffic-derived nanoparticulate matter (nPM, <200nm) can induce oxidative stress and inflammation in the brain (Morgan et al. 2011; Davis et al. 2013). To resolve the time course of brain responses, mice were exposed to nPM for 5, 20, and 45 cumulative hours over 1-

21 days to model effects of acute exposure. Because nPM can translocate into the brain *via* the olfactory receptor neurons lining the olfactory epithelium (OE) (Oberdörster *et al.* 2004*)*, we hypothesized that the OE will show the earliest responses to nPM, followed by olfactory bulb (OB) and caudal pathways and structures. OE, OB, and cerebral cortex were analyzed by Western blot for stress-responses sensitive to oxidation and inflammation. OE showed 30% increases in 4-hydroxynonenal (4-HNE) and 3-nitrotyrosine (3-NT) by 5h of exposure, and remained elevated through the 45h of exposure, whereas OB only responded at 45h. Olfactory marker protein (OMP) was slightly decreased in the OE at 45h by 20%, but unchanged in the OB. Apoptotic responses were evaluated with cleaved caspase-3, which increased by 20% in OE only after 20 and 45 hours. Cortex did not show these changes. By immunohistochemistry, the shortest exposure of 5 hours also induced 4-HNE and 3-NT in the OE, but not OB. The astrocytic marker GFAP was unchanged in OB. Iba1 positive monocyte counts were increased by 25% in OE turbinates and the glomerular layer of OB. These novel findings show rapid responses in the OE that we hypothesize will initiate subsequent early oxidative and inflammatory cascades into the brain. **References:** Davis, D. A., et al. Title: Microarray analysis of traffic-related air pollution and LPS treatment of mixed glia

Authors: *E. BACON[1], N. WOODWARD[1], M. LEVINE[2], C. SIOUTAS[1], T. MORGAN[1], C. FINCH[1];
[1]USC, Los Angeles, CA; [2]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Traffic-related air pollution (TRP) is a ubiquitous environmental toxin. However, little is known about the direct interaction TRP components have with cells. Increasing epidemiological evidence demonstrates TRP's role in autism and other developmental disorders (Perera et al 2012; Volk et al 2013; Woodward et al 2015). This study investigates brain cell transcriptional responses to nanoscale particulate matter (nPM) from urban TRP in mixed glial cultures (astrocytes:microglia, 3:1). The nPM from a local freeway is a subfraction of TRP, consisting of particles < 200 nm diameter, that was eluted from Teflon filters (Morgan et al 2011). Lipopolysaccharide (LPS, an endotoxin) was used for comparison with known inflammatory transcriptional responses. Mixed glia from neonatal rat cerebral cortex was treated with nPM (12ug/ml, 24 hours) and LPS (100ng/ml, 48 hours) and total RNA analyzed by Affymetrix Rat 230 2.0 Array. In nPM treated samples, 941 genes were upregulated, and 1089 downregulated vs. LPS, which had 615 upregulated genes, and 717 downregulated. Shared responses include 294 upregulated and 235 downregulated. Gene Ontology and KEGG pathway analysis showed large scale activation of numerous immune and stress pathways for both nPM and LPS treatment. The "response to tumor necrosis factor" and "response to interferon-gamma" were especially enriched in the altered transcripts shared by both treatments. A subset of genes was confirmed by q-PCR. Gene expression of tumor necrosis factor (TNF, 6.0 fold change for nPM) and receptor subunit (TNFrSF9, 7.5 fold change for nPM) were upregulated, while receptor associated factors TRAf6 and TRAF3ip were downregulated in nPM (0.4 and 0.3 fold change), yet unchanged in LPS treatment. Different responses to nPM and LPS indicate TRP-specific inflammatory responses that are separate from pathogen-generated LPS and other endotoxins. This microarray analysis provides a first step in identifying the specific gene transcripts and pathways involved in cellular response to direct nPM exposure, and gives new candidates for analysis of *in vivo* genomic responses to TRP.

Nacional Autónoma de México, Mexico City, Mexico; [6]INSTITUTO NACIONAL DE Neurología Y Neurocirugía, MEXICO CITY, Mexico

Abstract: Amyloid peptide is able to promote the activation of microglia and astrocytes in Alzheimer's disease (AD), and this stimulates the production of pro-inflammatory cytokines. Inflammation contributes to the process of neurodegeneration and therefore is a key factor in the development of AD. Some of the most important proteins involved in AD inflammation are: clusterin (CLU), complement receptor 1 (CR1), C reactive protein (CRP), tumor necrosis factor α (TNF-α), the interleukins 1α (IL-1α), 6 (IL-6), 10 (IL-10) and cyclooxygenase 2 (COX-2). In particular, COX-2 is encoded by the prostaglandin-endoperoxide synthase 2 gene (PTGS2). Since variations in the genes that encode these proteins may modify gene expression or function, it is important to investigate whether these variations may change the developing AD. Objetive: The aim of this study was to determine whether the presence of polymorphisms in the genes encoding the aforementioned proteins is associated in Mexican patients with AD. Method: Fourteen polymorphisms were genotyped in 96 subjects with AD and 100 controls by qPCR; the differences in allele, genotype and haplotype frequencies were analyzed. Additionally, an ancestry analysis was conducted to exclude differences in genetic ancestry among groups as a confounding factor in the study. Results: Significant differences in frequencies between AD and controls were found for the single nucleotide polymorphism (SNP) rs20417 within the PTGS2 gene (p= <0.0001**). Ancestry analysis revealed no significant differences in the ancestry of the compared groups, and the association was significant even after adjustment for ancestry and correction for multiple testing, which strengthens the validity of the results. We conclude that this polymorphism plays an important role in the development of the AD pathology and further studies are required, including their proteins

Title: Amyloid β and LPS inhibition of TGF-β signaling in primary rat microglia

Authors: K. O. AFFRAM, K. MITCHELL, S. GOPALASUBRAMANIAN, *A. J. SYMES; Pharmacol., USUHS, Bethesda, MD

Abstract: Persistent microglial activation and chronic neuroinflammation following CNS injury may contribute to long term detrimental sequelae of traumatic injury such as neurodegeneration and seizures. Reduction of this chronic neuroinflammation would therefore be beneficial to improved recovery from injury. TGF-β is a key anti-inflammatory cytokine that could reduce microglial activation and lessen neuroinflammation. We therefore wanted to determine whether TGF-β signaling is perturbed in microglia resulting in a reduction in its anti-inflammatory ability. Indeed, dysfunction of TGF-β signaling has been associated with prolonged neuroinflammatory states in neurodegenerative diseases including Alzheimer's disease. We previously have used LPS as an inflammatory stimulus in microglia, and shown that LPS treatment of primary rat microglia did result in reduced TGF-β signaling. We now have investigated the pathways that mediate this reduction of TGF-β signaling in LPS treated microglia. We also have determined that amyloid β (Aβ) treatment of microglia similarly reduces TGF-β signaling. TGF-β signals through binding to the TβRII receptor, complexing with TβRI to transduce signal. We found that LPS and Aβ dose dependently reduce TβR1 and TβRII mRNA in primary microglia thereby reducing the amount of receptor available to transduce TGF-β signals. To determine the effect of microglial activation on TGF-β mediated gene induction, we pretreated primary microglia with LPS or Aβ overnight followed by TGF-β for 6 hrs. LPS and Aβ reduced induction of the TGF-β induced genes, smad6 and TβR1. To determine which pathways may be involved in this effect, we used a series of pharmacological inhibitors of different pathways. Inhibition of the NFκb pathway (by BAY 11-7082) but not the MAP Kinase (by PD 98059) or IRF3/7 (by BX-795) pathways, prevented LPS and Aβ mediated repression of TβR1 mRNA expression. We also showed that LPS and Aβ treatment resulted in induction of mRNA encoding bambi and snoN, inhibitors of the TGF-β signaling pathway, providing a different mechanism for repression of TGF-β signaling. Finally we showed through propidium iodide cell cycle analysis that Aβ reduced TGF-β mediated microglial death enabling more microglia to survive. In conclusion, the TGF-β signaling pathway is reduced during activation of microglia with LPS or Aβ through NF-kB dependent pathways. Understanding the mechanisms

involved in dysregulation of TGF-β and other anti-inflammatory pathways during neuroinflammation could point to important therapeutic targets for chronic neuroinflammation.

Title: Generation of a floxed human/mouse-chimeric P2X7 receptor mouse

Authors: *T. KHAYRULLINA, A. T. HOPPER, L. DORLEUS, S. B. PODA, R. G. W. STAAL, P. D. WES, T. MÖLLER;
Lundbeck Res. USA, Paramus, NJ

Abstract: Pharmacological differences between rodent and human P2X7 receptor make preclinical studies of P2X7 receptor antagonist efficacy and safety challenging. Most currently available P2X7 receptor inhibitors show a 100-300 fold difference in activity between rodent (mouse and/or rat) and human P2X7 receptors. To overcome this significant hurdle in drug development we have generated a mouse were the endogenous P2X7 receptor gene has been replaced by a humanized version. Given the complexity of the rodent P2X7 receptor gene structure and regulation, simple replacement of the entire P2X7 receptor gene is unlikely to achieve the desired result. To address these issues in a systematical way we first generated a recombinant mouse/human chimeric P2X7 receptor, carrying the human extracellular domain and the mouse intramembrane and intracellular domains. This P2X7 receptor chimera maintained human pharmacological properties, while signaling effectively in mouse cells. Careful selection of genomic integration sites for generation of mice carrying the humanized chimera predicts mouse expression patterns. Addition of LoxP sites to the insert allows for cell specific excision (GFAP-Cre = astrocytes, CXCR1-Cre = microglia) of the chimeric P2X7 receptor for validation experiments. P2X7 receptor chimeric mice are viable and fertile. The detailed characterization of these mice is ongoing.

Title: Analysis of cortical thickness in patients with Acute-on-chronic liver failure

Authors: *S. K. YADAV[1], M. RANGAN[2], V. A. SARASWAT[2], E. WANG[1], F. MARINCOLA[1], R. K. GUPTA[3], M. HARIS[1];
[1]Sidra Med. and Res. Ctr., Doha, Qatar; [2]Dept. of Gastroenterology, Sanjay Gandhi Post Grad. Inst. of Med. Sciences,, Lucknow, India; [3]Fortis Mem. Res. Inst., Gurgaon, Delhi, India, India

Abstract: Acute-on-chronic liver failure (ACLF) often presents with liver failure as the first evidence of liver disease, manifested by serious complications such as hepatic encephalopathy (HE). This syndrome is generally thought that results from neuronal dysfunction, morphological changes in astrocytes, and neuronal loss leads to functional deficits of varying severity. Neuroimaging techniques including diffusion tensor imaging and MR spectroscopy have been used to characterize the brain tissue injury and altered cerebral metabolites in these patients. However, except for nature of tissue changes and metabolites alteration, regional cortical thickness integrity in ACLF is unknown. Here, we have evaluated the cortical thickness in patients with ACLF and compared the changes with normal healthy volunteers. In the current study, 10 patients with ACLF and 8 healthy controls were studied. Magnetic resonance imaging (MRI) was performed at 3-T clinical MR Scanner using a standard quadrature head coil. Conventional T2- and T1-weighted imaging and high-resolution T1-weighted structural imaging were performed on each subject. We used high-resolution T1-weighted structural images for measuring regional cortical thicknesses in ACLF and control subjects using FreeSurfer. Reduced cortical thicknesses were observed on left hemisphere in insular cortex, inferior temporal, and pre-central regions, whereas on right hemisphere, superior temporal, parstriangularis, and post-central regions showed reduced cortical thickness. These multiple brain sites are involved in regulating various functions including cognitive, autonomic, language, visual sensory and motor functions. We suggest that neuronal loss and decreased cellular density due to increased cerebral hyperammonemia, proinflammatory cytokines and free radicals might be possible reasons for reduced cortical thickness in these patients. Further, study in animal model may useful to assess this correlation, which may provide more accurate explanation for the reduced cortical thickness.

Nevertheless, the current method may easily implement on clinical scanner to evaluate and monitor the brain tissue changes in patients with liver failure during the course of treatment.

Abstract: Brain-derived neurotrophic factor (BDNF) expression was significantly enhanced with increasing differentiation of colon cancer and also increased with the advancing of the clinical staging. The co-expression of BDNF and TrkB receptor in colon cancer patients was found to be significantly associated with synchronous liver metastasis and peritoneal metastasis. In the presence of BDNF, the migratory activities of colon cancer cells, HCT116 and SW480, were found to be significantly enhanced. Our previous study reported that VEGF-VEGF receptor interaction promotes cancer motility. In this study, we found that the expression of VEGF was increased in response to BDNF stimulation. The enhancement of BDNF-induced cancer cell migration was antagonized by administrating a VEGF-neutralizing antibody. Hemeoxygenase

(HO)-1 is known to be involved in the development and progression of tumors. Expression of HO-1 was also elevated in response to BDNF stimulation, while BDNF-induced increase of cell migration was antagonized by inhibition of HO-1. Moreover, inhibition of HO-1 effectively reduced the BDNF-enhanced VEGF expression. These results indicate that BDNF enhances migration of cancer cells by regulation of VEGF/HO-1 signaling pathway. Our present study may provide insights to molecular mechanisms underlying how BDNF, VEGF/HO-1 promote cancer cell motility.

Abstract: Objective Evaluate executive functions in patients with frontal cerebral tumors. Method Twelve patients with diagnosis of frontal meningioma tumor type classified according to the anatomical location and a group of twelve healthy control participants matched for age, gender and education were evaluated. For the assessment of Executive Functions (EF) the following tests were applied: Backward digit span, Backward Corsi block test, Verbal fluency (semantic and phonemic), Tower of London-Drexel University version (TOL-DX), Trail Making Test (TMT) A and B, Stroop Test, Wisconsin Card Sorting test (WCST), Iowa Gambling Task (IGT), Exam Kenningar for exploration of Metaphorical Thinking. Results Comparisons among patient and healthy control groups revealed the following: 1) no significant difference was found for age and education and 2) in EF, the control group had higher scores on all tests, however statistical significant differences were found in the following tests: backward Corsi block test (p=0.04), semantic fluency (p=0.007), time of execution (p=0.009) and resolution (p=0.015) of the TOL-DX, time (p=0.004) and total errors of the TMT B (p=0.3), Stroop test (p=0.001), time of the IGT (p=0.05) and correct answer of the Kenningar Exam (p=0.02). In comparison, executive functioning related to laterality of tumors, significant differences were found in Stroop

Test (p=0.01) obtaining a higher score in patients with right lobe tumor and the number of attempts in the WCST (p=0.02) was higher in patients with left lobe tumor. Analysis between the medial, lateral and orbitofrontal regions revealed: 1) significant difference in the cognitive flexibility (correct answers of the WCST) in patients with orbitofrontal tumor have higher scores (p = 0.02), 2) in decision-making, patients with fronto-lateral tumor showed a greater number of choices of deck 3 (advantageous) in the IGT (p = 0.02). Conclusions One way to approach the knowledge of cognitive processes is by studying the functional changes in patients with brain damage. Differences in performance in tests of executive functioning were observed in patients with frontal brain tumors compared to healthy controls. Also, the execution is different between patients with right and left tumor, reinforcing differences in hemispheric localization. The results provide a better understanding of the brain executive dysfunctions caused by frontal cerebral tumors to thereby guiding more timely and effective intervention. Title: Development of highly potent, selective BET bromodomain inhibitors that are CNS penetrant and effective in rodent models of brain cancer

Authors: J. ALBERT[1], A. JOHNSTONE[3], C. PENAS[3], V. STATHIAS[3], S. BROTHERS[3], N. AYAD[3,2], S. JOHNSTONE[1], *C. R. WAHLESTEDT[3];

Abstract: Numerous highly potent, highly selective BET inhibitors have emerged and some (e.g. IBET-762) have advanced to clinical trials. We aimed to develop BET inhibitors as drug for untreatable forms of brain cancer including GBM (glioblastoma multiforme) and metastatic brain cancer. Unfortunately, we found that they are poorly suited as drugs for any indications that require high CNS drug exposure because they have high susceptibility to efflux transporters and low passive cellular permeability. To improve CNS penetration, we employed a structure-based design approach that involved (1) disrupting key transporter pharmacophore points and (2)

altering the physical properties to improve cellular permeability. In this manner we have identified EP313 which has strong potency (BRD4 IC50 7 nM), low efflux, high permeability moderate oral bioavailability in mouse (59%) and high CNS exposure. EP313 shows antiproliferative effects in TMZ-resistant cancer patient stem cell lines and dose-dependent tumor reduction in nu/nu mice that were centrally transplanted with luciferase-expressing GBM cell xenografts.

Title: Selective siRNA-mediated suppression of nSR100 (SRRM4) induces the cell death of small cell lung cancer

Authors: ***M. SHIMOJO**[1], Y. SHUDO[2], S. ITO[3];
[2]Psycosomatic Med., [3]Med. Chem., [1]Kansai Med. Univ., Hirakata/Osaka, Japan

Abstract: Small cell lung cancer (SCLC) is a highly malignant form of cancer, which originates from primitive neuroendocrine cells in the lung. SCLC cells express several autocrine neurotransmitters and neuropeptides and their respective receptors. It was reported that the expression of these neuronal markers is regulated by RE1-silencing transcription factor (REST). In SCLC cells, an SCLC-specific isoform of REST (sREST) is highly expressed while full-length REST expression is too low to detect, suggesting that the expression of sREST correlates with the pathogenesis of SCLC. We previously reported that the neural-specific SR-related protein of 100 kDa (nSR100) abnormally activates the alternative splicing of REST (Mol. Cancer Res. 11, 1258 (2013)) in SCLC cells. Repression of nSR100 by specific siRNAs affected the expression of REST and sREST proteins and mRNAs in SCLC cells, while no change in NSCLC cells. Expression of siRNAs showed low viability of SCLC cells, suggesting apoptosis induced.

There is recently increasing evidence that miRNA expression plays a fundamental role in gene regulation and may contribute substantially to cancer progression through translational repression. We analyzed the miRNA expression in SCLC cells using microarray analysis, suggesting that some of down-regulated miRNAs are predicted to interact with nSR100 mRNA. Analysis of these down-regulated miRNAs in patients' serum showed that the expression of a specific miRNA was significantly higher in SCLC patients than in other tumor patients. Furthermore we have found the miRNAs in SCLC patients' serum were selectively incorporated in the exosome. SCLC cells cultured on Matrigel in the condition which causes the up-regulation of nSR100 expression showed that the secretion of the miRNA in exosome was increased, while the intracellular miRNA significantly decreased. Taken together these results suggest that the miRNA targeting nSR100 might be a novel SCLC-specific biomarker. Overall the results of this study highlight the important role of nSR100 targeting apoptosis in SCLC.

Title: Neuroplasticity changes in rat brain following targeted Gamma Knife irradiation

Authors: ***J. CONSTANZO**[1], M. DESCOTEAUX[2], M. LEPAGE[1], L. TREMBLAY[1], M. DUMONT[2], J.-M. LONGPRÉ[3], K. KIRBY[3], S. GEHA[4], L. MASSON-COTÉ[1], P. SARRET[3], B. PAQUETTE[1];

Abstract: Purpose: Stereotactic radiosurgery (SRS) is a well-established treatment for many types of brain tumors. However, surrounding healthy tissues may also receive a significant radiation dose during SRS. This can lead to brain swelling, necrosis, and neuronal dysfunction, thus inducing delayed adverse effects such as cognitive decline and stroke-like symptoms. We thus propose to use neuroimaging (diffusion MRI (dMRI)) and behavioral assessment tools to enhance our understanding of the neuroplasticity changes associated with brain irradiation. Results: Thirty male Fisher rats were irradiated using a targeted irradiation in the primary

somatosensory area (S1), hippocampus and primary motor cortex (M1) of the right hemisphere. Using the Leksell Gamma Knife Perfexion®, the mean deposited dose into the S1, hippocampus and M1 structures were respectively, 113 ± 4 Gy, 24 ± 10 Gy, 41 ± 8 Gy. At different time points after irradiation, rats were scanned with a small animal MRI scanner (7T) using high angular resolution dMRI (HARDI) to assess the integrity of neuronal interconnections. HARDI tractography and diffusion metrics revealed displacements and breakdown in neuronal pathways. Also, brain-region specific sensitivity to irradiation was determined using different behavioral tests assessing: i) motor function (Rotarod and Actimetry), which revealed that brain irradiation did not affect motor performance (M1-related), ii) the anxiety-like behaviors and learning/memory performances (Elevated plus maze and Morris water maze), which were significantly decreased in rats exposed to gamma irradiation, probably reflecting right amygdala and hippocampus alterations, and iii) sensory pain behaviors (formalin test) that revealed dysfunction in descending pain inhibition (S1-related). In addition, myelin sheath damage and reactive astrogliosis were found around the radionecrosis in the surrounding white matter by immunohistochemistry. Conclusion: Altogether, our results revealed that SRS treatment induces region-specific plasticity (i.e. structural and function changes), as demonstrated by neuronal matrix remodeling using diffusion MRI and appropriate HARDI reconstruction, and changes in behavioral responses.

Title: Mechanisms underlying the sorting of growth factor receptors

Authors: *M. B. GIREUD[1,2], A. BEAN[3,4,2];
[1]Neurobio. and Anat., Ut Houston Hlth. Sci. Ctr., Houston, TX; [2]Univ. of Texas Grad. Sch. of Biomed. Sci., Houston, TX; [3]Neurobio. and Anat., UT Houston Hlth. Sci. Ctr., Houston, TX; [4]Pediatrics, M.D. Anderson Cancer Ctr., Houston, TX

Abstract: Membrane proteins (e.g. transporters, ion channels, receptors) reside on the cell surface and influence cellular behavior in response to extracellular signals. Regulating their residence time on the cell surface can modify the activity of these membrane proteins and allow for cellular adaptation according to environmental conditions. Removal of membrane proteins by endocytosis follows a canonical itinerary in which cargo passes through morphologically and biochemically defined organelles. After internalization from the plasma membrane and transport from early to late endosomes, proteins destined for degradation in the lysosome are internalized into the lumen of late endosomes via membrane invagination and vesicle fission. The resulting organelle, the multivesicular body (MVB), is characterized by a limiting membrane and the presence of internal vesicles. Proteins that are sorted into internal MVB vesicles are subject to degradation upon endo-lysosomal fusion, while those that remain on the limiting endosomal membrane are recycled. Ubiquitin facilitates the sorting of protein cargo into the internal vesicles of the MVB by allowing their interaction with components of the sorting machinery, the endosomal sorting complexes required for transport (ESCRTs). Defects in intracellular trafficking pathways can modulate the kinetics of membrane protein signaling by altering their surface expression that can contribute to the pathogenesis of diseases including various cancers and neurodegenerative diseases. To examine the mechanisms underlying endosomal sorting, we have established a cell-free assay that measures both MVB formation and the sorting of a cargo protein into the endosomal lumen (degradation), as well as vesicles that bud from endosomal membranes (recycling). Both sorting events are dependent on cytosolic proteins. We have isolated and characterized both vesicles and cargo that are sorted from endosomal membranes and have examined the cytosolic components required for both the inward and outward sorting events. These experiments have revealed requirements for various cytosolic proteins and suggest that the mechanisms underlying these two sorting events may be distinct. These mechanistic differences could possibly be exploited for therapeutic benefit in diseases such as glioblastoma, where EGFRviii is though to be continuously recycled resulting in uncontrolled cell growth.

Title: Neural etiology and characteristics of neurofibromas in human neurofibromatosis type 1 patients

Authors: *G. HOUK[1], J. P. WYMER[2], P. J. ALBRECHT[1], P. KNIGHT[3], H. WEINBERG[4], F. L. RICE[1];
[1]Integrated Tissue Dynamics, LLC, Rensselaer, NY; [2]Neurol., Albany Med. Col., Albany, NY; [3]Chilren's Tumor Fndn., New York, NY; [4]Plastic Surgery, Mount Sinai Sch. of Med., New York, NY

Abstract: In addition to neurofibroma tumors, NF1 patients experience chronic pain from unafflicted skin locations. With IRB approval from St. Peters Hospital, Albany, potential sources of this pain were investigated by multi-molecular immunofluorescence assessments of 3mm skin punch biopsies taken from palmar and dorsal hypothenar sites on the hand and from the distal leg of 19 NF1 and 16 control adult subjects. Labeling of all innervation with anti-protein-gene-product 9.5 (PGP) revealed a single, discrete, miniscule neuroma in at least 1 of the 3 biopsies from most of the NF1 subjects. Nearly all of these “microneuroma” were sprouting from the margin of specific structures - dermal papillae, sweat glands, arterioles, hair-follicles - that are normally targets of dense, multiple types of innervation, which was mostly still intact. The densely concentrated fibers had neurochemical features of C-fibers that expressed growth associated protein (GAP43) and lacked neuropeptides. Intermingled S100-labeled Schwann cells were in proportion to the fibers and lacked markers indicative of excessive proliferation thought to be the genesis of neurofibromas. In contrast to Schwannomas, neurofibromas are known to contain other cell components leading us to hypothesis that the microneuromas and their affiliated target structure may be the sites of neurofibroma genesis. To test this, we examined 20 overt small, neurofibromas (2-5mm) from 2 patients. Most contained evidence of a core structure, such as an overgrown hair follicle from which excessive, compact innervation spread outwards (like a mushroom cap) just below the subepidermal compact papillary dermis. GAP43-labeling revealed that the expanding nerve fibers remained extremely dense in the larger neurofibromas, where PGP expression diminished and failed to reveal most of the innervation. Schwann cells increased intermingled with and in proportion to (but not in excess of) the sprouting innervation. These results suggest that the etiology of neurofibromas may primarily be sprouting of small number axon terminals instead of excessive Schwann cell proliferation.

Abstract: In the majority of cases of patients with metastatic cancer of unknown primary origin, there is no an adequate therapeutic treatment. The objective of this study was to develop a model of nociception induced by bone metastasis through inoculating glioma within Wistar rat femur. The different stages of the cancer depended on the amount of inoculated cells, we injected between 50,000 and 100,000 cancer cells into the femur. It was used the von Frey test, Hargreaves plantar test, and for detection of spontaneous pain, the animals were filmed by 30 minutes and were quantified the number of forelimbs shake. Using this model, we could showed that glioma can remain in the bone marrow and have the capacity to produce osteolysis, bone fracture and peripheral and central pain, in similar way as it has been reported with bone metastasis caused by prostate cancer, breast and lung. The analysis of results showed changes in mechanical and thermal hypersensitivity and spontaneous pain, these behavioral changes occurred significantly after 14 days post-inoculation. We conclude that this model could be an excellent tool, showing for the first time that glioma may be maintained by the skeletal system, producing changes in the mechanical and thermal hypersensitivity and spontaneous nociception.

Title: The interaction of ETS domain protein Elk-1 with mitotic kinases and its phosphorylation in brain tumor model cells

Authors: *O. ARI UYAR[1], O. DEMIR[2], B. YILMAZ[2], I. AKSAN KURNAZ[3];
[1]Sci. Inst., Istanbul, Turkey; [2]Yeditepe University, Sci. Inst., Istanbul, Turkey; [3]Gebze Tech. University, Dept. of Mol. Biol., Kocaeli, Turkey

Abstract: Elk-1 is a member of Ets (E twenty-six) oncogene family of transcription factors that have important roles in development and disease. Elk-1 is known to be phosphorylated by PKC, MAPK and PI3K pathways and any abnormalities present in these pathways as well as changes in the protein structure and expression can give an advantage for the growth of tumors. Through various projects in our laboratory, we have identified a different mitotic role of the mitogenic transcription factor Elk-1 in various brain tumor model cell lines such as glioma, glioblastoma and neuroblastoma. Elk-1 is able to bind microtubules and microtubule related motor proteins in a phosphorylation dependent manner. The mitotic localization of Elk-1 transcription factor in mitotic spindle poles in prophase and metaphase, in midzone in anaphase, and in spindle midbody in telophase / cytokinesis transition has been demonstrated for the fist time which is most likely related to its non-transcriptional mitotic role. This mitotic localization of Elk-1 and its interaction with mitotic motor proteins indicates a non-transcriptional mitotic role of Elk-1. In the light of the in silico analysis within this framework has elucidated a number of potential mitotic kinase phosphorylation motifs on Elk-1 such as T133, S200 and S202 for Cdks, S106, T108 and S198 for Plk1, T199 and S200 for Aurora A kinase. Mitotic kinases have pivotal roles during regulation of this mechanism as well as cell cycle progression, centrosome maturation and microtubule dynamics that is pivotal for the formation of bipolar mitotic spindle and accurate segregation of chromosomes. Any abnormalities in the function of these kinases may lead to uncontrolled proliferation, aneuploidy, and genetic instability that lead cancer development and progression. Elucidating the possible interaction between Elk-1 and target mitotic kinases may help to understand the potential role of Elk-1 during mitosis and its contribution to brain tumor formation.

Title: Effect of tumor characteristic and location on language activation

Authors: *J. M. JANSMA[1,2], G.-J. RUTTEN[2];
[1]UMC Utrecht, Rudolf Magnus Inst. of Neurosci., Utrecht, Netherlands; [2]Dept. of Neurosurg., St. Elisabeth Hosp., Tilburg, Netherlands

Abstract: Introduction: Functional MRI can be an important tool to visualize and study brain activity in patients with a brain tumor. For instance, fMRI could be used to detect abnormal activity in specific locations. However, this is only valid if the overall pattern of activity is not substantially changed by the presence of the tumor. However, in order to interpret patterns of brain activity, it is important to know that the tumor does not change the activity pattern to such an extent that for instance spatial normalization might not be a valid tool anymore. In this study we tested the robustness of the activity pattern associated with a verb generation paradigm, a common and much applied clinical fMRI paradigm. Method: Patients with either a LGG on the left (N = 38) or right hemisphere (N = 17), or a HGG in the left (N = 31) or right hemisphere (N = 28) were included in the study. Al patients performed a verb generation task that is commonly used in clinical fMRI. All fMRI scans were produced using a 3T Philips scanner (PRESTO pulse sequence, voxelsize: 4x4x4 mm, TE: 1.5 sec), corrected for movement, and spatially smoothed (FWHM: 12mm). After preprocessing, a GLM was performed to extract beta scores per voxel, indicating level of involvement in the task. We spatially normalized all b-maps from all subjects in to MNI space using FSL software. Using the AAL atlas, we calculated the average activity for all 90 cortical and subcortical regions per subject and tested for differences in age as well as differences in activation between the four groups (ANOVA, $p< 0.01$, uncorrected). Results: Age of subjects differed significantly between groups ($F = 11.2$; $P < 0.01$), as HGG patients were significantly older (50.6 years) than LGG patients (37.1 years). None of the 90 analyzed ROIs showed a significant difference between the groups. Discussion: Results indicate that the characteristic (low grade or high grade) and hemisphere did not significantly affect the activity pattern related to verb generation, using common analysis techniques for fMRI such as linear spatial normalization after spatial smoothing. This result indicates that group level statistics based on common techniques are also valid for patient populations with a LGG or HGG tumor in left or right hemisphere.

Title: Lithium prevents irradiation-induced brain injury and long term cognitive dysfunction in the young rat

Authors: *C. ZHU[1], K. ZHOU[2], C. XIE[3], Y. ZHANG[4], T. LI[4], K. BLOMGREN[5];
[1]Ctr. For Brain Repair & Rehabilitation, Univ. of Gothenburg, Goteborg, Sweden; [2]Univ. of Gothenburg, Center for Brain Repair and Rehabilitation, Sweden; [3]Ctr. for Brain Repair and Rehabil., [4]Univ. of Gothenburg, Gothenburg, Sweden; [5]Karolinska Institutet, Stockholm, Sweden

Abstract: Background: There is growing evidence that lithium (Li) is protective in a variety of brain injury paradigms. Cranial radiotherapy in children usually results in cognitive as well as hypothalamic/pituitary dysfunction. Objective: Our aim was to investigate the effects of lithium treatment on cognitive and endocrine function in the juvenile brain after irradiation. Design/Methods: Male Wistar rats were injected with 2 mmol/kg LiCl i.p. on postnatal day 7 (P7) and additional lithium injections, 1 mmol/kg, were administered at 24 h intervals for up to 14 days (until P20). On P11 the whole brain received a single IR dose of 6 Gy. Blood samples were collected from the tail vein 1, 3, and 5 weeks after IR. Results: Irradiation-induced progenitor cell death in the subgranular zone of the hippocampus was reduced by lithium treatment. Neurogenesis was reduced by irradiation but was partly rescued by lithium. Inflammation in the hippocampus at 6 h after irradiation was reduced by lithium. Body growth was reduced by irradiation, but not by lithium treatment. Thyroid-stimulating hormone and growth hormone levels were decreased in irradiated rats but not in rats treated with lithium. Motor hyperactivity and anxiety-like behavior, as well as cognitive impairment after irradiation were normalized by lithium. Conclusion: Lithium can be safely administered to prevent both short-term and long-term damage to the immature brain caused by ionizing radiation.

Title: Evidence for the existence of tumor stem progenitor-like cell markers and aggressive prolactin-secreting tumors in the pituitary of fetal alcohol exposed rats

Authors: S. JABBAR[1], O. GANGISETTY[1], *D. K. SARKAR[2];
[1]Animal Sci., Rutgers, the State Univ. of New Jersey, New Brunswick, NJ; [2]Rutgers, SUNJ, New Brunswick, NJ

Abstract: Prolactin-secreting pituitary tumors (prolactinomas) are the most common pituitary tumors in humans. Majority of prolactinomas are adenomas and benign and slow growing, but in some cases, they are locally aggressive and invasive. In case of malignancy and aggressive tumor, stem progenitor-like cell (cancer stem cells; CSC) serve a critical role in the tumor microenvironments and in the processes of cancer cells proliferation, migration, invasion and angiogenesis. The evidence for the existence of CSC in rat pituitary tumors still needs to be elucidated. We determined whether fetal alcohol exposure enhances the population of CSC and aggressive prolactinomas in the pituitary in response to estradiol. Pregnant Fischer 344 rats were fed between gestational days 7 and 21 with a liquid diet containing alcohol (AF), pair-fed with isocaloric liquid diet (PF), or fed ad libitum with rat chow (AD). At 60 days of age, female offspring rats were ovariectomized and received a subcutaneous estradiol implant. These rats were sacrificed at 3 months after the estradiol implants. Estradiol treatment increased pituitary weight about 5-folds in AD and PF treated groups while increased about 30-folds in the AF treated group. Pituitary tumors were collected and enzymatically digested and cultured in serum-free and phenol red-free DMEM, and supplied with EGF, bFGF, and 1X B27 supplement in ultra-low attachment 24-well plate. The growing spheres were mechanically dissociated to make serial passaging. We assayed a panel of genes related to multipotency (OCT4, NANOG, KLF4, and CD133) and found mRNA expressions were significantly higher in pituitary spheres of AF animals as compared to AD and PF groups. Differentiated tumor cells of AF animals also showed strong nuclear p53 and monoclonal Ki67 and PRL immunoreactivity, higher mRNA levels of hemorrhage-associated genes (VEGF and MMP-9), and higher cell proliferation, migration and colony formation rates as compared to control groups. These data provide evidence for the existence of CSC and possible development of aggressive prolactinomas in the pituitary after estrogen treatment in fetal alcohol exposed female rats.

Title: Hippocampal subfield deformity in breast cancer patients with self-reported cognitive concerns

Authors: *A. APPLE[1], A. J. RYALS[2], L. I. WAGNER[2,3], D. CELLA[1,2,4,3], F. J. PENEDO[1,2,3], J. L. VOSS[2,4], L. WANG[1,5,3];
[1]Dept. of Psychiatry and Behavioral Sci., [2]Dept. of Med. Social Sci., [3]Robert H. Lurie Comprehensive Cancer Ctr., [4]Ken and Ruth Davee Dept. of Neurol., [5]Dept. of Radiology, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Objective. Cancer survivors including those who received chemotherapy have lingering cognitive problems, however the anatomical basis for those cognitive problems has yet to be found. Neuroimaging studies in this population suggest gray matter volume loss in several brain regions including the temporal lobe. Clinical studies report volume loss in the hippocampus and animal models of chemotherapy report cell loss in the dentate gyrus, a subfield of the hippocampus. However, few studies have performed detailed analysis of the hippocampus and its subfields on cancer patients. This study used high-dimensional deformation mapping analysis to test whether hippocampal subfields differ in breast cancer survivors who received adjuvant chemotherapy coupled with hormone blockade therapy. Furthermore, we explored how subfield abnormalities were related to subjective self-reported concerns and objective cognitive ability. Participants and Methods. 3T MPRAGE MRI images were acquired from 16 pre-menopausal breast cancer patients and 18 healthy controls. Breast cancer patients had undergone chemotherapy within eighteen months prior to the study, and they were all receiving estrogen-blockade therapy at the time of the study. Automated high-dimensional deformation mapping was used to compare hippocampal shape differences between groups Self-reported subjective concerns were assessed with NeuroQOL and PROMIS measures, and objective cognition was assessed with the NIH Toolbox Cognition Battery. Results. Patients reported significant cognitive concerns compared to controls, but did not differ on objective tests of cognition. Groups differed significantly in hippocampal shape ($p=0.016$). Using high-dimensional

deformation mapping, we localized this difference in deformation to specific sub-regions of the hippocampus. Relative to controls, patients showed inward deformation in the right CA1, (p=0.042) the left CA2-4 + dentate gyrus (, p=0.027), and the right subiculum (p=0.022). No associations were observed between deformation and measures of cognition or self-reported cognitive concerns in patients. Conclusions. This study is the first of its kind to examine subfield deformity as it relates to cognitive function in cancer patients. Although no differences in objective cognition were observed, given the morphological changes in hippocampal structure and self reported cognitive difficulties, it is possible that the neuropsychological measures are either not sensitive enough to detect the subjective deficits that patients reported or are measuring cognitive domains not directly associated with the detected damage.

Title: Blocking Aquaporin 1 ion channel function with AqB011 could be a new therapeutic approach for preventing cancer metastasis

Authors: ***M. KOURGHI**[1], J. PEI[2], M. DE IESO[2], A. YOOL[2];
[1]Physiol., [2]The Univ. of Adelaide, Adelaide, Australia

Abstract: Aquaporins (AQPs) are members of the major intrinsic family of proteins (MIPs) that allow pathways for water flux across cell membranes. AQPs are found across different organisms at all levels of life. To date 13 mammalian members of this family have been identified, AQP0-AQP12. AQP1 is a water channel, and under permissive conditions, also functions as a nonselective monovalent cation channel activated by intracellular cGMP. AQP1 expression facilitates cancer cell migration and spread in various cancer types including glioblastoma. Wild-type human AQP1 channels expressed in Xenopus laevis oocytes were characterized by two-electrode voltage clamp and optical osmotic swelling analyses. Cell migration was performed using wound closure assay in presence of a mitotic inhibitor to distinguish motility from proliferation. The current study has characterized a series of bumetanide derivatives for blocking effects on the ion channel function of AQP1, independent of the water channel permeability. The compound AqB011 imposed the most potent block of the

AQP1 ion channel (IC50 value of 15uM) but it had no effect on the water channel activity. The order of potency was AqB001 ≤ AqB006 < AqB050 < AqB007 < AqB011. These results were consistent with in silico models predicting energetically favoured binding of the compound to the channel. AqB001 had the lowest while AqB011 possessed the highest apparent binding affinity to the channel, with likely site of interaction of AqB011 being at loop D gating domain. Furthermore AqB011 was tested on AQP1 expressing cancer cell lines and found to significantly reduce the migration ability of the cancer cells. Therefore inhibition of Aquaporin 1 could an important new therapeutic approach for reducing cancer metastasis.

Title: Conditional knockout of Ankyrin-g in mouse forebrain: potential model of bipolar disorder

Authors: *S. ZHU[1], Z. CORDNER[1], J. KIM[2], X.-F. WANG[1], M. PLETNIKOV[1], K. TAMASHIRO[1], C. A. ROSS[1];
[1]Psychiatry, The Johns Hopkins Univ., Baltimore, MD; [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: The ANK3 locus, encoding Ankyrin-G, shows genome-wide significance in GWAS for bipolar disorder, and some significance for schizophrenia. In the central nervous system Ankyrin-G mainly localizes to the axon initial segment (AIS), where action the potential is initiated and propagated. Schizophrenia postmortem brain studies indicate decreased Ankyrin-G expression at axon initial segments of pyramidal neurons in the cortex. We have established a forebrain-specific Ankyrin-G conditional knockout (KO) mouse model, in which knockout is restricted to adulthood. Behavioral characterization showed that the forebrain conditional Ankyrin-G knockout model displays increased motor activity, increased exploratory activity, and less anxiety-like behavior, reminiscent of mania. At the AIS, pyramidal neurons of the cortex have strikingly decreased GABAergic marker positive presynaptic terminals, consistent with disinhibition. Chronic application of several anti-manic agents such as Lithium and Valproic Acid at therapeutic levels ameliorated the hyperactivity. Moreover, after social defeat stress, the mice displayed depression-like behavior. This forebrain-specific Ankyrin G conditional knockout mouse model may be useful as potential model of bipolar disorder, in order to explore neurobiological mechanisms, and to develop new therapeutic strategies for bipolar disorder and possibly schizophrenia.

Title: A developmental redox dysregulation leads to impaired thalamocortical network dysfunction in a mouse model of schizophrenia

Authors: *J. H. CABUNGCAL[1], P. STEULLET[1], R. KRAFTSIK[2], T. SALT[3], M. CUENOD[1], K. Q. DO[1];
[1]Dept. of Psychiatry, Univ. Hosp. of Lausanne, Lausanne-Prilly, Switzerland; [2]Dept. of Fundamental Neurosci., Univ. of Lausanne, Lausanne, Switzerland; [3]Inst. Ophthalmology - Visual Neurosci., Univ. Col. of London, London, United Kingdom

Abstract: Dysfunction of parvalbumin-expressing fast-spiking interneurons (PVI), essential for coordinating neuronal synchrony during sensory and cognitive processing, is a hallmark in the pathophysiology of schizophrenia (SZ). Oxidative stress as observed in schizophrenia affects PVI. The effect of oxidative stress, in PVI rich brain regions, during specific developmental time windows is lacking. One PVI rich brain region of interest is the thalamic reticular nucleus (TRN), a communication and gating hub between the thalamus and the cortex. Providing evidence that oxidative stress impairs normal TRN PVI developmental trajectory and function may provide better understanding of the role of TRN in the pathophysiology of SZ, and render it a candidate for drug target. We used mice with impaired synthesis of glutathione (Gclm KO) to investigate the effect of redox dysregulation on maturation and functional integrity of PVI in the TRN at various periods of postnatal development. A developmental redox dysregulation rendered PVI highly vulnerable to oxidative stress already in juvenile age (P20), which worsened at pubertal (P40) and adulthood (P90). The perineuronal net (PNN) surrounding mature PVI was impaired at pubertal (P40). PVI with little, or no surrounding PNN, were mostly affected by

oxidative stress in adulthood (P90). Elevated levels of oxidative stress, PVI and PNN deficit in the TRN can be prevented with the anti-oxidant N-acetylcysteine treatment. Preliminary electrophysiological recording in late adolescent indicates an abnormal connectivity between the TRN and the thalamocortical neurons. Our data show that PVI and their PNN are mostly compromised at adolescent (P40), when many changes in life take place. The data also reveals early vulnerability period of PVI in the TRN to oxidative stress and the need to develop therapeutic approaches based on anti-oxidant and redox regulator compounds for preventive treatment in young at-risk subjects. These findings suggest that a developmental redox dyregulation in the TRN could play a critical role in impairing the thalamocortical gating system in animal models of SZ, which could arise from the impact of genetic abnormalities on this circuitry during the neurodevelopmental period.

Title: Environmental stressors induce schizophrenia-like symptoms based on genetic dysfunction of cannabinoid type 2 receptor and K-Cl cotransporter KCC2

Authors: *H. ISHIGURO[1], K. TABATA[1], A. OKABE[2], N. MOTOHASHI[1], E. S. ONAIVI[3]; [1]Univ. of Yamanashi, Chuo, Yamanashi, Japan; [2]Div. of Physiome, Dept. of Physiology, Hyogo Col. of Med., Hyogo, Japan; [3]Dept. of Biol., William Paterson Univ., Wayne, NJ

Abstract: Major depression and schizophrenia are mental health problems associated with stressful events in life based on certain genetic background. In our previous study, we have

demonstrated a high incidence of polymorphisms in the Cannabinoid CB2 Receptor gene (CNR2) and K-Cl cotransporter gene (KCC2) in schizophrenia and depression in Japanese population. The CB2 receptor has behavioral roles in response to pharmacological, immunological and psychological stresses via HPA axis. KCC2 also works in schizophrenia by modulating GABAergic neural function in brain. Therefore, we further examined a functional relationship between stressors and those molecules using those knockout mice as schizophrenia and depression models in this study. First we have confirmed that neither Cnr2 knockout mice nor Kcc2 knockout mice did not show any difference in PPI and in Zero maze test. Then we tested several stressors in mice models. Methamphetamine was injected to those mice to examine their locomotion as acute response and as reverse tolerance. The Cnr2 knockout mice, but not Kcc2 knockout mice showed more locomotive activity after the acute treatment. Kcc2 knockout mice instead showed dramatic enhancement in locomotion after development of reverse tolerance. Poly-IC was injected i.p. to Cnr2 knockout mice, and their locomotor activity was measured 72 hours after the injection and compared with those of the wild type controls. The heterozygote mice relatively reduce their locomotion in the test cage. Also heterozygote Cnr2 knockout mice show more anxiety in Zero maze than wild type after Poly-IC injection. Either Fkbp5 expression in Cnr2 knockout mice brain or Gad1 expression in Kcc2 knockout mice brain were differed after they developed behavioral phenotypes above. It was interpreted that mice with those genetic dysfunctions develop psychiatric behaviors if they experienced several stresses. Further studies are required to determine specific fragile age to the stressors based on each genetic background in the etiology of those psychiatric diseases.

Title: The relationship between parvalbumin-positive interneuron density in the auditory and frontal cortices and hearing loss in a mouse model of 22q11.2 Deletion Syndrome

Authors: *F. A. ZINNAMON[1,2], S. S. WENAS[1], K. H. WANG[2], J. F. LINDEN[1];
[1]Ear Inst., Univ. Col. London, London, United Kingdom; [2]Unit on Neural Circuits and Adaptive Behaviors, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: 22q11.2 Deletion Syndrome (22q11DS) is a genetic syndrome that results from a 1.5-3Mb congenital multigene deletion on the long arm of chromosome 22. Occuring in 1:4000 live births, it is the most common genetic microdeletion syndrome. Approximately 25-30% of adults with 22q11DS develop schizophrenia during adolescence or adulthood. As one of the most significant known cytogenetic risk factors for schizophrenia, 22q11DS holds the potential to provide insight into neural systems abnormalities associated with schizophrenia and genetic risk for schizophrenia. The Df1/+ mouse model of 22q11DS recapitulates many features of human 22q11DS and schizophrenia, including cognitive impairment and frequent otitis media, a middle ear disease that can cause conductive hearing loss. In other model systems, both hearing loss and schizophrenia risk factors have been shown to be associated with abnormalities in parvalbumin-positive (PV+) inhibitory interneuron circuitry in the cortex. However, the relationship between hearing loss, genetic risk of schizophrenia, and PV+ interneuron circuitry remains poorly understood. Here we explored this relationship through studies of PV+ interneuron density in auditory and frontal cortices of WT mice and Df1/+ mice with and without conductive hearing loss. Previous work has shown that approximately half of Df1/+ mice have conductive hearing loss due to otitis media; moreover, the hearing loss is frequently monaural. We tested for otitis media or hearing loss in both left and right ears of Df1/+ mice and their WT littermates, using tympanic membrane inspection and/or auditory brainstem response measurements. Then, we performed PV+ immunohistochemistry on coronal sections through the auditory and frontal cortices of the mice, and quantified PV+ interneuron density across cortical layers. Comparing results between Df1/+ and WT mice, we found significant reductions in PV+ interneuron density in Df1/+ mice, especially in middle and lower layers of the primary auditory cortex. However, among the Df1/+ mice, we also found a significant correlation between reduced PV+ interneuron density in the auditory cortex and hearing loss in the contralateral ear. The results suggest that genetic risk of schizophrenia and developmental hearing loss could interact to produce cumulative abnormalities in PV+ interneuron networks in the cortex. Implications of these findings will be discussed in light of recent neurophysiological studies in Df1/+ mice and our ongoing investigations.

Abstract: Schizophrenia is a debilitating, heterogeneous psychiatric disorder characterized by positive symptoms such as psychosis and negative symptoms including social, emotional, and cognitive deficits. While positive symptoms can often be managed through antipsychotic treatment, there are very few effective therapies for negative symptoms, which severely impair normal functioning. The mechanisms underlying schizophrenia are poorly understood. There are strong genetic and environmental contributions to schizophrenia, and diverse neurotransmitter systems and neural subtypes are altered in schizophrenic patients, including deficits in parvalbumin-positive fast-spiking cortical interneurons. Recently, a significant genetic association was found between the microRNA-206 gene and schizophrenia. microRNAs are small, noncoding RNAs that are critical regulators of gene expression. microRNAs are enriched in the nervous system, and have been increasingly implicated in neuronal function, dysfunction, and psychiatric disorders. We describe a novel line of conditional miR-206 knockout mice that exhibit schizophrenia-like behavioral deficits, including impaired pre-pulse inhibition and performance in a cognitive task, and increased anxiety-like behaviors. miR-206 is known to be enriched in cortical inhibitory parvalbumin-positive neurons and is predicted to target several genes critical for GABAergic function. We find that miniature IPSC frequency is decreased in the prefrontal cortex of miR-206 knockout mice, consistent with decreased GABAergic signaling. These data support a critical role for miR-206 in proper function of inhibitory cortical neurons as well as sensorimotor gating and normal expression of cognitive and anxiety-like behaviors. Thus, miR-206 may be a candidate for the development of novel schizophrenia therapeutics.

Title: Deletion of slc6a7 which encodes PROT, the high-affinity sodium-dependent transporter for L-proline, results in multiple behavioural phenotypes relevant to psychiatric disorders

Authors: *D. C. HARRISON, K. BRACKENBOROUGH, J. ROBERTSON, M. HILL, P. GOETGHEBEUR, J. LAWRENCE, C. BENDER, J. DORAN, R. FRADLEY, S. NIZAMI, N. BRICE;
Takeda Cambridge Ltd, Cambridge, United Kingdom

Abstract: The amino acid L-proline has been proposed to act as a neuromodulator, or a neurotransmitter. In synaptosome experiments, it is released in response to calcium entry and several studies have shown alterations to glutamate-mediated post-synaptic potentials in response to L-proline. Additionally, there is a high affinity sodium dependent transporter specific for L-proline, PROT, found on pre-synaptic nerve termini. This is a member of the neurotransmitter transporter family which mediate re-uptake of neurotransmitters following synaptic action. We have generated a slc6a7 knockout mouse which lacks PROT. *In situ* hybridisation revealed a lack of mRNA for slc6a7 in all brain areas in KO mice, whereas WT mice expressed slc6a7 in cerebral cortex, thalamus, hippocampus and amygdala. Counterstaining with markers for glutamatergic and GABAergic neuronal types challenged the view that PROT is only found in glutamatergic neurons. Cortical, striatal and hippocampal synaptosomes prepared from slc6a7 KO mice had reduced uptake of radiolabelled L-proline compared with synaptosomes from WT mice. Slc6a7 KO mice were subjected to a battery of behavioural tests designed to detect phenotypes relevant to psychiatric disorders. KO mice showed enhanced cognitive performance in novel object recognition and spatial recognition tasks and an autoshaping test. In the elevated plus maze test, KO mice displayed increased anxiety compared to WT mice and in a tail suspension test the time spent immobile was reduced in KO mice. KO mice had a reduced hyperactivity response to the NMDA receptor antagonist MK-801, and reduced prepulse inhibition of the acoustic startle reflex. In a social interaction test there was no difference between WT and KO mice. Compared with other members of the neurotransmitter re-uptake family of transporters, PROT has received little attention as a putative drug target for psychiatric disorders, although inhibitors have been proposed as cognitive enhancers. These data suggest that the therapeutic potential for PROT inhibition is much broader and may encompass disorders such as schizophrenia, depression and anxiety.

Title: Analysis of the mechanism underlying anxiety-like behavior observed in neuron-specific Dnmt1 knock-out mice

Authors: *A. KIMURA[1], H. NOGUCHI[1], M. OTSUKA I.[2,3], K. IGARASHI[2,3], T. IMAMURA[1], M. NAMIHIRA[4,3], K. NAKASHIMA[1,3];
[1]Kyushu Univ., Fukuoka, Japan; [2]Hoshi Univ., Tokyo, Japan; [3]AMED-CREST, AMED, Tokyo, Japan; [4]Natl. Inst. of Advanced Industrial Sci. and Technol., Tsukuba, Japan

Abstract: Epigenetic modifications such as DNA methylation in the brain have become considered to be implicated in psychiatric disorders, since environmental factors, in addition to genetic factors, have appeared to be associated with such diseases. Recently, abnormal expression of DNA methyltransferase 1 (DNMT1) has been reported in the brains of bipolar disorder and schizophrenia patients. Missense mutations in DNMT1 were also suggested to contribute to the risk of schizophrenia. Thus, it is conceivable that the dysfunction of DNMT1 is one of the causal problems of psychiatric disorders. To reveal the relationship between the dysfunction of DNMT1 and psychiatric disorders, we generated neuron-specific Dnmt1 conditional knock-out (cKO) mice by crossing *Synapsin-Cre* and floxed *Dnmt1* mice. First we examined the expression of DNMT1 in the brains of *Dnmt1* cKO mice by immunohistochemistry, and found that neurons in dentate gyrus (DG) prominently lost DNMT1 expression. Next we performed behavioral analysis of Dnmt1 cKO mice and they showed anxiety-like behavior in the open field test. We also conducted microarray analysis by using cultured neurons from DG, in which Dnmt1 was knocked-down. Gene ontology (GO) analysis of

our microarray data revealed the enrichment of genes involved in voltage-gated calcium channel complex, voltage-gated potassium channel complex and dendritic formation. Furthermore, we compared our microarray data to the publicly available microarray data sets of hippocampus from bipolar disorder and schizophrenia patients, revealing that several genes in the above-mentioned GO terms are similarly up- or down-regulated. In addition, we performed sholl analysis of *in vitro* cultured neurons with Dnmt1 knockdown, and observed that the reduction of Dnmt1 expression increased the dendritic complexity. Taken together, these findings raise a possibility that the dysregulation of these gene expressions could be causes of the morphological change of neurons and the anxiety-like behavior observed in *Dnmt1* cKO mice.

Title: Abnormal hippocampal-mPFC connection in the KCNH2-3.1 transgenic mouse

Authors: *M. REN, G. CARR, Z. HU, Q. TIAN, T. M. HYDE, J. E. KLEINMAN, D. R. WEINBERGER, F. YANG;
The Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: The KCNH2-1A potassium channel conducts delayed-rectifier potassium currents that have a rapid activation and relatively slow inactivation in deactivation kinetics. Our previous work has identified a novel primate isoform of KCNH2-1A channel, the KCNH2-3.1 potassium channel, in human brain associated with schizophrenia. Over-expression of KCNH2-3.1 in cultured cortical neurons alters repetitive spiking rates by causing the changes of the KCNH2-3.1 channel properties. However, the consequence of lifelong over-expression of KCNH2-3.1 to neuronal function in the intact brain remains unknown. We have created a transgenic mouse expressing the KCNH2-3.1 isoform, with KCNH2-3.1 mRNA constitutively over-expressed in frontal cortex and hippocampus similar to that of schizophrenic postmortem brain. Expression of the KCNH2-3.1 channel alters spiking rates in pyramidal neurons in layer V of medial prefrontal cortex (mPFC) in these mice, analogous to that described in primary neuronal culture studies, and with remarkable schizophrenia-like behavior deficits, including working memory and object location memory in these mice. It has been proposed that failure of functional integration and flow of information between hippocampus and mPFC results in cognitive deficits in schizophrenia patients. The possibility of functional impairments between hippocampus and mPFC as key pathophysiological mechanisms associated with schizophrenic phenotypes in KCNH2-3.1 mice has not been explored before. In this study, we have made an *in vitro* brain slice preparation to preserve the ventral hippocampal afferent fibers projecting to mPFC, which allows us to induce the hippocampal-prefrontal dependent monosynaptic response in the slices assessed by *in vitro* slice whole-cell patch recording. Our data show that there is significant impairment in basal synaptic inputs from the ventral hippocampus projecting to pyramidal neurons in the layer 5/6 of KCNH2-3.1 mice (10 weeks old) compared to those in wild-type (WT) mice of the same age. Interestingly, there is no significant difference in the hippocampal-mPFC connections between KCNH2-3.1 mice and WT mice in juvenile mice (2-3 weeks old). This result implies that KCNH2-3.1-caused selective impairments in neural connections between hippocampus and mPFC that do not appear in early postnatal development but require experiential and developmental time. These findings provide further insights into the precise alterations in hippocampal-mPFC connectivity observed in this schizophrenia-associated animal model, and could ultimately help elucidate the molecular and cellular basis underlying schizophrenia pathogenesis.

Title: Prepulse inhibition deficit correlates with forebrain Neuregulin-1 Type III mRNA overexpression in a novel transgenic mouse model for schizophrenia

Authors: *J. C. OLAYA[1,3,4], T. KARL[3,2,5], C. L. HEUSNER[6], M. MATSUMOTO[6], C. SHANNON WEICKERT[2,3,4];
[1]Neurosci. Res. Australia, Ryde, Australia; [2]Neurosci. Res. Australia, Sydney, Australia; [3]Schizophrenia Res. Inst., Sydney, Australia; [4]Sch. of Psychiatry, Univ. of New South Wales, Sydney, Australia; [5]Sch. of Med. Sciences, Univ. of New South Wales, Sydney, Australia; [6]Astellas Res. Inst. of America LLC, Skokie, IL

Abstract: Neuregulin-1 (NRG1) is a well-characterized risk gene for schizophrenia (SZ). Elevations in NRG1 protein and transcripts have been found in SZ with a recent study showing that the transcript for the Type III isoform of NRG1 (NRG1-III) is overexpressed in the forebrain of SZ patients that carry a risk haplotype for the NRG1 gene. In light of this, a mouse overexpressing Nrg1-III specifically in the forebrain was created in order to assess how Nrg1-III overexpression might cause or contribute to SZ-related deficits. We hypothesised that Nrg1-III overexpressing transgenic mice would show behavioural deficits relevant to SZ such as prepulse inhibition (PPI) deficits as well as social and cognitive impairments. Male adult mice (10 Nrg1-III transgenic and 10 WT-like) between the ages of 30 to 34 weeks underwent a standardized behavioural test battery and brains were collected post testing to analyse mRNA expression levels of Neuregulin-1 Type III as well as for three housekeeper genes in the prefrontal cortex (PFC) using qPCR. Nrg1-III tg mice had an increase in normalized Nrg1-III mRNA expression in the PFC ($t=8.55$, $p<0.0001$, $n=12$-14) and displayed impaired learning of a fear-eliciting context ($F=3.81$, $p=0.024$, $n=7$-10), spent less time interacting with a novel social opponent ($t=2.789$, $p=0.044$, $n=10$) and had a deficiency in prepulse inhibition (140.2%, $F=11.281$, $p=0.004$, $n=9$-10) that negatively correlated with the normalized Nrg1 Type III mRNA expression in the PFC of mice of both genotypes [$r=-0.54$, $p=0.0261$]. Our findings confirm that the Nrg1-III tg mouse has a robust overexpression of Nrg1-III mRNA in forebrain (similar to that found in the disease state of a subset of SZ patients) and that this overexpression causes PPI deficits, social recognition and cognitive impairment. In addition, PPI performance may be reflected by Nrg1-III levels in the forebrain where increasing levels of Nrg1-III predicts worse PPI performance. Together, these results indicate that this novel transgenic mouse model has construct and face validity for SZ and provide evidence that an overexpression of Nrg1-III may contribute to the symptomatology of SZ.

Title: Behavioral screen in DLGAP1 mutant mice for phenotypes relevant to Obsessive Compulsive Disorder and Schizophrenia-like behaviors

Authors: ***M. RAMAKER**[1], E. V. HO[1], J. A. KNOWLES[2], N. H. KOMIYAMA[3], S. G. N. GRANT[3], S. C. DULAWA[1];
[1]Univ. of Chicago, Chicago, IL; [2]USC, Los Angeles, CA; [3]Edinburgh Univ., Edinburgh, United Kingdom

Abstract: Introduction: Recent Genome Wide Association Studies (GWAS) and de novo copy number variant (CNV) analyses have identified several genes relevant to psychiatric illnesses such as Obsessive Compulsive Disorder (OCD) and schizophrenia. One gene identified to be a susceptibility gene for both disorders is DLGAP1, which codes for a scaffolding protein present in the post-synaptic density of glutamatergic neurons. The present study aimed to screen DLGAP1 mutant mice for phenotypes relevant to OCD or schizophrenia-related behaviors. Methods: Male and female DLGAP1 knockout (KO), heterozygote (HT), and wild-type (WT) mice were evaluated in the following behavioral tests: open field, dig, splash, social interaction, nestlet building, prepulse inhibition, and forced swim. Fos mRNA was measured in orbital frontal cortex, caudate/putamen, and cerebellum. Results: Genotypic differences were observed in the dig, splash, and social interaction tests. Specifically, DLGAP1 KO males showed reductions in grooming in the splash test and exhibited reductions in number of digging bouts

and increases in latency to dig in the dig test. KO and HT males showed reduced sociability in horizontal measures in the social interaction test and there was a reduction across genders for vertical measures of sociability in the social interaction test. There were no genetic differences in: body weight, open field measures (horizontal, center time, or vertical activity, or spatial d) nestlet building, prepulse inhibition, or the forced swim test. There were also no effects of genotype for Fos expression in orbital frontal cortex, caudate/putamen, or cerebellum. Conclusions: DLGAP1 mutant mice showed alterations in social, anhedonic, and exploratory measures, which display relevance to schizophrenia-like phenotypes. On the other hand, this behavioral screen did not find alterations in behaviors relevant to OCD-like phenotypes. These data suggest that the DLGAP1 gene may contribute to some of the behavioral deficits involved in schizophrenia-like behaviors. Future studies examining whether drugs used to treat schizophrenia would be effective in reversing abnormal behaviors may further clarify the contribution of the DLGAP1 gene to phenotypes related to schizophrenia.

Title: Assessment of minocycline upon cognitive performance in mice haploinsufficient for the schizophrenia risk gene Mitogen-Activated Protein Kinase 7 (Map2k7)

Authors: *J. A. PRATT[1], B. J. MORRIS[2], R. L. OPENSHAW[2];
[1]Univ. Strathclyde, Glasgow, United Kingdom; [2]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Recent advances in understanding the genetic architecture of schizophrenia provide an opportunity to investigate the neurobiological role of risk variants upon neurotransmitter systems, brain networks and behaviour in rodent models and to assess their potential for drug discovery. Here we investigate mice haploinsufficient for Map2k7 (Map2k7+/-), a gene

functionally associated with schizophrenia [Winchester et. al., 2012 Human Molecular Genetics. 21: 4910-4921], in two translationally relevant cognitive tasks and in which schizophrenia patients show deficits: the 5-choice serial reaction time task (5-CSRTT) for attention and inhibitory control and the paired associates learning (PAL) task for object-in-place memory. Performance was also assessed before and after administration of minocycline, a tetracycline antibiotic currently undergoing clinical trials in schizophrenia. The 5-CSRTT requires mice to attend to responding, via nose poke, to a brief light stimulus in one of five spatial locations over ~100 trials and PAL necessitates mice to learn and report the correct location of three different images on a touchscreen. Eight- ten week old mice were trained on either the 5-CSRTT in a 9-hole operant chamber (Med Associates) (16 Map2k7(+/-) (9 male), 15 wild-type littermates (WT; 8 male)) or PAL in a touchscreen chamber (Campden Instruments) (10 Map2k7(+/-) (5 male), 10 WT (5 male)) until their performance stabilised. All mice were then given minocycline in their drinking water for 7 days (86mg/kg/day on average received) and re-tested on the 5-CSRTT/PAL on days 4 and 7. Data was analysed by repeated measures ANOVA with session as the within subjects factor and genotype as the between subjects factor. In the 5-CSRTT, while accuracy was unimpaired, Map2k7+/- mice missed significantly more target stimuli than WTs ($F(1,154)=42.36$; $p<0.001$) and all mice showed improvement in % missed after minocycline treatment, from Map2k7+/-: 7.8±3.1% to 11.8±1.7%; WT: 12.6±1.3% to 10.1±1.7% ($F(2,58)=2.95$;$p=0.06$). Map2k7+/- mice were also impaired in the PAL task: they made less correct responses ($p<0.001$; $f(1,72)=17.84$), and required more correction trials ($p=0.047$; $F(1,72)=4.08$) than WT littermates. Overall, Map2k7+/- mice display deficits in the 5-CSRTT and the PAL task and some of these deficits showed signs of improvement with administration of minocycline. These results support Map2k7+/- mice being an informative and translatable model of some aspects of schizophrenia, with potential for aiding future development of improved treatments.

Title: Interaction between Redox dysregulation and Neuroinflammation during early development could lead to PVI circuitry impairments in adulthood: relevance for schizophrenia

Authors: *D. DWIR[1], J.-H. CABUNGCAL[1], P. STEULLET[1], R. TIROUVANZIAM[2], K. Q. DO[1];
[1]Ctr. For Psychiatric Neurosci. (CNP), Prilly-Lausanne, Switzerland; [2]Res. Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Schizophrenia (SZ) is a major psychiatric disease which involves both genetic and environmental factors. Glutathione (GSH), a main cellular antioxidant and redox regulator, is decreased in CSF and brain of patients. The key GSH synthesizing genes present polymorphisms associated with the disease. Thus, a redox dysregulation during neurodevelopment may be a critical risk factor for SZ when genetic vulnerability for redox dysregulation and environmental stressors generating oxidative stress converge. Moreover, oxidative stress is known to induce inflammation. Anomalies in peripheral immune cells as well as dysregulation of immune-related genes have been reported in SZ. The interaction between both processes occurring at critical period during brain development may affect neurons vulnerable to elevated oxidative insults, such as parvalbumin-expressing interneurons (PVI), which circuit is impaired in post-mortem SZ brain. Mature cortical PVI are usually surrounded by a perineuronal net (PNN), which might be degraded by matrix metalloproteinases (MMPs), induced in pro-inflammatory condition and activated by oxidative stress. We used a transgenic mouse model with GSH deficit (GCLM -/-) that shows SZ related phenotype, to investigate the interaction between oxidative stress and neuroinflammation in early development, to account for the aversive effect on PVI/PNN circuitry in adult.We compared PVI, PNN and microglia level in the anterior cingulate cortex (ACC) of GCLM-/- and WT mice at peripuberty and in adulthood. In addition, mice were treated with a dopamine reuptake inhibitor (GBR) to pharmacologically induce additional oxidative insult from postnatal days (P) 10 to 20. GBR treatment in young mice led to a decreased PVI+ and PV-PNN+-IR, increased oxidative stress level and microglia activation in adult GCLM-/-, showing the tight interaction between the redox and inflammatory state. Microglia activation was more pronounced at peripubertal stage compared to adulthood, suggesting a stage specific vulnerability in GCLM-/-. We explored the role of RAGE, which is activated by ligands produced by oxidative stress, and found increased RAGE shedding in neurons as well as increased MMP9-IR in GCLM-/- at P40. Interestingly, a specific inhibitor of MMP9 prevented RAGE shedding and microglia activation in the ACC of P40 GCLM-/-, demonstrating the involvement of MMP9 and suggesting that this treatment could also limit oxidative stress and

PVI/PNN deficit. We propose that an interaction between redox dysregulation and pro-inflammatory condition via RAGE/MMP9 in early development is a potential trigger of structural and morphological impairments in adult.

Title: Effects of post-weaning isolation and the Nurr1-null heterozygous genotype on behavior

Authors: *J. B. EELLS, S. X. GUO-ROSS, T. E. BRANYAN;
Mississippi St Univ., Mississippi State, MS

Abstract: The NR4A2 gene encodes the protein Nurr1, a nuclear receptor similar to thyroid/steroid hormone receptors, that is essential for the differentiation, development and maintenance of mesencephalic dopamine neurons. Specifically, the Nurr1 null-heterozygous (+/-) genotype results in reduced nucleus accubens dopamine tissue levels and elevated open field activity. The combination of the +/- genotype and post-weaning isolation results in disrupted prepulse inhibition, elevated amphetamine stimulated dopamine release and attenuated Nurr1 protein in dopamine neurons. To investigate further the interactions between the Nurr1 +/- genoptype and post-weaning isolation, male +/+ and +/- mice were raised in either groups or isolation at weaning and tested on open field activity during their light phase (between 0800-1000) then 3 weeks later tested again during the dark phase (between 2000-2200). Analysis of open field activity found that the +/- mice were significantly more active in an open field than the +/+ mice. Isolation had no significant effect on open field activity in the light phase. However, testing in the dark phase resulted in a trend toward elevated activity of the isolated +/- mice with an exacerbated difference between isolated +/+ and +/- mice. The +/- genotype and isolation both resulted in a reduction in body weight. Data on body weight and open field activity suggest that, although there is a relationship between activity and body weight, reduced body weight is not always associated with elevated open field activity as the isolated +/+ mice had a similar average body weight as the group raised +/- mice, although these groups had significantly different activity. These data demonstrate an interaction between the +/- genotype and isolation

on open field activity during the dark phase which suggests that these treatments could disrupt circadian rhythms and potentially alter the temporal regulation of dopamine neurotransmission.

Title: *In vivo* application of CRISPR/Cas9 for studying Akt/Gsk3 signalling in regulation of mood

Authors: *J. KHLGHATYAN, S. CHAMBERLAND, K. TOTH, J. M. BEAULIEU; CRIUMSQ, Laval Univ., Quebec, QC, Canada

Abstract: Background. Neuropsychiatric disorders such as bipolar disorders, depression and schizophrenia represent a major public health problem, and a heavy burden for patients and their relatives. Drugs (such as mood stabilizers) used for management of these diseases shown to exert their effect partially by acting on Akt/Gsk3 pathway downstream of dopamine (DA) receptors. Moreover, this pathway is responsible for regulation of DA related behaviors. Ultimately, many schizophrenia risk genes encode proteins which either comprise or converge on this pathway. Few studies show that regulation of distinct behaviors by members of Akt/Gsk3 pathway may be brain region dependant. Therefore, more studies are needed to expand our knowledge on network specific regulation of behaviors by Akt/Gsk3 pathway. Additionally cell type specific involvement of Akt/Gsk3 signaling in regulation of behaviors remains elusive. Aim. To study the region and cell type specific role of Akt/Gsk3 pathway in regulation of behaviors. Results. Here we used the CRISPR/Cas9 technology to knockout Gsk3 gene in the mouse brain. First, gRNAs against Gsk3 were designed and validated *in vitro* by the Surveyor assay and western blot. For *in vivo* delivery, a dual viral system was implemented. One AAV viral vector was made containing the most active Gsk3 guide along with the fluorescent reporter (SpGuide6) while the Cas9 nuclease was part of second AAV viral vector (SpCas9). AAV5 viral particles were prepared and co-injected into the mouse brain. 2-3 weeks later, brains were dissected and *in vivo* Gsk3 knockout was validated by immunostaining. Moreover, functional consequences of Gsk3 knockout in particular networks of brain were assessed. Particularly knockout of Gsk3 gene in prefrontal cortex showed an anxiolitic effect in mice. Future directions. To understand the role of Akt/Gsk3 signalling in D2 neurons in particular networks of the brain, Gsk3 knockout will be

achieved in those neurons. For this reason conditional Cas9 knockin mice are crossed with D2Cre mice and expression of Cas9 in D2 neurons is observed. Upon delivery of SpGuide6 to different brain regions of D2CreCas9 mice, biochemical, functional and behavioral characterization will elucidate the role of Akt/Gsk3 cascade in D2 neurons in particular networks of the mouse brain.

Title: Role of GABAA receptor α1 subunit in ventral striatum medium spine neurons of erbb4-mutant mice

Authors: *H. GENG[1], X. LI[2];
[1]Inst. of Neuroscience, Zhejiang Univ., Zhejiang province, China; [2]Zhejiang Univ., Hangzhou Zhejiang, China

Abstract: Striatum is responsible for voluntary movements and cognitive functions and its dysfunction may lead to neuropsychiatric diseases. In this study, we observed that erbb4, a schizophrenia risk gene, has densely expressed in striatum. We found the expression of GABAA receptor alpha 1 subunit was significantly increased after knockout of ErbB4 in striatum; and the GABAergic transmissions on medium spiny neurons were also increased. Furthermore, we observed schizophrenia-like behaviors including hyperactivity and impaired social novelty recognition in these knockout mice. Intriguingly, these abnormalities were rescued by interfering with the expression of GABAA receptor alpha 1 subunit in ventral rather than dorsal striatum. These results indicates that ErbB4 is essential for GABAergic synaptic formation in ventral striatum and provides a new perspective for the understanding the role of ErbB4 and GABAergic synapses in the pathological process of neurodevelopment disorders.

Title: Dopamine D3 receptor antagonism rescues dopamine transporter knockdown-induced deficit in sensorimotor gating and cognition

Authors: *P.-K. CHANG;
Chang-Gung University/ Grad. Insititute of Biomed. Sci., Kwei-Shan Tao-Yuan, Taiwan

Abstract: Long-term stimulation in dopaminergic signaling is thought to underlie the pathophysiology of a number of psychiatric disorders, such as psychosis, mania and attention-deficit/hyperactivity disorder (ADHD). These conditions are associated with cognitive deficits such as disturbances in attention processes as well as learning and memory, suggesting that persistent changes in dopaminergic signaling may alter neural mechanisms and lead to disease progress. Of central dopamine system, dopamine D3 receptors have a pre- and postsynaptic localization in brain stem nuclei, limbic parts of the striatum, and cortex. Their widespread influence on dopamine release, function, and on several other neurotransmitter systems makes them an attractive target for therapeutic intervention. So far, all clinically used antipsychotics are not D2-selective but also have affinity towards D3 receptors. On the other hand, dopamine transporter knockdown (DAT-KD) mice exhibit a persistent 70% increase in extracellular dopamine levels than wild-type mice, hence has been widely used as a mania model. In this study, we found DAT-KD mice exhibited a loss in pre-pulse inhibition (PPI) and object recognition tests. However, these functional loss could be rescued by acute exposure of D3 selective antagonist, FAUC365. Next, we compared the behavioral outcome and biochemical phenotype between DAT-KD and D3/DAT double mutants to determine the role of D3 receptor on psychosis. Both mice exhibited hyper-locomotor activity and enhanced stereotypy. Accordingly, DAT-KD exhibited a loss in PPI and object recognition test, but D3/DAT double mutant mice preserved these functions. Overall, the present data implicate dopamine D3 receptors participate a functional role in sensorimotor gating and cognition.

Title: SLC10A4 knockout mice show abnormal event-related potentials in response to an auditory paired-clicks gating test: implications for psychiatric disorders

Authors: *K. E. LEAO[1], M. M. HILSCHER[1], R. N. LEAO[1], H. PETTERSSON[2], M. BLUNDER[1], K. KULLANDER[2];
[1]UFRN / Brain Inst., Natal, Brazil; [2]Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: Slc10A4 is a vesicular monoaminergic and cholinergic associated transporter, and SLC10A4-knockouts (ko) show indications of a greater vulnerability to psycomimetic drugs making them a potential animal model for psychiatric diseases. Here, we use low dose ketamine (5mg/kg and 20mg/kg) to challenge animals and measure alterations in auditory event-related potential profiles to elucidate temporal components that could serve as markers for psychiatric disorders. Human electro-encephalogram (EEG) studies indicate an impaired sensory filtering capacity of auditory paired-clicks in schizophrenia and/or bipolar disorders. These event-related potentials seen in human EEGs in response to paired-clicks have distinct temporal peaks and can be semi-replicated by intrahippocampal electrode recordings in rats and mice. We compare auditory event-related potentials in freely moving mice chronically implanted with 16 channel intrahippocampal electrodes in SLC10A4 ko mice and control littermates. We found that intrahippocampal signal polarity and temporal acuity was strongly influenced by electrode placement within the layers of the hippocampus, which may explain the lack of consistency in previous studies that used single recording electrodes. We found a 'typical' response, with smaller amplitude to the second click, only in certain distinct layers for both controls and ko's following saline injections. In general, SLC10A4-ko's displayed a more complex waveform with extra peaks compared to control littermates. Low dose ketamine mildly affected event-related potentials in control animals but strongly alter the waveform in ko mice. Preliminary results from pre-pulse inhibition show SLC10A4 ko's to startle even following a low sound level prepulse, whereas controls do not. Taken together, these results indicate that SLC10A4-ko animals, with alterations in modulatory neurotransmission systems, are more sensitive to low dose ketamine as well as to startle tests than controls. Our results also indicate a role of Slc10A4 in psychiatric disorders and suggest that this transporter may be a target for psychotherapy.

Title: NMDAR-knockout in parvalbumin interneurons sensitises not protects mice from the effects of MK801

Authors: *A. BYGRAVE, S. MASIULIS, D. BANNERMAN, D. KAETZEL;
Univ. of Oxford, Oxford, United Kingdom

Abstract: The glutamate hypothesis of schizophrenia suggests that N-methyl D-aspartate receptor (NMDAR) hypofunction is central to the disease. In particular, a functional deficit of NMDA receptors (NMDARs) on parvalbumin (PV) positive interneurons has been proposed to be at the core of the pathology of schizophrenia. The non-competitive NMDAR antagonist Dizocilpine (MK801) leads to a paradoxical increase in cortical activity via dis-inhibition of pyramidal neurons because fast spiking interneurons appear more sensitive to the action of NMDAR antagonists. In two previous studies, genetically modified mice lacking NMDARs selectively on PV interneurons (PV-NR1 KO) were reported to be protected from the hyperlocomotor inducing effects of MK801, identifying PV neurons as an important target of the drug. In this study we tested the hypothesis that PV-NR1 KO mice are protected from the hyperactivity and cognitive impairments induced by MK801. Surprisingly, and in contrast to previous studies, we found that PV-NR1 KO mice were sensitised, not protected, to MK801 challenge. PV-NR1 KO mice did not show hyperactivity in response to MK801 challenge but their reduced locomotion resulted from catalepsy, not ineffectiveness of the drug. Furthermore, MK801 impaired performance in a test of working memory at lower doses in PV-NR1 KO than in control mice. These findings challenge the theory that psychotropic effects of MK801 are primarily mediated via PV interneurons.

Title: Amphetamine-induced locomotive activity in heterozygous Disc1 mutant mice

Authors: *C.-C. LAI[1], L.-J. LEE[1,2,3];
[1]Grad. Inst. Anat. and Cell Biol., [2]Grad. Inst. of Brain and Mind Sci., Natl. Taiwan University, Col. of Med., Taipei, Taiwan; [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Disrupted-in-Schizophrenia-1 (DISC1) is a susceptibility gene for several psychiatric illnesses, such as autism and schizophrenia. To study the pathogenesis of these disorders, various Disc1 mutant mouse models were established. In our group, Disc1 mutant mice were generated by introducing the 129S6/SvEv 25-bp deletion Disc1 variants into the C57BL/6J strain. In this study, a battery of behavioral tasks was conducted to evaluate the behavioral phenotypes and cognitive function in the heterozygous Disc1 mutant (Het) mice. In open field test, novel object recognition test, Y-maze test, and prepulse inhibition test, no significant differences were noted between wildtype (WT) and Het mice. However, after received an intraperitoneal injection of amphetamine (5 mg/kg), compared with WT mice, greater locomotive activity was noticed in Het mice. Our results suggested that Disc1 deficit in one allele dose not significantly affect basic behavior and cognition in mice. However, lacking one WT Disc1 allele dose produce greater reaction following the challenge of psychostimulant such as amphetamine. These phenotypes in Het mice resemble the condition in patients with schizophrenia. Our results also suggest a role of dopaminergic system dysfunction in the pathogenesis of schizophrenia.

Title: Increased striatal dopamine d2 receptor activity is associated with increases in population activity of substantia nigra dopamine neurons

Authors: *M. O. CHOHAN[1,3], M. CAZORLA[5], H. MOORE[1,3], C. KELLENDONK[2,3,4];
[1]Integrative Neurosci., [2]Mol. Therapeut., New York State Psychiatric Inst., New York, NY;
[3]Psychiatry, [4]Pharmacol., Columbia Univ., New York, NY; [5]Inst. Curie, Paris, France

Abstract: Midbrain dopamine (DA) neurons are important modulators of striatally dependent behaviors. In schizophrenia (SCZ), there is excessive striatal DA d2 receptor (D2R) transmission, particularly in the associative caudate. While most antipsychotic drugs in use block D2Rs, the mechanisms by which therapeutic benefits are achieved remain unclear. One compelling hypothesis of particular relevance to antipsychotic drug action is that D2R blockade in the striatum induces depolarization block in DA neurons lowering their population activity. We recently identified a critical role for D2Rs in the regulation of basal ganglia functional connectivity: D2Rs chronically regulate density of axon collaterals bridging the 'direct' striatonigral and 'indirect' striatopallidal pathways in the globus pallidus (GP) by modulating medium spiny neuron (MSN) excitability. Modeling increased striatal D2R function in a mouse model, we found that in mice overexpressing striatal D2Rs (D2ROE mice), increased D2R expression is associated with increased inhibition of GP and a disruption of direct pathway mediated locomotor behavior. In the present study we decided to determine whether increased postsynaptic D2R function has an impact on the presynaptic DA neuron activity in the substantia nigra, a region known to send dense projections to the associative caudate. Using single unit *in vivo* extracellular recording methods in anesthetized mice, we recorded from nigrostraital DA neurons before and after switching off the transgene in adult animals. We found an increase in the number spontaneously active DA neurons in mice with increased D2R function. The increased population activity was recovered following switching off the transgene in adulthood. However, increased D2R function did not seem to affect basal firing frequency and burst parameters (percent spikes fired in bursts and burst rate) of DA neurons. By modulating GP neuronal activity, bridging collaterals may regulate DA neuron population activity - disinhibiting nigrostriatal DA neurons in D2ROE mice that have increased bridging collaterals in the GP. Since chronic haloperidol treatment decreases bridging collaterals in the mouse, we asked whether this is associated with a decrease in population activity. Wild-type mice were treated with 1 mg/kg haloperidol using minipumps for 2 weeks. We found a decrease in population activity of DA neurons while firing frequency and burst parameters remained unchanged. Our data suggest bi-directional regulation of DA population activity by striatal D2Rs, which could be a consequence of D2R-mediated anatomical changes in the striatal output pathways.

Title: Sexually dimorphic effects in a double-risk model of psychosis

Authors: *D. SCOTT, C. TAMMINGA;
Psychiatry, UT Southwestern, Dallas, TX

Abstract: Schizophrenia is a serious mental illness affecting approximately 1% of the world's population. It is characterized by positive symptoms, also referred to as psychosis, as well as negative symptoms and cognitive dysfunction. Although many of the negative and cognitive symptoms are easily modeled in experimental animals, thus giving insight into the basic mechanisms underlying these specific symptoms, animal models of the positive symptoms have been weak in providing a valid representation of psychosis. In order to better model the positive symptoms of schizophrenia, we utilized a double-risk model combining genetic risk (with mice carrying a dominant negative form of the schizophrenia-associated gene DISC1) with environmental stress (maternal deprivation), which is known to increase the risk of developing schizophrenia. We conceptualize psychosis as a memory disorder, induced by hippocampal hyperactivity as indicated by human imaging and postmortem tissue studies. We hypothesize that environmental risks will increase the severity of tissue pathology accompanying the genetic profile for schizophrenia, which reveals itself in behavioral deficits relevant to psychosis and memory, as well as increased activity in the CA3 subfield of the hippocampus. To address this hypothesis, we exposed wild-type (WT) and DISC1-deficient (TG) mice to either a mild (one hour daily) or severe (three hours daily) maternal deprivation stress from P2 to P14. Once these animals reached adulthood, they were tested in a battery of behavioral experiments, and examined for signs of increased hippocampal neuronal activity. Results suggest maternal deprivation and DISC1 deficiency selectively decrease fear conditioning in female, but not male mice, though the effects are not additive, suggesting these two risk factors may share a common biological mechanism for schizophrenia. Furthermore male mice display hyperactivity only when exposed to a mild, but not severe, maternal deprivation stress, with TG mice showing no difference from WT mice. Studies are underway examining neuronal activity in the hippocampal subfields by way of quantifying c-fos expression. Overall, these results suggest a distinct sex difference in the susceptibility of animals to both the environmental as well as genetic risk factors contributing to psychosis, and further research is needed to determine how these correlate

with hippocampal hyperactivity. The overall development of a strong inference animal model of psychosis would satisfy a high medical need in schizophrenia research.

Title: Socio-communicative deficits in serine racemase knockout mice

Authors: *A. E. YOUNG[1], M. T. PISANSKY[2], J. C. GEWIRTZ[3];
[2]Neurosci., [3]Psychology, [1]Univ. of Minnesota- Twin Cities, Minneapolis, MN

Abstract: Evidence suggests that reduced function of glutamatergic NMDA receptors contributes to the pathophysiology of schizophrenia. NMDA receptor function is modified endogenously via the allosteric modulator D-serine, which is synthesized by the enzyme serine racemase. Schizophrenia is characterized in part by deficits in social-communicative, emotional, and cognitive domains. To examine the effects of serine racemase dysfunction in each of these domains, we subjected mice harboring a deletion of this gene to a number of relevant behavioral tests. Juvenile serine racemase knockout mice exhibited reduced social interactions and emissions of ultrasonic vocalizations. Consistent with previous findings, adults showed deficits in prepulse inhibition, a measure of sensorimotor gating. Lastly, we are conducting experiments to assess socially transmitted fear behavior of serine racemase knockout mice as a measurement of socio-emotional cognition. These results suggest reduced glutamatergic neurotransmission via the NMDA receptor gives rise to abnormal behaviors in the socio-communicative domain that parallel some of the negative symptoms associated with schizophrenia.

Title: Mouse brain expression and function of Regulator of G protein Signaling-12 (RGS12) in sensorimotor gating and locomotive behaviors

Authors: *J. D. GROSS, V. SETOLA, K. A. WIX, D. P. SIDEROVSKI;
Physiol. & Pharmacol., West Virginia Univ. Sch. of Med., Morgantown, WV

Abstract: "Regulator of G protein Signaling" (RGS) proteins accelerate the rate of GTP hydrolysis by heterotrimeric G protein alpha subunits, thereby inhibiting G protein-coupled receptor signaling. Regulator of G protein signaling-12 (RGS12) exerts this canonical GTPase-accelerating activity via its central RGS domain and also performs other signal regulatory functions via a complex multidomain architecture composed of an N-terminal PDZ and phosphotyrosine binding (PTB) domain, two Ras-binding domains (RBDs), and a C-terminal GoLoco motif. Independent studies that performed exome sequencing of schizophrenic (SCZ) and schizoaffective (SZA) patients and their parents have identified de novo Rgs12 variants within two affected probands (Xu et al., 2011 and Guipponi et al., 2014), both of which are predicted to be non-synonymous missense mutations. Our lab has now shown that RGS12 is expressed in the mouse CNS within deep lateral cortical layers, striatum, hippocampus, and claustrum -- regions associated with the pathogenesis of SCZ. Furthermore, we recently found that Rgs12-deficient mice exhibit altered responsiveness in prepulse inhibition of acoustic startle and display altered locomotor responses to several psychotomimetic and psychostimulant drugs. Further investigation into the CNS function of RGS12 may illuminate novel therapeutic approaches for treating psychiatric diseases such as SCZ.

Title: Neuregulin 1 and cholinergic control of behavior in mice

Authors: *L. SERVILIO[1,2], K.-F. LEE[2];
[1]UC San Diego, San Diego, CA; [2]Salk Inst., La Jolla, CA

Abstract: Neuregulin 1 (Nrg1) is a genetic risk factor of schizophrenia and has been shown to play many important roles in the central and peripheral nervous systems. While Nrg1 is widely studied, its function in the cholinergic circuitry of the brain remains largely unknown. Changes in cholinergic activity can have widespread effects throughout the brain, thus it is important to understand how Nrg1 regulates this circuitry. We used mice with a conditional knockout of Nrg1 in cholinergic neurons to investigate resulting anatomical and behavioral changes. We found that in wild type mice Nrg1 is expressed in cholinergic projection neurons of basal forebrain and the brainstem, where it forms clusters around the soma and proximal dendrites of these cells. Nrg1 is often localized to synapses where presynaptic neurons are also cholinergic. Further, Nrg1 influences the localization of muscarinic receptors at these synapses. In the conditional knockout mice, Nrg1 clustering was abolished and M2 muscarinic receptors were distributed more evenly around the cell body. The conditional knockout mice exhibited several interesting behavioral phenotypes suggesting disruption of cholinergic activity, including decreased prepulse inhibition and increased vocalizations. This evidence suggests that Nrg1 plays an important role in the cholinergic circuitry of the mouse brain, and disruption of this gene solely in cholinergic pathways can lead to marked behavioral changes with potential implications for neuropsychiatric diseases.

Title: Mitochondrial dysfunction in humanized DISC1-Boymaw mice

Authors: *K. K. HIGA, B. JI, M. A. GEYER, X. ZHOU;
Psychiatry, UC San Diego, La Jolla, CA

Abstract: The Disrupted in Schizophrenia 1 (DISC1) translocation, a mutation found across several generations of a large Scottish family, is the most promising causal genetic lesion for schizophrenia, bipolar disorder, major depression, and other psychiatric disorders. Two fusion genes_DB7 and BD13, from DISC1 on chromosome 1 and Boymaw on chromosome 11_are generated by the translocation. We found that expression the DB7 fusion gene in cultured cells inhibits oxidoreductase activity, rRNA expression, and protein translation. In addition, the DB7 protein colocalizes with mitochondria, where it abolishes mitochondrial membrane potential. To study the effects of the translocation *in vivo*, we developed humanized "DISC1-Boymaw" mice that express both human fusion genes. In addition to reduced rRNA synthesis and protein expression, the heterozygous (HET) DISC1-Boymaw mice exhibit exaggerated locomotor responses to ketamine, as well as mild depressive-like behaviors, not observed in their wildtype (WT) littermates. We hypothesize that expression of the DB7 protein causes mitochondrial dysfunction, which leads to impaired ATP production and an increased reliance on glycolysis as a means of energy production, both of which have been observed in patients with psychiatric disorders. Consistent with this hypothesis, we have found that activation of AMPK, an energy sensor that is activated due to high AMP/ATP ratio (i.e., low energy), is increased in HET mice. Furthermore, we have found that the respiratory exchange ratio (volume of CO2 produced / volume of O2 consumed) is higher in HET mice than in WT mice, suggesting a bioenergetic shift from oxidative phosphorylation to glycolysis. Mitochondrial dysfunction may disrupt the AMPK-mTOR protein pathway, leading to the observed inhibition of protein translation. Reduced protein translation can affect neurotransmission and plasticity necessary for normal brain development and function. Understanding the mechanisms and consequences of mitochondrial dysfunction on ATP production and protein translation in the DISC1-Boymaw mice may help elucidate the molecular pathways for the pathogenesis of schizophrenia, bipolar disorder, and major depression in the Scottish family and the general population of psychiatric patients.

Title: Partial genetic deletion of neuregulin 1 modulates the effects of chronic stress on dendritic morphology in adolescent mice

Authors: *D. J. CLARKE[1,2,3,4], T. CHOHAN[2,4,3], M. S. KASSEM[2], S. Y. FOK,[2], M. R. BENNETT[2], J. C. ARNOLD[4,2,3];
[1]Pharmacol., The Univ. of Sydney, Werrington Downs, Australia; [2]Brain and Mind Res. Inst., Sydney, Australia; [3]Bosch Inst., Sydney, Australia; [4]Pharmacol., Univ. of Sydney, Sydney, Australia

Abstract: Neuregulin 1 (Nrg1) is a neurotrophic factor and a schizophrenia susceptibility gene. Dendritic spine atrophy has been observed in the schizophrenia brain. Chronic restraint stress promotes alterations in dendritic morphology including a decrease in dendritic spine density in the medial prefrontal cortex and the hippocampus, and an increase in dendritic spine density in the basolateral amygdala. On this background, we aimed to examine whether partial genetic deletion of Nrg1 modulated stress-induced changes in dendritic morphology. Adolescent wild-type (WT) and neuregulin heterozygous (Nrg1 HET) mice underwent 6 h of restraint stress per day for a total of 21 days. 24 h following the last restraint stress session the mice were sacrificed and the brains extracted for Golgi staining and analysis. Chronic restraint stress during adolescence promoted opposing effects on dendritic spine density in the prelimbic cortex, with a stress-induced increase in Nrg1 HET mice and a decrease in WT mice. Stress-induced reductions in dendritic complexity in the prelimbic cortex were more pronounced in Nrg1 HET mice relative to WT mice. Stress promoted greater dendritic spine atrophy in Nrg1 HET than WT mice in the CA1 region of the hippocampus. Nrg1 HET mice appeared to confer resilience to stress-induced dendritic spine atrophy in the infralimbic cortex, as stressed WT mice displayed reduced dendritic spine density compared to controls, whereas no significant changes were observed between stressed and non-stressed Nrg1 HET mice. Interestingly, Nrg1 hypomorphism did not influence the effects of stress on the basolateral amygdala, as stress increased dendritic spine density equally in both WT and Nrg1 HET mice. We also show for the first time that partial genetic deletion of Nrg1 alone promoted dendritic spine density reductions in the CA3 region of the hippocampus. The present results confirm that Nrg1 deficiency during adolescence modulates the effects of stress on dendritic morphology.

Title: Mutations in the BLOC-1 subunits dysbindin, muted, and pallidin regulate levels of excitatory and inhibitory markers in the hippocampus

Authors: M. ARNOLD[1], *J. L. LARIMORE[2], V. FAUNDEZ[3];
[1]Agnes Scott Col., Atlanta, GA; [2]Biol. Dept., Agnes Scott Col., Decatur, GA; [3]Emory Univ., Atlanta, GA

Abstract: Dysbindin protein levels are reduced in post-mortem brains of patients diagnosed with Schizophrenia (SZ). Dysbindin and its interacting proteins, including BLOC-1 complex members, may also be involved in disease pathogenesis. Current theories in SZ research hypothesize symptoms may be due in part to an imbalance in the excitatory and inhibitory (E/I) signals in cortex and hippocampus. To determine if dysbindin and BLOC-1 complex members may regulate E/I balance, we examined mRNA and protein levels of E/I markers in the hippocampus of mice null for BLOC-1 alleles. We propose that different subunits of the BLOC-1 complex have different phenotypic presentation therefore contributing to the wide spectrum and complexity of neurodevelopment disorders.

Title: Knockdown BCL9 by using *in utero* electroporation results in neural developmental and electrophysiological deficits via Wnt signaling pathway

Authors: *W. LI;
Shanghai Jiao Tong Univ., Shanghai, China

Abstract: B-cell CLL/lymphoma 9 (BCL9) was identified in a B-cell acute lymphoblastic leukemia cell line, and associated with tumor progression via β-catenin and Wnt signaling pathway. The association studies suggested that BCL9 was also related to schizophrenia and bipolar disorder. However, the function of BCL9 in the brain is poorly understood. Here, we found that BCL9 was highly expressed in mouse brain during development and knockdown BCL9 in the neural system could significantly altered the Wnt signaling pathway. Interestingly, knockdown of BCL9 by using *in utero* electroporation could severely disturb the migration of cortical neurons, and the affected migrating neurons displayed aberrant action potentials. Our findings indicated that elimination of BCL9 function in the brain might contribute to the pathogenesis of developmental neuropsychiatric disorders.

Title: Development of schizophrenia-relevant cognitive abnormalities during adolescence: a translational study in mice

Authors: *M. CIAMPOLI, F. PAPALEO;
Neurosci. and Brain Technologies, Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: A microdeletion of the chromosome 22 band q11.2 results in the so called 22q11.2 deletion syndrome (22q11DS). By late adolescence/early adulthood up to one-third of patients with 22q11DS develop schizophrenia, making 22q11DS the most commonly known genetic syndrome associated with this psychiatric disorder. In an effort to set the ground towards the development of early detection and early intervention strategies relevant to schizophrenia, we developed a set of preclinical tasks enabling to assess preadolescent-adolescent development of behavioral phenotypes relevant to schizophrenia. In particular, we are applying this newly-developed battery of tasks to LgDel mutant mice that carry the same 1.5 Mb deletion of the human 22q11DS. This mouse model is a unique tool to validate and elucidate early developmental abnormalities relevant to schizophrenia. Despite this, no studies had so far checked the impact of the 22q11 microdeletion in behavioral phenotypes from birth to adolescence in mice. We first set the best experimental conditions to characterize Startle and Pre-Pulse Inhibition (PPI) abilities from pre-pubertal to adolescent. Using these settings we unraveled altered startle responses in the LgDel mice at pre-pubertal (PND 14) ages. Moreover we found that sensorimotor gating deficits in LgDel mice started to appear during adolescence (PND 35). Next, we implemented a modified version of the 5-Choice Serial Reaction Time Task (5CSRTT) in order to be able to measure attentional control in adolescent mice. Adolescent wild type mice were able to acquire and perform this new paradigm, advancing across the different stages and environmental manipulations in less than fifteen days (PND 24-36). We are now testing LgDel mice. Overall, our experiments are starting to elucidate new ways to test also in mice schizophrenia-relevant phenotypes. This will be important in the context of the development of early therapeutic intervention in schizophrenia.

Title: Behavioral pattern separation in a transdiagnostic anxiety population

Authors: *K. C. KLEMENHAGEN[1], R. HEN[2], H. B. SIMPSON[3,4], A. J. FYER[3];
[2]Psychiatry, Neuroscience, Pharmacol., [3]Psychiatry, [1]Columbia Univ., New York, NY; [4]Anxiety Disorders Clin. and the Ctr. for OCD and Related Disorders, New York State Psychiatric Inst., New York, NY

Abstract: Animal model studies have demonstrated a role for adult neurogenesis within the dentate gyrus of the hippocampus in anxiety-like behavior and in responses to stress. One paradigm tested in these animal models is behavioral pattern separation. Electrophysiologists first described pattern separation in the hippocampus, where neurons within the circuitry of the hippocampus are thought to discriminate between similar inputs. At a higher level of organization, behavioral pattern separation refers to behavioral discrimination between similar stimuli. Behavioral pattern separation is negatively affected by manipulations causing loss of adult neurogenesis in animal models, and by mild cognitive impairment (C. Stark) and binge drinking and stress (S. Becker) in humans. Here, we apply the Behavioral Pattern Separation - Objects / Mnemonic Similarity test of Stark and the Concentration Matching Task (spatial pattern separation) of Becker to a transdiagnostic sample of anxiety patients and controls. We hypothesize that a subset of anxious patients cutting across diagnosis categories will have deficits in behavioral pattern separation, which may contribute to their mood disorder. Furthermore, behavioral pattern separation performance may positively correlate with self-report measures of mood, and with report of physical activity, a dramatic modulator of neurogenesis levels in animal models, in both patients and controls. The ability to identify a group of patients with putative decreases in adult neurogenesis via translational behavioral paradigms will help to develop individual-specific treatments for mood disorders, as well as contribute to stratification of patients for more effective studies of novel treatments targeting hippocampal adult neurogenesis.

Title: Abnormalities in the assembly process of mitochondrial complex I in schizophrenia: a possible cause for mitochondrial dysfunction

Authors: *O. BERGMAN[1], R. KARRY[2], D. BEN-SHACHAR[3];
[1]Med., [2]Psychiatry, Lab. of Psychobiology, Technion – Israel Inst. of Technol., Haifa, Israel;
[3]Lab. of Psychobiology, Dept. of Psychiatry, Rambam Hlth. Care Campus, the Ruth and Bruce Rappaport Fac. of Medicine, Technion-Israel Inst. of Technology., Haifa, Israel

Abstract: Abnormalities in mitochondrial oxidative phosphorylation system are observed in several mental disorders including schizophrenia, specifically in complex I (CoI). We have previously reported altered mRNA and protein levels of the labile subunits of CoI: NDUFV1, NDUFV2 and NDUFS1, in brain postmortem specimens and peripheral cells of schizophrenia patients. Notably, patients diagnosed with CoI deficiency portray a variety of schizophrenia-like symptoms. We therefore hypothesize that holo-CoI assembly may contribute to mitochondrial dysfunction in schizophrenia. Mitochondria were isolated from Epstein-Barr virus (EBV) transformed lymphocytes of schizophrenia patients and healthy subjects. Clear-native PAGE CoI in-gel activity assays also showed a significant reduction in schizophrenia cell lines (69.6±11.8 vs. 113.6±10.9 OD/mg protein/hr, P=0.008). While blue-native PAGE showed no difference in CoI holoenzyme protein levels, its sub/super-complexes, its synthesis rate, determined by the incorporation of 35S-methionine labeled mitochondrial subunits into holo-CoI, was significantly lower in patient cell lines (2.3±0.6 vs. 0.65±0.15, normalized OD, P=0.01). The synthesis rate of the mitochondrial subunits did not differ between the two cohorts. However, the import of in-vitro translated 35[S]-methionine labeled NDUFV2 labile subunit of patients was impaired. Both patient-derived mitochondria and protein synergistically contributed to this decreased import. Concomitantly, mitochondria/cytosol ratio of NDUFV1 and NDUFV2 protein/pre-protein was reduced in schizophrenic cells. Interestingly, protein levels, detected by immunoblotting, of 8 different subunits of CoI were similar in healthy and patients samples. However, only the labile subunits showed a significantly higher coefficient of variance in control compared to patient samples, suggesting a slower exchange of this preexisting CoI subunits for newly imported ones, which may hinder this repair process. These abnormalities were associated with reduced CoI-driven respiration as well as with a pathological interaction of CoI with dopamine, a major substance in schizophrenia, in patients as compared to healthy subjects. Taken together, the data suggest that impairment in labile subunits incorporation into the holo-CoI in schizophrenia, which occur at the final stage of assembly, contributes to its abnormal activity and thereby to mitochondrial multifaceted dysfunction reported in schizophrenia.

Title: MicroRNA level reductions in Mediodorsal thalamus with 5HTTLPR-SS genotype

Authors: *K. A. YOUNG, E. S. CARTER, D. L. PAPPALARDO-CARTER;
Psychiatry & Behavioral Sci., Texas A&M HSC / Central Texas VA, Temple, TX

Abstract: The mediodorsal thalamus (MD) provides powerful glutamateric input to the frontal cortex and is an important node in limbic circuitry. We have previously observed neuronal loss in this nucleus in older cases with schizophrenia (SKZ), elevated numbers of neurons in a younger cohort of major depression (MDD) cases, and a strong influence of the serotonin transporter 5HTTLPR genetic variant on thalamic neuron populations. Most recently, we observed alterations in microRNAs (miRs) in both MDD and SKZ and global deficits in miR levels in suicide cases in the MD. In the present study, we examined the influence of 5HTTLPR on miR levels in the MDD. MiR levels and 5HTTLPR genotype with rs23456 following the "triallelic" convention were assessed in RNA/DNA extracted from frozen MD specimens of the Stanley Foundation Research Consortium (12 MDD, 12 SKZ and 14 controls) using PCR and Exiqon Human miRnome V1.M RT-PCR panels, resulting in an N = 577 MD-expressed miRs. A common pattern was that 5HTTLPR SS alleles were associated with reduced miR levels compared to SL genotype across many miR species, as evidenced by a significant reduction in total miR load ($p<0.027$), controlling for diagnosis, age, gender and PMI. The most reliably affected SL>SS miRs (abundant miRs with p's <0.02) included miRs-7d*, 1979, 320a, 432, 532-5p, 664 and 92b. Interestingly Mir-432, which targets ELK1 (a transcription factor binding to 5HTTLPR), has previously been found to be decreased in SKZ blood. The 7 SS-reduced miRs targeted PTPRD, CNIH, FAM19b, and TOB1 mRNAs as a group. Several of these genes have been previously associated with either SKZ (CNIH, TOB1 and PTPRD) or MDD (TOB1). MiR-377 had the most reliable evidence for elevated levels compared to SL/LL. Several miRs expressed at relatively low levels displayed significantly altered but skewed distributions suggestive of selective miR editing in SS or LL genotypes, with loss of probe annealing potentially due to edited miR sequences. There was no relationship between 5HTTLPR genotype and MD mRNA levels for DGCR8, Drosha or Dicer transcripts. The present data support a pathophysiological phenotype consisting primarily of reduced miR levels in the MD nucleus of the thalamus associated with the 5HTTLPR-SS genotype.

Initiative for Integrative Psychiatric Research, iPSYCH, Aarhus, Denmark; [3]Ctr. for Integrative Sequencing, iSeq, Aarhus Univ., Aarhus, Denmark; [4]Res. Unit for Mol. Med., Aarhus Univ. Hosp., Skejby, Denmark

Abstract: Genetic evidence has repeatedly implicated the *BRD1* gene in schizophrenia and bipolar disorder. The BRD1 protein is involved in histone modification and regulates the expression of genes located adjacent to its genomic binding sites. *Brd1*$^{+/-}$ mice show behavioural phenotypes congruent to schizophrenia and depression symptoms, accompanied by disturbances in neurochemistry, imbalanced excitatory-inhibitory neurotransmission and changes in neuronal morphology. In order to dissect the molecular changes underlying the phenotypes in female *Brd1*$^{+/-}$ mice, which show reversible depression-like behaviours as well as cognitive deficits, we performed quantitative neuroproteomic analyses of protein extracts from frontal cortex, hippocampus and striatum using isobaric tagging of peptides combined with mass spectrometry using high-energy collision cells for fragmentation. In total, we detected more than 1500 proteins in each sample. We found varying numbers of differentially abundant proteins (DAPs) in the samples with as few as around 20 in whole-cell extracts from hippocampus and as high as 200-300 in extracts from frontal cortex. Ingenuity Pathway Analysis of the DAPs indicated among others that key signalling pathways for normal brain function (e.g. the dopamine, GABA and glutamate receptor signalling) are affected in female *Brd1*$^{+/-}$ mice. A total of 17 DAPs remained significant upon FDR control, all but one identified in frontal cortex samples. Strikingly, two of the proteins (LRP1 and TMX2) are encoded by genes that in humans are located in loci showing genome wide significant association with schizophrenia. Neuronal LRP1 seems to play a role in NMDA receptor-dependent intracellular signalling whereas the function of TMX2 remains

elusive. Of further notice, we found increased amounts of ARP2, ARP3, and their activator N-WASP in the cortex of female *Brd1*$^{+/-}$ mice. Loss of ARP2/3 function in excitatory neurons of the frontal cortex leads to a reduction in the number of normal axonal-spine synapses, enhanced pyramidal neuron excitation as well as frontal cortex–VTA/SNc circuit activation thereby elevating striatal dopamine (stDA) and inducing locomotion. We speculate whether reverted levels of these proteins could relate to the decreased stDA and normal (amphetamine non-inducible) locomotion seen in female *Brd1*$^{+/-}$ mice. In conclusion, we have mapped a number of neuroproteomic changes that collectively could explain the phenotypes of female *Brd1*$^{+/-}$ mice and pave the way for further dissection of its underlying causes.

Abstract: The bromodomain-containing 1 gene (BRD1) gene has been implicated with brain development and susceptibility to psychiatric disorders. BRD1 interacts in a histone acetyltransferase complex with K(lysine) acetyltransferase 7 KAT7 (also known as HBO1 or MYST2) and the BRD1 chromatin and protein interaction network is enriched for schizophrenia

risk genes. Further investigations of Brd1+/- KO mice identified global cerebral hypo-acetylation of histone H3K14 combined with schizophrenia-associated behaviors, cognitive deficits and altered cortical inhibitory neurotransmission. Whole transcriptome profiling (RNA-seq) on striatal and cortical tissue from Brd1+/- and WT mice have identified expression of genes encoding synaptic proteins implicated in glutamatergic signaling, as well as a lowered expression of the marker for fast-spiking interneurons, parvalbumin (Pvalb) in Brd1+/- compared to WT mice. We hypothesized that excitocytoxicity cause the loss of fast-spiking, pvalb+ interneurons and that this neurotoxic effect can be rescued by restoring the normal histone acetylation level. To investigate this, we examined the maturation of inhibitory networks in developing primary cortical cultures derived from Brd1+/- and WT P0 mice. Cells were cultured for 12, 18, and 24 DIV before they were fixed and IF stained using Nf200, Psd-95, Pvalb and Gad67 antibodies. We found that cultures from Brd1+/- mice mature later than WT and further degenerate faster with fractions of mature neurons (incl. GABAergic neurons) being lower at both 12 and 24 DIV but not 18 DIV. In line with our data from mouse brains and supporting our hypothesis, we found an accelerated decrease of Pvalb+ neurons and a significant increase in neurite Psd-95 puncta density at 18 and 24 DIV in Brd1+/- cultures compared to WT. In order to find a suitable drug for reversing the effect of reduced Brd1 expression and thus hypo-acetylation, we correlated our RNA-seq data with brain expression data from mice treated with HDACi 4b (Jia et al. 2014) and identified a negative correlation of differentially expressed genes involved in glutamatergic signaling. We are currently testing the effect of both HDACi 4b and valproic acid using IF staining, RNA-seq, and ChIPseq in order to monitor a potential rescue on the level of phenotype, gene expression and histone acetylation in primary neurons derived from Brd1+/- and WT mice. The results from this analysis will be presented at the conference.

Title: The implication of the schizophrenia-associated BRD1 gene in brain morphology

Authors: *P. L. QVIST[1], S. F. ESKILDSEN[2], S. RINGGAARD[3], H. STODKILDE-JORGENSEN[3], O. MORS[4], A. D. BORGLUM[5], J. H. CHRISTENSEN[5];

Abstract: Schizophrenia is a common and devastating disorder but its etiology remains largely unknown. Whereas pharmacological and genetic studies have collectively pointed to underlying deficits relating to neuro-differentiation, -development and -plasticity, no clear structural basis for the disorder has been established. The bromodomain-containing 1 (BRD1) gene has been implicated with both brain development and susceptibility to schizophrenia and male mice with decreased Brd1 expression (Brd1+/- mice) display schizophrenia-associated behaviors and altered striatal dopamine transmission. In the present study we attempt to determine the correlation between reduced Brd1 expression and cerebral pathology in male Brd1+/- mice using magnetic resonance imaging (MRI). MR images of eight 15 weeks old freshly sacrificed adult male mice (4 Brd1+/- and 4 wild type (WT)) were acquired with a 9.4T Agilent small-bore scanner (Agilent, Santa Clara, CA, USA) using a 20-mm surface coil (RAPID Biomedical Rimpar, Germany) for signal reception. The images were acquired using a 3D fast gradient echo sequence with repetition time (TR) = 13.7 ms, echo time (TE) = 6.9 ms, flip angle = 20°, matrix size = 400 × 400 × 400, field-of-view = 4.0 × 4.0 × 2.0 cm, spatial resolution = 100 × 100 × 50 μm (highest resolution in coronal direction), number of averages = 4, and acquisition time = 2:26 hours. An average model fitting the C57Bl/6j mouse brain atlas was created from images from the eight pilot scans and 52 labels from the atlas were then mapped to the individual images. In this study, we observed no overall changes in cerebral volume between Brd1+/- and WT mice and we did not find any differences in ventricle volumes as has repeatedly been reported in patients with schizophrenia. However, despite the low number of animals included, we observed nominally significant volumetric differences in several brain regions. Particularly the striatum appeared to be reduced in Brd1+/- mice compared to WT mice, thus potentially establishing a link between the molecular, biochemical and behavioral findings in Brd1+/- mice and a neuropathological phenotype. Although more mice need to be included in the study and our findings need to be validated by stereological measures in fixed brains, our preliminary data suggest Brd1 is implicated in brain architecture in mice.

Title: Defective axonal mitochondrial trafficking in a DISC1 translocation mouse model

Authors: *L. MURPHY[1], E. L. V. MALAVASI[1], H. S. TORRANCE[1], M. DIDIER[2], D. J. PORTEOUS[1], J. K. MILLAR[1];
[1]Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Sanofi, Montpellier, France

Abstract: Disrupted In Schizophrenia 1 (DISC1) was first identified as a candidate gene for major mental illness due to its disruption by a balanced t(1;11) translocation that co-segregates with psychiatric illness in a large Scottish family. DISC1 regulates the trafficking of mitochondria in axons and this potentially implicates mitochondrial homeostasis in psychiatric illness. We have access to a novel mouse model of the t(1:11) translocation developed by Sanofi. Compared to wild type mice, heterozygous t(1;11) mice exhibit reduced DISC1 mRNA and protein expression, consistent with the reduced DISC1 expression levels in lymphoblastoid cell lines derived from translocation carriers in the Scottish family. To test for potential effects of the t(1:11) translocation on axonal mitochondrial trafficking, hippocampal neurons isolated from homozygous and wild type mouse embryos were used for time-lapse imaging of mitochondrial motility. Measurements were collected from fifty axon segments over three independent cultures of neurons from each genotype. Several parameters were analysed, including percentage motility, direction of movement, and displacement. No change in the number of moving mitochondria, or their direction of movement was detected. However, net displacement of retrograde, but not anterograde, moving mitochondria was significantly lower in homozygous versus wild type neurons, lending additional support to our hypothesis that mitochondrial trafficking defects increase susceptibility to psychiatric illness.

Title: Regulation of trafficking of a surface protein by DISC1: a live cell imaging approach

Authors: *K. MILLAR[1], E. L. V. MALAVASI[1], M. DIDIER[2], Z. TARNAUSKAITE[3], D. J. PORTEOUS[1];
[1]Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Sanofi, Paris, France; [3]Human Genet. Unit, Inst. of Genet. and Mol. Med. at the Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: The multifunctional scaffold protein Disrupted-In-Schizophrenia 1 (DISC1) is a risk factor for psychiatric disorders including major depression, bipolar disorder and schizophrenia. DISC1 is involved in many biological processes of central importance for neuronal development and function, including organelle trafficking. In axons, DISC1 regulates mitochondrial movement, a function that is likely mediated by its association with trafficking-protein-Kinesin-binding-1 (TRAK1), a protein that links mitochondria to kinesin and dynein for microtubule-based trafficking. DISC1 is also known to regulate the microtubule-based trafficking of synaptic vesicles and mRNA granules along neurites. If deregulated, all these processes have the potential to affect neuronal function, suggesting that the integrity of the trafficking function of DISC1 may be important for the maintenance of normal neuronal activity. Here, we hypothesised that DISC1 may also be involved in the regulation of the trafficking of surface proteins in neurons. To test this, we expressed surface protein X labelled with the photoconvertible fluorescent protein Dendra2 in hippocampal neurons and directly visualised the motility of X-Dendra2 in live dendrites. Bulk movement of X-Dendra2 molecules along dendrites was recorded by live confocal time lapse imaging after photoconversion of a small region within the dendrite, and fluorescence intensity data were analysed using a bespoke algorithm. We observed that X-Dendra2 molecules travel bidirectionally within dendrites, spreading proximally and distally from the photoconversion region. Overexpression of wild-type human DISC1 significantly reduced X-Dendra2 movement in the proximal direction, but had little or no effect on movement in the distal direction. By contrast, expression of the common single nucleotide variant DISC1-607F, which is associated with intermediate phenotypes for psychiatric illness, promoted the movement of X-Dendra2 towards the distal portion of dendrites, without affecting spreading in the proximal direction. To further test for the involvement of DISC1 in X-Dendra2 trafficking, we carried out the same measurements in hippocampal neurons isolated from a novel Disc1 mouse model in which expression of endogenous full-length Disc1 is lost. We observed that in null neurons, dendritic X-Dendra2 movement is reduced specifically in the proximal direction. Taken together, these results suggest for the first time that DISC1 may be involved in the

regulation of trafficking of surface-expressed proteins in neurons, with a possible modifying effect of a candidate disease-related DISC1 variant.

Title: Neurogranin deficiency causes neuronal immaturity in the dentate gyrus and frontal cortex of adult mice

Authors: *H. HAGIHARA[1,2], S. HATTORI[1,2], Y. TAKAMIYA[1,2], F. L. HUANG[3], K.-P. HUANG[3], T. MIYAKAWA[1,2,4];
[1]Fujita Hlth. Univ., Toyoake/Aichi, Japan; [2]CREST, JST, Kawaguchi, Japan; [3]Program of Developmental Neurobiology, NICHD, NIH, Bethesda, MD; [4]Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Previous genome-wide association studies have suggested a link between schizophrenia and neurogranin (Nrgn), a neuron-specific protein abundantly expressed in brain regions implicated in memory and cognitive function, such as the hippocampus and cortex (Stefansson et al, 2009; Schizophrenia Working Group of the Psychiatric Genomics Consortium, 2014). Nrgn knockout (KO) mice exhibit schizophrenia-relevant behavioral phenotypes, such as increased locomotor activity, abnormal anxiety-like behavior, impaired social behavior, and working memory deficits (Miyakawa et al, 2003; Hattori et al, this meeting). However, the molecular alterations underlying these behavioral abnormalities are still unclear. We previously reported that in the patients with psychiatric disorders, such as schizophrenia and bipolar disorder, and in some animal models of these disorders, certain cell types in the hippocampal dentate gyrus (DG) and frontal cortex are in a pseudo-immature status (Yamasaki et al, 2008; Walton et al, 2012; Ohira et al, 2013; Takao et al, 2013; Hagihara et al, 2014). Based on the findings, we proposed that the pseudo-immaturity of the brain cells might be an endophenotype of these psychiatric disorders (Hagihara et al, 2013). Here, we investigated whether Nrgn KO mice exhibit this phenotype in their brain. In the DG, mRNA expressions of immature and

mature granule cell (GC) markers were not changed in almost all young Nrgn KO mice (20 weeks old) showed increased expression of immature GC markers and decreased expression of mature GC markers in the DG, suggesting a pseudo-immature phenotype. This suggests that both undetermined (e.g., stress and aging) and genetic factors might act together to reverse matured GCs to a pseudo-immature status. Interestingly, immunohistochemical analyses revealed patch-like expression for calbindin, a marker of mature GCs, in the DG of older mice. Patch-like expressions of several genes including calbindin have been shown in the cortex of patients with autism (Stoner et al, 2014). In our mutant mice, the medial frontal cortex had decreased number of cells expressing parvalbumin, which could be used as a marker of mature fast-spiking interneurons, without a gross decrease in cell density, suggesting another pseudo-immature phenotype. Decreased parvalbumin level is also observed in the cortex of patients with schizophrenia. Together, these findings suggest that Nrgn deficiency causes pseudo-immaturity in certain types of neurons in the DG and frontal cortex. Our results are consistent with the idea that neuronal immaturity in the brain is an endophenotype of schizophrenia.

Abstract: Through a genome-wide association studies for schizophrenia, single nucleotide polymorphisms of the Neurogranin (NRGN) gene have been confirmed to be associated with the disorder. In addition, neurogranin immunoreactivity has been shown to be dramatically decreased in the prefrontal cortex of patients with schizophrenia. These findings suggest that NRGN is one of the most promising risk genes for schizophrenia. Neurogranin is a neuronal postsynaptic protein C kinase substrate that is abundantly expressed in brain regions important for cognitive function, including the hippocampus and cortex. Previous studies indicated that neurogranin is involved in synaptic plasticity and long-term potentiation and that knockout (KO) of Nrgn leads to aberrant behavioral phenotypes involving deficits in cognitive functions and abnormal emotional behaviors in mice. To further investigate the functional roles of neurogranin in the central nervous system, we subjected Nrgn KO mice to a comprehensive battery of behavioral tests. Consistent with the results of previous studies, increased locomotor activity, abnormal anxiety-like behavior, impaired social behavior, and deficits in working memory were observed in Nrgn KO mice. The mutant mice also exhibited abnormal depression-like behaviors and impaired sensorimotor gating. In addition, the dentate gyrus in the adult mutant mice exhibited an immature phenotype, which has been proposed as a novel endophenotype of psychiatric disorders, including schizophrenia. These observations collectively indicate that Nrgn KO mice may represent a novel animal model of schizophrenia.

Abstract: Genetic and environmental factors are thought to be involved in the pathogenesis of schizophrenia. Despite extensive efforts to clarify the underlying disease mechanisms, the main cause and pathophysiology of schizophrenia remains unclear. The lifetime prevalence is

approximately one percent, with onset of disease frequently occurring in early adulthood. We previously reported that a certain subtype of schizophrenic patients exhibit idiopathic carbonyl stress with high plasma pentosidine levels and serum vitamin B6 depletion, which is referred to as carbonyl stress, without underlying diabetes or chronic kidney disease that are the two major cause of elevation of advanced glycation end products (AGEs). Furthermore, we found the correlation between carbonyl stress and clinical features such as high ratio of inpatients, long duration of hospitalization, higher daily doses of anti-psychotics and lower educational status, suggesting that those patients might be treatment-registrant cases. We attempted to find associations between cognitive impairments and biochemical data. Schizophrenics were divided into four groups by their levels of pentosidine and vitamin B6, and we assessed the symptom severity by the Manchester Scale Japanese version (MS-J), the cognitive function by Wechsler Adult Intelligence Scale 3rd version (WAIS-III) and Wisconsin card sorting test (WCST). We found that symptoms in high-risk group with high pentosidine and low vitamin B6 had a tendency to severe incoherence of thought and lower performance for digit span compared to that of other groups. Our preliminary data suggest that carbonyl stress might be associated with impaired working memory in schizophrenia. The comprehensive information covering *in vitro* and *in vivo* studies is important for evidence-based personalized medicine and hopefully more effective treatment for schizophrenic patients.

Title: Abnormal glutathione pathway in postmortem dorsolateral prefrontal cortex from people with schizophrenia

Authors: *Y. ZHANG, V. S. CATTS, C. S. WEICKERT;
Neurosci. Res. Australia, Randwick, Australia

Abstract: Oxidative stress is associated with increased production of reactive oxygen species (ROS) and decreased antioxidant defences. Increased oxidative stress can cause tissue injury and cellular damage in the central nervous system. The glutathione (GSH) pathway is the most important antioxidant system to protect against oxidative stress in human brain. GSH is

biologically synthesized by the rate-limiting enzyme glutamyl-cysteine ligase (GCL). GSH exists in a reduced form (GSHR) which is oxidized to GSSG when ROS are detoxified by GSH peroxidase (GPx). In this study, we examined the GSH antioxidant system in post-mortem brain from patients with schizophrenia. The quantities of glutamyl-cysteine ligase subunit C (GCLC), GSHR and total GSH in the pathway were measured. It is hypothesized that an abnormal GSH pathway is associated with schizophrenia. Dorsolateral prefrontal cortex from 37 schizophrenia cases and 37 matched controls were studied. Western blotting was used to examine the GCLC protein levels. The levels of GSHR and total GSH were determined by spectrophotometry. The difference in the GCLC and GSH levels between schizophrenia and controls were analysed by independent t-test analysis. We found that there is no significant difference [t(72)-1.077, p=0.285] in the levels of GCLC/β-actin between people with schizophrenia (1.67+0.58) and control subjects (1.55+0.55). However, we found that levels of GSHR/internal control in schizophrenia (1.05+0.25) were significantly less than in control subjects (1.23+0.25) [t(66)3.048, p=0.003]. Moreover, we found that levels of total GSH/internal controls in schizophrenia (1.01+0.25) were significantly less than in controls (1.16+0.21) [t(66)2.615, p=0.011]. In our study, there was no difference of the GCLC level between schizophrenia and controls; but less GSHR and less total GSH in people with schizophrenia than in controls. A decrease in GSHR and total GSH indicate impaired antioxidant defences in the prefrontal cortex of people with schizophrenia. In future studies, GPx protein will be measured to determine if it is consistent with our measures of GSH. Furthermore, we will seek to determine how oxidative stress relates to other neuropathological changes (i.e. increased inflammation) in schizophrenia.

Title: Autofluorescence as a quantitative measurement of schizophrenia patient-derived lymphoblast responses to stress

Authors: *X. INDURKHYA[1], A. RAMOS[2], N. ELKINS[2], T. TSUJIMURA[2], K. ISHIZUKA[2], A. SAWA[2], C. KORTH[1];
[1]Institüt Für Neuropathologie/Uniklinik Düsseldorf, Düsseldorf, Germany; [2]Johns Hopkins Hosp., Baltimore, MD

Abstract: Background The accumulation of autofluorescence (AF) within a cell is understood to be part of the normal aging process. This AF, termed lipofuscin, is the exclusive criteria for the definition of ceroid, which is any non-lipofuscin AF. After the discovery by the Sawa lab of elevated AF in cell lines derived from schizophrenic patients, we investigated this AF as schizophrenia-related ceroid. We tested the response of this ceroid to stress and investigated whether riboflavin was the source of the AF. **Methods** Lymphoblast lines derived from the immortalized lymphocytes of schizophrenia patients (n=8) and controls (n=7) were used for this study. FAD concentrations were measured in all cell lines. Cells were synchronized with serum starvation, treated with extra riboflavin (30 μM) and treated with oxidative stressors rotenone (10 μM) and hydrogen peroxide (100 μM). Results were analyzed via the largest AF peak identified in the cells at ex450/em530. AF was analyzed with photospectroscopy conducted in a microplate reader on live cells; alternatively, autofluorescent speckles were counted on images of fixed cells obtained via fluorescence microscopy with standard GFP filters (ex470/40, em525/50). **Results** There was no significant difference in the FAD concentrations of schizophrenia cell lines as compared to controls. The addition of riboflavin appeared to have no effect on the AF, except to cause an indiscriminate increase in intensity. However, serum starvation synchronization and rotenone appeared to affect the schizophrenia lines differently from the controls. **Discussion** Our results suggest that while riboflavin may be involved in the disease and even a component of the AF, it is not the principle source. Based on our data, there may be two schizophrenia subtypes: one with diminished FAD and one with elevated FAD. The schizophrenia patient-derived cells demonstrated a hypersensitivity to the oxidation-induced AF. They simultaneously showed insensitivity to the starvation-induced AF observed in control lines. Thus, we can narrow down the molecular source of the AF to distinct cellular circuitry.

Inst. at Phoenix Children's Hosp., Phoenix, AZ; [4]Phoenix Veteran Affairs Healthcare Syst., Phoenix, AZ; [5]Interdisciplinary Grad. Program in Neurosci., [6]Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: Sleep abnormalities are a common symptom in psychiatric disorders. Approximately 30-80% of patients with schizophrenia report disturbed sleep. The most common disturbances reported in patients are reduced sleep efficiency, decreased total sleep time, and increased sleep latency. However, the cause of sleep disturbances in schizophrenia is unknown. Both genetic and environmental factors influence schizophrenia risk. The immediate early gene (IEG) early growth response 3 (*Egr3*) has been associated with schizophrenia risk in human populations and decreased levels of EGR3 protein have been found in postmortem brain tissue from patients. *Egr3*-deficient mice display behaviors associated with schizophrenia pathophysiology. Interestingly, exposure to light induces high levels of *Egr3* expression in the suprachiasmatic nucleus (SCN), a brain area critical for circadian rhythms. The potential roles of *Egr3* in both schizophrenia and the response of SCN neurons to light led us to hypothesize that loss of *Egr3* may disrupt sleep-wakefulness regulation in mice. To test this hypothesis, male and female adult wild type (WT) and *Egr3 -/-* mice were monitored for one week in individual, non-invasive sleep monitoring cages. This system uses piezoelectric materials as highly-sensitive pressure detectors to determine a sleep profile for each animal. We found that male and female *Egr3 -/-* mice slept less compared with WT mice and that these differences were most profound during light/dark transitions. Female mice of both genotypes slept less than male mice, demonstrating an effect of gender on sleep. These data suggest that *Egr3* contributes to cumulative sleep and thus support our hypothesis. Notably, serotonin 2A receptor (5-HT_{2A}R) deficient mice also display a similar decrease in overall sleep compared to WT mice as that we found in *Egr3 -/-* mice. Prior findings from our laboratory suggest that *Egr3* may regulate cortical 5-HT_{2A}R expression. Similar sleep disruptions in *Egr3* and 5-HT_{2A}R deficient mice are additional support that thesegenes may interact functionally. Future studies determining additional biological mechanisms that contribute to sleep abnormalities may increase our understanding of pathophysiology of schizophrenia and other psychiatric disorders.

Title: Developmental decline of NR2B expression in PFC in the MAM model for schizophrenia: consequences and mechanism

Authors: *Y. GULCHINA, M. A. SNYDER, W.-J. GAO;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The prefrontal cortex (PFC) encodes cognitive features that are integral for appropriate behavioral response to environmental demands. In particular, working memory function is an essential constituent process of prefrontal-dependent higher order cognitive functions. The NMDA receptor is a molecular substrate of learning and memory functions, with the NR2B subunit intimately linked to working memory. In schizophrenia (SCZ), working memory and other prefrontal-dependent cognitive functions are impaired prior to the emergence of psychosis, and patients' functional capabilities are directly dictated by these impairments. Thus, it seems likely that NMDA, particularly NR2B, dysfunction is a feature of early cognitive decline in this disorder. Given the unique profile of NR2B expression in the developing brain, we hypothesize that disrupted NR2B expression in an animal model for SCZ is the crux of early cognitive deficits in this disorder. We utilized the MAM model for SCZ to address this hypothesis. Our data support that downregulation of NR2B is a feature of juvenile (p21) and adolescent (p45) development in PFC in MAM-exposed animals via Western blot and whole-cell patch clamp recording. We observed that layer V pyramidal neurons from juvenile MAM-exposed rat medial PFC demonstrated a reduction in NMDA-mEPSC amplitude. Later, NMDA-mEPSC frequency was reduced in adolescent MAM-exposed animals. To confirm the synaptic nature of these deficits, we will proceed with evoked recordings of saline- and MAM-exposed medial PFC. Epigenetic mechanisms are well poised to contribute to this altered NR2B expression in MAM-exposed PFC. We have identified a selective increase in H3K27me3, a repressive histone modification, in juvenile MAM-exposed PFC. To further probe the role of epigenetic mechanisms in regulating NR2B expression, we will explore the role of repressor proteins, such as the REST complex, specifically at the Grin2b promoter in developing PFC with the chromatin immunoprecipitation assay. We expect enrichment of these repressor proteins at

the Grin2b promoter is at the core of NR2B dysfunction in this neurodevelopmental model for SCZ.

Title: A negative feedback loop controls NMDA receptor function in cortical interneurons via Neuregulin 2/ErbB4 signaling

Authors: ***D. VULLHORST**[1], R. M. MITCHELL[1], C. KEATING[1], S. ROYCHOWDHURY[1], I. KARAVANOVA[1], J.-H. TAO-CHENG[2], A. BUONANNO[1];
[1]Section on Mol. Neurobio., NICHD, NIH, Bethesda, MD; [2]EM Facility, Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: The Neuregulin receptor ErbB4 is an important modulator of GABAergic interneurons and neural network synchronization. However, little is known about the endogenous ligands that engage ErbB4, the neural processes that activate them or their direct downstream targets. Here we demonstrate that the NMDA receptor is both effector and target of Neuregulin 2 (NRG2)/ErbB4 signaling in cortical interneurons. We use double immunofluorescence in-situ hybridization and newly generated mouse and rabbit monoclonal antibodies to show that interneurons co-express ErbB4 and NRG2, and that NRG2 accumulates as an unprocessed pro-form on cell bodies atop subsurface cisterns. Evidence based on post-fixation immunofluorescence cytochemistry, live-cell imaging and Western blotting analysis of NRG2 protein demonstrates that NMDA receptor activation rapidly triggers shedding of the signaling-competent NRG2 extracellular domain. Unexpectedly, a proteomics analysis of proteins that associate with ErbB4 upon activation by NRG2 revealed GluN2B-containing NMDA receptors themselves as targets of NRG2/ErbB4 signaling. Electrophysiological recordings of whole-cell currents in cultured hippocampal neurons and of synaptically evoked EPSCs in acute PFC slices show that NRG2 rapidly and potently down-regulates NMDA, but not AMPA, receptor currents. These effects are mediated directly on ErbB4-positive GABAergic interneurons, and are not observed in ErbB4-negative pyramidal neurons. Our findings reveal an intimate reciprocal

relationship between ErbB4 and NMDA receptors with possible implications for the modulation of cortical microcircuits associated with cognitive deficits in psychiatric disorders.

Title: Tyrosine hydroxylase, GAD67, vGLUT1, and vGLUT2 proteins in the substantia nigra/ventral tegmental area in schizophrenia

Authors: *K. E. SCHOONOVER[1], L. A. MCCOLLUM[2], R. C. ROBERTS[2];
[1]Psychology and Behavioral Neurosci., [2]Psychiatry and Behavioral Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Schizophrenia (SZ) is a serious mental illness with positive, negative, and cognitive symptoms. The substantia nigra/ventral tegmental area (SN/VTA) provides the largest dopaminergic (DA) input to the brain, and projects to the striatum that is the primary locus of action for antipsychotic drugs (APDs). The SN also receives both GABAergic and glutamatergic inputs that regulate neuronal activity. This study compared tyrosine hydroxylase (TH), glutamate decarboxylase (GAD67), and vesicular glutamate transporters (vGLUT1 and vGLUT2) in control and SZ postmortem human SN/VTA. The SZ cohort is tested as a whole and then divided by treatment status or treatment response. Postmortem caudal SN was obtained from the Maryland Brain collection. SZ (n=13) cases were compared to matched controls (NC, n=12). The SZ group was then subdivided by treatment status: no APD (SZ-Off, n=4 or on APD (SZ-On, n=9); or treatment response: treatment resistant (TR, n=5) and treatment responsive (RESP, n=4). Western blot analysis was used to measure protein levels of vGLUT1, vGLUT2, TH, GAD67, and actin. Optical density values were normalized to actin and the average NC value. NC vs. SZ: SZ had higher levels of TH compared to NC ($p = 0.01$), with a similar result for GAD67 ($p = 0.004$). vGLUT1 and vGLUT2 protein levels did not significantly differ between

the NC and SZ groups. NC, SZ-on, SZ-off: An ANOVA showed between group differences for TH, GAD67, and vGLUT2. TH protein levels were higher in SZ-on compared to NC ($p = 0.008$). GAD67 protein levels were also higher in SZ-on compared to NC ($p = 0.003$). In contrast, SZ-off had higher levels than NC ($p = 0.041$), with no difference between SZ-on and NC. Protein levels of vGLUT1 did not significantly differ, but showed a similar pattern to that of vGLUT2. NC, TR, RESP: An ANOVA showed between group differences for TH and GAD67. TR had significantly higher TH levels than NC ($p = 0.001$) and SZ-off ($p = 0.045$). Similarly, GAD67 levels in TR were significantly higher than NC ($p = 0.004$). No significant differences among groups were observed for vGLUT1 or vGLUT2. In summary, TH and GAD67 protein levels were increased in the caudal SN in SZ compared to controls, which could possibly be an APD effect; TR had higher levels of TH and GAD67 than NCs. vGLUT1 tended to be higher in SZ, especially in SZ-off, with no relationship to treatment response. vGLUT2 was increased in SZ-off, and had no relationship to treatment response. These data suggest abnormalities in DA and GABA transmission in SZ with a possible relation to treatment response. Glutamatergic inputs to the SN in SZ from subcortical regions (as marked by vGLUT2) may be elevated in SZ-off and normalized by APDs.

Title: Clozapine reduces Toll-like receptor 4/NF-κB-mediated inflammatory responses through Akt inhibition in microglia

Authors: *S. KIM[1], Y. KIM[2], S. SHIN[3];
[1]Dongguk Univ. Intl. Hosp., Ilsandong-Gu, Goyang-Si, Gyeonggi-Do, Korea, Republic of;
[2]Dongguk Univ., Gyeonggi-do, Korea, Republic of; [3]Konkuk Univ., Seoul, Korea, Republic of

Abstract: Clozapine (CZP) is an atypical antipsychotic agent used in the treatment of psychotic disorders including schizophrenia and bipolar disorder. Accumulating evidence suggests that neuroinflammation is closely associated with the pathogenesis of schizophrenia as well as bipolar disorders. In this study, we investigated the effect of CZP on anti-inflammatory activity in lipopolysaccharide (LPS)-stimulated microglia. CZP treatment suppressed LPS-induced phosphorylation of IkBα at Ser-32 and of p65/RelA at Ser-468, as well as NF-kB-dependent

transcriptional activity, as revealed by a cis-acting reporter assay system and analysis of NF-κB target gene expression. CZP downregulated LPS-induced Akt phosphorylation at Ser-473. Pharmacological Akt inhibitors ameliorated LPS-induced NF-kB activation, whereas ectopic expression of the constitutively active form of Akt (gag-Akt) abrogated the inhibitory effect of CZP on LPS-induced NF-kB phosphorylation. Removal of extracellular Ca2+ by EGTA or sequestration of intracellular Ca2+ by BAPTA-AM attenuated LPS-induced Akt phosphorylation. Treatment with calmodulin (CaM) antagonists and the CaM kinase inhibitor, KN-93, also prevented LPS-induced Akt and NF-κB activation. Ca2+/CaM-mediated Akt activation is critical in LPS-induced NF-κB activation in microglia. CaM antagonism by CZP plays an important role in anti-inflammatory activity through the inhibition of Akt-mediated NF-kB activation. The antipsychotic CZP could be a promising agent for prevention of TLR4-mediated neuroinflammation.

Title: Cholinergic muscarinic receptor expression in post mortem brain tissue of schizophrenia patients

Authors: ***N. P. THOMAS**[1], E. SCARR[1], B. DEAN[2];
[1]Psychiatry, Univ. of Melbourne / Psychiatry, Parkville, Australia; [2]Mental Hlth., The Florey Inst. of Neurosci. and Mental Hlth., University of Melbourne, Australia

Abstract: Schizophrenia (SCZ) represents a complex mental health syndrome that likely represents a group of psychiatric conditions. A crucial step towards understanding the aetiology of SCZ, and developing better diagnosis and treatments is to identify potential subgroups within the diagnosis. This corresponds with a defined subgroup of schizophrenia subjects denoted muscarinic receptor deficient schizophrenia (MRDS). Making up 25% of the SCZ population, these subjects are separated due to their marked loss (75%) in cortical [3H] pirenzepine binding (specifically binds M1 subclass of muscarinic receptors), measured in post-mortem brain tissue. It has also been previously demonstrated that within the caudate putamen (C.P) there is

significantly reduced [3H] pirenzepine (PZP) and [3H] 5,11-dihydro-11-(((2-(2-((dipropylamino)methyl)-1-piperidinyl)ethyl)amino)carbonyl)6H-pyrido(2,3-b)(1,4)-benzodiazepin-6-one methanesulfonate (AF-DX) (specifically binds the M2/ M4 subclasses) binding in SCZ. However, it is not known if the extent of binding decreases are predominately driven by MRDS subjects, as they are in the cortex, regarding [3H]PZP. Therefore, in order to better understand the changes in muscarinic receptors in the C.P from subjects with SCZ, and to delineate whether the MRDS subgroup were identifiable by a marked loss of [3H]PZP in the sub-cortical region, we measured [3H]PZP and [3H]AD-FX-384 binding to C.P from 40 SCZ subjects, 20 of which were MRDS, and 20 non-psychiatric controls. Results:The level of [3H]PZP binding was significantly lower in the C.P from subjects with SCZ to CTRL ($p < 0.004$). There was significant variance in [3H]PZP binding when comparing MRDS, other SCZ subjects, and CTRL ($p < 0.001$), shown to be due to the lower levels of binding to C.P from subjects with MRDS compared to controls (p 0.0001). There was no significant difference between other SCZ subjects and CTRL. The level of [3H]AF-DX binding was significantly lower in the C.P from subjects with SCZ to CTRL ($p = 0.003$). There was significant variance in [3H]AF-DX-384 binding when comparing MRDS, other SCZ subjects, and CTRL ($p < 0.001$), shown to be due to the lower levels of binding to C.P from subjects with MRDS compared to controls (p 0.0001). There was no significant difference between other SCZ subjects and CTRL. Conclusions: Lower binding levels of [3H]PZP and [3H]AF-DX-384, indicative of M1 and M2/4 receptors respectively, within the C.P from subjects with SCZ are predominately driven by MRDS subjects, defined by their loss of cortical M1 muscarinic receptors. Title: Investigating the role of the schizophrenia risk gene ZNF804a in early brain development

Authors: ***Y. ZHOU**[1,2], F. DONG[1], X. JIANG[1], C. MCSWEENEY[1,2], Y. MAO[1,2];
[1]Penn State University, Biol. Dept., State College, PA; [2]Huck Inst. of the Life Sci., State college, PA

Abstract: ZNF804a was the first gene to reach genome-wide significance for psychosis when SNP rs1344706 was shown to be significantly associated combining SZ and bipolar disorder diagnoses. Several follow up genome-wide associated studies (GWAS) have replicated the association of rs1344706 with SZ and other psychosis in different populations. Although the association with SZ has been reported since 2008, the molecular function of ZNF804a remains unclear. We found that ZNF804a expression is high in the embryonic brain but decreased in the adulthood and ZNF804a localizes in both nucleus and dendrites. We performed *in utero* electroporation using B6 wild type mice on embryonic day 15 (E15) and transfected the neuronal progenitor cells with ZNF804a overexpression (OE) and knockdown (KD) constructs, both were tagged with GFP. On E18, the electroporated embryos were collected and the brains were processed with cryo-sectioning and fluorescent immunocytochemistry (ICC) staining. Quantitated results of GFP positive neuron showed overexpressing ZNF804a *in utero* significantly increased the migration of new born neuron, while knockdown endogenous ZNF804a significantly decreased the neuronal migration. To determine how ZNF804a regulates neuronal migration, we conducted the yeast two hybrid screen and identified novel proteins that interact with ZNF804a. Taken together, our study paved the road of understanding the molecular mechanism of ZNF804a and demonstrated its significant role for major mental illness in neuronal development.

Title: Regulation of AMPAR subunits by miR-137 and neuregulin: Implications for schizophrenia

Authors: ***K. THOMAS**[1], B. ANDERSON[1], D. HAWKINS[1], Q. GU[1], N. SHAH[1], G. BASSELL[1,2];
[1]Cell Biol., [2]Neurol., Emory Univ., Atlanta, GA

Abstract: Schizophrenia is a debilitating cognitive disorder that affects approximately 1% of the world's population yet has no cure, no known cause, and no means of prevention. In 2011 a schizophrenia genome wide association study (GWAS) identified a patient-associated single nucleotide polymorphism near the gene for the microRNA (miRNA) miR-137. miRNAs are small noncoding RNAs that inhibit protein synthesis by silencing translation and/or promoting degradation of target mRNAs, which the miRNAs bind via complementary base pairing. Recent studies suggest that miR-137 plays a pivotal role in neuronal development and function, and many of its predicted and/or validated targets are also schizophrenia-associated risk loci. In the present study, we focus on the relationship between miR-137, neuregulin-1 (Nrg), and the AMPA receptor subunits GluA1 and GluA2, all of which are associated with schizophrenia susceptibility. Luciferase assay experiments suggest that miR-137 directly regulates GluA1 levels, and western blot experiments confirm that miR-137 regulates GluA1 and GluA2 levels in primary cortical neuron cultures. Additional luciferase assay experiments indicate that Nrg stimulation increases the activity of a firefly luciferase Gria1-3'UTR reporter. Acute stimulation of neuronal cultures with a soluble form of Nrg also leads to upregulation of GluA1 and GluA2. Fluorescence *in situ* hybridization experiments confirm that miR-137 localizes to the dendrites of primary cortical neurons but that dendritic levels are unchanged by acute Nrg stimulation. However, Nrg may regulate interactions between miR-137 and the RNA-induced silencing complex (RISC) component Ago2. Mutation of a predicted miR-137 binding site ablates the effect of Nrg, indicating that Nrg may regulate GluA1 through a miR-137-dependent mechanism. We propose that Nrg stimulation causes RISC to release miR-137, allowing the translation of Gria1 mRNA and production of new GluA1 protein. Nrg may regulate GluA2 by a similar mechanism or through a GluA1-dependent mechanism. Together these data elucidate a novel schizophrenia-associated translational control pathway and provide a basis for future studies examining how Nrg regulates miRNA activity and the functional consequences of this AMPAR subunit upregulation.

Title: The value of interleukin 6 as a peripheral diagnostic marker in schizophrenia

Authors: *K. A. CHASE[1,2], J. J. CONE[3], C. ROSEN[1], R. P. SHARMA[1,4];
[1]Psychiatry, Univ. of Illinois At Chicago, Chicago, IL; [2]Dept. of Human Genet., [3]Neurobio., Univ. of Chicago, Chicago, IL; [4]Jesse Brown Veterans Affairs Med. Ctr., Chicago, IL

Abstract: Background: Patients with schizophrenia have alterations in immune system functioning. This, coupled with studies indicating the impact of maternal illness on offspring development, strongly implicate associations between the inflammasome and schizophrenia. As such, the dynamic and complicated protein interleukin 6 (IL-6), both a pro- and anti-inflammatory cytokine, has been examined for its role in the development, course, symptomology, and applicability as a biomarker of schizophrenia. IL-6 and sIL-6R serum levels are significantly elevated in patients with schizophrenia, with implications on symptom severity. Methods: In this study, we examined IL-6 mRNA levels by real-time RT-PCR from fresh extracted peripheral blood mononuclear cells (PBMC) in 106 participants, including 53 patients with schizophrenia and 53 healthy individuals. Changes in mRNA expression were measured using qRT-PCR with β-Actin and GAPDH for normalization. Results: We found that peripheral PBMC IL-6 mRNA levels could function as a predictor of a diagnosis of schizophrenia. Furthermore, in participants with schizophrenia, we also found elevated levels of IL-6 mRNA with earlier ages of illness onset and worse positive symptom presentation, as measured by the Positive and Negative Syndrome Scale. Discussion: These findings provide important and continued support for a pathophysiological role for inflammation in patients with schizophrenia. Future utilization of peripheral IL-6 mRNA levels could potentially function as yet another tool in a clinician's tool belt during an initial diagnosis and tailoring of individualized treatment plans for patients with schizophrenia. Conclusions: Associations between a pro-inflammatory state and schizophrenia have been one of the more enduring findings of psychiatry, with various lines of evidence suggesting a compelling role for IL-6 in the underlying pathogenesis of schizophrenia.

Abstract: Recent technological advances in large-scale human genetics has ben able to start to unveil the genetic architecture of schizophrenia (SCZ). While the identification of a variety of risk factors suggests a broad convergence in developmental, glutamatergic, and postsynaptic density (PSD) pathways, it is not clear if these sets of molecules associates in common signaling mechanisms at different developmental stages and subcellular localization. Here, using immunopurification and proteomics assays, we identified the spatial and temporal context where common and rare SCZ risk factors are associated. We determined 3360 in-vivo protein-protein interactions across 36 protein complexes and defined major clusters for enrichment of SCZ risk factors at mouse embryonic day 14 (e14) and adult PSD. Mutations in SCZ risk factors modifies the composition of these protein complexes trough protein domain interactions regulated by protein domains/ligand phosphorylation, and cluster a discrete number of protein domains defining molecular functions. These results were integrated into a software platform: Psychiatric Protein/Pathways Resource (PsyPPRes) that allows to prioritize SCZ candidate risk factors and place them within their molecular context.

Title: Histone phosphorylation in schizophrenia and normal subjects; at the end of the cascade

Authors: R. P. SHARMA[1,2], B. FEINER[1], *J. K. MELBOURNE[1], K. A. CHASE[1,3];
[1]Psychiatry, Univ. of Illinois At Chicago, Chicago, IL; [2]Jesse Brown Veterans Affairs Med. Ctr., Chicago, IL; [3]Univ. of Chicago, Chicago, IL

Abstract: Background: Histone modifications in peripheral blood cells are susceptible to multiple epigenetically active bio-chemicals in circulation. These organic molecules, which include all drugs of abuse and most psychotropic drugs, can activate kinase phosphorylation signaling cascades that penetrate to the level of nuclear chromatin and act directly on the histone H3 tail at the Serine 10 position. Methods: Peripheral blood cells (PBMC) from normal controls (n=42) and subjects with schizophrenia (n=37) were extracted using the Ficoll method. Participants with schizophrenia were diagnosed using the SCID and clinical measures obtained include symptom inventories (PANSS) and overall social functioning (Heinrichs-Carpenter scale). H3S10phos histone modification levels were measured in acid histone extracts of PBMC, using a commercially available ELISA assay. Results: Participants with schizophrenia had a significant and approximately 50% increase in average levels of H3S10phos in their peripheral blood cells when compared to normal controls. Increased levels of H3S10phos were associated with several dimensions of the PANSS and the Heinrichs-Carpenter, both indicating improved symptom presentation and quality of life. Conclusions: These results encourage further characterization of peripheral blood levels of histone modifications to facilitate epigenetic research in living patients. It also suggests that kinase cascades, emanating from membrane receptors, maybe an alternate approach to opening restrictive chromatin with the objective of improved genomic response to therapeutics.

Title: Domain analysis of TRIOBP-1 implies a common basis underlying its actin polymerization activity and its aggregation in schizophrenia

Authors: *N. J. BRADSHAW, R. MARREIROS, C. KORTH;
Heinrich Heine Univ., Duesseldorf, Germany

Abstract: The presence of aggregates of specific proteins in the brain can be used to characterize multiple neurodegenerative conditions, and arises as a result of imbalances in protein homeostasis during the development of the condition. We have previously proposed that similar protein deposits may arise in subsets of patients suffering from chronic mental illness, and were able to determine that proteins produced by two established schizophrenia risk factors, DISC1 and dysbindin, could be seen to aggregate specifically in the brains of a subset of patients with major mental illness. To detect other such proteins not previously implicated by genetics, we employed an antibody proteomics approach, identifying TRIOBP-1 as an additional protein which putatively shows schizophrenia-specific aggregation in the brain. The propensity for both over-expressed and endogenous TRIOBP-1 protein to aggregate was then confirmed in a variety of systems. The TRIOBP-1 protein is predicted to consist of an N-terminal Pleckstrin homology domain, as well as extensive predicted coiled-coil regions. In order to investigate the domain structure of TRIOBP-1 in more depth, and specifically in order to determine which elements of the protein were implicated in both its normal function and in its aggregation propensity, a large number of constructs were subcloned containing combinations of structural elements of TRIOBP-1. These were expressed in both neuroblastoma cell lines and in E. coli for recombinant protein production. In this manner, we have now identified a central segment of the protein, as being critical for the aggregation of the coiled-coil C-terminal segment of TRIOBP-1. The N-terminal section of TRIOBP-1 shows no such propensity, but was seen to be localized to the actin cytoskeleton by this same central region, implying a common underlying relationship between the aggregation and actin-binding features of TRIOBP-1. We have also found the first evidence that the N- and C-terminal portions of TRIOBP-1 may play distinct roles in the promotion of actin polymerization by TRIOBP-1. Experiments to confirm the relevance of TRIOBP-1 aggregation to schizophrenia in the wider population are currently underway. Through probing a protein misfolding event seemingly present in at least a subset of patients, we hope to determine both its potential utility as a biomarker, and more generally to understand a physiological element of chronic mental illness which has the potential to lie downstream of both genetic and environmental risk factors.

Title: *In vivo* biochemical studies with xanomeline emphasize the importance of the M4 subtype of muscarinic receptors

Authors: *M. POPIOLEK, J. HARMS, S. GRIMWOOD;
Neurosci. Res. Unit, Pfizer, Cambridge, MA

Abstract: Preclinical and clinical studies suggest that muscarinic receptor (mAChR) activation may be therapeutically beneficial for the treatment of schizophrenia and Alzheimer's disease. This is best exemplified by work with xanomeline, whose efficacy is thought to be via co-activation of M1 mAChRs, which are Gαq-coupled, and M4 mAChRs, which are Gαi-coupled. *In vivo* biochemical studies were performed to investigate the effect of xanomeline on intracellular signaling cascades in the mouse brain. Phosphorylated 3'-5'-cyclic adenosine monophosphate (cAMP)-response element binding protein (pCREB) was measured as an indicator of M4 activity due to preferential expression of M4 mAChRs on the striatal D1 expressing medium spiny neurons of the direct pathway, as well as the modulatory role they play in mediating signaling in these cells. Administration of 3.2 mg/kg xanomeline (15 min, s.c.) significantly decreased (~25%) striatal pCREB levels, relative to vehicle-treated controls. This effect was blocked by the M4-preferring mAChR antagonist tropicamide (10 mg/kg i.p; 20 min), but not by the M1-preferring mAChR antagonist VU-0255035 (32 mg/kg i.p.; 30 min). Similar decreases in striatal pCREB levels observed with xanomeline treatment were also shown for the M4-selective PAM, PT-3763 (3.2 mg/kg s.c.; 15 min). Effects by xanomeline and PT-3763 on pCREB were not, however, robustly apparent in either the hippocampus or prefrontal cortex. These data suggest that xanomeline mediates striatal pCREB effects through the M4 subtype of mAChRs.

Title: The effect of lithium on the alleviation of AKT1-related neuromorphological and behavioral deficits in P19 cell line, primary cell culture, and Akt1 mutant mice

Authors: *C.-Y. CHANG[1], D.-Z. LUO[2], T.-W. WANG[5], V. STUDER[6], W.-S. LAI[2,3,4]; [2]Psychology, [3]Grad. Inst. of Brain and Mind Sci., [4]Neurobio. and Cognitive Sci. Ctr., [1]Natl. Taiwan Univ., Taipei, Taiwan; [5]Life Sci., Natl. Taiwan Normal Univ., Taipei, Taiwan; [6]Interdisciplinary institute for Neurosci., Univ. Bordeaux, Bordeaux, France

Abstract: Schizophrenia is a severe neuropsychiatric disorder that is hypothesized to result from genetic predisposition and disturbances in early brain development. Accumulating evidence from human genetic and animal studies suggests that AKT1 is a susceptible gene for schizophrenia. Emerging evidence indicates that a sex-specific role of Akt1 in the modulation of methamphetamine induced hyperlocomotion, depression-like behavior, sensorimotor gating function, and neuromorphology. Our recent study also revealed that Akt1-deficit mice are insensitive to antipsychotic drugs, but glycogen synthase kinase 3 (GSK3, a key downstream kinase for Akt1) inhibitor might have therapeutic potential. Given the fact that lithium is a GSK3 inhibitor and a mood-stabilizing drug for the treatment of bipolar disorder, it is of great interest to evaluate the therapeutic potential of lithium on the alleviation of Akt1-related neuromorphological and behavioral deficits. Taking advantage of P19 embryonal carcinoma cells, rat hippocampal primary cell culture, and Akt1 heterozygous mutant (Akt1+/-) mice as our models, a series of experiments was conducted *in vitro* and *in vivo*. First, using Ascl1 to differentiate P19 embryonal carcinoma cells into neurons, we examined the effect of AKT1/2 inhibitor on the neuromorphological alterations in DIV3 and the rescue effect of lithium. Quantitative analyses of Tuj1-immunostained P19-driven neurons revealed that AKT1/2 inhibitor resulted in a 60% reduction of neurite length but no difference was found in the number of differentiated neurons. But the reduction of neurite outgrowth can be rescued by the treatment of Lithium (0.5 & 1 mM). In hippocampal primary cell culture, a similar (60%) reduction in neurite length was observed in DIV3 as well. And such reduction can be alleviated by the optimal dose of lithium (8 & 10 mM) treatment. Based on these results and our previous findings, a set of 3 behavioral tasks was performed in Akt1+/- female mice and their wild-type littermate controls after chronic administration of lithium (100 mg/kg, i.p., twice per day) or saline. Compared to WT controls, chronic treatment of lithium alleviated observed behavioral impairments in Akt1+/- mice, especially in the tail suspension task and acoustic PPI. The treatment of lithium also dampened methamphetamine-induced stereotypic behaviors in both groups compared to their saline controls. Collectively, out findings suggest the therapeutic potential of lithium for the treatment of schizophrenia and the importance of GSK3 as a new therapeutic target.

Title: Electrophysiological characterization of tgDISC1 rats: a preclinical model of DISC1opathies

Authors: ***M. VENZI**[1,2], S. TROSSBACH[3], R. MARREIROS[3], C. KORTH[3], N. BRANDON[4], E. ÅBERG[1,2];

Abstract: DIsrupted in SChizophrenia 1 (DISC1) is a gene originally associated to chronic mental diseases (CMD) (schizophrenia, depression and bipolar disorder) in a Scottish pedigree. Since then, a wealth of genetic and biological data have further strengthened the association between DISC1 and CMD (Brandon and Sawa, 2011). Importantly, alterations in DISC1 have also been independently found in a subgroup of CMD patients from the Stanley Medical Research Institute Consortium Collection (Leliveld et al. 2008). Insoluble aggregates of DISC1 protein were identified in the post-mortem brain tissue of these patients; this finding, coupled with molecular evidence of the cell-invasiveness of DISC1, suggests that a group of DISC1 dependent brain disorders could be clustered together as protein conformational disorders, or 'DISC1opathies' (Korth, 2012). To further investigate DISC1opathies, a rat line mildly overexpressing human DISC1 under the PrP promoter was recently generated (Korth, et al.). The tgDISC1 line is characterized by: 1) DISC1 aggregates in medial prefrontal cortex and striatum 2) behavioral phenotypes such as aphetamine hypersensitivity and hyperexploratory behavior 3) a molecular phenotype of striatal dopaminergic dysfunction (e.g., an increase in the proportion of dopamine D2 receptors in the high affinity state). To characterize the electrophysiological phenotype(s) of the tgDISC1 rats, ongoing experiments are being carried out with tgDISC1 (n=8) and wild-type littermates (n=8) implanted with fronto-parietal EEG and EMG electrodes; the animals will be recorded monthly with a telemetry system between 3 and 12 months. Here we

will present preliminary longitudinal data on the tgDISC1 animals describing alterations in sleep architecture, sleep spindles and EEG power spectra. In parallel, brain aggregates in tgDISC1 rats will be measured semi-quantitatively via western blotting in independent groups of animals at 3 and 6 months. Finally, we will present preliminary extracellular ensemble recordings performed in tgDISC1 freely moving animals with silicon probes implanted in the dorsal striatum. Title: Rat models of schizophrenia using NMDA antagonist Dizocilpine

Authors: *Q. CHANG, W. LACSINA, C. N. COHRON, T. HANANIA;
PsychoGenics Inc., Montvale, NJ

Abstract: Studies have shown that animals models involved in glutamatergic pathways are important tools to study negative and cognitive symptoms of schizophrenia. NMDA receptor antagonist dizocilpine (MK-801) elicit schizophrenia-like symptoms in humans and in animal models. In the present studies, we assessed the effects of acute administrations of MK-801 on recognition memory and executive function. We also tested the efficacies of memory enhancer galantamine, antipsychotics olanzapine and clozapine, as well as selective 5-HT2A receptor antagonist volinanserin (MDL100907) in reversing the MK-801 induced deficits. Subjects were exposed to acute MK-801 (0.15 mg/kg) 30 min. prior to behavioral tests. For serial reversal learning (RVL) test, subjects had been sufficiently trained and acquired the tasks prior to MK-801 exposure. For novel object recognition (NOR) test, rats were naïve to testing prior to MK-

801. In both assays, MK-801 provided deficit models in order to assess efficacies of compounds. The results indicated that MK-801 treatments induced impairments in recognition memory in NOR test and deficits in executive function in RVL test. Administration of acetylcholinesterase (AChE) inhibitor galantamine (1 mg/kg) significantly saved impairment of recognition memory in NOR test. In RVL test, olanzapine (0.3 and 1 mg/kg), clozapine (3 mg/kg) and MDL 100907 (1 mg/kg) all showed efficacy in saving reversal learning deficit caused by MK-801 treatment. These studies provide examples of memory impairment and treatment in animal models of schizophrenia, and demonstrated that deficit of executive function shown in animal models of schizophrenia are sensitive to the atypical antipsychotic clozapine and olanzapine. These results, together with our results obtained (and reported) earlier from rat models of schizophrenia using phencyclidine (PCP), are likely relevant to the cognitive impairments and negative symptoms (such as impaired social functioning shown in PCP models) of schizophrenia. Therefore these animal models can provide useful tools for the evaluation of novel antipsychotics.

Title: Risperidone prevents gender-sensitive depression of hippocampal excitatory transmission in a rat model of schizophrenia

Authors: ***A. S. PERETZ**[1], E. PATRICH[1], Y. PIONTKEWITZ[1], I. WEINER[2], B. ATTALI[2]; [1]Physiol., Sackler Sch. of Med. / Tel Aviv Univ., Tel Aviv-Yafo, Israel; [2]Tel Aviv Univ., Tel Aviv-Yafo, Israel

Abstract: Schizophrenia is associated with behavioral and brain structural abnormalities, of which the hippocampus appears to be one of the most consistent region affected. Electrophysiological studies performed on the poly I:C model of schizophrenia suggest that alterations in hippocampal synaptic transmission and plasticity take place in the offspring. However, these investigations yielded conflicting results and the neurophysiological alterations responsible for these deficits are still unclear. Here we performed for the first time a longitudinal study examining the impact of prenatal poly I:C treatment and of gender on hippocampal

excitatory neurotransmission. In addition, we examined the potential preventive/curative effects of risperidone (RIS) treatment during the peri-adolescence period. Excitatory synaptic transmission was determined by stimulating Schaffer collaterals and monitoring fiber volley amplitude and slope of field-EPSP (fEPSP) in CA1 pyramidal neurons in male and female offspring hippocampal slices from postnatal days (PNDs) 18-20, 34, 70 and 90. Depression of hippocampal excitatory transmission appeared at juvenile age in male offspring of the poly I:C group, while it expressed with a delay in female, manifesting at adulthood. In addition, a reduced hippocampal size was found in both adult male and female offspring of poly I:C treated dams. Treatment with RIS at the peri-adolescence period fully restored in males but partly repaired in females these deficiencies. A developmental and sex dependent decrease in hippocampal excitatory transmission occurs in the offspring of poly I:C treated pregnant mothers. Pharmacological intervention with RIS during the peri-adolescence period can cure in a gender-sensitive fashion early occurring hippocampal synaptic deficits.

Title: Developing translatable biomarkers of schizophrenia: assessment of three NMDA receptor antagonist-based pharmacological mouse models of schizophrenia using the auditory steady state response (ASSR)

Authors: *K. A. RICHARDSON[1], E. BUERGER[1], Y. HIRANO[2,3], K. SPENCER[2], D. GERBER[1], M. LEVIN[1];
[1]Galenea Corp, Wakefield, MA; [2]Dept. of Psychiatry, VA Boston Healthcare system and Harvard Med. Sch., Boston, MA; [3]Grad. Sch. of Med. Sciences, Kyushu Univ., Kyushu, Japan

Abstract: Cognitive impairments associated with mental illness remain a major area of unmet medical need. One factor contributing to the difficulty in discovering effective CNS therapeutics is the absence of reliable translational biomarkers for use as objective measures of drug efficacy. Synchronized neural oscillations, which are conserved across species, are associated with distinct

cognitive functions in certain frequency ranges (e.g. gamma: 30-100 Hz), and abnormalities in particular oscillations have been observed in various neuropsychiatric disorders. For example, deficits in gamma oscillations in schizophrenia patients have been demonstrated using auditory steady state response (ASSR) (Spencer et al. Biol Psychiatry 2008, Spencer et al. BMC Neuroscience 2009). Recent results have suggested that this alteration in gamma activity is not confined to auditory evoked potentials, but is also reflected in spontaneous power (Hirano et al. JAMA Psychiatry 2015). ASSR phase-locking factor (PLF) was found to be decreased at 40 Hz stimulation whereas induced power during stimulation and between stimuli (baseline) was increased across the gamma band in patients relative to healthy controls. Here we examined 3 glutamatergic, pharmacological mouse models of schizophrenia (PCP, Ketamine and MK-801; administered IP) using ASSR. Male C57BL/6 mice were implanted with microwire tungsten bundles placed in primary auditory cortex. Local field potentials (LFP) were recorded during presentation of click trains of various frequencies (20-100 Hz). Evoked power in the LFP was increased at lower frequencies of stimulation (20-50 Hz) in all three models. At higher stimulation frequencies, the observed effects depended on the model: PCP increased evoked power, Ketamine decreased evoked power and MK-801 had no effect on evoked power. Phase-locking at 20 Hz was generally increased in all 3 models. These results are in contrast to the observed decreases in evoked power and PLF at 40 Hz in the human disease condition. Analysis of induced power in the mouse models, however, showed alterations in power similar to those observed in patients. During the baseline period (between stimuli), induced power in all three models was increased in the gamma band (30-100 Hz). During the stimulus period, induced power in the gamma band in PCP and Ketamine models was also increased. In summary, we find that the NMDA receptor antagonist-based pharmacological models of schizophrenia recapitulate only a subset of electrophysiological findings in human schizophrenia patients as assessed with ASSR.

Title: Effect of resveratrol on schizophrenia-like behavior induced by immunogenic challenger by poly(I:C) during pregnancy

Authors: *F. R. FERREIRA[1], T. R. P. POMBO[2], V. P. L. GONÇALVES[2], R. L. FROZZA[1], S. S. GUTERRES[3], A. R. POHLMANN[3];

Abstract: Schizophrenia (SZ) is considered a neurodevelopmental disorder with important genetic component. Some authors suggest that, at least in a subgroup of patients, SZ might be caused by congenital alterations induced by environmental factors, particularly infections by some microorganisms. Despite clear evidences showing that maternal infection and maternal immune activation increases risks for SZ and autism, the mechanisms involved still are fully unknown. On the other hand, resveratrol (3,4',5-trihydroxy-trans-stilbene), a natural non-flavonoid polyphenol with antioxidant and anti-inflammatory activity, has shown protective effects against a number of cardiovascular and neurodegenerative diseases. The potential of resveratrol as protective agent to inflammatory insults during pregnancy still remains to be investigated. Here, we are using prenatal stimuli with poly(I:C)(=polyriboinosinic-polyribocytidilic acid), an established infection-based model, to investigate whether the treatment with resveratrol prevents the congenital SZ-like behavior. Pregnant mice received six doses of microencapsulated resveratrol (3,6 mg/Kg, i.p., per day, starting at E6) or empty microcapsules. The dams also were challenger once with poly(I:C) (30 mg/Kg), i.p., at E9, or saline. The behavioral impairments related to SZ to the pups were analyzed at day P61 using object recognition (OR) and social integration (SI) tests. There were no any effects to the poly(I:C) immunogenic challenge, resveratrol treatment or interaction for the pups when they were tested to OR. However, pups from dams stimulated with poly(I:C) showed reduction to the interaction time with unfamiliar mouse, when exposed together with a familiar mouse, at the SI test. Pups from dams stimulated with poly(I:C) and treated with resveratrol spent more time exploring unfamiliar mouse, when exposed together to a familiar mouse, an behavior similar to observed to the control group. These preliminary results suggest that treatment with resveratrol might prevent some of the SZ-like behavior at pups from dams exposed to infection. Therefore, the protective effect of resveratrol to congenital neurodevelopmental diseases might be broadly investigated.

Title: Reversal learning but not set-shifting deficits in the methylazoxymethanol acetate model of schizophrenia: a partial replication with implications for N-Methyl-D-aspartate receptor treatment for cognitive deficits in schizophrenia

Authors: *A. J. WHYTE, T. SCHARBERT, D. O' HAGAN, H. MARSTON, D. S. TAIT, V. J. BROWN;
Univ. of St Andrews, St Andrews, United Kingdom

Abstract: In rats, treatment with methylazoxymethanol acetate (MAM) on embryonic day 17 generates a model of schizophrenia, the phenotype of which includes ventricular enlargement, hippocampal (HIPP) and frontal cortex (FTX) pathologies, and behavioural deficits consistent with those found in patients with schizophrenia. To probe the effectiveness of N-Methyl-D-aspartate receptor (NMDAR) positive allosteric modulator ORG49209 in treating schizophrenia-related cognitive deficits, we obtained a cohort of MAM-treated rats (Sprague Dawley, Charles River) for testing in the attentional set-shifting task (ASST). The ASST measures executive functioning through a series of two-choice discriminations. Key measures in the ASST include the reversal stages and the extradimensional shift stage (ED), which requires the subject to respond to a previously irrelevant dimension. Patients with schizophrenia display increased trials to criterion (TTC) and errors, during reversal stages and the ED a finding also reported for MAM-treated rats in the rodent ASST, which uses digging medium and odour as discriminative dimensions. To confirm these previous findings in MAM-treated rats, we performed two baseline tests. In both the initial and the repeat baseline tests we found increased TTC and errors during the first reversal stage in MAM-treated rats compared to saline controls. However, neither test unveiled a set-shifting deficit in MAM-treated rats as they did not display elevated TTC during the ED compared to controls. We next examined the effect of ORG49209 on ASST performance using a Latin square design (0, 3, 10 mg/kg/ml). Treatment with ORG49209 abolished the reversal learning deficit by reducing TTC in MAM-treated rats and increasing TTC in saline controls, suggesting potential efficacy of ORG49209 in schizophrenia. Our anatomical and histological results revealed reductions in gross brain weight, enlargement of the lateral ventricles, FTX and HIPP microcephaly, and disruption of the CA2/CA3 cell layers in MAM-

treated rats compared to controls all consistent with previous reports. Reductions in parvalbumin positive (PV+) interneurons were evident in the dentate gyrus but not any other regions however, a result that is inconsistent with reports of reductions in PV+ interneurons throughout the FTX and HIPP. Despite the cohort of MAM-treated rats we examined only partially exhibiting the reported phenotype, our results with ORG49209 suggest that the underlying pathology in this cohort is responsive to enhancement of NMDAR activity a finding that is consistent with previous reports on schizophrenia-related cognitive deficits.

Abstract: Two highly selective serotonin 2C (5-HT2C) agonists (+)-JJ-3-42B and (+)-JJ-3-45B have been designed and tested for their ADME-Tox properties as well as their ability to work in animal models of schizophrenia-like behaviors. In the *in vitro* ADME-Tox tests, both compounds showed low plasma-protein binding, high Caco-2 and MDCK-MDR1 biomembrane

permeability, high microsomal stability, and excellent cytochrome P450 and hERG safety. Both compounds displayed no nephrotoxicity or neurotoxicity at a high concentration (150 μM) and both were negative in the Ames fluctuation test. Additionally, compound (+)-JJ-3-42B had a half-life of 1.8 h and a bioavailability (%F) of 53 in mice. Oral administration of (+)-JJ-3-42B to mice at a dose of 10 mg/kg provided a maximal brain concentration of 5.2 μg/g and a brain/plasma concentration ratio of greater than 10. Compounds (+)-JJ-3-42B and (+)-JJ-3-45B were examined in three behavioral tests. (a) In amphetamine-induced hyperlocomotion, both compounds significantly reduced the hyperactivity in mice at the doses of 10 mg/kg and 20 mg/kg, while 20 mg/kg (+)-JJ-3-42B normalized this response. (b) Amphetamine-disrupted prepulse inhibition (PPI) was rescued with compound (+)-JJ-3-42B in a dose range of 1-4 mg/kg, with 2 mg/kg showing the best efficacy. Additionally, (+)-JJ-3-45B also restored PPI at a 0.5-2 mg/kg dose range, with 0.5 mg/kg showing the highest efficacy. (c) In preliminary studies with the NR1 knockdown (NR1-KD) mice, both compounds (+)-JJ-3-42B and (+)-JJ-3-45B partially normalized object recognition memory at doses of 5 and 1 mg/kg, respectively. Together, the above ADMET and animal behavioral data support the further development of the selective serotonin 2C agonists, (+)-JJ-3-42B and (+)-JJ-3-45B, as potential anti-schizophrenic drugs.

Title: Prior D2 antagonist antipsychotic drug treatment prevents response to novel target compounds in MAM model of schizophrenia: potential circumvention using aripiprazole

Authors: *S. SONNENSCHEIN, K. M. GILL, S. A. MILLER, A. A. GRACE;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Novel target compounds for the treatment of schizophrenia have shown promise preclinically, but failed to show efficacy in clinical trials, which has led some to conclude that results from preclinical studies do not translate to the human condition. However, there is an important difference: preclinical research is performed on drug naïve rats, whereas clinical trials

are performed on patients that have received only brief withdrawal from years of prior antipsychotic drug treatment despite potential pervasive changes to the DA system. We recently found that withdrawal from repeated haloperidol (HAL) treatment interferes with the ability of a novel target compound to reverse the hyperdopaminergic state and hippocampal hyperactivity in the methylazoxymethanol acetate (MAM) neurodevelopmental model of schizophrenia. In the current study, we examined whether this would also occur with other, mechanistically distinct, first and second-generation antipsychotic drugs, with a focus on the D2 partial agonist aripiprazole (ARI). Electrophysiological recordings were conducted from spontaneously active DA neurons in the ventral tegmental area of anesthetized normal rats following 7d withdrawal from repeated HAL (0.6 mg/kg), clozapine (CLO; 10 mg/kg), or ARI (10 mg/kg) treatment for 21 d, p.o. Compared to vehicle-treated animals, rats withdrawn from repeated HAL and CLO treatment demonstrated reduced spontaneous DA neuron activity, likely due to depolarization block. This effect was not observed following ARI withdrawal, in which there was no change in DA neuron activity. This provides preliminary evidence that, in contrast to HAL and CLO, ARI may not induce depolarization block in VTA DA neurons. Lack of evidence for depolarization block and/or DA supersensitivity following repeated ARI treatment would suggest that it may be an effective transitional drug to test novel potential antipsychotic drugs without requiring an extended withdrawal period.

Title: Locomotor activity in zebrafish larvae as a behavioural screen for drugs targeting 5-HT_{2C} and/or melatonin receptors

Authors: N. RIBEIRO PALHA, *A. DEKEYNE, S. VEIGA, W. BOUCHERON, P. DELAGRANGE, C. LOUIS, P. LESTAGE;
Inst. De Recherches Servier, Croissy Sur Seine, France

Abstract: Background. As an organism model at the interface between cellular-based assays and mammalian models, zebrafish (*Danio rerio*) is becoming increasingly popular for drug discovery processes. For instance, locomotor response to alternating periods of light and dark in zebrafish larvae has been proposed as a high-throughput *in vivo* screening test for efficacy/toxicity

assessment of neuroactive drugs (Ellis et al., 2012). However, few studies have been conducted to characterize *in vivo* mechanisms of action of potential new therapeutics. This work aimed at deciphering actions of prototypical serotonin (5-HT)$_{2C}$ and melatonin (MT) agonists/antagonists on larval locomotor response. Since orthologous genes to human 5-HT$_{2C}$ and MT receptor genes have been identified in zebrafish, specificity of action of agonists was also checked by use of morpholino-induced knockdown technology (Nasevicious & Ekker, 2000). Method**.** Five days post-fertilization wild-type larvae or morphants were individually placed in a 96-well microtiter plates, in E3 medium. Drug solutions prepared in DMSO were added to wells. Plates were then introduced in a tracking system (ZebraBox, ViewPoint). The total distance moved per light/dark cycle was recorded for 2 rounds of 10 min light + 14 min dark. After tracking, individual viability or morphological alterations were assessed, and gene silencing in morphants was checked by quantitative RT-PCR. Results**.** Control larvae displayed higher activity during dark *vs* light periods, a behavioural profile which is blocked by intermediate concentrations (3-10-30 µM) of the selective 5-HT$_{2C}$ agonist, Ro600175. This effect could not be related to sedation since higher concentration (100 µM) increased activity during light periods. Hypoactivity induced by Ro600175 (10 µM) was concentration-dependently reversed by selective 5-HT$_{2C}$ antagonists (SB242084, RS102221 and S32006) and was decreased in 5-HT$_{2C}$ morphants. Melatonin, MT antagonists (S20928 and luzindole) and the antidepressant, agomelatine, which possesses mixed 5-HT$_{2C}$ antagonist and MT agonist properties, all concentration-dependently decreased the activity during dark periods. Conclusion**.** Locomotor activity in zebrafish larvae may be proposed as a behavioural screen for "pure" 5-HT$_{2C}$ receptor antagonists, but not for melatonin agonists, nor for compounds endowed with additional MT agonist activity such as agomelatine-like drugs. In this latter case, blockade of melatoninergic activity with specific antagonists or morpholinos would be necessary to unmask 5-HT$_{2C}$ antagonist properties. Title: Blocking cortical GABAA receptors impairs sociability in rats

Authors: *T. A. PAINE, N. SWEDLOW, L. SWETSCHINSKI;
Neurosci., Oberlin Col., Oberlin, OH

Abstract: *Background:* Schizophrenia is a chronic, often debilitating, disorder characterized by positive, negative and cognitive symptoms. Negative symptoms, including asociality and anhedonia, are not adequately treated by currently available medications and appear to contribute to poor outcomes of people with schizophrenia. Post-mortem analyses find reduced expression of GAD_{67} (a GABA synthesis protein) and GAT_1 (a GABA reuptake transporter) in the prefrontal cortex (PFC) of individuals diagnosed with schizophrenia; changes in these proteins suggest decreased PFC GABA function in schizophrenia. The goal of the current experiment was to determine if decreasing cortical GABA function is sufficient to cause behavioral changes reminiscent of the negative symptoms of schizophrenia. *Methods:* Rats were implanted with guide cannulae aimed at the medial PFC. Over the course of 2 weeks rats were tested on a battery of tests: the social interaction test, the social preference test and the sucrose intake test. Prior to each test rats where infused with either bicuculline (0.0, 12.5, or 25.0 ng/0.5 µl/side) or L-allylglycine (0.0, 5.0, or 10.0 µg/0.5 µl/side). *Results:* Intra-cortical infusions of the $GABA_A$ receptor antagonist bicuculline (12.5 or 25 ng/0.5 µl/side), but not the GABA synthesis inhibitor L-allylglycine, decreased both the number of social interactions and the time spent engaged in social interactions. Similarly, bicuculline (25 ng/0.5 µl/side), but not L-allylglycine, infusions reduced the rats' social preference. Neither drug affected sucrose preference. *Discussion*: Blockade of $GABA_A$ receptors, but not inhibition of GABA synthesis, decreased sociability. This effect cannot be explained by a reduction in the intrinsic rewarding property of social interactions. These results are support our previous findings that blockade of $GABA_A$ receptors, but not GABA synthesis, causes schizophrenia-like cognitive symptoms (i.e., impaired attention and decision-making). Combined these data suggest that reduced activation of $GABA_A$ receptors, rather than reduced synthesis *per se*, leads to schizophrenia-like changes in behavior.

Title: The use of preclinical assessments of anhedonia and motor function to understand dopamine D2 receptor-mediated behavioral effects

Authors: *D. B. HORTON[1], K. DLUGOLENSKI[2], N. C. STRATMAN[2], C. J. SCHMIDT[2], T. A. CHAPPIE[2];

Abstract: Drugs exhibiting functional dopamine D2 receptor antagonism have been characterized by a multitude of behavioral effects including motor dysfunction and anhedonia in the clinic. While motor effects can easily be assessed preclinically through locomotor activity assessments, FOBs, clinical sign monitoring or catalepsy tests, anhedonia risk can be a bit more difficult to understand. The intracranial self-stimulation (ICSS) model utilizes operant responding for electrical stimulation to assess reward sensitivity or motivation to determine the potential rewarding or anhedonic effects of drugs. The purpose of the current work was to better understand the level of translation this model has to predict negative affect or anhedonia in the clinic and the relationship that these effects have to locomotor and catalepsy assessments. Literature has shown that >70% D2 receptor occupancy is needed to induce negative subjective effects and motoric dysfunction in the clinic. The current work employed *ex vivo* receptor occupancy (RO) techniques to determine doses of two classic D2 receptor antagonists, eticlopride and haloperidol, which would afford similar D2 RO levels in rats and the effect of these doses on ICSS, locomotor activity, and catalepsy assessments, was determined. To assess ICSS effects, rats with bipolar stainless steel electrodes implanted in the medial forebrain bundle were initially trained to spin a wheel for electrical stimulation. Once stable responding was achieved, the current was held constant and a discrete trial task of varying frequencies was used to determine the ICSS threshold or the frequency at which the stimulation became rewarding. Once stable ICSS thresholds were established, the effect of eticlopride and haloperidol on ICSS thresholds were assessed as a within subjects design. In a separate group of rats, horizontal and vertical locomotor activity was assessed using automated test chambers with infrared photo-beam systems and catalepsy assessments were manually scored using a bar at a height of 10 cm above the testing surface. The current results show that eticlopride and haloperiodol, at clinically relevant D2 ROs, increased ICSS thresholds, decreased locomotor activity, and induced catalepsy at higher doses. Furthermore, the assessment of the magnitude of effect at relevant D2 ROs allows for a better understanding of what effects in these preclinical models might translate to the clinical. Taken together, the current work highlights the importance of these preclinical models to understand the potential anhedonic and motoric safety concerns associated with drugs targeting the dopaminergic system.

Title: Rapastinel (GLYX-13) produces rapid transcriptomic changes associated with synaptic signaling and remodeling: toward the elucidation of the mechanisms that underlie glutamatergic rapid-acting antidepressants

Authors: *M. E. SCHMIDT[1], A. L. GROSS[1], R. A. KROES[1], J. S. BURGDORF[2], J. R. MOSKAL[1,2];
[1]Naurex, Evanston, IL; [2]Biomed. Engineering, McCormick Sch. of Engineering, Northwestern Univ., Falk Ctr. for Mol. Therapeut., Evanston, IL

Abstract: Rapastinel, an allosteric NMDAR modulator with characteristics of a glycine-site partial agonist, and ketamine, a NMDAR antagonist, are two rapid-acting and long-lasting antidepressants. Given their similar antidepressant activity but divergent pharmacology, the transcriptomic profiles underlying the molecular mechanisms were assessed. Focused microarrays were used to examine changes in the expression of 1,178 CNS-specific genes in the rat medial prefrontal cortex at 1hr, 24hrs, and 2 weeks following treatment with a single, optimal antidepressant dose of either rapastinel (3mg/kg, IV) or ketamine (10mg/kg, IV). SAM analysis was used to quantify significant gene expression changes and was followed by functional annotation and identification of enriched biological pathways using DAVID, GSEA, and IPA. Rapastinel significantly enriched synaptic signaling pathways at 1hr post-dosing including; vesicle trafficking, ion channel activity, and a range of second messenger pathways. The effect of ketamine on these synaptic signaling pathways was not significant until 24hrs following treatment. Long-term potentiation (LTP) was enhanced by rapastinel at 24hrs and persisted up to 2 weeks, whereas ketamine only enriched LTP at 24hrs. Both rapastinel and ketamine enriched pathways related to synaptic remodeling, including cellular morphogenesis and differentiation. However, individual gene expression differences showed that rapastinel clearly induced these changes quicker, at 1hr and 24hrs, while ketamine did not affect these transcripts until 24hrs and 2 weeks. These data lend support to the hypothesis that rapastinel facilitates the enhancement of synaptic signaling through remodeling at the synapse by direct activation of the NMDA receptor, while ketamine likely produces these effects through an indirect pathway via downstream activation.

Title: The involvement of dopamine D_1 signaling on the cognitive function and the cataleptic effect of a phosphodiesterase 10A inhibitor, PDM-042 in rats

Authors: ***S. MAEHARA**, K. ARAKAWA, N. YUGE, S. FURUSAKO;
Mochida Pharmaceut. Co., Ltd., Gotemba, Shizuoka, Japan

Abstract: Phosphodiesterase 10A (PDE10A) is a new potential target for the treatment of schizophrenia. PDE10A, via hydrolysis of cAMP and cGMP, regulates intracellular cyclic nucleotide signaling cascades within the striatal medium spiny neurons. PDE10A inhibitors activate both the D_2 receptor-expressing indirect pathway and the D_1 receptor-expressing direct pathway in the striatal medium spiny neurons. Here we examined the pharmacological effects and the involvement of dopamine D_1 signaling of the potent, selective, orally available, and brain penetrable PDE10A inhibitor, PDM-042 in rats. PDM-042 inhibited human and rat PDE10A activities with IC_{50} values of less than 1 nM. The compound was more than 1000-fold selective against other PDEs and had no significant off-target activities against other pharmacological targets including large panels of GPCRs, enzymes, and ion channels. The radiolabeled PDE10A inhibitor, [^{3}H]PDM-042 exhibited saturation binding curves and high affinity with a K_d value of

8.5 nM for membranes prepared from rat striatum. PDM-042 itself and other structurally unrelated PDE10A inhibitors displaced [^{3}H]PDM-042 binding to PDE10A in a concentration-dependent manner. *In vivo* PDE10A occupancy rate of PDM-042 showed a good correlation with both the dose and the plasma concentration of PDM-042. In behavioral tests, PDM-042 dose-dependently (0.1 to 1 mg/kg, p.o.) attenuated the conditioned avoidance response (CAR), a well established preclinical predictor of antipsychotic activity. PDM-042 at doses of 1 and 3 mg/kg, p.o. showed better discrimination of a novel object from a familiar one 48 hours after the acquisition trial in the object recognition test, indicating its favorable effect on cognitive function. A D_1 receptor antagonist, SCH23390, significantly blocked the increase of object recognition memory caused by PDM-042 without affecting recognition index by itself. Regarding side effects, PDM-042 had a minimal effect on catalepsy even at a 30-fold higher dose (10 mg/kg, p.o.) than the efficacious dose in the CAR, while risperidone elicited catalepsy in a dose-dependent manner. SCH23390 significantly enhanced the duration of catalepsy caused by PDM-042 (1 mg/kg, p.o.) in a dose-dependent manner (0.003 to 0.03 mg/kg, s.c.), while SCH23390 alone slightly increased the duration of catalepsy up to 0.1 mg/kg, s.c.The present results suggest that PDE10A inhibitor may be the novel treatment of schizophrenia with antipsychotic actions, cognitive enhancing effects, and few extrapyramidal side effects, and that the enhancement of D_1 signaling involves in the cognitive enhancing effect and the cataleptic effect of PDE10A inhibitor in rats.

Title: The atypical antipsychotic amisulpride shares discriminative stimulus properties with benzamide derivatives, but not with antipsychotic, antidepressant, or anxiolytic drugs from other chemical classes

Authors: *T. J. DONAHUE[1], K. A. WEBSTER[1], T. M. HILLHOUSE[3], C. H. COOPER[1], K. W. LOVELESS[1], E. M. LEVIT[1], A. R. GRANT[1], R. YOUNG[2], E. O. DE OLIVEIRA[4], J. H. PORTER[1];

VA; [3]Dept. of Pharmacol., Univ. of Michigan, Ann Arbor, MI; [4]Ctr. for Drug Discovery, Georgetown Univ., Washington, DC

Abstract: Amisulpride, a benzamine derivative, is a second generation (atypical) antipsychotic drug used to treat both schizophrenia (at high doses) and depression (at low doses). The relatively selective binding profile of amisulpride distinguishes it from most other antipsychotic drugs, by primarily targeting dopamine D2 and D3 receptors and serotonin 5-HT2B and 5-HT7 receptors, where it displays functional antagonist activity. Approved in Europe, amisulpride displays an atypical clinical profile with efficacy for both positive and negative symptoms and with reduced extrapyramidal motor effects. The present study compared the discriminative stimulus properties of amisulpride to other benzamide derivatives and to antipsychotic, antidepressant, and anxiolytic drugs. Adult male C57BL/6 mice (N=14) were trained to discriminate 10 mg/kg rac-amisulpride from vehicle in a two-lever drug discrimination task for food reinforcement in an average of 35.7 sessions (range 6-89). The amisulpride dose-response curve (0.078 - 20.0 mg/kg) yielded an ED50 = 0.73 mg/kg 95% (CI = 0.47-1.13 mg/kg). Substitution testing with other benzamide derivatives revealed that amisulpride fully generalized (> 80% Drug Lever Responding) to sulpiride ED50 = 7.29 mg/kg (C.I. = 3.73-14.28 mg/kg) and partially to raclopride at 0.10 mg/kg (62.7% DLR) and tiapride at 40.0 mg/kg (76.4% DLR), but not to nemonapride or zacopride. In contrast, the antipsychotic drugs haloperidol, chlorpromazine, clozapine, olanzapine, risperidone, quetiapine, and aripiprazole; the antidepressant drugs fluoxetine, mianserin, imipramine, and bupropion; and the anxiolytic drug chlordiazepoxide did not produce amisulpride-appropriate responding during substitution testing. These findings demonstrate that the atypical antipsychotic amisulpride shares discriminative stimulus properties with some, but not all, benzamide derivatives such as the antipsychotic sulpiride that are structurally similar; however, amisulpride does not share discriminative stimulus properties with antipsychotic, antidepressant and anxiolytic drugs that belong to other drug classes. These results demonstrate that amisulpride possesses a unique discriminative stimulus.

Title: Suppression of spreading depolarization and stabilization of dendritic spines by rapastinel (GLYX-13), an NMDA receptor glycine-site functional partial agonist

Authors: *X.-L. ZHANG[1], C. W. SHUTTLEWORTH[3], J. R. MOSKAL[4], P. K. STANTON[2]; [2]Cell Biol. & Anat., [1]New York Med. Coll, Valhalla, NY; [3]Dept. of Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM; [4]Dept. of Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: Cortical spreading depolarization (SD) is a slow self-propagating wave of mass cellular depolarization in brain tissue, thought to be the underlying cause of migraine scintillating scotoma and aura, and associated with stroke, traumatic brain injury, and termination of status epilepticus. The N-methyl-D-aspartate subtype of glutamate receptor (NMDAR), which gates influx of calcium and is an important trigger of long-term synaptic plasticity, is also a contributor to the initiation and propagation of SD. The current study tested the potential of pharmacological modulation of NMDAR activity through the obligatory co-agonist binding site, to modulate the propagation of SD triggered by a focal elevation in extracellular [K+] in stratum radiatum of field CA1, and modulate the effects of SD on dendritic spine morphology, in hippocampal slices *in vitro*. A novel NMDAR functional glycine site partial agonist, rapastinel (aka GLYX-13), sometimes prevented the induction of SD, and when it occurred, significantly slowed its rate of propagation. In a subset of slices, a primary SD triggered by a focal puff of high [K+] resulted in a delayed, secondary SD initiated at the border between pyramidal cell bodies and stratum oriens. Rapastinel always blocked the induction of these secondary SDs. The passage of SD through CA1 stratum radiatum produced a rapid retraction of apical dendritic spines which reversed to an overshooting increase in spine volume after neuronal depolarization had recovered. Rapastinel improved the rate and extent of return of dendritic spines to their original sizes and locations following SD, suggesting that NMDAR modulators can protect synaptic connections in the brain from structural alterations elicited by SD. These data indicate that NMDAR modulation to renormalize activity may be an effective new treatment strategy for suppression or amelioration of the contribution of SD to short and long-term symptoms of migraine attacks, as well as SD following stroke and traumatic brain injury.

Title: Changes in brain volume in response to estradiol levels, amphetamine sensitization and haloperidol treatment in awake female rats

Authors: D. MADULARU[1], *P. P. KULKARNI[2], C. F. FERRIS[2], W. G. BRAKE[1]; [1]Psychology, Concordia Univ., Montreal, QC, Canada; [2]Psychology, Northeastern Univ., Boston, MA

Abstract: Estrogen has been shown to further ameliorate symptoms when administered in conjunction with antipsychotics in patients with schizophrenia. We have previously shown that chronic haloperidol (HAL) treatment reduces amphetamine (AMPH)-induced locomotor activity in AMPH-sensitized rats, but only when paired with high levels of the estrogen, 17-β estradiol. In addition, we reported estradiol-dependent responses to AMPH in AMPH-sensitized rats as measured by functional magnetic resonance imaging. It is thus clear that estradiol and antipsychotics both affect the rat brain, however the mechanism by which this occurs is unknown. The aim of the current study was to assess this interaction by investigating the effects of estradiol, AMPH and HAL on brain volume changes in awake female rats. Repeated exposure to AMPH resulted in an overall reduction in brain volume, regardless of hormonal status (i.e. no, low or high estradiol). Similarly, chronic HAL treatment further reduced brain volume compared to acute treatment. Hormonal status affected hippocampal volume with rats receiving low estradiol replacement showing larger volume; this difference was no longer significant after repeated exposure to AMPH. Finally, we found changes in volume in response to AMPH throughout hippocampal components (i.e. CA1, CA2, CA3 and dentate) as well as components of the mesocortical system. In conclusion, brain morphology seems to be influenced by hormonal status, as well as exposure to AMPH and haloperidol treatment. These findings implicate areas where estradiol, amphetamine and antipsychotics may be producing volumetric changes in the brain, pointing the way to where future studies should focus.

Title: GLYX-13 ameliorates acute ketamine and sub-chronic ketamine- and phencyclidine-induced memory deficits in C57BL/6J mice

Authors: ***H. Y. MELTZER**[1], L. RAJAGOPAL[1], J. S. BURGDORF[2,4], J. R. MOSKAL[3,4]; [1]Northwestern Univ. Sch. of Med., Chicago, IL; [2]Falk Ctr. for Mol. Therapeut., [3]Biomed. Engineering, McCormick Sch. of Engin., Northwestern Univ., Evanston, IL; [4]Naurex Inc., Evanston, IL

Abstract: Background: Rapastinel (GLYX-13) is a tetrapeptide (Thr-Pro-Pro-Thr-amide) which acts as an N-methyl-D-aspartate receptor (NMDAR) glycine site functional partial agonist. It is currently in development, as is the NMDAR noncompetitive antagonist, ketamine, as a rapidly acting antidepressant. Acute or sub-chronic (sc) administration to rodents of the NMDAR antagonists, ketamine and phencyclidine (PCP), produces transient or enduring, respectively, deficits in novel object recognition (NOR), an analog of human declarative memory. We predicted that rapastinel would not impair NOR and might be able to ameliorate the cognitive deficit produced by ketamine or PCP in rodents. Methods: Four cohorts of male C57BL/6J mice (N=10-12 per group) were used for these studies. The method for studying NOR has been reported (Horiguchi et al., 2012, Psychophamacology (Berl). 221(2): 205-15). In the acute study, mice were given saline (sal, i.v.), ketamine (30 mg/kg, i.p.) or rapastinel (1 mg/kg; i.v.)+acute ketamine (30 mg/kg; i.p.) 30 min prior to NOR testing. For the sc studies, groups of mice were given sal, PCP (10 mg/kg; b.i.d. or ketamine (30 mg/kg; b.i.d) for 7 days, followed by 7 days washout). The scPCP and scketamine mice were given rapastinel (0.3 or 1 mg/kg; i.v.) 30 min prior to NOR testing. The scsal group received saline. Results: Ketamine impaired NOR as indicated by a discrimination index of -0,008, due to equivalent exploration of novel and familiar

objects. Prior treatment with rapastinel (1 mg/kg) significantly prevented the ketamine-induced NOR deficit (**P<0.01). Rapastinel (1 mg/kg, i.v. ***P<0.001), but not 0.3 mg/kg (P>.05), significantly reversed both the scPCP- and scketamine-induced NOR deficit. NOR was normal in the sal-treated mice. Conclusion: These findings suggest that rapastinel differs from ketamine in not producing an acute disruption of NOR and can prevent the NOR impairment produced by acute ketamine. Its ability to restore NOR after scPCP or scketamine is consistent with its learning and memory enhancement in a variety of hippocampal-dependent learning tasks, in both young adult and learning-impaired aged rats. Similar effects have been reported with atypical antipsychotic drugs which are effective in improving cognitive impairment in schizophrenia, whereas acute ketamine has been reported to produce cognitive impairment and psychopathology in some normal volunteers and patients with schizophrenia. Testing of rapastinel to treat cognitive impairment in schizophrenia and major depression is indicated.

Title: The effects of rapastinel (GLYX-13), a NMDA receptor allosteric modulator, on the mTOR signaling pathway transcriptome

Authors: ***A. L. GROSS**[1], M. E. SCHMIDT[1], R. A. KROES[1], J. S. BURGDORF[2], J. R. MOSKAL[1,2];
[1]Naurex Inc, Evanston, IL; [2]Biomed. Engineering, McCormick Sch. of Engineering, Northwestern Univ., Falk Ctr. for Mol. Therapeut., Evanston, IL

Abstract: Activation of the mTOR signaling pathway in the rat medial prefrontal cortex (MPFC) is known to be part of the molecular mechanism underlying the rapid-acting antidepressant effect of ketamine, a NMDA receptor (NMDAR) antagonist. Rapastinel has characteristics of a glycine-site partial agonist. It also produces rapid, and long-lasting antidepressant effects, but without the side-effects seen with ketamine. A comparison of mTOR signaling pathway gene expression patterns between rapastinel and ketamine was undertaken using a Qiagen mTOR pathway-specific qRT-PCR array. Rats were given a single, optimal antidepressant dose of either rapastinel (3 mg/kg, IV) or ketamine (10 mg/kg, IV), and gene expression was measured in the MPFC at 1 hour, 24 hours, and 2 weeks post-dosing. At 1 hr post-administration, rapastinel led to the upregulation of 8 genes (Akt3, Mapk1, Pik3r1, Prkab2, Prkca, Stk11, Tsc1, Gsk3b), as compared to ketamine, which upregulated 16 genes (Akt3, Mapk1, Pik3r1, Prkab2, Prkca, Stk11, Tsc1, Insr, Kras, Mlst8, Nras, Prkaa2, Pten, Prs6ka2, Ddit4, Sgk1). Rapastinel, unlike ketamine, downregulated Prkag1, which leads to enhanced mTOR complex formation. After 24 hr, there were minimal gene expression changes detected by either rapastinel or ketamine. Expression of only one gene was affected by rapastinel (Redd2, a negative regulator of both mTORC1 and mTORC2 was downregulated) and 4 genes were affected by ketamine (Redd1, and Sgk1 were both upregulated, and Ppp2r4 and Ilk, modulators of the mTOR complex formation, were both downregulated). After 2 wks, no transcriptomic changes were observed following rapastinel. However, the differential expression of Redd1 and ppp2r4 persisted, and Hspa4 was also upregulated following ketamine. Treatment with rapastinel and ketamine both markedly impacted the mTOR signaling pathway transcriptome within 1 hr. However, ketamine modulated significantly more genes in this transcriptome than rapastinel and the effects of ketamine persisted for up to 2 wks post dosing.

Title: The fast-off hypothesis revisited: A functional kinetic study of antipsychotic antagonism of the dopamine D2 receptor

Authors: *J. NILSSON[1], K. SAHLHOLM[2], H. ZEBERG[2], S. ÖGREN[2], P. ÅRHEM[2];
[1]Dept. of Neurosci., [2]Karolinska Institutet, Stockholm, Sweden

Abstract: Rapid dissociation from the dopamine D2 receptor (D2R) has been proposed to confer antipsychotic atypicality. Furthermore, antipsychotic D2R affinities have been proposed to reflect differences in dissociation rate constants (koff), while association rate constants (kon) were claimed to be similar (Seeman and Kapur, 2000). However, kon was not directly measured in previous studies. Since affinity is determined by the ratio koff /kon, low-affinity D2R antagonists would be atypical antipsychotics, and vice versa. This so-called "fast-off" hypothesis has recently inspired the development of new fast dissociating D2R antagonists. We recently reported on the relative rates of response recovery from D2R antagonism using electrophysiology to measure D2R-induced opening of G protein-coupled inward rectifier K+ channels (GIRK). Whereas no response recovery was observed with haloperidol (typical antipsychotic), differences in rates of recovery upon washout of chlorpromazine (typical) and clozapine (atypical) were surprisingly small. Furthermore, lipophilic compounds displayed a component of antagonism which could not be washed out. Recent studies suggest that lipophilic membrane accumulation can cause underestimation of ligand koff. We thus tested whether increasing the dopamine (DA) concentration 100-fold to outcompete lipophilic antagonists from the D2R binding site would affect recovery from antipsychotic inhibition. We also reexamined the variability of antipsychotic kon, capitalizing on the GIRK assay's temporal resolution. We

estimated kon from the experimental recordings, using an expression derived from a kinetic scheme assumed to describe the binding process. Our new data indicate that the kons of antipsychotics vary more widely than previously claimed, whereas koffs are more similar across compounds. Moreover, lipophilicity-driven accumulation might interfere with koff estimation, as increasing the dopamine concentration revealed a surprisingly fast recovery from inhibition by haloperidol, which in our previous study exhibited long-lasting D2R antagonism. Finally, affinities calculated using our kon and koff estimates correlate well with functional potency (IC50) determined using our GIRK assay, and with affinities reported from radioligand binding studies.

Title: Insulin-like growth factor i produces an antidepressant-like effect through modulation of n-methyl-d-aspartate receptor-independent long-term potentiation-like synaptic plasticity

Authors: *E. M. COLECHIO[1], J. BURGDORF[2], X.-L. ZHANG[4], A. GROSS[5], R. A. KROES[5], P. K. STANTON[4], J. R. MOSKAL[5,3];

Abstract: Growth factors play an important role in regulating neurogenesis, synapse formation, and may be involved in modulating the antidepressant response to conventional antidepressants. To date, insulin-like growth factor I (IGFI) is the only growth factor that has shown antidepressant properties in human clinical trials. However, its mechanism of action remains unclear. A single dose of IGFI IV (0.1 mg/kg) or intra-medial prefrontal cortex (MPFC; 0.1-1 μg) activated IGFI receptors (IGFIRs) in the MPFC and reversed the depressive-like phenotype of chronic unpredictable stress using the Porsolt, sucrose preference, novelty induced hypophagia, and ultrasonic vocalization models at 1 hr to 2 weeks post-dosing in rats. These effects were blocked by pretreatment with either the IGFIR antagonist JB1 or the protein

synthesis inhibitor anisomycin. When the AMPA/kainate antagonist NBQX was administered 24 hrs post-IGFI injection, the long-lasting antidepressant-like effects of IGFI were blocked. Application of IGFI (200 nM) to rat hippocampal slices *in vitro* increased synaptic strength both in Schaffer collateral CA1 synapses and in medial prefrontal cortex layer V synapses. IGFI-induced potentiation of synaptic strength was blocked by JB1 and anisomycin, but not the NMDAR antagonist D-AP5. When rats were treated with IGFI (0.1 mg/kg IV), and hippocampal slices were prepared 24 hrs later, stimulus-evoked long-term potentiation (LTP) at Schaffer collateral-CA1 synapses was larger than that observed in saline controls. These data support the conclusion that the antidepressant-like effects of IGFI are mediated by a NMDA receptor independent LTP-like synaptic plasticity mechanism requiring both IGFIR activation and ongoing protein synthesis.

Title: Rapastinel (GLYX-13), an N-methyl-D-aspartate functional glycine site partial agonist, is efficacious in rat surgical models of neuropathic pain

Authors: *N. GHOREISHI-HAACK[1], J. BURGDOF[2], R. M. BURCH[3], J. R. MOSKAL[3,2]; [1]Naurex Inc, Skokie, IL; [2]Northwestern Univ., Evanston, IL; [3]Naurex Inc., Evanston, IL

Abstract: Rapastinel is an amidated tetrapeptide (Thr-Pro-Pro-Thr-amide) currently in Phase II clinical trials for major depressive disorder, and is also being developed as a therapeutic for neuropathic pain. Previously, it was shown that rapastinel (5 mg/kg IV) produces an analgesic effect in the late phase of the rat formalin model of neuropathic pain. Medial prefrontal cortex (prelimbic or infralimbic) injection of rapastinel (0.1, 1, or 10 μg/side) produced an analgesic effect in the late phase of the rat formalin model (compared to saline vehicle) for up to 1 month following a single dose as measured by weighted pain score. Rapastinel was also evaluated in two rat surgical models of the neuropathic pain: the Chung (spinal nerve ligation) and the Bennett (chronic sciatic nerve constriction) models. Pain responses were measured using Von Frey filaments and Dixon up-down method. At ED100 (5mg/kg, IV), rapastinel produced a robust analgesic effect (as compared to saline vehicle) in these models at 1 hr, 24 hrs and 1 week following a single dose, without any adverse effects. In comparison, the analgesic effect of a single dose of gabapentin (150 mg/kg PO) was observed at 1 hr but not 24 hrs or 1 week. In addition, rapastinel was evaluated in two rat models of nociceptive pain: the carrageenan inflammatory model and the tail flick model. Pain responses in response to carrageenan (administered in the plantar surface of the right hind paw) were measured using Von Frey filaments and the Dixon up-down method. Pain responses for the tail flick model were measured by tail withdrawal latency in response to a radiant heat stimulus. Rapastinel did not produce any effect when evaluated in either of these models. Rapastinel did not produce sedation or psychotomimetic-predictive effects in the rotarod or the open field test across a wide dose range (therapeutic index of > 100). These data show that rapastinel has therapeutic potential for the treatment of neuropathic pain

Title: Rapastinel (GLYX-13), an allosteric NMDA receptor modulator, exerts its antidepressant effects by acting at a novel NMDA receptor binding site

Authors: *R. A. KROES[1], J. S. BURGDORF[2], A. L. GROSS[1], M. A. KHAN[1], X. ZHANG[3], R. M. BURCH[1], P. K. STANTON[3], J. R. MOSKAL[1,2];

Abstract: Rapastinel, a NMDAR modulator that has characteristics of a glycine site partial agonist, is currently in Phase II clinical development for treatment-resistant depression. The present studies detail the *in vitro* characteristics of rapastinel. Functional glycine site agonist effects were measured using [3H]MK-801 potentiation assays in membrane extracts prepared from rat cortex and human NR2 subtype-expressing HEK cells. In cortical extracts, rapastinel exhibits partial agonist activity (EC50 64nM; 26.1% activity relative to glycine). In recombinant human NR2-expressing HEK cells, partial agonist activity of rapastinel was also demonstrated at all 4 receptor subtypes (EC50 of 14pM, 2.4nM, 19.9nm, and 7.8pm and activities of 39.5%, 39.0%, 56.8%, and 59.2%, at NR2A, NR2B, NR2C, and NR2D, respectively). Functional antagonist effects were determined using pA2 response shift analysis of NMDAR current from CA1 pyramidal neurons in rat hippocampal slices. Rapastinel also demonstrated antagonist-like activity (Kp 1.3μM) in hippocampal slices in the presence of glycine. Direct interaction of rapastinel at the glycine site of the NMDAR was assessed by (i) radioligand displacement of [3H]glycine and [3H]L-689,560, (ii) [3H]MK-801 binding in the presence of 5,7 dichlorokyneurenic acid (DCK), and (iii) [3H]MK-801 binding in recombinant hNR2-expressing HEK cells containing a mutant, non-functional glycine site. Radioligand competition studies showed that rapastinel had no effect on [3H]glycine binding in cortical membranes, and while glycine and D-cycloserine competed with the high affinity glycine site antagonist [3H]L-689,560, rapastinel did not. Rapastinel remained fully active in the presence of 5,7DCK. Point mutations within the glycine site, while totally inhibiting glycine activity, had no effect on the ability of rapastinel to modulate channel opening in any of the NMDAR subtypes. Rapastinel did not influence the ability of glutamate, spermidine, or ifenprodil to modulate NMDAR channel opening. Molecular modeling in silico identified a potential high affinity rapastinel binding site within the amino terminal domain of NR2B. Point mutagenesis of critical amino acids within this binding site, while leaving glycine activity unaffected, significantly inhibited rapastinel activity in [3H]MK-801 assays using recombinant human NMDAR2B-expressing HEK cells. These data suggest that rapastinel is an allosteric NMDAR modulator with glycine-site partial agonist properties attributable to binding to a novel site on the NMDAR.

Title: NRX-1074, an NMDA receptor modulator with glycine site partial agonist properties, induces rapid and long-lasting antidepressant-like effects in rats

Authors: ***J. S. BURGDORF**[1], R. A. KROES[2], X. L. ZHANG[3], A. L. GROSS[2], R. M. BURCH[2], P. K. STANTON[3], M. A. KHAN[2], J. R. MOSKAL[2,2];

[1]Falk Ctr. for Mol. Therapeutics, McCormick Sch. of Engin., Northwestern Univ., Evanston, IL; [2]Naurex Inc., Evanston, IL; [3]New York Med. Col., Valhalla, NY

Abstract: Rapastinel (GLYX-13) is an allosteric NMDA receptor (NMDAR) modulator with characteristics of a glycine-site partial agonist that shows rapid and long-lasting antidepressant activity in rodent models and humans with a favorable side-effect profile. NRX-1074 is an orally bioavailable analog of rapastinel (Thr-Pro-Pro-Thr-amide) that is benzylated at the second proline. The present studies describe the *in vitro* and *in vivo* pharmacology of NRX-1074. NMDAR activation was assessed by measuring [3H]MK-801 binding to rat cortical membranes in the presence of glutamate but in the absence of glycine. Antidepressant-like effects were determined using the rat Porsolt test at 1hr, 24 hrs and 1 week post-dosing. Learning and memory effects were measured using the positive emotional learning (PEL) test. Long-term potentiation (LTP) was measured at Schaffer collateral CA1 synapses in rat hippocampal slices prepared 24 hrs to 4 wks post-dosing. Sedative and/or ataxic effects were measured in the rat Rota-Rod test at 0.5 to 24 hrs post-dosing. Oral bioavailability was measured in rat plasma by LC/MS/MS. NRX-1074 is more potent than rapastinel in activating the NMDAR (EC50 0.2 pM vs. 64 nM), producing an antidepressant-like effect in the Porsolt test (ED50 5 ng/kg IV vs. 1 mg/kg IV), and facilitating hippocampal LTP (equivalent enhancement at 0.01 mg/kg IV vs. 3 mg/kg IV). NRX-1074 (1 mg/kg PO) also enhanced learning and memory in the PEL test. Unlike rapastinel, NRX-1074 is orally bioavailable and does not exhibit a U-shaped dose response curve in the Porsolt and LTP assays. Similar to rapastinel, NRX-1074 does not show sedative and/or ataxic effects in the Rota-Rod test (NOEL > 100 mg/kg PO). These data demonstrate that NRX-1074 is an orally bioavailable analog of rapastinel that shows increased potency, a wider therapeutic dose range, and does not show the side effects typically found with NMDAR antagonists.

Title: The role of glucocorticoid receptors in the development of behavioural sensitisation to MK-801

Authors: *E. LEFEVRE[1], S. ALEXANDER[1,2], D. W. EYLES[1,2], T. H. J. BURNE[1,2]; [1]Queensland Brain Inst., Brisbane, Australia; [2]Queensland Ctr. for Mental Hlth. Res., Wacol, Australia

Abstract: Behavioural sensitisation can occur as a result of repeated and intermittent psychostimulant exposure and is used in rodents to model addiction and schizophrenia pathophysiology. There is evidence to suggest that sensitisation can be modulated by stress-induced factors including corticosterone (CORT) signalling via glucocorticoid receptors (GR's). The N-methyl-D-aspartate receptor (NMDAR) antagonist MK-801 is commonly used to induce NMDAR hypofunction in animals as a pharmacological model of schizophrenia. Few preclinical studies have examined the effects of stress on MK-801 sensitisation. Therefore, the present study sought to determine whether GR antagonism could inhibit the development and expression of sensitisation to the locomotor stimulatory effects of MK-801, as is reported for sensitisation to other psychostimulants. Firstly, the MK-801 sensitisation paradigm was established by modulating factors including MK-801 dose, context and rat strain. Overall, we found that Sprague Dawley (vs. Wistar) rats developed a robust sensitisation to an intermediate dose (0.25mg/kg compared to 0.1 and 0.5mg/kg) of MK-801 and this sensitisation was unaffected by the context in which MK-801 administrations were paired (home vs. novel). Based on these foundations, the effect of concomitant treatment with the GR antagonist mifepristone (RU486, 20mg/kg) on MK-801 (0.25mg/kg) induced sensitisation was examined. Adult male Sprague Dawley rats were assigned to four treatment groups: vehicle+Saline, vehicle+MK-801,

RU486+Saline and RU486+MK-801. Injections (i.p.) were administered once daily for 7 consecutive days in the test context. After 5 days withdrawal in the home cage, the expression of sensitisation was determined by challenging all groups with MK-801 (0.25mg/kg). We show that co-administration of RU486 with MK-801 augmented the development of sensitisation over the 7 day period, as well as the locomotor response to MK-801 challenge after withdrawal. Interestingly, the RU486+Saline group also displayed an enhanced response to MK-801 challenge, indicating RU486 may have long-term effects of its own. The results suggest GR antagonism has a facilitatory rather than inhibitory effect on MK-801 sensitisation, contrary to original predictions. Thus, future studies will investigate plasma CORT levels throughout the sensitisation paradigm to determine whether RU486 and MK-801 have an additive effect on CORT signalling. In conclusion, this study suggests that stress-related neural mechanisms mediating sensitisation to MK-801 is different to that of other psychostimulants.

Title: Antagonism of serotonergic 5-HT2A receptors is a sufficient, but not necessary mechanism for clozapine's discriminative stimulus properties in mice

Authors: *A. JONES[1], K. A. WEBSTER[2], C. E. MCOMISH[3], J. H. PORTER[2];
[1]Virginia Commonwealth Univ., Midlothian, VA; [2]Psychology, Virginia Commonwealth Univ., Richmond, VA; [3]Psychiatry, Columbia Univ. Med. Ctr., New York, NY

Abstract: One theory about the underlying neuropharmacological mechanisms responsible for the "atypicallity" of antipsychotic drugs like clozapine is the ratio of binding affinity to serotonergic 5-HT2A receptors relative to dopaminergic D2 receptors (Meltzer et al 1989). Previous studies in our lab have shown that antagonism of 5-HT2A receptors in mice is sufficient to engender clozapine-appropriate responding (Philibin et al 2009) and other studies have shown that 5-HT2A antagonism is important for some of clozapine's behavior effects such as locomotor suppression (McOmish et al 2012). The present study determined whether or not antagonism of 5-HT2A receptors is a necessary mechanism for clozapine's discriminative stimulus cue in mice by determining if 5-HT2A knockout (KO) mice could acquire clozapine's discriminative stimulus. Twelve male 5-HT2A KO mice and twelve male wild type (WT) B6129

mice were trained to discriminate 1.25 mg/kg clozapine from vehicle in a standard 2 lever drug discrimination assay for food reward. Both 5-HT2A KO and WT mice acquired the clozapine discriminative cue with WT mice (mean = 25.2 days, SEM = 3.3) acquiring the cue faster than KO mice (mean = 34.7 days, SEM = 3.8). Clozapine generalization testing revealed ED50 values of 0.61 mg/kg and 0.68 mg/kg for the 5-HT2A KO and WT mice, respectively. The atypical antipsychotic olanzapine produced full substitution for clozapine's cue in both the 5-HT2A KO mice (ED50 = 0.47 mg/kg) and WT mice (ED50 = 0.18 mg/kg). The typical antipsychotic haloperidol did not substitute for clozapine in either the 5-HT2A KO mice (42 % Drug Lever Responding at 0.4 mg/kg) or the WT mice (42% DLR at 0.4 mg/kg). Interestingly, the 5-HT2A KO mice appeared to be less sensitive to the rate suppressing effects of the atypical antipsychotics clozapine and olanzapine, but not to the typical antipsychotic haloperidol. These results are in agreement with findings by McOmish et al (2012) that 5-HT2A antagonism is important for clozapine's behavior locomotor suppression effects in mice. Finally, these results demonstrate that antagonism of serotonergic 5-HT2A receptors is not necessary (although sufficient) for mice to acquire clozapine's discriminative stimulus. We are currently exploring the mechanisms underlying clozapine's discriminative cue in 5-HT2A KO mice.

Title: Repeated paroxetine differentially modulates acoustic startle in adolescent male and female rats

Authors: *E. M. ALDERSON, Z. R. HARMONY, V. REAL, C. A. CRAWFORD;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Major depression is a common problem in adolescents. Unfortunately, many of the medications that are effective at relieving the symptoms of depression in adults are ineffective in adolescent populations. In addition, the most popular class of antidepressants, the selective serotonin reuptake inhibitors (SSRIs), can induce suicidal ideation in adolescents. The

mechanisms responsible for this paradoxical increase in suicidal ideation are unknown, but recent research in our laboratory suggests that paroxetine may increase anxiety in adolescent rats. In an attempt to extend these findings, we assessed the effects of repeated paroxetine treatment on the acoustic startle response (ASR), which is a measure of anxiety. Male and female Sprague-Dawley rats (N=262) were injected with paroxetine (1.25, 2.5, 5 or 10 mg/kg, IP) or vehicle for 10 consecutive days starting on postnatal day (PD) 35. Rats were then tested for ASR across 5 days starting 1, 7, or 28 days after the last drug treatment. On the first test day, rats were given 31 acoustic startle trials followed by 24 pre-pulse inhibition (PPI) trials. On the next four days, rats were given 31 acoustic startle trials to test for habituation of the ASR. Repeated paroxetine administration had a sex-dependent effect on the body weights of adolescent rats. Male rats treated with 10 mg/kg paroxetine showed a decrease in weight gain, while females given 1.25 mg/kg paroxetine exhibited a slight increase in body weight. Male rats were more sensitive to ASR than female rats, because the magnitude of the ASR was greater for males on all test days. At each age tested, exposure to paroxetine (10 mg/kg) increased habituation of the ASR (i.e., the magnitude of the ASR decreased from the first to the fifth test day) but only in male rats. Interestingly, there was a marginal interaction between sex and test day when the PPI scores were analyzed. Specifically, male rats showed increased PPI relative to females, with the greatest sex difference occurring 28 days after the last drug treatment. Overall, these data show that adolescent female rats exhibit less anxiety-like behavior than males after repeated paroxetine treatment, and these paroxetine-induced effects are still apparent four weeks after the last drug treatment.

Title: Modulation of ERK1/2 signaling pathway is the mechanism involved in antidepressant-like activity of zinc

Authors: *B. SZEWCZYK[1], P. MISZTAK[1,2], B. POCHWAT[1], A. RAFALO[1,3], M. SOWA-KUCMA[1], G. NOWAK[1,2];

[1]Inst. of Pharmacol. PAS, Krakow, Poland; [2]Pharmacobiology, Jagiellonian Univ. Med. Col., Krakow, Poland; [3]Inst. of Zoology, Jagiellonian Univ., Krakow, Poland

Abstract: Depression is one of the most debilitating medical problems concerning modern society. Over the years, a few pharmacological strategies for treating depression have been developed. Unfortunately, these strategies mainly based on interaction with monoaminergic system, are not sufficient to achieve a satisfactory level of remission in depressed patients. Recently, the N-methyl-D-aspartate (NMDA) receptor antagonists have been taken into account as alternative, potential antidepressants. Zinc (Zn) is an example of NMDA receptor antagonists which showed antidepressant-like activity in the numerous preclinical studies. It is hypothesized that antidepressant-like effects of Zn are very complex, engaging many neurotransmitters systems. Recent data indicated that serotonin and especially 5-HT1A serotonin receptors may be involved in antidepressant-like activity of Zn. Because, activation of serotonin 5-HT1A receptors are associated with activation of extracellular signal-regulated kinases 1/2 (ERK1/2) transduction signaling pathway, we tried to evaluate the involvement of ERK1/2 pathway in the antidepressant like activity of Zn using behavioral and biochemical approaches. In the Forced Swim Test (FST) performed in rats we found that the anti-immobility effect of Zn (2.5 and 5mg/kg) is prevented by MEK1/2 inhibitor U0126 (5μg/site). Moreover, we observed that active in FST Zn doses (2.5, 5 and 11.5 mg/kg) reduced the ERK1/2 phosphorylation level both in prefrontal cortex (PFC) and hippocampus (Hp) in rats, measured with Enzyme Linked-Immuno-Sorbent Assay (ELISA) method. The Zn induced reduction of ERK1/2 phosphorylation levels was observed after 15, 30 and 60 minutes in PFC, however in the Hp the effect of Zn was short lasting and was only observed after 15 and 30 minutes after Zn administration. Furthermore we showed that pretreatment with 8-OH-DPAT (5-HT1A receptor agonist; 2.5 mg/kg) prevented the Zn (5mg/kg) induced decrease in ERK1/2 phosphorylation in PFC but not in the Hp. In summary, behavioral studies indicated that antidepressant-like effect of Zn depends on the activation of ERK1/2 signaling pathways. However biochemical studies suggested that inhibition rather than activation of ERK1/2 is associated with acute Zn treatment and that Zn induced changes in ERK1/2 phosphorylation level may involve modulation of 5-HT1A signaling pathway. For an explanation of these discrepancies more detailed studies are required to describe the exact mechanisms of the Zn induced changes in ERK1/2 signaling pathways.

Title: Hdac6 inhibition induced α-tubulin acetylation translocates Gαs from lipid-rafts: a novel mechanism for antidepressant action

Authors: *H. SINGH[1,2], J. SCHAPPI[3], A. PRADHAN[4], M. RASENICK[5,2];
[1]PHYSIOLOGY AND BIOPHYSICS, UNIVERSITY OF ILLINOIS AT CHICAGO, CHICAGO, IL; [2]Jesse Brown VAMC, Chicago, IL; [3]Physiol. and Biophysics, [4]Psychiatry Inst., Univ. of Illinois at Chicago, Chicago, IL; [5]Physiol. and Biophysics and Psychiatry, Univ. of Illinois a Chicago, Chicago, IL

Abstract: Histone deacetylase-6 (HDAC-6) enzymes involved in deacetylation of α-tubulin have been shown to be upregulated during neuropsychiatric conditions. HDAC6 knockout mice mimicked traditional antidepressant treatments. Nonetheless, a possible role for HDAC6 inhibitors in treatment of depression remains elusive. Previously we have shown that the treatment with monoamine based antidepressant drugs results in activation of G-protein subunit, Gαs, by facilitating movement out of membrane microdomains, (lipid-rafts), resulting in sustained cAMP production. Studies have also demonstrated interplay between tubulin and Gαs in lipid-rafts. Once out of lipid-raft domains, Gαs, couples with adenylyl cyclase-6 (AC-6). Although Gαs interacts directly with tubulin to modify microtubule dynamics, tubulin also acts as an anchor for Gαs in lipid rafts. Based on HDAC-6 roles in modifying α-tubulin acetylation and our data showing Gαs interactions with tubulin in lipid-raft domains, we hypothesize that acetylation of α-tubulin disrupts tubulin-Gαs anchoring, rendering Gαs free to activate AC-6 in non-raft domains. To test this, C6 glial cells were treated with HDAC-6 inhibitor, Tubastatin-A. Acetylation status of α-tubulin and localization of Gαs subunit in/out of lipid-raft membrane domains was studied. Chronic treatment with Tubastatin-A not only induced increased acetylation of a α-tubulin but also moved Gαs out of lipid-rafts, without changing total Gαs. Fluorescence Recovery After Photobleaching (FRAP) on C6 cells stably expressing Gαs-GFP, was conducted and cells pretreated with Tubastatin-A showed an "antidepressant signature". Finally, brains from mice undergoing repeated swim stress were examined and these showed decreased acetylation of α-tubulin and translocation of Gαs subunits out of lipid-rafts relative to controls. These findings suggest HDAC6 inhibition resembles chronic antidepressant treatment. Therefore, compounds that decrease tubulin-Gαs interactions by increasing acetylation of a α-tubulin may show promise for antidepressant action.

Title: Sex, age and genotype differences in the responses to stress and antidepressant treatments

Authors: *C. NASCA[1], D. ZELLI[1], B. BIGIO[2], J. KOGAN[1], T. LAU[1], E. M. WATERS[1], B. S. MCEWEN[1];
[1]Neuroendocrinology, [2]Ctr. for Clin. and Translational Sci., The Rockefeller Univ., New York, NY

Abstract: Depression and anxiety are caused by three hits -genes, early-life experiences and stress- and are among the most common disabling medical conditions worldwide with prevalence twice as high in women than men. Excitatory amino acids, principally glutamate, are key players and normalizing their activity, through the use of external drugs, like acetyl-L-carnitine (LAC), is important for reactivation of neurochemical and morphological plasticity. Such plasticity is impaired by stress and is loss with aging. Recently, we showed that acute restraint stress (ARS) causes increased anxiety-like behavior along with a decrease in the presynaptic inhibitor of glutamate release, mGlu2 receptors, in the hippocampus of young BDNF homozygous Val male mice. Here, we investigate the effect of sex, age and genotype in the stress responses and antidepressant/anxiolytic treatments. We found that a subset of aged-matched heterozygous Met young males and females with anxiety/depressive-like behaviors show a deficit in mGlu2 expression in the hippocampal ventral dentate gyrus (vDG) along with up-regulation of the epigenetic repressor of gene transcription, REST. These molecular deficits are rapidly corrected, along with rescue of mood abnormalities, by the oral treatment with the novel antidepressant LAC using a dose that in females is twice as the one that shows efficacy in males. Young heterozygous Met males and females also differ in their response to ARS. Indeed, young heterozygous Met males show a decreased anxiety along with an elevation of mGlu2 receptors

and decrease in REST in hippocampus, whereas this positive response to stress is not observed in young heterozygous Met females, which show an exacerbation of anxiety. In regard to the age effect, we found that old heterozygous Met males show an anxiety-like behavior, which is still evident after ARS, suggesting a loss of plasticity with age in the stress response. Moreover, old heterozygous Met females show no anxiety-like behavior at baseline, but they do show anxiety after ARS, suggesting that aging exacerbates a stress response since old heterozygous Met females after stress show the same phenotype of young heterozygous Met females before applying any stress. A RNAseq specifically-targeted to the vDG is underway to reveal the clusters of genes that lead to the individual differences in response to stress and next-generation treatments. These findings suggest striking individual differences in the stress and antidepressant responses based on the sex, age and genotype and points to a window of opportunity for intervention whereby the BDNF signaling on glutamatergic function may be a target for novel epigenetic therapies.

Sciences, State Univ. of New York at Buffalo, Buffalo, NY; [5]Depts Behav Med. & Psych, Pharm, West Virginia Univ. Hlth. Sci. Ctr., Morgantown, WV

Abstract: Ferulic acid (FA; 4-hydroxy-3-methoxy-cinnamic acid) is a main polyphenolic component of the Chinese herb Radix Angelicae Sinensis, which exhibits antidepressant-like effects through the serotonergic and noradrenergic systems. However, the potency of FA is limited in terms of antidepressant activity. The present study examined the synergistic potential of FA combined with piperine, a bioavailability enhancer, on mouse behaviors sensitive to

antidepressants, and investigated the possible mechanism. In the tail suspension and forced swimming tests (TST and FST), FA (3-180 mg/kg) alone reduced immobility with the maximal effect of only approximately 60%. Piperine, at a dose (10 mg/kg) that did not produce a significant effect on TST and FST behavior, potentiated the antidepressant-like effects of FA with the potency doubled. Consistent with the behavioral results, data from neurochemical (monoamines in the frontal cortex, hippocampus, and hypothalamus) and biochemical (monoamine oxidase, MAO) assays supported the synergistically enhanced monoaminergic function following the treatment with FA in combination with piperine. The results support the concept that the combination strategy might be an alternative therapy in treatment of psychiatric disorders with great efficacy and minimal side effects.

Title: Modified lipid raft anchoring of the G protein, Gαs subsequent to chronic antidepressant treatment, is independent of monoamine transporters but requires type 6 adenylyl cyclase (AC6)

Authors: *J. SCHAPPI, M. RASENICK;
Physiol. & Biophysics, Univ. of Illinois At Chicago, Chicago, IL

Abstract: Antidepressants of different chemical classes promote the redistribution of $G_{\alpha}s$ from lipid rafts into non-raft membrane fractions. The net result of this redistribution is increased $G\alpha_s$ coupling with transmembrane adenylyl cyclase (AC), and increased cAMP production. These changes are demonstrated via cell fractionation, functional assays, and imaging studies including FRAP (Fluorescence Recovery After Photobleaching). This phenomenon is seen in animals as well as in cell lines used in our laboratory, such as C6 glioma and PC12 pheochromocytoma. These cell lines, however, lack neurotransmitter reuptake transporters, suggesting that response to monoamine centered antidepressants entails more than inhibition of neurotransmitter reuptake

transporters or inhibition of monoamine breakdown. Furthermore, while these neural and glial cells showed an "antidepressant response", $G\alpha_s$ localization and cAMP production in kidney epithelial cells like COS1 and HEK293 were unchanged by antidepressant treatment. Similarly, membranes from liver and kidney of rats treated chronically with antidepressant did not show the same response as brain from those same animals. In this study we sought to determine whether cellular antidepressant response, with respect to increased cAMP signaling and $G\alpha_s$ localization, is dependent on the type of AC isoform expression. Cell lines lacking this $G\alpha_s$ antidepressant response, such as HEK293, become responsive after transfection with AC6. Likewise, knockdown of AC6 but not other isoforms in responsive cell lines such as C6 glioma abolishes the antidepressant response. Thus, it is suggested that AC6 performs an anchoring function for $G\alpha_s$ outside of rafts, affixing the translocated $G\alpha_s$ into the non-raft domain and facilitating an antidepressant-induced increase in adenylyl cyclase activity.

Title: GIRK2 channel KO of neurons expressing dopamine transporters mimics the effect of antitussives on the forced swimming in mice

Authors: *I. HONDA[1], K. ARAKI[2], S. HONDA[1], F. SOEDA[1], S. MISUMI[1], K. YAMAMURA[2], K. TAKAHAMA[3,4];

[1]Dept. Env. Mol. Health. Sci. Grad. Sch. Pharm. Sci., Kumamoto Univ., Kumamoto, Japan; [2]Inst. of Resource Develop. and Analysis, Kumamoto Univ., Kumamoto, Japan; [3]Res. Inst. for Drug Discovery, Sch. of Pharmacy, Kumamoto Univ., Kumamoto, Japan; [4]Kumamoto Hlth. Sci., Univ.,, Kumamoto, Japan

Abstract: We previously reported that centrally acting antitussives inhibit G-protein-coupled inwardly rectifying potassium (GIRK) channel currents in brain neurons. In addition, these drugs at antitussive effective doses ameliorated the symptoms of animal model of various intractable brain diseases including depression. Several lines of evidence suggest that such ameliorating actions may be caused by the inhibitory action on GIRK channels coupled to dopamine receptors. In this study, therefore, we tried to generate *Girk2* conditional knockout mice and assessed depression-related behaviors of the mice. To generate GIRK2 floxed mice, we engineered the targeting vector for introducing two loxP motifs into the exon4a of Girk2 gene. Homologous recombination was induced by using CRISPR/Cas system. GIRK2 floxed mice were crossed with mice carrying the CRE recombinase gene under the control of the dopamine transporter (DAT) promoter and these mice were named GIRK2$^{DAT\ KO}$ mice (*Girk2floxed/floxed*:DAT-Cre(+)). GIRK2 floxed mice (*Girk2floxed/floxed*: DAT-Cre(-)) and DAT-Cre(+) mice (*Girk2*+/+: DAT-Cre(+)) were regarded as control mice. GIRK2$^{DAT\ KO}$ mice do not show any visibly abnormal phenotype. Their locomotor activity was comparative to that of control mice in open field test. Next, we carried out forced swimming test to assess depression-related behaviors in GIRK2$^{DAT\ KO}$ mice. GIRK2$^{DAT\ KO}$ mice significantly decreased immobility time in forced swimming test as well as effect of antitussives. These results suggest that the antidepressant-like effect of antitussives may be caused through the inhibitory actions on GIRK channel in neurons expressing DAT.

Title: Ketamine Treatment translocates G¬αs From lipid Raft Domains similar to, but on a time scale distinct from, other antidepressants

Authors: *N. WRAY, J. SCHAPPI, M. RASENICK;
physiology and biophysics, Univ. of Illinois At Chicago, Chicago, IL

Abstract: Depression is a significant public health problem for which currently available medications are often ineffective and their therapeutic effects routinely delayed by 1-2 months. We have previously shown that chronic treatment with TCA, SSRIs, and SNRIs translocate $G\alpha_s$ from lipid raft domains to associate with adenylyl cyclase and increase cAMP. We had observed this through direct assay of adenylyl cyclase, cell fractionation that showed Gsa translocating to non-raft cell membrane domains and Fluorescence Recovery after Photobleaching (FRAP). We hypothesized that Ketamine would also have a similar but rapid acting effect mimicking its quick acting effect in depressed patients. C6 cells stably -transfected with GFP-$G\alpha_s$ were treated with 10 uM Ketamine for 15 minutes and 24 hours. The cell lysates of C6 cells were collected, processed for lipid raft isolation, and subjected to Western blot analysis using antibodies to $G\alpha_s$. GFP-$G\alpha_s$- C6 cells transfected with were subjected to FRAP analysis. Both methods produced results that indicate that $G\alpha_s$ translocates from lipid raft domains. These results show that short-term treatment of ketamine creates the same antidepressant signature (translocation of Gαs from lipid rafts), as does sustained treatment with conventional antidepressants. The ability to monitor a consistent series of quantifiable measures associated with antidepressants in a simple cellular model may provide a platform to both study and develop new antidepressant compounds. Such a platform will also be able to serve as a simple detector for speed of onset of antidepressant efficacy.

Title: Targeted modulation of Kv7/KCNQ channel in dopaminergic neurons of ventral tegmental area affect the neuronal excitability and behavior of depression model

Authors: L. LI, H. SUN, D. JIE, C. NIU, N. GAMPER, *X. DU, H. ZHANG;
Hebei Med. Univ., Hebei, China

Abstract: Over the years accumulated evidence implicate the mesolimbic dopamine (DA) system originating in the ventral tegmental area (VTA) in the pathogenesis and treatment of depression. The firing activity of VTA DA neurons is the key determinant in controlling the dopaminergic transmission and the depression-like behavior. Ion channels are the basic controlling components of neuronal excitability including the midbrain dopaminergic neurons, and such are the targets for new antidepressants. Kv7/KCNQ channels are voltage-dependent potassium channels composed of homo- and heteromeric complexes of five different KCNQ subunits (Kv7.1-Kv7.5, KCNQ1-5,). It has been suggested Kv7/KCNQ channels could be an important modulator of dopaminergic neuron excitability and dopaminergic transmission. Kv7.4/KCNQ4 is dominantly expressed in VTA DA neurons and presents potentially to be a target for related diseases of dopaminergic pathways. In this study we attempted to study the consequence of specific modulation of Kv7.4/KCNQ4 in VTA DA neurons, with major interests in the role of Kv7.4/KCNQ4 in DA neuron excitability and depression. Using both newly found elective activator and KCNQ4-/- mice, we first found that Kv7.4/KCNQ4 was a potent modulator of VTA DA neuron excitability in both *in vivo* and *in vitro* experiments. We further showed that Kv7.4/KCNQ4 played an important role in dopamine-induced inhibition of VTA DA activity which was mediated through auto D2 receptor and Gi/o protein pathway. Finally we found selective Kv7.4/KCNQ4 opener improved depression-like behavior of social defeat mice

model. We concluded that targeted modulation of Kv7.4/KCNQ4 K+ channels could be a new strategy for treating depression.

Title: RNAseq reveals clusters of genes in the ventral dentate gyrus that induce resistance to antidepressant treatment

Authors: ***A. A. MATHE**[1], C. NASCA[2], B. BIGIO[3], V. SOUSA[4], P. SVENNINGSSON[4], B. S. MCEWEN[2];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Lab. of Neuroendocrinology, [3]Ctr. for Clin. and Translational Sci., The Rockefeller Univ., New York, NY; [4]Karolinska Inst., Stockholm, Sweden

Abstract: The life-time depression risk is about 20 % (F>M) and yet less than 50% of affected individuals fully respond to available treatments. This prompts an imperative need to elucidate the underlying mechanisms of treatment resistance. We have focused on the glutamatergic and neuropeptide Y systems and used high-throughput analysis of gene expression changes in animal models of depression and in response to antidepressant treatments. Recently, ours and other laboratories showed that 3 days of intraperitoneal administration of the novel antidepressant acetyl-L-carnitine (LAC) induces rapid and long lasting antidepressant effects in both genetically-depressed Flinders Sensitive line (FSL) rats and following stress. Epigenetically, LAC increases expression of the metabotropic glutamate receptor, mGlu2, in the ventral DG (vDG). Here we found that LAC orally administered corrects the depressive-like phenotype of FSL, whereas, after stress exposure, LAC restored immobility time at the forced swim test only in a subset of FSL rats. These findings suggest that stress induced a resistance in the brain responses to antidepressant treatment. Thus, we employed a RNA-seq analysis of the vDG of FSL rats before/after LAC and before/after stress to shed light on the clusters of genes that

induced resistance to the antidepressant treatment. We first validated our micro-dissection approach by examining the expression of the lactate gene, which is known to be absent in the vDG. We identified ~1000 transcripts differentially expressed in three biological replicate experiments. Using pathway and GO analyses, we identified ten cohorts of transcripts. Remarkably, the largest groups of differentially expressed transcripts consisted of regulators of gene transcription, inflammatory response pathways, glutamate signaling genes, fatty acid oxidation and oxidative stress. Among the large number of genes identified by RNA-seq analysis and subsequent qPCR validation on larger biological replicate cohorts, we found that resistant FSL rats show reduced levels of the epigenetic activator of gene transcription P300, which has been recently implicated in the individual responsiveness to stress. Next-generation sequencing is providing revolutionary advances in the identification of novel candidates for therapeutic intervention. Moreover, understanding the individual differences in stress sensitivity and in the responses to antidepressant treatments may provide important knowledge for identifying markers of risk and resilience to stress that can be used to promote early intervention and develop therapeutic next-generation treatments.

Title: Chronic antidepressants accumulate in lipid rafts and modify acylation state of the G protein, Gαs promoting translocation of Gαs from cholesterol-rich plasma membrane microdomains

Authors: S. J. ERB[1], A. CZYSZ[2,3], *M. M. RASENICK[4,5,6,1];
[1]Dept. Biopharmaceutical Sci., Univ. Illinois Col. of Pharm., Chicago, IL; [2]Neurosci. Program, [3]Med. Scientist Training Program, [4]Dept Physiol, Biophysics, [5]Dept. of Psychiatry, Univ. Illinois Coll Med., Chicago, IL; [6]Jesse Brown VAMC, Chicago, IL

Abstract: Depression is a significant public health problem for which currently available medications are often ineffective and their therapeutic effects routinely delayed by 1-2 months.

Previous studies from our laboratory have shown that: 1) Gαs, the protein that activates adenylyl cyclase, is increasingly localized to lipid rafts in depressed subjects and 2) that chronic antidepressant treatment mediates translocation of Gαs out of lipid rafts. Translocation of Gαs presents a potential mechanistic explanation for the delayed onset of therapeutic action, but the precise molecular mechanisms orchestrating Gαs translocation remain. Significant evidence suggests that localization of Gαs to the plasma membrane is facilitated through N-terminal palmitoylation, and it also appears that the localization of Gαs to lipid rafts requires palmitoylation. Gradual accumulation of antidepressants in lipid rafts and antidepressant-induced depalmitoylation of Gαs is suggested to be a causative factor in mediating translocation of Gαs to non-raft regions of the plasma membrane. We have generated stably transfected C6 glioma cells with Gαs-GFP N-terminal acylation mutants to prevent Gαs palmitoylation (Cys3Ser) or to generate Gαs that is both myristoylated and palmitoylated (Asn6Ser). The latter mutation renders Gαs,Gαi like. Both mutant Gαs-GFP constructs generate antidepressant insensitive Gαs. Furthermore, immunoprecipitation of Gαs with conformation specific nanobodies reveal that molecular partners of Gαs are influenced by Gαs acylation state and directed through chronic antidepressant treatment. These results may provide new molecular targets that allow for the discovery of novel therapies for depression.

Title: Dorsal hippocampus P2X7 and prefrontal cortex P2X4 receptor expression is modulated by stress and desipramine treatment

Authors: *D. E. RIBEIRO[1], M. A. P. SILVA[2], P. C. CASAROTTO[3], C. BIOJONE[3], S. R. L. JOCA[2];
[1]Departament of Pharmacology, Sch. of Med. of Ribeirão Preto, Univ. of, Unversity of São Paulo, Ribeirão Preto, Brazil; [2]Sch. of Pharmaceut. Sci. of Ribeirão Preto - Univ. of São Paulo, Ribeirão Preto - São Paulo, Brazil; [3]Neurosci. Ctr. - Univ. of Helsinki, Helsinki, Finland

Abstract: There is evidence pointing a potential involvement of P2X7 (P2RX7) and P2X4 (P2RX4) receptor in mood disorders. In humans, P2RX7 polymorphism is associated to development of depression. In animal models, the lack of P2RX7 induce antidepressant-like behavior: P2RX7 KO mice exhibit antidepressant-like phenotype and systemic administration of a preferential P2XR antagonist results in antidepressant-like behavior in mice. Lastly, mice treated with a P2RX4 positive allosteric modulator induced a depressant-like behavior. Therefore, the aim of this study was to investigate if the behavioral effects induced by stress and antidepressant treatment is associated to alterations in the P2RX7 and P2RX4 expression in cortex and hippocampus, which are structures crucial to stress copying and antidepressant response. The learned helplessness model (LH) was used in order to access behavioral effects of antidepressant treatment due its good predictive and face validity. LH is a classical and widely used model of depression based on the observation that exposure to uncontrollable stressors induces behavior deficits. Adult male rats were submitted to LH pre-test session (40 inescapable footshocks: 0.4 mA, 10 s duration, 30-90 s interval) and were treated with vehicle or desipramine 25 mg/kg (DES) for seven days, and were tested 1 hour after the last injection. The test session consisted of 30 escapable footshocks (0.4 mA, 10 s duration, 30-90 s interval) preceded by a tone (60dB, 670Hz) that started 5s before each shock and lasted until its end. Animals could avoid the shock during sound presentation or interrupt its presentation by crossing to the opposite side of the chamber (escape). Absence of one of these behaviors was considered an escape failure. An independent group of rats was submitted to LH pre-test session (stressed group) or habituation in the same apparatus (non-stressed group), and then the rats were treated with vehicle or DES for seven days, and killed 1 hour after the last injection in order to have their prefrontal cortex and hippocampus dissected. P2RX7 and P2RX4 expression in prefrontal cortex and hippocampus was determined by western blotting. DES treatment decreased the number of escape failures of rats submitted to the LH paradigm ($t_{17}= 3.16$; $p<0.05$). The animals submitted to LH pretest session showed an increase in the dorsal hippocampus P2RX7 expression ($F_{2,14}=7.282$; $p<0.05$) and a decrease in the prefrontal cortex P2RX4 expression ($F_{2,16}=4.560$; $p<0.05$). These effects was prevented by the DES treatment. Therefore the purinergic signaling can be involved in stress response and antidepressant treatment.

Title: Agomelatine reverses the behavioral deficits and the reductions in synaptic, GABAergic and glial makers induced by chronic unpredictable stress in the rat prefrontal cortex

Authors: *M. BANASR[1], M. THOMAS[1], A. LEPACK[1], G. SANACORA[1], R. DUMAN[1], C. GABRIEL[2], E. MOCAER[2];

Abstract: Growing evidence demonstrate that drastic morphological and cellular changes occurs in the limbic brain regions of patients with MDD. Post-mortem studies report anomalies of GABAergic neurons function, reduced astrocyte number and neuronal atrophy of pyramidal neurons in the prefrontal cortex (PFC) of MDD patients. Using the chronic unpredictable stress (CUS) paradigm, we previously demonstrated that chronic stress induces depressive-like behavioral deficits as well as molecular changes similar to the cortical alterations reported with human depression. Here, we used this model to test the therapeutic efficacy of agomelatine, a novel antidepressant acting as a melatonergic receptor agonist and serotonergic (5-HT2C) receptor antagonist at both the behavioral and cellular level. Adult Sprague-Dawley rats were subjected to CUS (2 stressors/day) for 35 days. For the last 3 weeks of the CUS exposure, animals were injected with agomelatine (40mg/kg, i.p) or fluoxetine (5mg/kg, i.p). At the end of the experiment, animals (6 groups, n=8 per group) were tested in the sucrose preference test and in the novelty suppressed feeding test. We found that treatment with agomelatine or fluoxetine increased sucrose preference and decreased latency to feed in animals subjected to CUS, demonstrating that agomelatine or fluoxetine treatment reversed CUS-induced anhedonia- and anxiety-like deficits. At the cellular level, we examined the effects of chronic treatment with agomelatine or fluoxetine on the expression levels of key protein involved in the function GABAergic neurons, astrocytes or synaptic plasticity using western blot analysis. Preliminary data suggest that chronic treatment with agomelatine blocked the CUS-induced reductions of the expression of phospho/total mTOR (-29%), PSD95 (-20%), Synapsin-1 (-29%), GAD67 (-21%), GLT1 (-15%) and GFAP (-19%) in the PFC. Chronic treatment with fluoxetine also reversed these effects. Further studies examining the effects of agomelatine on CUS-induced changes in

protein expression in the dorsal and ventral hippocampus are underway. Altogether our results confirmed the antidepressant-like efficacy of chronic treatment with agomelatine as indexed by reversal of stress-induced anhedonia- and anxiety-like deficits and suggest that prevention of key cellular changes associated with synaptic loss and cortical GABAergic and astrocytic dysfunction contribute to the antidepressant action of agomelatine. Further studies will be needed to evaluate the kinetics of the improvement for each antidepressant.

Title: Imipramine affects circulating BDNF, prolactin and ACTH in time dependent manner

Authors: ***M. KUSMIDER**, A. FARON-GÓRECKA, J. SOLICH, J. WÓJCIKOWSKI, D. ZURAWEK, P. PABIAN, W. DANIEL, M. DZIEDZICKA-WASYLEWSKA;
Pharmacol., Inst. of Pharmacol. P.A.S., Krakow, Poland

Abstract: Antidepressant action requires time for improvement to appear. Usually several weeks of treatment are needed to see mood stabilization. The biological psychiatry can’t explain this phenomenon as yet. Several theories address this, with the most recognized neurotrophin/neuroplasticity theory, with BDNF as the core molecule. The present data are connected with two clinical situations: so called compliance, linked with effectiveness/adverse effects ratio, and the antidepressant discontinuation syndrome. Our research focus on changes in rat nervous system following single and chronic antidepressant administration, changes that appear as the function of time. The study was performed on male rats, of Wistar HAN strain. The experiments were carried out with accordance to bioethical committee of Institute of

Pharmacology PAS. For 20 days animals were receiving daily i.p. injections with saline (SAL 2ml/kg) or Imipramine (IMI 10mg/kg/2ml). On 21st day half of animals treated previously with saline received singledose of IMI 10mg/kg i.p. Therefore, since that day, we had 3 groups of animals: receiving SAL, IMI chronically, and IMI once. Next, animals have been left with no additional treatment for next 21 days. During that time, at certain time points (3h, 72h, 7days and 21days after last injection) 5 animals of each group were sacrificed and plasma, serum and brain tissue was collected for further analysis. HPLC analysis of plasma samples revealed that IMI and its metabolite, desipramine, were present in samples only 3h after last injection, at the 72h and next time points the analytes were undetectable. Plasma and serum concentrations of BDNF, prolactin (PRL) and ACTH were detected by the means of Luminex technology. Chronic IMI treatment tended to flatten the natural differrence between plasma and serum concentration of BDNF (the neurotrophin is released from platelets during clotting). During discontinuation we observed oscillations in BDNF concentrations in both IMI-chronic, and IMI-once groups, reaching the highest levels at the 21st day. PRL and ACTH, which we considered as the indicators of stress have been elevated at 72h and 21days of drug discontinuation, but only in a group treated with IMI chronically. The most important conclusion we made is that the elevation of BDNF plasma level could be achieved not only with the IMI presence in the animal, but also after couple of weeks of drug discontinuation.

Title: The regulation mechanism of miR-16 on serotonin related neural circuits through PI3K signaling pathway in Chronic Mild Stress rats model

Authors: Z. HU[1], *M. FANG[2], Y. YANG[2];
[1]Dept. of Obstetrics and Gynecology. Hangzhou Red Cross Hosp., Hangzhou, China; [2]Zhejiang Univ., Zhejiang, China

Abstract: The pathogenesis of depression is generally recognized as dysfunction of the serotonin system. Recently, miR-16 has been discovered to affect function of the serotonin transporter in

antidepressant drugs. Our study aims to explore the molecular mechanism of miR-16 on the structure and function of 5-HT related neural circuits. 5-HT and miR-16 inhibition was employed, and changes were analyzed with optogenetics tools combined with magnetic resonance imaging, fluorescent tracer technique and molecular biological methods. From our previous results, stressed rats showed typical symptoms of depression, atrophy appeared in the hippocampus and amygdala neurons, reduced number of dendritic spines and changed their morphology. There were also obvious changes in cytoskeleton protein expression. Seven days after MiR-16 lentivirus injection, RT-PCR and Western Blotting were used to examine the mRNA and protein expression of key proteins in PI3K signaling pathways in the hippocampus, including MiR-16, 5-HTT, 5-HT2a, mTOR, AKT, P-AKT, PI3K. And the results indicated that expressions in the miR-16 group were higher than the CMS (chronic mild stress) group in both mRNA and protein levels. Results from behavioral experiments also revealed the similar phenomenon. The sucrose consumption test and open field test were chosen to detect depression like behavior at the time points of seven days pre and post injection. The MiR-16 group appeared to have a higher sucrose intake rate and mobile number than the CMS group. Therefore, we concluded with a hypothesis that miR-16 could play a role in 5-HT related neural circuits and anti-depressive roles through hippocampal PI3K signaling pathways.

Title: Ketamine-induced inhibition of glycogen synthase kinase-3 contributes to the augmentation of AMPA receptor signaling

Authors: ***S. GRIECO**[1,2], C. AMADEI[2], K. DOWNEY[2], R. JOPE[2,1], E. BEUREL[2,1]; [1]Biochem., [2]Univ. of Miami, Miami, FL

Abstract: Sub-anesthetic doses of ketamine have been found to provide rapid antidepressant actions, indicating that the cellular signaling systems targeted by ketamine are potential sites for therapeutic intervention. Ketamine acts as an antagonist of N-methyl-D-aspartate (NMDA) receptors, and animal studies indicate that subsequent augmentation of signaling by α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors is critical for the antidepressant outcome. Here we tested if the inhibitory effect of ketamine on glycogen synthase kinase-3 (GSK3) affected hippocampal cell-surface AMPA receptors. Treatment with an antidepressant dose of ketamine increased the hippocampal membrane level of the AMPA receptor GluR1 subunit, but did not alter the localization of GluR2, GluR3, or GluR4. This effect of ketamine was abrogated in GSK3 knockin mice expressing mutant GSK3 that cannot be inhibited by ketamine, demonstrating that ketamine-induced inhibition of GSK3 is necessary for up-regulation of cell surface AMPA GluR1 subunits. AMPA receptor trafficking is regulated by PSD95, a substrate for GSK3. Ketamine treatment decreased the hippocampal membrane level of phosphorylated PSD-95 on Thr-19, the target of GSK3 that promotes AMPA receptor internalization. These results demonstrate that ketamine-induced inhibition of GSK3 causes reduced phosphorylation of PSD-95, diminishing the internalization of AMPA GluR1 subunits to allow for augmented signaling through AMPA receptors following ketamine treatment.

Title: xCT epigenetically promotes homeostatic regulation of the glutamate system in the responses to stress: implications for next-generation treatments

Authors: *D. A. ZELLI, B. S. MCEWEN, C. NASCA;
Neuroendocrinology, The Rockefeller Univ., New York, NY

Abstract: Stress acts synergistically with excitatory amino acids to induce either protective or damaging effects on the brain, and dysregulated glutamate homeostasis has been associated with several psychiatric and neurological disorders. Glutamate genes present logical targets to develop novel therapeutic strategies with a rapid onset of action. Previous studies have shown rapid antidepressant effects of either ketamine, which blocks NMDA receptors, or acetyl-L-carnitine (LAC), which up-regulates mGlu2 via acetylation of histone H3 on lysine 27. Preliminary data from our laboratory reveal that chronic restraint stress (CRS) results in susceptible individuals in anxiety and depressive-like phenotypes at the light dark and forced swim test, respectively. Molecularly, CRS mice have reduced hippocampal levels of the xCT exchanger, which facilitates cystine uptake into glial cells in exchange for glutamate to the extracellular space, along with decreased levels of the presynaptic inhibitor of glutamate release, mGlu2 receptors, which have been recently identified as biomarkers of individual susceptibility to stress and antidepressant treatments. Sub-regionally, CRS-induced xCT-mGlu2 changes appear to be localized to the ventral dentate gyrus (vDG). We also found that 3-days of oral treatment with the acetylating agent N-acetyl-cystine (NAC) increases xCT expression in the vDG while also increasing mGlu2 levels in the same sub-region and this corrects the behavioral abnormalities induced by CRS more rapidly than spontaneous recovery and treatment with the SSRI, fluoxetine. Moreover, we found that, in parallel with the results described above on the CRS-induced transcriptional down-regulation of xCT expression in the vDG, CRS decreases levels of the transcriptional activator P300 in the vDG and this deficit is corrected by NAC treatment. These findings reveal a previously unknown role for xCT in a homeostatic regulation of the vDG in the stress responses in relation to anxiety and depressive-like behaviors and antidepressant action. Together, our results have implications for disorders in which glutamatergic transmission is dysregulated, revealing that prolonged stress can produce potentially maladaptive neural and behavioral responses that can be corrected by novel epigenetic therapies, such as the acetylating agent NAC and L-acetylcarnitine, targeted to promote resilience by producing compensatory mechanisms.

Title: Stress induced elongation of pyramidal, but not stellate, neurons in the basolateral amygdala with implications for next generation treatment

Authors: ***T. LAU**[1], B. BIGIO[2], D. ZELLI[1], B. S. MCEWEN[1], C. NASCA[1];
[1]Neuroendocrinology, [2]Ctr. for Clin. and Translational Sci., The Rockefeller Univ., New York, NY

Abstract: The hippocampus is a target of stress and stress hormones. Structural and functional hippocampal changes have been associated with the onset and exacerbation of psychiatric disorders, such as depression and anxiety. Stress effects on the brain, however, are not exclusive to the hippocampus but they also involve the amygdala which is increasingly recognized as a target of stress. Additionally, there are emerging evidence showing the ventral hippocampus, which projects to the amygdala, to be a target of stress hormones and antidepressants with functions and connectivity that are distinct from the dorsal hippocampus. Here we examined the effects of chronic stress on the amygdala by subjecting C57BL/6N mice to 21 consecutive days of chronic restraint stress (CRS) and then we examined neuron morphology within the subregions of the amygdala. Behavioral assessments were carried out using the forced swim and light dark test 24 hours after the last episode of stress to measure depression and anxiety-like levels, respectively. Mice were sacrificed shortly after the behavioral assessments. An additional group of stressed mice was treated orally with the novel antidepressant L-acetylcarnitine (LAC) for 3 days. The extracted brains were then processed using the Rapid Golgi Staining Kit. Amygdala neurons were distinguished as pyramidal or stellate based on their morphology. Results revealed that pyramidal neurons from CRS animals exhibited greater total dendritic length compared to unstressed control mice. Furthermore, the dendrites from the stressed group were more elaborate at a closer distance to the soma compare to the control group, showing greater dendritic lengths and more intersections. Interestingly, LAC treatment corrected CRS-induced mood abnormalities, but, LAC treated mice also showed an even greater dendritic length compare to both control and stress groups, suggesting that a counter-regulatory mechanism may be involved in the fast antidepressant effects of LAC. The number of intersections for each group correlated in a similar pattern where the stress group displayed more intersections compare to the control group but with the LAC group showing the highest number of intersection. In contrast, little effect of CRS was seen in the BLA stellate neurons and in the lateral amygdala neurons. At present, RNAseq is underway to understand the clusters of genes that mediated stress effects in the amygdala. These results underscore the importance of better understanding how stress induces structural and functional changes in higher-level cognitive brain regions with implication for the development of drugs with better profiles of efficacy and tolerability.

Title: Sex- and sert-associated differences in stimulated serotonin neurotransmission revealed by fast microdialysis

Authors: *H. YANG[1], M. M. SAMPSON[2], D. SENTURK[3], A. M. ANDREWS[4];
[1]Psychiatry, [2]Mol. Toxicology, [3]Biostatistics, [4]Psychiatry, Chem. & Biochemistry, Hatos Ctr. for Neuropharmacology, Semel Inst. for Neur, UCLA, Los Angeles, CA

Abstract: *In vivo* microdialysis is widely used to study neurotransmitter levels in the brain to determine how they respond to biological challenges. We combined our recent improvements in the temporal resolution of online serotonin sampling with a brief K+ stimulus paradigm to investigate evoked serotonin release. Mice with constitutive loss of serotonin transporter (SERT) expression and wildtype littermates were assigned to one of five groups: (1) wildtype male (N=7); (2) wildtype male with acute serotonin-selective reuptake inhibitor (SSRI) escitalopram (ESC) perfusion (N=8); (3) SERT knockout male (N=6); (4) wildtype female metestrus/diestrus (N=5); and (5) wildtype female proestrus/estrus (N=5). Estrous phase was determined by vaginal smear immediately after the completion of dialysis. We observed stimulated serotonin overflow with 120 mM K+ pulses as brief as 1 min in conjunction with 2 min online dialysate sampling and analysis in ventral striatum. After 1-min K+ stimulation, all wildtype male subjects exhibited detectable stimulated serotonin overflow. By contrast, 5/8 ESC-treated males and one each from the other groups failed to respond to the 1-min high K+ stimulus. Stimulated serotonin levels in female mice during the high estrogen period of the estrous cycle (proestrus/estrus) were similar to serotonin levels in male wildtype male mice (1-5 min stimuli). By contrast, stimulated serotonin overflow during the low estrogen period in female mice (metestrus/diestrus) was

elevated to the same extent as in male wildtype mice with local SERT inhibition by ESC. Stimulated serotonin levels in knockout mice were considerably higher than all other groups throughout the stimulation paradigm. We conclude from the latter that serotonin release is greatly potentiated as a result of life-long loss of SERT. After repeated maximal stimulation (6-min stimuli), evoked serotonin overflow decreased only in groups with the highest levels of stimulated overflow (i.e., SERT knockout, wildtype with acute local ESC-treatment, and female during the metestrus/diestrus) at shorter inter-stimulus intervals. When combined with brief K+ stimulation, fast microdialysis enables dynamic changes in serotonin transmission associated with normal female hormonal cycles, and pharmacologic compared to genetic loss of SERT function to be delineated.

Title: The key targets of antidepressants revealed by functional brain connectome analysis in macaques

Authors: Q. LV[1], J. PU[1], G. LI[2], Z. WANG[1], Z. SHEN[1], Q. JIANG[1], L. YANG[1], Z. XUE[2], H. HU[1], *Z. WANG[1];
[1]Inst. of Neurosci., Shanghai, China; [2]Dept. of Anesthesiology, Zhongshan Hosp., Shanghai, China

Abstract: Most antidepressants currently available to clinical patients usually require weeks to take effect, and only limited number of patients with depression achive alleviation to lesser or greater extents. Growing studies have consistently demonstrated that a single-dose of N-methyl-D-aspartate (NMDA) antagonist ketamine produces rapid (within hours) antidepressant response, even in patients with treatment-resistant depression. Although numerous studies have focused on uncovering the underlying molecular mechanisms, identifying the key brain areas preferentially targeted by two types of antidepressants may provide novel insights into development of efficacious pharamacological therapy. Here we combined the resting-state functional magnetic

resonance imaging (fMRI) and graph theoretical analysis to quantitatively assess the brain regions influenced by sertraline and ketamine. Fifteen healthy macaque monkeys were involved, and received a single-dose administration of ketamine (0.5 mg/kg, n=9), sertraline (5mg/kg, n=11) and saline (n=9) as control. The interval between two experimental conditions was spaced at least one month to avoid carry-over effects. Resting-sate fMRI data were acquired in anesthetized animals on a Siemens Trio 3T scanner with an enhanced gradient insert AC88. To maximize the antidepressant effects on the brain network, scans were scheduled ~18 hours and ~4 hours after the administration of ketamine and sertraline, respectively. We observed large-scale decreased functional connectivity caused by sertraline and ketamine compared to the saline group. Specifically, network based analysis showed that a single-dose of ketamine and sertaline both modulated extensive connections with nucleus accumbens (NAc) and subgenual anterior cingulate cortice (sgACC) ($p < 0.05$, corrected). In contrast with the sertraline group, ketamine intake down-regulated the functional connectivity between dorsal prefrontal cortex (dPFC), superior temporal gyrus and putamen ($p < 0.05$, corrected). This finding suggests that dPFC, superior temporal gyrus, putamen together with NAc and sgACC may represent the key target brain regions to achieve rapid and efficacious antidepressant effects.

Title: Acupuncture decreases dendritic arborization and dendritic spine density in basolateral amygdala in social isolated rats

Authors: ***A. DAVILA HERNANDEZ**, M. DEL ANGEL-MUÑOZ, S. ZAMUDIO, C. CAMPOS-RODRIGUEZ, R. GONZALEZ-GONZALEZ, E. RAMIREZ-SAN JUAN;
Inst. Politecnico Nacional, Mexico, Mexico

Abstract: Introduction: Depression is one of the most common psychiatric disorders; it displays high rates of lifetime prevalence, early age of onset, high chronicity, and social role impairment, and is characterized by a depressed mood and anhedonia. It is associated to neuromorphological changes in some structures, such as: hipoccampus and amygdala related to severity of symptoms. Due the importance of depression and undesirable effects of conventional treatment, is necessary

to use complementary therapies such as acupuncture, a non-pharmacological treatment, simple procedure and, without adverse effects, which has demonstrated clinical efficacy in depression, and using embedding thread in acupoints can be a prolonged stimulus for at least three weeks. Objective: to evaluate the effect of embedding thread in acupoints on pyramidal neurons morphology in the basolateral amygdala of social isolated rats (a depression model). Methods: 60 Sprague-Dawley male rats were used and randomly divided in six groups, with 10 rats each: a control group, social isolated group (SI), social isolated + embedding thread group (SI+AC), social isolated + sham embedding thread group (SI+sham), social isolated + fluoxetine group (SI+FX), and social isolated + vehicle group (SI+VH). Animals were weaned on postnatal day (PD) 21 and submitted to social isolation for eleven weeks, the control group was housed in social conditions. On PD 77, the SI+AC was anesthetized with sodium pentobarbital (28 mg/kg) and embedded thread in acupoints (BL15, BL18, BL21, BL23, Du20 and, Ex 3). The sham group was punctured without embedded thread, the SI+FX was subcutaneously treated with fluoxetine (2 mg/kg/day) during the following 21 days, the SI+VH received saline solution. After the treatments, the animals were sacrificed by overdose of sodium pentobarbital and perfused intracardially with 0.9% saline solution. The brains were removed, processed by the Golgi-Cox stain and analyzed by the Sholl method. Results: The dendritic morphology study showed that the social isolated animals presented an increase in dendritic length of pyramidal cells from basolateral amygdala, acucatgut (SI-AC) induced a reduction in dendritic length, at the same level of control group, and, acucatgut or treatment with fluoxetine also decreased the density of dendritic spines, although in the SI+FX did not reach the level of the control group. Conclusions: 1. Social isolation in rats induces dendritic morphology changes in basolateral amygdala, similar to those that have been observed in patients with first episode of depression. 2. Embedded thread in acupoints reversed the neuromorphological effects of social isolation.

Title: Glucocorticoids-IL6 crosstalk allows identification of inherent individual differences that predict and promote vulnerability to social stress

Authors: *B. S. MCEWEN[1], C. NASCA[1], G. E. HODES[2], V. KANA[2], E. J. NESTLER[2], S. J. RUSSO[2];
[1]Lab. of Neuroendocrinology, The Rockefeller Univ., New York, NY; [2]Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Stressful experiences superimposed on top of inherent individual differences can lead susceptible individuals to develop debilitating mental and physical diseases, whereas other individuals are resilient and show cognitive flexibility to the same stressor. Recently, we introduced a rapid screening method for identifying susceptible individuals among an inbred population of mice. Individuals that show increased expression of hippocampal mineralocorticoid receptors (MR), before any applied stress, display increased levels of anxiety- and depressive-like behaviors after exposure to stress along with reduced levels of the presynaptic inhibitor of glutamate release, mGlu2 receptors. Here, we tested whether individual differences in hippocampal MR expression correlate with inherent differences in the peripheral immune system that have been shown to predict and promote vulnerability to social defeat stress (SDS). Previous studies found that mice with higher levels of IL-6 released from leukocytes following *ex vivo* LPS stimulation prior to stress, show low levels of social interaction after chronic SDS. Using the light-dark test (LD), we screened an inbred population of C57bl6 male mice and obtained leucocyte profiles along with IL-6 levels at baseline and from *ex vivo* stimulated leukocytes before applying chronic SDS. We found that mice identified as high susceptible in the LD show higher prestress levels of circulating Ly6chi monocytes and more IL-6 release when stimulated *ex vivo* with LPS and before any applied stressor. No difference in IL-6 without LPS stimulation was found. Furthermore, the peripheral leukocyte profiles show no difference in the Cd45 leukocyte population but a slight increase in neutrophils in susceptible mice compared with resilient mice, suggesting that prestress increased IL-6 levels are largely due to the Ly6chi monocytes and neutrophil populations. These results show that mice prone to develop a susceptible phenotype had higher hippocampal levels of MR and greater IL-6 release following *ex vivo* stimulation with LPS. Together, our findings suggest that the LD and hippocampal MR levels are features that connect with the vulnerability to social defeat stress as well as other stressors, providing tools to screen for inherent differences in the susceptibility to develop stress-related mood disorders. Moreover, the correlation between peripheral markers of inflammation (like IL-6) and LD (which identifies individuals with higher hippocampal MR) may offer the opportunity to develop prophylactic therapeutic strategies, pharmacological or behavioral, to prevent the deleterious effects of stress in susceptible individuals.

Abstract: An exciting discovery in the field of modern neuropsychopharmacology was the finding that a single sub-anesthetic dose of the N-methyl-D-aspartate (NMDA) receptor antagonist ketamine can induce both rapid and sustained antidepressant-like effects in treatment-resistant depressed patients and in animal models of depression. Despite the progress made in the identification of the behavioral and neurobiological mechanisms underlying the antidepressant-like effects of ketamine, knowledge regarding its effects in the female sex is limited. In the present study, male and female C57BL/6J mice were administered increasing doses of ketamine (i.e. 3 mg/kg, 5 mg/kg, 10 mg/kg) or saline (0.9% NaCl). The rapid and sustained antidepressant- and anxiolytic-like behavioral effects of ketamine were assessed in the forced swim test (FST) and the novelty-suppressed feeding (NSF) test at 30 min, at 24 h or at 7 days post-administration. In our experimental setup, female mice responded to lower doses of ketamine than males in the FST, at 30 min and at 24 h, while no effects were evidenced in the NSF test. Importantly, only the highest dose of ketamine (i.e. 10 mg/kg) induced both rapid and sustained antidepressant-like effects in both sexes in the FST and thus was subsequently selected for neurochemical estimations. Mice of both sexes were administered ketamine (10 mg/kg) or saline and were sacrificed at 30 min (rapid effects) or at 24 h (sustained effects) post-injection. Neurochemical analysis of monoamines (i.e. serotonin, dopamine and their metabolites) and excitatory amino acids (glutamate and aspartate) was performed with high performance liquid chromatography (HPLC) in brain regions implicated in the neurobiology of major depression. According to our data, ketamine induced sex-dependent dopaminergic alterations in the nucleus accumbens and also affected cortical and hippocampal excitatory amino acids in a sex-specific manner. These findings highlight the critical role of sex in the manifestation of antidepressant-like neurobehavioral responses to ketamine in mice.

Title: Resistance to chronic antidepressant treatment: a behavioural and neurogenic study in a neuroendocrine-based mice model of anxiety/depression

Authors: ***M. MEKIRI**, A. M. GARDIER, D. J. DAVID, J.-P. GUILLOUX;
UMRS1178, Châtenay Malabry, France

Abstract: Major depressive disorder (MDD) is a major and highly debilitating disease. Despite major improvements in the field of antidepressant drug treatments, MDD still suffers from a low rate of treatment response, as 60% of MDD patients do not respond adequately to pharmacological treatment. Moreover, resistance to antidepressant treatment, which refers to an inadequate response to two consecutive treatments with drugs having a different pharmacological mechanism of action (1), occurs in ≈30% of patients. Although preclinical studies suggest that suppressing adult hippocampal neurogenesis impacts part of the effects of chronic antidepressant, yet no study observed a lack of antidepressant drug response associated with altered neurogenesis. Moreover, β-arrestins proteins levels in peripheral blood mononuclear cells (PBMC) are altered in the MDD subjects and restored after antidepressant drug treatment (2). Yet, we do not know if alterations of proteins expression involved in the β-arrestin pathway are associated with non-response to antidepressant drugs. Here, we studied non-response and resistance to antidepressant drugs in a neuroendocrine mouse model of anxiety/depression based on a chronic corticosterone administration (35 µg/ml, p.o., for 4 weeks). Emotionality score in CORT-treated mice was assessed using various behavioural tests (3). In a translational manner, response in mice was defined as a 50% decrease in initial emotionality score. CORT-treated animals display a higher z-score than control mice. Fluoxetine was then administered (18 mg/kg/j, p.o., for 4 weeks), and non-responder mice (≈30%) were switched to chronic imipramine administration (40 mg/kg, p.o., 4 weeks). About 30% of mice did not respond adequately to both therapeutic strategies and were characterized as “treatment-resistant” mice. Animals showing lack of treatment response displayed altered neurogenesis in the dentate gyrus

of the hippocampus, with lower cell survival, decreased neuronal maturation and lower dendritic arborization compared to responder mice. We isolated PBMC from the blood of these mice to assess whether non-response to treatment is associated with alterations of proteins involved in the β-arrestin pathway. Overall, our results support that treatment resistance is observable in an animal model of the disease, and that impaired response to antidepressant drug treatment is associated with altered hippocampal neurogenesis in adult mice. Title: 'Sequester stress': the development of a novel animal model for life stress and a depression-like phenotype

Authors: *B. L. KOPP[1], C. LYONS[2], B. MYERS[1], M. B. SOLOMON[1], J. P. HERMAN[1], *F. CORREA[2];
[1]Psychiatry and Behavioral Neurosci., [2]Summer Undergraduate Res. Fellowship Program, Univ. of Cincinnati, Cincinnati, OH

Abstract: Chronic exposure to stressors is frequently used to model a depression-like phenotype in rodents. Significant loss often triggers depressive episodes in humans, and currently there are no rodent models that emphasize loss to induce long-term stress. To this end, we developed "sequester stress" as a novel and potentially translational model of stress and depression-like

characteristics. Sequester stress entails exposing adult male Sprague Dawley rats to environmental enrichment for 1 month and subsequently removing them from enrichment for 2-3 weeks, to model the removal of a positive stimulus rather than the application of a negative experience. Environmental enrichment consists of 10 rats per 1mm3 cage, with wire mesh walls for climbing and novel toys rotated in every week. Upon sequestration, rats are placed into standard single housing. In comparison to both single housed controls and continuously enriched controls, the enrichment sequestered rats (ES) have increased immobility in the forced swim test (FST), increased body weight gain, blunted corticosterone and ACTH responses to a novel stressor, and increased initial sucrose consumption. Antidepressant treatment with imipramine reverses the FST and body weight phenotypes. Although rewarding, environmental enrichment increases corticosterone and ACTH responses to stress and decreases body weight gains. Therefore, we compared the effect of ES with other regimens that cause prolonged stress activation, repeated restraint and chronic variable stress. The ES phenotype was specific to enrichment deprivation, and does not generalize to loss of chronic habituating or unpredictable stress. Furthermore, we test whether the exclusive loss of the social component or exercise component of environmental enrichment is sufficient to produce the phenotype. Together, our studies indicate that the sequester model produces a novel and robust rodent phenotype, addressing symptoms of 'atypical' depression, which include hyperphagia, weight gain, and hypothalamo-pituitary-adrenocortical axis suppression.

Title: Effect of imipramine on the peripheral th2/th1 cytokine production in the rat serum in the time-dependent sensitization paradigm

Authors: *A. FARON-GÓRECKA, M. KUśMIDER, J. SOLICH, P. PABIAN, D. ŻURAWEK, B. ZEMłA, M. DZIEDZICKA-WASYLEWSKA;
Inst. of Pharmacol. PAS,, Krakow, Poland

Abstract: Time-dependent sensitization (TDS) has been described in animal models over the past 40 years (Antelman et al., 2000). It is a phenomenon that occurs in a variety of biological systems, and corresponds to the cellular and systems response to a foreign or stressful stimulus. The exposure to the stimulus triggers the responses typical of that particular biological system, which are progressively amplified with time. This phenomenon has potential major implications for clinical pharmacology. Antidepressant action also may be a fruitful paradigm to understand the relevance of TDS for psychopharmacological treatment. Our previous results confirm this hypothesis – we have shown that the shortening of immobility time in the forced swim test induced by a single dose of imipramine (IMI) persisted throughout the whole experimental period (21 days) and was similar to that seen in a group of animals treated repeatedly (21 days) with the drug (Kuśmider et al., 2006). There are data implicating the inflammatory theory of depression (e.g. higher levels of inflammation increase the risk of depression, remission of clinical depression is often associated with a normalization of inflammatory markers), therefore we tried to correlate the TDS paradigm using IMI treatment with immunological theory of depression. In our experimental studies, using Luminex Technology, we measured the peripheral th2/th1 cytokine production (BioRad Assay) in the serum of rats treated with IMI (10 mg/kg) chronically (21 days, 21x) and rats treated with single dose of IMI (1x) at the beginning and remained in the experiment free of further drug administration for next 20 days. During that time, at certain time points (3h, 72h, 7days and 21days after last injection) 5 animals of each group were sacrificed and plasma, serum and brain tissue was collected for further analysis. All experiments were carried out in accordance with Bioethical Committee at the Institute of Pharmacology, Polish Academy of Sciences, Krakow, Poland. The study was performed on male rats, of Wistar HAN strain. After 3 h following IMI treatment a th1 shift was observed in both groups: treated chronically and with single dose of IMI ($p<0.05$ vs control group). After 72h and 7 days no changes in th2/th1 shift were observed, only after 21 days in animals chronically receiving IMI, th2 shift was observed. In addition, after 7 days of IMI withdrawal, the changes in cytokines: IL10, IL1alfa, IL12, IL-5 were similar in both groups (1x and 21x of IMI). Our results do not suggested directly the correlation between TDS paradigm and immunological theory of depression, however some data (e.g. those observed after 7 days) may indicate this relationship.

Title: FosB expression in ventral hippocampus regulates behavior in the social defeat model of depression

Authors: *C. MANNING, S. COOPER, A. EAGLE, M. THIBAULT, P. GAJEWSKI, M. MAZEI-ROBISON, A. ROBISON;
Michigan State Univ., East Lansing, MI

Abstract: The ventral hippocampus is implicated in stress responses and motivated behaviors, and thus is an attractive target for studying the mechanisms of susceptibility and antidepressant actions after chronic social defeat stress (CSDS). We are therefore examining the role of the transcription factor ΔFosB in the ventral hippocampus in mediating behavioral responses to social stress and antidepressant effects on these behaviors. Chronic fluoxetine (Prozac©) ameliorates the behavioral deficits seen in susceptible animals after CSDS, and we report here that chronic fluoxetine also significantly increased the number of FosB reactive cells in all subregions of the ventral hippocampus. Further, Western blot revealed that chronic fluoxetine induces both ΔFosB and full-length FosB isoforms in the hippocampus of both animals exposed to defeat and controls. In order to determine whether ventral hippocampus FosB proteins play a role in behavioral responses to stress, we used targeted AAV-mediated expression of ΔJunD, a dominant negative variant of the FosB binding partner, in ventral hippocampus. We observed that inhibition of FosB transcriptional activity decreased the social interaction time after a single submaximal defeat compared to controls, suggesting that inhibition of FosB makes animals susceptible to stress. Taken together, these data suggest that FosB in the ventral hippocampus is a powerful modulator of the depressive-like symptoms induced by CSDS. We are currently investigating sex differences in stress- and fluoxetine-dependent induction of FosB proteins as well as their role in projections from the ventral hippocampus to other limbic and cortical regions important for stress responses.

Title: Pharmacological potentiation of KCNQ channel currents in midbrain dopamine neurons functions as a mechanistically distinct antidepressant

Authors: *A. K. FRIEDMAN[1], B. JUAREZ[1], S. M. KU[1], H. ZHANG[1], J. J. WALSH[1], D. CHAUDHURY[1], D. M. DIETZ[1], M. RIBADERNEIRA[2], E. WONG[2], R. NEVE[3], M.-H. HAN[1,4]; [1]Ichan Sch. of Med. at Mount Sinai, New York, NY; [2]CNS Pain Innovative Med. Unit,, AstraZeneca, Wilmington, DE; [3]McGovern Inst. for Brain Research, MIT, Boston, MA; [4]Friedman Brain Inst., New York, NY

Abstract: Although major depressive disorder is the second leading cause of disability worldwide, with less than half of patients achieving remission, there continues to be limited mechanistic diversity among the available antidepressants. This makes it imperative to develop new therapeutics. In particular, novel strategies may arise from utilizing recent insights into the understanding of natural resilience to social stress. Specifically these findings have demonstrated the importance of maintaining healthy activity of the dopamine (DA) neurons of the ventral tegmental area (VTA) in regulating mood. Thus, we explored the VTA DA circuit for novel therapeutic targets. Utilizing the well-established preclinical model of depression known as the chronic social defeat stress paradigm we demonstrated that resilient animals homeostatically maintain healthy DA neuron activity through a compensatory upregulation of potassium (K+) channels. To identify the K+ channel subunits necessary for this self-tuning plasticity we infused a selective inhibitor of KCNQ channels, XE-991, into the VTA of resilient mice. The inhibition of the KCNQ channels revealed the underlying stress-induced VTA hyperactivity and social avoidance. To determine if upregulation of this current is sufficient to behaviorally convert previously social avoidant and anhedonic mice we specifically expressed KCNQ3 in VTA dopamine neurons by injecting a Cre-inducible HSV-LS1L-KCNQ3-eYFP into the VTA of TH-Cre susceptible mice. The viral overexpression of KCNQ3 reversed both the stress induced hyperactivity and the susceptible phenotype. Specifically, expressing the KCNQ3 channel exclusively in the VTA to nucleus accumbens pathway reversed the social avoidance behavior. Together, this work indicated that the M-currents mediated by KCNQ channels as a valid therapeutic target for treating stress-induced depressive behavior. Therefore, we utilized currently available pharmacological K+ channel openers, flupirtine, BMS-204352 and retigabine and tested for antidepressant actions. Following a single infusion to the VTA of susceptible mice, there was a reversal of social avoidance and anhedonia indicating an antidepressant effect. Towards our translational goal, we found that repeated intraperitoneal injection of FDA-approved drug retigabine (ezogabine) also showed a consistent antidepressant effect. These

findings demonstrate that in naturally resilient mice KCNQ channel currents counteract the pathophysiological hyperactivity of VTA DA neurons and pharmacological potentiation of this process may function as a mechanistically unique antidepressant.

Title: Bioenergetics of Desipramine: a functional proteomic study

Authors: *F. FERRARI, A. GORINI, R. F. VILLA;
Dept. of Biol. and Biotech., Univ. of Pavia, Pavia, Italy

Abstract: BACKGROUND - Brain energy metabolism abnormalities in mood disorders were shown in neuroimaging studies on humans, indicating the normalization of tissutal bioenergetics after antidepressants (ADs) treatment [1]. In some experimental studies, ADs are inhibitors of mitochondrial function, while others indicate positive effects on mitochondrial energy metabolism. These conflicting results are due to the fact that the macro-heterogeneity of brain areas and ADs differential effects on pre-synaptic and on post-synaptic terminals have not been considered before. METHODS - The effects of 21-day treatment with the tricyclic antidepressant Desipramine (15 mg/kg, i.p.) were evaluated on energy metabolism of rat frontal cerebral cortex. Two populations of intra-synaptic mitochondria ("light" - LM; "heavy" - HM) were isolated according to Villa et al. [2] and the following enzyme activities have been assayed: citrate synthase (CS), succinate dehydrogenase (SDH), malate dehydrogenase (MDH) for Krebs' cycle; NADH-cytochrome c reductase (CCR), cytochrome oxidase (COX) for Electron Transport Chain; glutamate-oxaloacetate transaminase (GOT), glutamate-pyruvate transaminase (GPT) for glutamate and related amino acids metabolism. RESULTS - In controls, energy-linked enzyme activities are differently expressed in LM and HM, whose metabolic individuality is reflected by enzyme kinetics, as previously shown in physiological aging, experimental physiopathology and pharmacological treatments [3, 4]. In fact, in controls, SDH, COX, GOT and GPT activities were

higher in LM. Desipramine treatment decreased MDH, SDH and GPT activities in LM, while it enhanced CS and COX activities in HM. CONCLUSIONS - Desipramine modified the catalytic properties of energy-linked enzymes differentially respect to the types of intra-synaptic mitochondria, explaining at subcellular level and on functional proteomic basis the previously observed conflicting results about ADs on mitochondria. In this research, Desipramine exerted on the energy metabolism distinctive effects on pre-synaptic terminals and present data allow to integrate from a bioenergetic point of view the pharmacodynamic features of this paradigmatic drug. The study proceeds evaluating the effects of Fluoxetine on functional proteomics. REFERENCES - [1] Moretti et al 2003. Mol Psychiatry, 8:773-85; [2] Villa et al 1989. Title: Potential antidepressant effects of kappa opioid receptor agonists following social defeat stress

Authors: ***A. LAMAN-MAHARG**, M. Z. MCMACKIN, E. O. SANCHEZ, K. L. CAMPI, B. C. TRAINOR;
Univ. of California, Davis, Davis, CA

Abstract: Psychosocial stress leads to activation of kappa opioid receptors (KOR) which in turn facilitate depressive-like behaviors. This has generated a strong interest in the development of KOR antagonists as a potential novel class of antidepressant. However, most studies showing stress-induced activation of KOR focus on more short-term effects of stress and only study males. New evidence suggests that long-term effects of stress (over weeks or months) have important implications for KOR function, and that there may be sex differences. We examined the effects of social defeat stress on KOR action using California mice (Peromyscus californicus), a monogamous species in which social defeat can be studied in both males and

females. Behavioral observations were conducted two weeks after three episodes of social defeat or control conditions. A 10 mg/kg i.p. injection of KOR agonist U50,488 reduced social interaction behavior in females naïve to defeat. However, in stressed females U50,488 exerted an antidepressant effect, increasing social interaction to the level of controls treated with vehicle. In males there was a trend for U50,488 to reduce social interaction behavior in stressed males, suggesting a sex specific impact of social defeat. In addition, control females formed a conditioned place aversion to 2.5 mg/kg U50,448 and this aversion was blocked by stress. These results indicate that defeat stress may induce long-term changes in KOR activation in females. Ongoing studies are investigating additional measures of depressive-like behaviors and potential mechanisms underlying this effect. These data suggest that KOR agonists could potentially have novel antidepressant effects in the context of stress-induced psychiatric disorders.

Title: Further characterization of the discriminative stimulus properties of the noncompetitive N-Methyl-D-aspartate (NMDA) receptor antagonist ketamine in rats

Authors: C. M. MERRITT[1], A. M. JONES[1], J. C. CORNELISSEN[1], B. L. JOSEPH[1], K. A. WEBSTER[1], T. M. HILLHOUSE[2], *J. H. PORTER[1];
[1]Psychology, Virginia Commonwealth Univ., Richmond, VA; [2]Pharmacol., Univ. of Michigan, Ann Arbor, MI

Abstract: Findings that the noncompetitive N-Methyl-D-aspartate (NMDA) receptor antagonist ketamine produces rapid and sustained antidepressant effects in patients with major depressive disorder has engendered a great deal of interest in glutamatergic targets for the treatment of depression. However, the abuse liability of ketamine remains a concern. The subjective effects of drugs, which may be associated with both abuse-related and therapeutic effects, can be assessed with the drug discrimination paradigm. Drug discrimination procedures also provide information about the underlying receptor mechanisms that mediate a drug's subjective effects (i.e. its discriminative stimulus properties). We previously reported that ketamine's discriminative stimulus properties appear to be mediated only by antagonism of NMDA receptors as only the

noncompetitive NMDA antagonists MK-801 and memantine fully substituted for ketamine. The present study was designed to further characterize ketamine's discriminative stimulus properties with selective ligands tested alone and in combination with ketamine in Sprague-Dawley rats trained to discriminate 10.0 mg/kg ketamine from saline is a two-lever drug discrimination procedure for food reinforcement. As expected, the noncompetitive NMDA antagonist phencyclidine (1.78 mg/kg) fully substituted for ketamine. In contrast, substitution testing with the selective ligands raclopride (dopamine D2/D3 antagonist), quinpirole (D2/D3 agonist), U69593 (opioid kappa agonist), scopolamine (cholinergic muscarinic antagonist), oxotremorine (muscarinic agonist), yohimbine (alpha 2 adrenoceptor antagonist), pyrilamine (histamine H1 antagonist), ritanserin (serotonin 5-HT2 antagonist), and naloxone (opioid mu antagonist) failed to reveal any ketamine-appropriate responding. Interestingly, when tested in combination with a low, non-discriminated dose (2.5 mg/kg) of ketamine, both raclopride (D2 antagonist, 0.18 mg/kg dose) and quinpirole (D2/D3 agonist, 0.056 mg/kg dose) produced a significant increase in ketamine-appropriate responding (57% drug lever responding and 61% drug lever responding, respectively). While ketamine's discriminative stimulus properties are primarily mediated by antagonism of NMDA receptors, these results reveal that the dopamine system may interact with ketamine's discriminative stimulus properties.

Title: A novel class of fast-acting antidepressants: converging evidence using genetic knockdown and two mechanistically distinct GLO1 inhibitors

Authors: *K. M. MCMURRAY[1], P. S. SIDHU[3], P. ELKIN[2], V. RAWAL[2], L. A. ARNOLD[3], A. A. PALMER[1];
[1]Human Genet., [2]Univ. of Chicago, Chicago, IL; [3]Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Major depressive disorder (MDD) is a highly prevalent and debilitating psychiatric disorder. Despite a variety of available treatments for MDD, positive patient outcomes are limited due to a slow onset of therapeutic effects (2-4 weeks), adverse side effects (weight gain, insomnia) or a lack of response to treatment in a large portion of patients (~50%). Thus, identifying novel systems and molecular targets for treatment is of paramount importance. We recently identified Glyoxalase I (GLO1) as a novel target for the treatment of depression. GLO1 is a ubiquitous cellular enzyme responsible for the detoxification of methylglyoxal (MG), which is a byproduct of glycolysis. We previously showed that MG is a competitive partial agonist at GABA-A receptors and that inhibition of GLO1 increases MG concentrations within the brain and reduces anxiety-like behaviors in mice. While GABA-A receptor agonists are not typically used to treat depression, associations between Glo1/MG and depression-like behavior were previously seen in mice. Thus, we investigated the effects of GLO1 inhibition on depression-like behavior in mice using both genetic knockdown and two mechanistically distinct small molecule GLO1 inhibitors. The tail suspension test (TST) and forced swim test (FST) are assays of antidepressant efficacy. Mice treated acutely with antidepressants spend more time performing escape-oriented behaviors than immobile postures relative to no treatment. We found that both genetic and pharmacological inhibition of GLO1 by two mechanistically distinct inhibitors reduced immobility in the TST and FST without affecting locomotor behavior in the open field test. The chronic FST and olfactory bulbectomy (OBX) models selectively respond to chronic treatments (14 day) with classical antidepressants (Fluoxetine; SSRI) mimicking the clinical time-course of antidepressant action in humans. Mice were tested in both chronic FST and OBX to establish a time-course of therapeutic onset. We found that pharmacological inhibition of GLO1 reduced depression-like behavior in models sensitive to chronic treatment with classical antidepressants to a similar extent as fluoxetine by 14 days of treatment. Further, pBBG reduced depression-like behavior in these models and upregulated proteins associated with antidepressant onset (BDNF, pCREB/CREB) by 5 days of treatment suggesting that GLO1 inhibitors may be novel fast-acting antidepressants.

Title: Estrogen receptor β regulation of bdnf-5-ht dual signaling: mechanistic and therapeutic implications for menopausal depression

Authors: *A. CHHIBBER, S. K. WOODY, L. ZHAO;
Univ. of Kansas, Lawrence, KS

Abstract: Depression is likely not a single disorder but a heterogeneous syndrome comprised of multiple pathological phenotypes of distinct causes. Depression currently affects 350 million people worldwide and 19 million Americans each year. Women are 70% more likely to develop depression than men, and susceptibility to depression is highest during the endocrine transition from premenopause to postmenopause. Estrogen receptor β (ERβ) has been indicated to be involved in the pathophysiology of mood disorders; however, the underlying mechanisms are poorly understood. In this study, we sought to investigate the role of ERβ in the regulation of brain-derived neurotrophic factor (BDNF) and serotonin (5-HT) signaling that have been hypothesized as two major and interrelated pathways associated with depression. Our analyses in ERα and ERβ knockout mouse (ERα-/- and ERβ-/-) models demonstrated that BDNF was significantly down regulated in ERβ-/- but not ERα-/- mice, and ERβ-/--mediated response was brain region-specific. A nearly 50% reduction in BDNF level was found in the hippocampus of ERβ-/- mice; in contrast, the changes in BDNF were at a much smaller magnitude and insignificant in the cortex and hypothalamus of these mice. These data were further validated in two ERβ-/- rat models, one with targeted deletion of exon 3 and the other with deletion of exon 4 in the ERβ gene. We found that ERβ deficiency in both models resulted in a significantly reduced level of both BDNF and its receptor, tyrosine kinase B (TrkB), in the hippocampus of ERβ-/- rats. Our further analyses in primary hippocampal neurons indicated that activation of ERβ significantly enhanced BDNF-TrkB signaling and the downstream cascades involved in neurogenesis and synaptic plasticity. Clinical studies have shown that depression decrease BDNF levels in the hippocampus which can be reversed back to the normal levels after the antidepressant treatment. Thus, our findings suggest that ERβ signaling perturbation and the resultant decreased BDNF-TrkB signaling could play a role in the increased susceptibility for depression associated with menopause. In addition to BDNF signaling, our study also addresses the deficits in postsynaptic 5-HT signaling associated with ERβ signaling deficiency in the hippocampus, which adds additional insights into our understanding of the mechanisms by which ERβ could play an essential role in both the development and intervention of depressive disorders in perimenopausal and menopausal women.

Title: Behavioral effects of single dose ketamine injection on adult rats exposed to chronic unpredictable mild stress

Authors: *E. ULUPINAR[1], E. POLAT[2], O. O. AYDIN[2], E. G. AYDIN[3];
[2]Neurosci., [3]Pharmacol., [1]Eskisehir Osmangazi Univ., Eskisehir, Turkey

Abstract: NMDA receptor antagonist ketamine has been associated with rapid and effective anti-depressant effects in patients with treatment-resistant major depression. Effects of a single dose of ketamine may start within hours and sustain for up to 2 weeks. Chronic unpredictable stress is an animal model mimicking the stressful events that may precipitate clinical depression in humans. In this study, we investigated the behavioral effects of single ketamine injection in chronically stressed animals. Adult male Sprague-Dawley rats (n=12) were subjected daily to a random pattern of unpredictable mild stressors for 28 days. Control rats were handled daily during the same period. After the final stressor, half of the rats from each treatment and control group received an intraperitoneal injection of ketamine (10 mg/kg), while others receiving equal volume of saline injections. Next day, rats were tested for behavioral effects in the forced swim, sucrose preference, open field and suspension tests. Following intracardiac perfusion, body, brain and adrenal weights were measured. Animals subjected to stress had significantly higher adrenal to body weight ratios, and displayed decreased immobility in the forced swim test suggesting that the stress paradigm induced higher levels of blood corticosterone and a depression-like phenotype. However, ketamine injection did not alter the immobility time of stressed animals in the forced swim test. No difference was observed in the open field test and sucrose consumption of animals was also similar following ketamine injections. Suspension test scores of stressed animals were worse than controls, but ketamine improved the test performances of animals. Our results suggest that the depressive-like behavior induced by chronic unpredictable mild stress was not completely reverted by single dose ketamine injection. These observations are not consistent with previous reports that sub-anesthetic doses of ketamine have acute and potent antidepressant effects in humans and animal models. Therefore, further studies needs to be done to reveal antidepressant efficacy of ketamine not only at behavioral level, but also at morphological and molecular level.

Title: Characterization of the discriminative stimulus properties noncompetitive N-Methyl-D-aspartate (NMDA) receptor antagonist ketamine in C57BL/6 mice

Authors: *R. PANDEY, C. W. KALINOWSKI, K. W. LOVELESS, K. A. WEBSTER, J. H. PORTER;
Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Ketamine is a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist with dissociative anesthetic properties, and it has long been considered a club drug as certain countries continue to have problems with a high level of ketamine abuse. Despite its abuse profile ketamine has been shown to produce both rapid and long-lasting antidepressant effects in patients with major depressive disorder, especially treatment-resistant patients; however, its abuse liability limits its outpatient use. Identifying the receptor mechanisms associated with ketamine could help lead to drug development of a novel treatment for depression. The present study investigated the interoceptive effects of ketamine as a discriminative cue in a standard two lever drug discrimination study for food reinforcement. Male C57BL/6 mice were trained to discriminate 10 mg/kg of ketamine from vehicle in a two-lever drug discrimination task (10 min injection time, sc). Mice quickly acquired ketamine's discriminative cue (mean = 19.6 days, SEM = 1.21, range 8-29). Then, a ketamine generalization curve (2.5 mg/kg - 20.0 mg/kg) was conducted and yielded an ED50 = 4.38 mg/kg (95% = CI 4.03 mg/kg-4.76 mg/kg). A time course was conducted (0-100 minutes) to examine the behavioral pharmacokinetic effects of ketamine and revealed that ketamine was rapidly absorbed producing full generalization at the 0 and 10 minute injection times, but was eliminated quickly as only vehicle-appropriate responding was evident by 30 minutes. Substitution testing with the NMDA receptor antagonists, phencyclidine (PCP), memantine, and MK-801 produced full substitution for ketamine's discriminative stimulus. PCP fully substituted at 3.2 mg/kg, yielding an ED50 = 1.23 mg/kg (95% CI = 1.00 mg/kg - 1.53 mg/kg), producing significant rate suppression. MK-801substituted at 0.1 and 0.18 mg/kg, yielding an ED50 = 0.08 mg/kg (95% CI 0.07mg/kg - 0.09mg/kg) with no reduction in response rates. Memantine substituted at 20.0 mg/kg, yielding an ED50 = 9.17 mg/kg (95% CI = 7.23 mg/kg - 11.64 mg/kg), producing significant rate suppression. We also tested the selective serotonin reuptake inhibitor antidepressant fluoxetine (2.5 - 20 mg/kg) and

the tricyclic antidepressant imipramine (1.0 - 17.8 mg/kg). Both drugs failed to substitute for ketamine at any of the doses tested. This study replicates previous findings in ketamine discrimination with rats, demonstrating that ketamine's discriminative stimulus properties are primarily mediated by antagonism at glutamatergic NMDA receptors. Finally, ketamine's interoceptive effects appear to be independent of its antidepressant-like properties.

Title: Impact of alternative RNA splicing of ERβ on ovarian hormone deficiency-induced depression and estrogen therapy effectiveness in female rats

Authors: *X. HOU[1], S. O. ADEOSUN[2], R. HILL[2], B. ZHENG[2], J. WANG[2,3,4,1];
[1]Program in Neurosci., [2]Dept. of Pathology, [3]Dept. of Psychiatry and Human Behavior, [4]Dept. of Pharmacol. and Toxicology, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Depression is a serious psychiatric condition that interferes with patients' daily life. Women are more susceptible to depressive disorders than men, with a particularly high risk during hormone fluctuations especially at menopause. Estrogen therapy (ET), an effective treatment for perimenopausal depression, often fails to ameliorate symptoms when initiated late after the onset of menopause. Our previous work suggested that the differential effects of ET might be mediated via the alternative RNA splicing of estrogen receptor (ER) β. To further understand the mechanism, we used a customized RT2 Profiler PCR Array to examine expressions of 84 RNA splicing factors in the frontal cortex from female rats receiving E2 or

vehicle 6- (early) or 180- (late) day after ovariectomy (OVX). To study the ER isoform specific effects in the late treatment, two additional 180-day OVX rat cohorts received ERβ or ERα selective agonists. Results showed that OVX increased (SFRS7 and SFRS16) or decreased (ZRSR2 and CTNNB1) mRNA levels of splicing factors in the frontal cortex, while early E2 treatment largely reversed these. Early E2 also decreased ERβ2 expression in leukocytes, increased rat swimming time in the forced swim test and increased TPH2 RNA and protein expression in the dorsal raphe. DPN, an ERβ selective agonist, but not E2 or PPT, and ERα selective agonist, achieved similar results in the late treatment. These data support that the effectiveness of ET is mediated by alternative splicing of ERβ, and ERβ specific ligands may serve as an effective treatment late after the onset of menopause.

Title: The effect of allopregnanolone infusion on GABAa receptor subunits mRNA expression in the prefrontal cortex of rats

Authors: *M. S. NIN[1], F. B. ALMEIDA[2], G. AGNES[3], H. M. T. BARROS[2];
[2]Pharmacolgy, [3]Mol. Biol., [1]UFCSPA, Porto Alegre, Brazil

Abstract: Allopregnanolone is a neurosteroid capable of producing an antideprssant-like effect in rats. It is believed that this effect is due to its interaction with the GABAA receptors (GABAA-R), in which allopregnanolone plays a role as a positive modulator. However, allopregnanolone influence on GABAA-R subunits mRNA expression in specific brain regions is still not completely elucidated, as well as its asymmetrical role. In this work, we evaluated the effect of bilateral infusion of three doses of allopregnanolone (low: 1.25 μg/rat; intermediate: 2.5 μg/rat; and high: 5 μg/rat) in the prefrontal cortex of Wistar male rats on the mRNA expression of GABAA-R subunits γ2 and δ in both hemispheres of the same region infused using the realtime quantitative PCR technique (endogenous control genes: β-actin and GAPDH). As results, there was no difference between hemispheres on the δ subunit mRNA expression ($P = 0.971$), but the high dose of allopregnananolone was able to increase its mRNA expression when compared to controls ($P = 0.001$) and the low dose ($P = 0.004$). In the γ2 subunit, the right

hemisphere had a higher mRNA expression than the left hemisphere in the controls (P = 0.007) and in the low dose (P = 0.011). The γ2 mRNA expression was increased only in the left hemisphere by the high dose when compared to controls (P = 0.013) and the low dose (P = 0.007), while in the right hemisphere there was no significant change. These results indicate that allopregnanolone is capable of increasing the mRNA expression of δ and γ2, the latter being specifically on the left hemisphere, normalizing an asymmetry found in animals with no treatment.

Title: Treatment with high-voltage electric potential (HELP) induces tolerance to psychosomatic stress and increases cortical BDNF levels

Authors: *K. YAMATO[1], T. HORI[1,3], Y. NAKAJO[1,4], H. KATAOKA[2], J. C. TAKAHASHI[2], H. YANAMOTO[1,5];
[1]Lab. of Neurol. and Neurosurg., [2]Dept. of Neurosurg., Natl. Cerebral and Cardiovasc. Ctr., Suita, Japan; [3]Hakuju Inst. for Hlth. Sci. Co. Ltd., Tokyo, Japan; [4]Res. Laboratory, Rakuwa-kai Otowa Hosp., Kyoto, Japan; [5]Dept. of Cardiovasc. Science, Div. of Surgical Med., Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Development of depressive disorders is common throughout life. Decreased intracerebral brain-derived neurotrophic factor (BDNF) level has been identified as an etiologic factor in the pathogenesis of depression. Recently, we found that repetitive treatment with high-voltage electric potential (HELP) increases brain BDNF levels, enhances learning and memory, and affords tolerance to infarct lesion development in mice. However, direct evidence showing that HELP-induced increase in BDNF levels results in improved tolerance to development of depressive symptoms is lacking. In the present study, we investigated the effect of HELP on the development of a depressive symptom by subjecting mice to an unpleasant psychosomatic stress (swimming). C57BL/6J mice were exposed to 6.0 (17.3 kV/m), 7.8 (22.5 kV/m), or 9.0 kV (26.0 kV/m) HELP at 60 Hz for 5 hours per day for 21 consecutive days. After this treatment, the total climbing time (time spent in trying to escape from the water) after training on a forced swim stress was measured. In addition, regional BDNF levels in the brain were measured before and

after stress exposure. The climbing time was significantly increased in the treatment group compared with the control group (P<0.05, Bonferroni correction). HELP treatment increased BDNF levels in the cortex. BDNF levels in the cortex, but not in the caudate putamen and hippocampus, correlated with induction of tolerance. Repetitive exposure to HELP induces tolerance against development of depressive symptoms, accompanied by increases in cortical BDNF levels. Thus, repeated HELP treatment has an antidepressant effect.

Title: The antidepressant-like effects of BU10119, a novel kappa opioid receptor antagonist, in the novelty-induced hypophagia task in mice

Authors: *S. J. BAILEY[1], A. ALMATROUDI[1], C. P. BAILEY[2], S. M. HUSBANDS[2]; [2]Pharm. & Pharmacol., [1]Univ. of Bath, Bath, United Kingdom

Abstract: Antagonists at kappa-opioid receptors have been proposed as novel antidepressants. The standard high-affinity, selective kappa-antagonists have a long lasting duration of action which potentially limits their use (Carroll and Carlezon 2013. J Med Chem 56: 2178-2195). We have previously shown that the combination of buprenorphine (1mg/kg) with naltrexone (1mg/kg) produced a functional short-acting kappa-antagonist, that was non-sedating and non-rewarding, with antidepressant like effects in the forced swim test and novelty-induced hypophagia task (Almatroudi et al. 2015. J. Psychopharmacol. In Press). We have developed a novel compound that combines the properties of buprenorphine/naltrexone combination into a single compound (Cueva et al. 2015. J Med Chem, In Press), thereby simplifying dosing and treatment regimens and avoiding abuse potential. Here, we present preliminary data that BU10119 is a functional kappa antagonist with antidepressant-like effects in mice. Adult male CD-1 mice (8-9 weeks) were used. For novelty-induced hypophagia, mice were individually housed and trained for 3 days to consume condensed milk. On test days, mice were injected intraperitoneally (10 ml/kg) with saline, buprenorphine/naltrexone combination (1 mg/kg),

fluoxetine (20 mg/kg) or BU10119 (1mg/kg) one hour prior to testing behaviour. The latency to drink and consumption were recorded in the home cage (day 4) and in the novel cage (day5). One-way ANOVA, revealed that there was a significant effect of drug treatment on the latency to drink in the novel cage ($F(4, 45) = 9.15$, $P<0.001$) but not consumption ($F(4, 45) = 1.25$, $P=0.3$). BU10119 is a relatively short acting kappa-antagonist with little efficacy at the mu-opioid receptor. BU10119 has demonstrated activity in the novelty-induced hypophagia test that is consistent with the behavioural effects of fluoxetine and therefore has an antidepressant-like profile.

Title: Striatopallidal Gpr88 regulates anxiety-like behaviour and dopaminergic driven locomotion

Authors: *A. MEIRSMAN[1], J. BECKER[2], B. KIEFFER[3];
[1]I.G.B.M.C., Illkirch, France; [2]INRA UMR-0085, CNRS UMR-7247, ,, Physiologie de la Reproduction et des Comportements,, NOUZILLY, France; [3]McGILL Univ., DOUGLAS INSTITUTE, MONTREAL, QC, Canada

Abstract: GPR88 is a brain orphan G protein coupled receptors, highly and mainly expressed in the striatum, specifically in medium spiny neurons (MSNs) of both the striatonigral (co-expressing dopamine D1 receptors_D1R and Substance P) and striatopallidal (co-expressing dopamine D2 receptors_D2R and adenosine A2A receptor_A2AR) pathway (Massart, Eur J Neurosci 2009). Previous reports (Logue, Mol Cell Neurosci; Quintana, Nature Neurosci 2012) show that Gpr88 Knockout (KO) mice display behavioral deficits evocative of striatal dysfunction, and our recent work also demonstrates emotional deficits (Meirsman in revision). However, no study to date has addressed the specific function of Gpr88 in each of the two main MSNs subpopulations. To elucidate GPR88 function in striatopallidal MSNs we induced the Gpr88 gene knockout exclusively in these neurons and assessed behavioral performance of

conditional KO mice (cKO). The cKO of Gpr88 in striatopallidal MSNs was obtained by crossing Gpr88-floxed mice with A2A-Cre mice (Durieux, Nature Neurosci 2009). Cell-specific deletion was verified using fluorescent *in situ* hybridization with D1R, D2R and Gpr88 probes. We then evaluated motor functions (e.g., locomotor activity in the open Field, rotarod), locomotor responses to dopaminergic agonists (SKF and Quinpirole) and anxiety-like behaviors (e.g., elevated-Plus Maze, Light-Dark) in conditional A2A-Gpr88 mice. Results indicate that, as for total Gpr88 knockout mice, A2A-Gpr88 mice show hyperactive behaviour in a novel environment and decreased anxiety-like behavior. In contrast to the total null mutant, however, A2A-Gpr88 mice show no motor coordination deficit, and also show increased and decreased D1R (SKF) and D2R (Quinpirole) agonist-induced locomotor response, respectively. We conclude that Gpr88 in the striatopallidal pathway regulates locomotion and exploratory behaviour, possibly by regulating D1R and D2R dopaminergic transmission, and also modulate anxiety-like behavior by mechanisms that remain to be determined.

Ctr., Lausanne, Switzerland; [3]Brain Mind Inst., EPFL, Lausanne, Switzerland; [4]King Abdullah Univ. of Sci. and Technol., Thuwal, Saudi Arabia; [5]Univ. of Leicester, Leicester, United Kingdom

Abstract: Recent studies have highlighted the involvement of the arginine-decarboxylation product agmatine in depression. Most notably, it has been shown that this compound has

antidepressant properties in rodents and that agmatinase (Agmat), the agmatine-degrading enzyme, is upregulated in the brains of mood disorders patients. We have previously shown that mice lacking CREB-regulated transcription coactivator 1 (CRTC1) associate behavioral and molecular depressive-like endophenotypes, as well as blunted responses to classical antidepressants. Here, the molecular basis of the behavioral phenotype of Crtc1 knockout (KO) mice was further examined using microarray gene expression profiling. This analysis revealed an upregulation of Agmat in the cortex of Crtc1 KO mice. Quantitative polymerase chain reaction and Western blot analyses confirmed Agmat upregulation in Crtc1 KO mice prefrontal cortex and hippocampus. Immunohistochemical data showed that Crtc1 KO mice display more agmatinase-expressing cells than wild-type mice in several brain regions, including the prefrontal cortex and the CA1, CA3 and dentate gyrus regions of the hippocampus. We also observed that agmatinase was most notably expressed in parvalbumin and somatostatin interneurons. At the behavioural level, acute agmatine treatment rapidly (30 min) improved the depressive-like behavior of Crtc1 KO mice in the forced swim test, suggesting that exogenous agmatine has a rapid antidepressant effect through the compensation of agmatine deficit due to upregulated Agmat. In wild type mice PFC, agmatine rapidly increased Brain-derived neurotrophic factor (BDNF) protein levels and decreased eukaryotic elongation factor 2 (eEF2) phosphorylation, indicating that agmatine might be a fast-acting antidepressant with NMDA receptor antagonist properties. Collectively, these findings implicate Agmat in the depressive-like phenotype of Crtc1 KO mice, refine current understanding of the agmatinergic system in the brain and highlight its putative role in major depression.

Title: Depression-like behavior and response to chronic stress in mice lacking brain serotonin

Authors: *G. MADDALONI[1], S. MIGLIARINI[1], F. NAPOLITANO[2], A. USIELLO[2], M. PASQUALETTI[1,3];
[1]Univ. of Pisa, Pisa, Italy; [2]Ceinge Biotecnologie Avanzate, Naples, Italy; [3]Cnt. for Neurosci. and Cognitive Systems, Inst. Italiano di Tecnologia, Rovereto, Italy

Abstract: During their lives, virtually all living organisms have to face disturbing forces that upset their homeostasis. These forces, called stressors, trigger a stress response, an innate adaptive response whose task is restoring normal balance of the organism, essential for survival. In vertebrates the brain is central in the adaptation to stress, both in the perception of the stressors and in the organization of the stress response. However, due to a combination of genetic factors and environmental agents, not always a stress response is able to face the stressors, and a maladaptive stress response further destabilizes animal homeostasis, generating stress-related neuropsychiatric disorders such as depression and anxiety. Serotonin (5-hydroxytryptamine, 5-HT) is a neurotransmitter that has a central role in normal brain function modulating several physiological processes including mood regulation and emotional behavior, and it has been implicated both in an adaptive and maladaptive stress response. Indeed, several polymorphisms identified in genes involved in serotonin signaling are associated with neuropsychiatric diseases such as depression and anxiety. Moreover, according to the monoamine hypothesis of depression, a reduction of serotonin signaling could be one of the major causes. Current antidepressants act on serotonergic signaling, elevating 5-HT concentration in the synaptic cleft, and showing therapeutic effects 2 to 4 weeks after administration, with a considerable number of patients resistant to the treatment. Therefore, the precise role of serotonin in the modulation of emotional behavior in health and disease needs to be further elucidated. We used a Tph2 knock-out mouse model to evaluate the consequences of brain serotonin depletion on the emotional behavior testing adult animals for behavioral despair. Tph2 mutant mice displayed reduced depression-like behaviors in the forced swim test, in the tail suspension test, as well as in the novelty food suppressed test. We then asked how exposure to Unpredictable Chronic Mild Stress (UCMS), an effective paradigm for inducing depression-like symptoms in rodents, could influence the behavior of animals lacking brain serotonin. Results showed that UCMS induces depressive-like behavior in the forced swim test in both Tph2 -/- and control littermates with a greater increase in immobility between non-stressed and stressed mutant mice than between non-stressed and stressed wt animals. Finally, we are currently treating stressed Tph2 -/- mice with ketamine, a NMDA-R antagonist with rapid and effective antidepressant action, in order to asses if 5-HT is required for its therapeutic effect.

Title: MRI and MRS characterization of Crtc1 knockout mice limbic structures: investigating neurobiology of mood disorders

Authors: *A. CHERIX[1,2], R. GRUETTER[3,4], H. LEI[6,5], J.-R. CARDINAUX[2,7];
[1]Ecole Polytechnique Fédérale De Lausanne, Lausanne, Switzerland; [2]Ctr. Hospitalier Universitaire Vaudois, Ctr. for Psychiatric Neurosci., Lausanne, Switzerland; [3]Ecole Polytechnique Fédérale De Lausanne, Lab. for Functional and Metabolic Imaging, Lausanne, Switzerland; [4]Univ. of Lausanne, Dept. of Radiology, Lausanne, Switzerland; [5]Univ. of Geneva, Dept. of Radiology, Geneva, Switzerland; [6]Ecole Polytechnique Fédérale de Lausanne, Ctr. for Biomed. Imaging, Lausanne, Switzerland; [7]Univ. of Lausanne, Service of Child and Adolescent Psychiatry, Lausanne, Switzerland

Abstract: *In vivo* magnetic resonance (MR) imaging (MRI) and spectroscopy (MRS) are two non-invasive techniques of choice for investigating and monitoring brain metabolic and structural changes in mood disorders, which are poorly understood. Discrepancies between human studies reflect however the lack of comprehension of their pathophysiology and reinforce the need for an endophenotypic characterization, which can be provided by animal models. We have investigated the metabolic and volumetric status of a previously reported mouse model of mood disorders lacking an important brain plasticity gene, Crtc1 (CREB-regulated transcriptional coactivator 1). Crtc1 knockout (KO) animals are considered as relevant for studying mood disorders, because they show neurobehavioral depressive-like endophenotypes, as well as late-onset obesity, together with monoaminergic system dysfunctions (Breuillaud, et al. Biol Psychiatry. 2012, 72(7):528-36 ; Breuillaud, et al. Nature Medicine. 2009, 15(9) :989 - 990). Metabolic and volumetric profile alterations were determined with T2-weighted MRI together with 1H-MRS of prefrontal cortex (PFC), dorsal/ventral hippocampus and amygdala. Crtc1 KO mice showed reduced glutamate (-12%, p=0.0056) and GABA (-26%, p=0.03) in PFC, whereas a marked reduction of the energy metabolite phosphocreatine (-20%, p=0.03) was visible in the dorsal hippocampus. KO mice also showed a strong ventricle shrinkage correlating (p=0.01) with swelling of surrounding gray matter. Such alterations are consistent with human MR findings in mood disorders (Sanacora, et al. Neuropharmacology. 2012, 62(1):63-77; Stork and Renshaw. Mol Psychiatry. 2005, 10(10):900-19), which suggested that the GABA/glutamatergic system or the energy metabolism are impaired in specific regions of the brain. This mouse model should thus allow a better understanding of the molecular mechanisms underlying the changes of MRI/MRS markers observed in human mood disorders.

Abstract: The circadian molecular clock regulates monoaminergic systems that control reward behaviors and are relevant to addiction. We investigated how disruptions in the homologous circadian transcription factors, CLOCK and NPAS2, lead to differential physiological alterations in mesolimbic circuitry and sensitivity to drugs of abuse. Using *Clock* mutant mice (*Clock*19), a model of bipolar mania, we measured excitatory synaptic strength of medium spiny neurons

(MSNs) in the nucleus accumbens (NAc), an area that receives a dense dopaminergic (DA) projection from the ventral tegmental area (VTA) and is critical for motivated behavior. *Clock* mutant mice display an increased preference for cocaine and abnormal VTA DA signaling which may affect plasticity in target regions. In addition to reduced levels of GluA1 protein and alterations in intrinsic membrane properties, they also have reduced AMPA-mediated synaptic strength of MSNs with no change in presynaptic release of glutamate indicating a postsynaptic adaptation. These changes represent potential compensatory mechanisms as a result of increased DA transmission. We also examined the effect of viral-mediated knock down (KD) of NPAS2 in C57BL/6J mice on the conditioned response to cocaine and synaptic strength of MSNs. Both a global *Npas2* mutation along with NAc-specific NPAS2 KD caused a decrease in cocaine preference and KD produced an increase in mEPSC amplitude in MSNs compared with scramble virus. The results of our study suggest an important role for circadian transcriptional mechanisms in the regulation of synaptic activity and reward-related behavior. They also highlight differential roles of two homologous circadian proteins in these important functions.

Title: The histone deacetylase inhibitor SAHA improves the depressive-like behavior of CREB-regulated transcription coactivator 1-deficient mice: possible relevance for treatment-resistant depression

Authors: *J.-R. CARDINAUX[1,2], E. M. MEYLAN[1,2], O. HALFON[2], P. J. MAGISTRETTI[3,4,1]; [1]Ctr. Dynamics, Brain Mind Institute, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: Major depression is a highly complex disabling psychiatric disorder affecting millions of people worldwide. Despite the availability of several classes of antidepressants, a substantial percentage of patients are unresponsive to these medications. A better understanding of the neurobiology of depression and the mechanisms underlying antidepressant response is thus critically needed. We previously reported that mice lacking CREB-regulated transcription coactivator 1 (CRTC1) exhibit a depressive-like phenotype and a blunted antidepressant response to the selective serotonin reuptake inhibitor fluoxetine. In this study, we similarly show that Crtc1 knockout (ko) mice are resistant to the antidepressant effect of chronic desipramine in a behavioral despair paradigm. Supporting the blunted response to this tricyclic antidepressant, we found that desipramine does not significantly increase the expression of brain-derived neurotrophic factor (Bdnf) and orphan nuclear receptors (Nr4as) in the hippocampus and prefrontal cortex of Crtc1 ko mice as it does in wild-type animals. Epigenetic regulation of neuroplasticity gene expression has been associated with depression and antidepressant response, and histone deacetylase (HDAC) inhibitors have been shown to have antidepressant-like properties. Here, we show that unlike conventional antidepressants, chronic systemic administration of the HDAC inhibitor SAHA partially rescues the depressive-like behavior of Crtc1 ko mice. This behavioral effect is accompanied by an increased expression of Bdnf, but not Nr4as, in the prefrontal cortex of these mice, suggesting that this epigenetic intervention restores the expression of a subset of genes by acting downstream of CRTC1. These findings suggest that CRTC1 alterations may be associated with treatment-resistant depression, and support the interesting possibility that targeting HDACs may be a useful therapeutic strategy in antidepressant development.

Title: Increased depression-like behavior in response to stress in a mouse model with mitochondrial complex I dysfunction

Authors: *T. L. EMMERZAAL[1], M. ROELOFS[1], B. GEENEN[1], K. SCOTT[2], B. GRAHAM[3], W. CRAIGEN[3], G. MING[3], E. MORAVA[2], R. RODENBURG[4], T. KOZICZ[1,2];

Abstract: Depression has long been thought to be caused by a decrease in monoamines, from which the serotonin hypothesis is the most prominent one. Recently the hypothesis that suboptimal mitochondrial function contributes to the pathobiology of depression has been put forward. To test this hypothesis, a new genetically engineered mouse model was generated with decreased mitochondrial function. These animals have a mutant Ndufs4 allele that consists of a gene trap insertion in an early intron of the locus. This results in a premature termination of the coding sequence and deficiency of the NDUFS4 protein. As a small amount of wild type protein is still produced, these animals are viable beyond 18 months of age, unlike constitutive Ndufs4 knockouts that die by 8 weeks of age. Ndufs4 encodes a structural subunit of complex I, an essential component of the electron transport chain and oxidative phosphorylation. This specific mutation leads to a 70% reduction of complex I activity. To test the hypothesis that suboptimal mitochondrial function is involved in the etiology of depression, Ndufs4 deficient and wild-type animals were either subjected to acute stress or chronic variable stress. We found that these transgenic animals show increased depression-like behavior as reflected by increased immobility in the Porsolt swim test. No differences were found in anxiety using the marble burying and novelty suppressed feeding tests. Also no differences were found in plasma corticosterone measurements between wild-type and deficient animals. On the other hand, preliminary data show a decreased neuronal activation in the central amygdala, investigated by cFos expression, an immediate early gene involved in neuronal activation. This decreased neuronal activation was however not found in the paraventricular nucleus of the hypothalamus. Overall, these results support the hypothesis that impaired mitochondrial function increases the risk to develop depression.

Title: Role of the microglial T cell death associated gene-8 (TDAG8) receptor in depression-like behavior

Authors: *L. L. VOLLMER, R. AHLBRAND, S. N. SCHMELTZER, R. SAH;
Psychiatry and Behavioral Neurosci., Univ. Of Cincinnati, Cincinnati, OH

Abstract: Recent evidence suggests that immune dysfunction may play a role in the pathophysiology of depression. Pro-inflammatory cytokines, including TNF alpha (TNF-α), interleukin 6 (IL-6) and, interleukin IL-1β, are increased in plasma and cerebral spinal fluid (csf) of depressive subjects. These cytokines are mediators of sickness behavior, and have been found to influence the progression and severity of depression. Immune-modulatory targets are therefore important for understanding the pathophysiology of depression. The T cell death associated gene-8 (TDAG8) receptor is a proton-sensing G-protein-coupled receptor (GPCR) expressed on immune cells in both the CNS and periphery. Our previous work has shown modulation of inflammatory cytokine IL-1β by the TDAG8 receptor in the central nervous system (CNS). Given the link between depression and inflammation, the present study was undertaken to investigate the role of TDAG8 in depression relevant behaviors. TDAG8-deficient (TDAG8-/-) mice were screened in the forced swim test (FST) and sucrose preference paradigm. A significant reduction of immobility in the FST was observed in TDAG8-/- mice compared to wild type (TDAG8+/+) mice. These differences were not due to genotype induced alterations in motor activity as TDAG8+/+ and TDAG8-/- mice displayed similar activity in the home cage or novel context. TDAG8-/- mice showed significantly higher consumption of sucrose compared to TDAG8+/+ mice, although sucrose preference was not significantly different between genotypes. Ongoing studies are investigating the role of TDAG8 in behavioral outcomes following chronic mild stress, a rodent model of depression, complimented with neurochemical endpoints such as cfos and microglial activation. Although further validation is warranted, our preliminary results suggest an association of the TDAG8 receptor with depression-like behavior and its potential as an immune-modulatory target in depression. Title: Impaired executive function and a depressive-like phenotype in gabra5-/- mice

Authors: ***S. W. KEMP**[1], N. K. CHAN[2], M. MILENKOVIC[2], A. J. RAMSEY[2], E. SIBILLE[2], B. ORSER[2];
[1]Dept. of Physiol., [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Background: Accumulating evidence suggests that reduced function of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) contributes to the pathogenesis of mood disorders. Patients with major depression have reduced GABA levels in the brain, and the expression levels of extrasynaptic GABAA receptors are reduced in suicide victims. In particular, the α5 subtype GABAA receptor is implicated in both depression and anxiety-related disorders. Here, we sought to determine whether reduced expression of α5GABAA is associated with depression and/or an anxiogenic behavioral phenotype in mice. Mice were also assessed on executive function memory tasks, which have been shown to be impaired in patients with mood disorders. We postulated that a decrease in α5 expression would lead to increases in depressive-like and anxiogenic behavior, and impaired executive function. Methods: Approval from the local animal care committee was obtained for all experiments. Males and females were evaluated. Mice were randomly assigned to one of two treatment groups (n=10 per group): α5 wildtype (Gabra5+/+), or α5 knockout (Gabra5-/-). Animals were serially assessed in a battery of behavioral tests which included: (1) open field test (OFT); (2) light-dark maze; (3) puzzle box; (4) elevated plus maze (EPM); (5) forced swim test (FST), and; (6) tail suspension test (TST). The same cohort of animals was tested on each behavioral paradigm. Results: Gabra5-/- mice display a depressive-like phenotype when compared to Gabra5+/+ animals as evidenced by tests of behavioral despair such as the TST [$t(17)=2.98$, $p<0.01$]. In addition, results from the puzzle box task indicate that Gabra5-/- animals are cognitively impaired compared to Gabra5+/+ animals in measures of executive functioning [$t(17)=2.83$, $p<0.01$]. Interestingly, sexual dimorphism was displayed in this assessment, with female animals displaying increased memory and executive function irrespective of genetic condition [$t(17)=2.7$, $p<0.05$]. Conclusion: A genetic knockdown of α5GABAA receptors leads to a depressive-like and cognitively impaired phenotype in mice. These results suggest that pharmacological manipulation that selectively upregulates extrasynaptic α5GABAA receptors may provide a novel treatment strategy for patients with depression.

Title: Evaluation of home cage social behaviors in mutant mitochondrial DNA polymerase transgenic mice

Authors: ***G. KURATOMI**, Y. ARIME, S. SUZUKI, K. AKIYAMA;
Dokkyo Med. Univ. Sch. of Med., Tochigi, Japan

Abstract: Mutant mitochondrial DNA polymerase (POLG) transgenic (Tg) mice that express mutant POLG with defective 3'-5' exonuclease activity under the promoter of calcium/calmodulin dependent protein kinase II α were reported to demonstrate forebrain specific accumulation of multiple deleted mitochondrial DNA, mood disorder-like phenotypes, and periodic wheel-running activity pattern associated with estrous cycle. In this study, we evaluate the long-term home cage social behaviors and anhedonic-like behavior of Tg mice. For behavioral observation, six pairs of 20-week old female Tg mice and control C57BL/6J (B6) mice were housed on a 12 h light/dark cycle (lights on between 6:00 and 18:00) and used for experiments. A heterozygous Tg mouse was paired with a female wild-type sibling, which had been cagemates since weaning, and bred in a polycarbonate cage (22 × 32 × 13.5 cm) with a transparent lid for 24 days. Home cages were consecutively recorded using digital video cameras which were placed above the cage and eligible for recording at night. The video files of the first hour of dark phase were analyzed every other day. The total duration and frequency of behaviors in Tg pairs were blind scored to rate aggressive behaviors (chase, food competition, boxing posture), non-aggressive behaviors (huddle, allogrooming, body contact), non-social behaviors (feeding, self-grooming) using Solomon Coder beta 15.03.15 and were compared with those in B6 control pairs. Social interaction test with unfamiliar female mouse was conducted the day after the end of the 24-day observation (day 25). Sucrose preference was tested using two-bottle choice procedure between bottle containing a 1% sucrose solution and water-containing bottle for 2 days (day 27, 28) after 2-day habituation. The whole study was formally approved by the animal care and use committee of Dokkyo Medical University School of Medicine. The

behavioral observation of matched pairs of Tg and B6 mice in home cage revealed that Tg mice showed significantly longer duration of food competition ($p = 0.012$) and nose to body contact for their cagemates ($p = 0.049$) as compared in B6. Tg mice also significantly chased their cagemates more frequently than B6 did ($p = 0.022$). In contrast, Tg mice spent significantly less time in self-grooming compared with B6 ($p = 0.019$). There were no significant differences between Tg and B6 in the time spent in the interaction zone in social interaction test. In sucrose preference test, sucrose consumption also showed no significant difference between Tg and B6. These results indicate mutant POLG Tg mice show manifestation of high levels of aggressive social interactions in the home cage environment.

Title: Impaired hippocampal reward-related activity in the DISC1 mutant mice

Authors: *Y. HAYASHI[1], A. SAWA[3], T. HIKIDA[2];
[2]Med. Innovation Ctr., [1]Kyoto Univ. Grad. Sch. of Med., Kyoto, Japan; [3]Dept. of Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Cognitive deficit is one of the symptoms of mental disorders, and the deficit seem to result from an inability to integrate information in the neural systems. We showed that a transgenic mouse expressing a dominant-negative form of DISC1, a risk gene for neuropsychiatric disorders, exhibited impaired performance in reward-place association task only when combined with a mild isolation stress. Previous studies show that hippocampal CA1 cells exhibit an elevated activity at reward zone as well as their place field activity during the task, suggesting that the hippocampus is one of the integration site for multiple information. CA1 cells in the mutant mice showed normal place cell property, but their activity at reward zone was diminished. This abnormality in hippocampal activity may underlie the learning deficit of the mutant mice.

Title: Serotonin depletion affects serotonergic neuronal circuits in adult mice

Authors: ***M. PRATELLI**[1], B. PELOSI[1,2], S. MIGLIARINI[1], M. PASQUALETTI[1,3]; [1]Univ. of Pisa, Pisa, Italy; [2]Lab. of Neural Differentiation, Inst. of Neuroscience, UCL, Brussels, Belgium; [3]Cnt. for Neurosci. and Cognitive Systems, Inst. Italiano di Tecnologia, Rovereto, Italy

Abstract: Serotonin is a neurotransmitter synthesized in two steps with tryptophan hydroxylase 2 (Tph2) as the rate-limiting enzyme and it is implicated in the modulation of numerous physiological processes including mood, sleep, aggressivity and sexual behavior. Serotonergic neurons provide a profuse innervation to the whole CNS. The synthesis of serotonin and the expression of its receptors early in embryonic development, as well as its maternal and placental sources to the foetus, have led to the hypothesis that serotonin could act as a growth regulator in specific developmental events such as neurogenesis, neuronal migration and circuitry formation. However, the precise role of serotonin in specific morphogenetic activities during CNS development remains poorly understood. To address the consequences of time-controlled serotonin depletion on CNS development, we have generated a Tph2 conditional (floxed) allele and used it in combination with a Tph2-GFP knockin mouse line allowing the visualization of serotonergic neurons and fibers (Migliarini et al., 2013). Besides the severe abnormalities in the serotonergic circuitry formation observed in Tph2 knockout mice, serotonin depletion in adult animals induces an increase of the density of serotonergic fibers projecting to the hippocampus.

These results show that the mature serotonergic system exhibits a previously unexpected plasticity and that appropriate serotonin homeostasis is crucial not only for proper development of the serotonergic neuronal circuit but also for its maintenance during adulthood. Migliarini et al. Mol Psychiatry 2013 18: 1106-18.

Title: Decreased somatostatin expression and behavioral abnormalities in a somatostatin-IRES-CRE mouse line

Authors: ***S. MOLAS**, P. GARDNER, A. TAPPER;
Brudnick Neuropsychiatric Res. Institute, Dept. of Psychiatry, Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Somatostatin (Sst) is a modulatory neuropeptide frequently expressed by GABAergic neurons. The role of Sst-positive inhibitory neurons has recently been studied using the knock-in transgenic mouse line Sst-IRES-Cre (Jackson labs stock number: 13044), which harbors an internal ribosome entry site and the Cre recombinase gene within the Sst locus. Therefore, this line is expected to drive Cre expression under the Sst promoter without altering the endogenous levels of Sst. However, few investigations have addressed the validity and reliability of this Cre-driven model. The present study demonstrates that mice homozygous for the Cre allele ($Sst^{Cre+/+}$) exhibited significantly reduced levels of endogenous Sst as compared to their wild type (WT) littermates ($SSt^{Cre-/-}$). The loss of Sst expression could be observed in the hippocampus and cortex, from P0 to P60, and appears to be compensated by an upregulation of the Sst receptors. Behaviorally, adult $Sst^{Cre+/+}$ male mice exhibited reduced locomotor activity during the active phase of the circadian cycle, similar to Sst knockout mice. Moreover, in the elevated plus maze $Sst^{Cre+/+}$ mice spent less time in the open arms compared to WT mice indicating increased baseline anxiety levels. By contrast, female $Sst^{Cre+/+}$ mice were hyperactive towards the end of the active phase of the circadian cycle. In addition, they spent similar time in the open arms of the elevated plus maze indicating normal anxiety-like response. Importantly, in both male and

female mice, the expression of Sst and behavioral abnormalities were partially rescued in the heterozygous $SSt^{Cre+/-}$ littermates. To determine if Cre expression in the Sst-IRES-Cre line was appropriately restricted to neurons expressing Sst, we crossed $Sst^{Cre+/+}$ mice with an Ai9 td-Tomato reporter strain. The double transgenic offspring expressed the red fluorescent protein in the majority of Sst immunopositive neurons. However, tomato red was detected in Sst immunonegative neurons within several brain areas including those not reported to express Sst. In summary, our study reveals important alterations in the Sst-IRES-Cre mouse line including behavioral abnormalities and Cre driving expression in non-Sstergic neurons that could lead to experimental misinterpretations, especially when working with homozygous animals.

Title: Enhanced adult hippocampal neurogenesis via regulation of perforant path activity: a novel treatment for stress- induced depression?

Authors: *S. YUN[1], P. D. RIVERA[1], R. REYNOLDS[1], N. ITO[1], B. L. ROTH[2], D. M. CHETKOVICH[3], A. J. EISCH[1];
[1]UT Southwestern Med. Ctr., Dallas, TX; [2]Northwestern Univ., Chicago, IL; [3]Univ. of North Carolina, Chapel Hilll, NC

Abstract: A major problem with current antidepressants is that ~50% of patients will relapse. A better understand of the neural circuitry underlying depressive behaviors and antidepressive treatments will help us develop more effective treatments for Major Depressive Disorder (MDD). Recent studies – including those showing decreased hippocampal dentate gyrus (DG) progenitors and neuron number in unmedicated humans with MDD, and the requirement of adult DG neurogenesis for certain effects of antidepressants in some strains of rodents – suggest that enhancement of hippocampal neurogenesis may be a useful treatment for depression. Our hypothesis is that controlled enhancement of DG input via the glutamatergic perforant path (PP) is antidepressive via increased DG neurogenesis. While entorhinal cortex (Ent) deep brain stimulation and thus PP activation improves spatial memory and enhances DG neurogenesis (Stone et al., 2011), it is unknown whether Ent stimulation can also be antidepressive. We used two independent methods to stimulate PP activity and/or increase excitability of Ent Layer II stellate neurons in rodents: Ent knockdown of the brain-specific hyperpolarization-activated cyclic nucleotide-gated (HCN) channel auxiliary subunit TRIP8b, and PP stimulation via the chemogenetic Designer Receptors Exclusively Activated by Designer Drugs (DREADD) technology. Thus far, the results support our hypothesis. For example, knockdown (KD) of Ent TRIP8b increases hippocampal neurogenesis and promotes neuronal maturation, and also improves performance in behavioral measures of hippocampal dependent memory (e.g. CFC) and antidepressant efficacy (e.g. FST). Moreover, enhanced neurogenesis induced by Ent TRIP8b KD is required for antidepressant efficacy. As a cell type specific approach, enhanced excitability of glutamatergic neurons – via stereotaxic infusion of AAV-hM3Dq-mcherry into medical and lateral Ent Layer II - enhances hippocampal neuroplasticity. We are currently examining whether enhanced stellate cell excitability is antidepressant. Also, we are screening what molecular pathway in the DG plays role in antidepressant via enhanced DG activity using unbiased approach. These results will reveal whether highly promising targets for the treatment of depression – DG neurogenesis and PP activity – work together to regulate affective behaviors. In addition to exploring this novel connection and suggesting better paths for treatment, these aims will notably advance our understanding of the molecular, cellular, and neuro-circuit level regulation of depression-related behaviors.

Title: Impaired fast-spiking interneuron function in a genetic mouse model of depression

Authors: *J.-F. SAUER, M. STRUEBER, M. BARTOS;
Albert-Ludwigs Univ. Freiburg, Freiburg, Germany

Abstract: Rhythmic neuronal activity provides a frame for information coding by co-active cell assemblies. Abnormal brain rhythms are considered as potential pathophysiological mechanisms causing mental disease, but the underlying network defects are largely unknown. Here we show that mice expressing truncated Disrupted-in-Schizophrenia 1 (Disc1), which mirror a high-prevalence genotype for human psychiatric illness, show behavioral despair in broadly accepted assays of depression-related behavior in rodents. Theta and low-gamma synchrony in the prelimbic cortex (PrlC) are impaired in Disc1 mice and inversely correlated with the extent of behavioral despair. While weak theta activity is driven by the hippocampus, disturbance of low-gamma oscillations is caused by local defects of parvalbumin-expressing fast-spiking interneurons: First, the number of fast-spiking interneurons is reduced in the prelimbic cortex of Disc1 mice. Second, these neurons receive fewer excitatory inputs. Finally, Disc1 fast-spiking interneurons form fewer release sites on their target principal cells. Computational analysis indicates that weak excitatory input and inhibitory output of fast-spiking cells may lead to impaired gamma oscillations. Our data therefore link network defects with a risk gene mutation underlying depression in humans.

Title: Chronic lithium treatment rescued Akt3 KO mice depressive and anxiety-like behaviors

Authors: ***Y. BERGERON**, G. BUREAU, M.-É. LAURIER-LAURIN, E. ASSELIN, G. MASSICOTTE, M. CYR;
Med. biology, Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: The protein kinase B (PKB/Akt) is found in three distinctive isoforms: PKBα/Akt1, PKBβ/Akt2, and PKBγ/Akt3. Although they display high homology and similar structural organization, recent findings illustrate that each of these isoforms play distinctive physiological role. Akt3 is well expressed in the brain and is critical for postnatal brain development, suggesting this isoform could play a role in cerebral functions. In this study, we have investigated the impact of Akt3 deletion on behaviors, synaptic plasticity and biochemical signaling. First, our results show that cognitive functions remained intact in the Akt3 KO mice, since no difference is observed in two different cognitive tests related to the hippocampus, the Morris water maze and the novel object recognition test. In addition, electrophysiology on Akt3 KO hippocampal slices shows that neither STP nor LTP levels is modified compared to WT hippocampal slices. However, Akt3 deletion induces several behavioral anomalies: reduced

prepulse inhibition, social behavior deficits as well as high level of depressive and anxiety-like behaviors. Biochemical investigations reveal that Ak3 deletion does not modulate levels of total Akt1 and Akt2 in the anterior cortex, striatum, hippocampus and cerebellum. However, levels of GSK3α/β phosphorylated at serine 21/9 are decreased in the anterior cortex, hippocampus, striatum and cerebellum of Akt3 KO mice; no change in levels of total GSK3α/β is observed. In order to verify whether the decreased phosphorylated GSK3α/β levels could be related to the observed depressive and anxiety-like behaviors, a lithium diet was chronically administrated to Akt3 KO and WT mice. Lithium is a mood modulator known to modulate GSK3α/β phosphorylation. This treatment increases levels of phosphorylated GSK3α/β and rescues the depressive and anxiety-like behaviors observed in Akt3 KO mice. These results suggest that GSK3α/β may contribute to the depressive and anxiety-like behaviors found in the Akt3 KO mice and support that an isoform-specific mechanism may define the neuronal signaling of Akt in psychiatric illnesses-related behaviors.

Title: Isoflurane anesthesia activates TrkB neurotrophin receptor signaling and produces rapid antidepressant-like effects

Authors: ***H. ANTILA**[1], D. POPOVA[1], J. LINDHOLM[1], I. YALCIN[2], T. RANTAMÄKI[1], E. CASTRÉN[1];

[1]Neurosci. Ctr., Univ. of Helsinki, Helsinki, Finland; [2]Inst. of Cell. and Integrative Neurosciences, Strasbourg, France

Abstract: Brain-derived neurotrophic factor BDNF and its receptor TrkB are involved in the mechanism of action of conventional antidepressant drugs and rapid-acting antidepressant ketamine. Enhanced BDNF-dependent neuronal plasticity has been suggested to mediate the therapeutic effects of antidepressant drugs. Isoflurane, a commonly used volatile anesthetic, has been shown to produce rapid antidepressant effects in patients with treatment resistant depression. We have here investigated whether isoflurane activates signaling pathways known to be involved in the antidepressive effects in rodents. We have also studied the effects of isoflurane on neuronal plasticity and mouse behavior. Anesthetic dose of isoflurane rapidly activated TrkB receptor and increased signaling via mTOR pathway in the mouse prefrontal cortex and hippocampus. The phosphorylations of CREB, Akt, P70S6kinase, 4E-BP1 and GSK3beta were significantly increased after 30 minutes of isoflurane treatment. Isoflurane facilitated long-term potentiation in the hippocampus when measured 24 hours after the treatment. A single isoflurane treatment led to a rapid antidepressant-like behavioral effect in the forced swim test in wild-type mice but not in mice overexpressing the dominant-negative TrkB receptors, suggesting that the behavioral effects of isoflurane in the forced swim test are mediated via TrkB receptor. Furthermore, in the neuropathic pain model of depression a single isoflurane anesthesia rapidly normalized the anxiogenic phenotype in the novelty suppressed feeding test. In conclusion, single and brief treatment with commonly used anesthetic isoflurane produces molecular, functional and behavioral effects that resemble those produced by conventional antidepressant drugs and ketamine. These findings encourage studying further the potential of isoflurane anesthesia as a treatment option for major depressive disorder both in experimental models and human patients.

Title: Co-activation of multiple serotonin receptors underlies sustained potentiation of synaptic transmission by fluoxetine in the hippocampus

Authors: *A. M. VAN DYKE, A. J. KALLARACKAL, X. CAI, S. M. THOMPSON; Physiol., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Serotonin (5-HT) and its receptors have long been major targets in the pharmacological treatment of depression. Despite their widespread use, the mechanism of action underlying the therapeutic efficacy of SSRIs like fluoxetine remains poorly understood. Our laboratory has shown that raising endogenous 5-HT can potentiate certain excitatory synapses, including those that are weakened in depression models, and that this potentiation is necessary for the therapeutic behavioral action of antidepressants. In the hippocampus, activation of G_i/G_o-coupled 5-HT_{1B} receptors potentiates glutamatergic signaling in temporoammonic (TA) to CA1 pyramidal cell synapses in the stratum lacunosum-moleculare (SLM). This occurs due to the phosphorylation of the AMPA receptor subunit GluA1 at serine 831 via recruitment of the Phospholipase C/Ca2+/Calmodulin-dependent Protein Kinase II (PLC/Ca2+/CaMKII) signaling cascade. Selective activation of 5HT1BRs produces a *transient* potentiation, whereas elevation of endogenous 5-HT with the SSRI fluoxetine *persistent* potentiates TA-CA1 synapses in a 5HT1BR-dependent manner. We hypothesized that fluoxetine's sustained potentiation of hippocampal TA-CA1 synapses is due to the co-activation of 5-HT_{1B}R and a G_S-coupled serotonin receptor causing activation of PKA signaling. We have addressed this hypothesis by using various pharmacological tools to disrupt/activate specific receptors and their respective signaling pathways. We have observed that antagonists of 5-HT_{1B}Rs prevents the potentiation of TA-CA1 field potentials by both fluoxetine and anpirtoline. Disruption of PKA signaling had no effect on 1B-mediated potentiation but inhibition of PKA did prevent the sustained potentiation by fluoxetine. Antagonists of the various G_s-coupled 5-HTRs revealed that 5-HT_6R was underlying this activation of PKA by fluoxetine, whereas 5-HT_4R or 5-HT_7R antagonists had no effect. Conversely, co-activation of 5-HT_{1B}Rs and 5-HT_6Rs, with their respective agonists, produced a sustained increase in synaptic transmission. Western blotting is in progress to determine the time course of kinase activation and AMPA receptor phosphorylation under different conditions. Taken together these data suggests that the SSRI fluoxetine raises endogenous 5-HT resulting in the co-activation of multiple 5-HTRs to produce an increase in glutamatergic transmission. 5-HT_{1B}R activation initially induces the increase in synaptic strength through PLC/Ca2+/CaMKII dependent phosphorylation of AMPA receptors and 5-HT_6R activation maintains this increase through the recruitment of PKA signaling.

Title: Ursolic acid protects against depressive-like behavior induced by chronic unpredictable stress and *in vitro* corticosterone-induced reduction on cell viability

Authors: *A. S. RODRIGUES, A. B. R. HRYB, A. R. S. COLLA, N. PLATT, V. LIEBERKNECT, F. L. PAZINI, M. P. CUNHA, M. P. KASTER;
Univ. Federal de Santa Catarina, Florianopolis, Brazil

Abstract: Ursolic acid (UA), a pentacyclic triterpenoid, exhibits antidepressant-like effects in behavioral tests predictive of antidepressant activity. This study investigated its ability to prevent the depressive-like behavior induced by chronic unpredictable stress (CUS), an animal model that mimics human depression. Additionally, its ability to counteract the corticosterone-induced reduction on cell viability in mouse hippocampal neuronal cell line was also evaluated. All experiments were approved by the Ethics Committee of the Institution. Male Swiss mice (60 day-old, 40-45 g) were submitted to CUS procedure during 14 days. In the last 7 days, mice received UA (0.1 mg/kg, p.o.) or fluoxetine (10 mg/kg, p.o., positive control). On 15th day, immobility time, anhedonic behavior and locomotor activity were evaluated in the tail suspension test (TST, 6-min session), splash test (5-min session) and open-field test (6-min session), respectively. The mRNA expression of anti-apoptotic (Bcl-2) and pro-apoptotic (Bax) proteins in hippocampal tissue was evaluated using qRT-PCR. For *in vitro* experiments, HT22 cells were subcultured in 96-well plates at a seeding density of 6 × 103 cells per well. Cells were pretreated during 48 h with UA (5, 15 μM) or vehicle (DMSO 0.1%) in DMEM with 10% FBS and 24 h after with corticosterone (50 μM) or vehicle. Cell viability was measured by a colorimetric assay with MTT. Results were analyzed by two-way ANOVA followed by Newman-Keuls test, when appropriate (significant when $p<0.05$). Repeated treatment with UA prevented the depressive-like behavior (increased immobility time in the TST and latency to grooming in the Splash Test) without altering locomotor activity of mice. UA also prevented the increased hippocampal Bax mRNA expression and the decreased Bcl-2/Bax mRNA ratio caused by CUS. The *in vitro* assays showed that incubation with UA (5, 15 μM) alone during 48 h did not alter hippocampal neuronal viability, but was able to prevent the reduction in cell viability induced by corticosterone (50 μM). The results indicate a robust effect of UA in reversing

behavioral and biochemical alterations induced by CUS in mice and to protect against corticosterone-induced cell viability in mouse hippocampal neuronal cell line.

Title: Amantadine reduces depressive behavior in rodent models of depression

Authors: *J. NGUYEN, B. BRIGHAM;
Adamas Pharmaceuticals, Inc., Emeryville, CA

Abstract: Amantadine HCl is an NMDA receptor (NMDAr) antagonist approved for the treatment of influenza and Parkinson's disease. In addition to its glutaminergic activity, amantadine has also been shown to modulate other neurotransmitter systems, inhibit microglial activation, and elevate levels of brain-derived neurotrophic factor (BDNF). Amantadine has also been shown to have antidepressant properties in animal models of depression and in small clinical trials. Recently, ketamine, another NMDAr antagonist, has been shown to produce a rapid antidepressant response in patients with treatment-resistant depression. In clinical trials, the antidepressant effect of a single dose of ketamine was significant within an hour of administration and can last up to 7 days. In several models of depression in rodents, a single dose of ketamine alleviates depressive behavior whereas a single dose of standard antidepressants (ie, a selective serotonin uptake inhibitor, SSRI, or a tricyclic antidepressant, TCA) has no effect. However, ketamine also has dissociative properties and abuse liabilities, limiting its overall use as an antidepressant. Here, we characterized the antidepressant properties of amantadine using multiple models of depression and determined the time of onset of antidepressant activity. First, in the chronic social defeat model, male C57BL/6J mice were subjected to daily aggression by CD-1 mice over a period of 10 days, which produced enduring and clinically relevant depressive phenotypes such as social avoidance, reduced locomotion, and anhedonia. Second, in the forced swim test, male Sprague-Dawley rats were placed in a container of water and the immobility time, a measure of despair, was recorded over a 5 minute interval. We demonstrate that amantadine when administered in repeated doses produced a statistically significant antidepressant effect. More importantly, when administered in a single acute dose, amantadine

reduced depressive symptoms in a dose-dependent fashion whereas fluoxetine (an SSRI) had no effect. Together, the data suggest that amantadine may have clinical utility as an antidepressant with a rapid onset of activity, and provide a framework for further clinical evaluation.

Title: NLRP3 inflammasome is activated by psychological stress: a potential role of NLRP3 inhibitor beta-hydroxybutyrate's antidepressant effect

Authors: *T. YAMANASHI[1], M. IWATA[1], N. KAMIYA[1], T. YAMAUCHI[1], R. S. DUMAN[2], K. KANEKO[1];
[1]Tottori Univ., Tottori, Japan; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Stress decreases neurogenesis and synaptogenesis in the adult hippocampus, contributing to depressive-like behaviors in rodent models, but the mechanisms by which stress causes neuronal damage remain unknown. We have previously reported that interleukin-1beta (IL-1beta) decreases neurogenesis and causes depressive behavior. We have also demonstrated that stress increases ATP and IL-1beta in the hippocampus, and that administration of the purinergic P2X7 receptor (P2X7R) antagonist (A-804598) ameliorates both of these effects of IL-1beta in the hippocampus, as well as decreased neurogenesis and depressive behavior caused by stress. Activation of microglia and inflammatory responses also occurs via pathogen and damage associated molecular patterns (PAMPs and DAMPs) that bind to toll like receptors; when combined with ATP-P2X7R triggered K+ efflux, this leads to the induction of large multi-protein complex termed the NLRP3 inflammasome, and mature IL-1beta is released. These findings indicate that ATP release plays a critical role in stress-induced inflammatory responses and depressive behavior, but direct evidence for ATP and NLRP3 in the effects has not been demonstrated. Here, we investigated how ATP stimulates IL-1beta release, and developed a new

strategy for the treatment of depression. We hypothesized that psychological stress activates NLRP3 inflammasome via ATP elevation. We confirmed that immobilization stress activates NLRP3 inflammasome in the adult rat hippocampus, as measured by a co-immunoprecipitation-western blotting method. We also confirmed that A-804598 ameliorates NLRP3 inflammasome activation induced by immobilization stress. We are currently investigating whether inhibitors of NLRP3, notably beta-hydroxybutyrate (BHB), have antidepressant and anxiolytic actions. BHB is a ketone body that supports mammalian survival during states of energy deficit. Recently it has been reported that BHB suppresses activation of the NLRP3 inflammasome in response to ATP by preventing K+ efflux and reducing NLRP3 oligomerization. Preliminary studies indicate that BHB administration prevents anxiolytic behaviors induced by chronic unpredictable stress in rodents. These studies are consistent with the hypothesis that NLRP3 inhibitors are novel targets for antidepressant drug development.

Sch., Hannover, Germany; [5]Univ. Helsinki, Helsinki, Finland; [6]Fac. of Pharmaceut. Sci., Tokushima Bunri Univ., Tokushima, Japan

Abstract: About 30% of people suffering from major depressive disorder (MDD) do not achieve remission with antidepressant drugs (AD). For the development of novel antidepressant treatments and the understanding of pathophysiological mechanisms underlying therapy

resistance, valid animal models of therapy-resistant MDD are of special interest. Christensen et al. (2011, Neuroscience,196:66-79) exposed rats to chronic mild stress (CMS) and selected rats which responded or did not respond to the AD citalopram, thereby proposing an animal model for pharmacoresistant MDD. In the present study we pursued two aims: 1) To further determine the predictive validity of the model, 2) to correlate therapy efficacy with changes of the brain-derived neurotrophic factor (BDNF). Pharmacoresistant MDD patients often respond to electroconvulsive therapy. Therefore we compared chronic citalopram treatment and electroconvulsive stimulations (ECS) in rats, to test whether clinical response patterns can also be found in the experimental setting. Male Wistar rats were exposed to CMS for 21 days before the onset of treatment. CMS was continued during treatment period. The selection of responders and nonresponders was based on anhedonic-like behavior measured by the sucrose consumption test (SCT). Moreover, we established an evaluation tool according to the Hamilton Rating Scale for Depression (HAM-D), which measures the severity of a set of symptoms such as motivation and anxiety. Therefore, we performed the open field test, the novelty induced hypophagia test, the forced swim test (FST), and the social interaction test. Finally, we compared the Bdnf-DNA methylation and BDNF protein expression levels in blood, prefrontal cortex and hippocampus of treatment responders and nonresponders. Based on the SCT, we observed resistance to citalopram, but a high response rate to bifrontal ECS applied via cortical screw electrodes. The response rate was much lower when all tests were taken into account. Further, there was a high variation in the response rate depending on the test performed. The tests with the most homogeneous outcome were the SCT and FST. No correlation between treatment response and BDNF changes could be detected. The CMS model seems to have a high predictive value for therapy-resistant MDD. The classification of resistant and responsive rats depends on the underlying test to determine depressive-like behavior. This could bias subsequent investigations such as molecular or biochemical changes. Further, selection of responders and nonresponders minimizes group size and could be an explanation why we did not find a correlation between BDNF changes and therapy response.

Title: Chronic social defeat mouse assay for assessing anti-depression therapies

Authors: *J. T. PUOLIVALI[1], S. ALASTALO[1], A. NURMI[1], O. KONTKANEN[1], B. HENGERER[2], K. A. ALLERS[2];
[1]Charles River Discovery Res. Services, Kuopio, Finland; [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim am Rhein, Germany

Abstract: The current paradigms for testing anti-depression therapies have little face validity and predictive validity within only a very narrow range of mechanisms of action and a narrow therapeutic window. The chronic social defeat (CSD) model is ethologically relevant and has robust depressive-like endpoints. Moreover, the paradigm allows for either chronic or acute anti-depressant treatments with any specified dosing paradigm. Depressed patients have elevated levels of blood-brain-barrier penetrant cytokines in brain. In addition, depressed patients have elevated microglia, and elevated levels of quinolinic acid suggesting the induction of microglial indoleamine 2,3-dioxygenase 1 (IDO1). It has been shown that depending on concentration, quinolinic acid can either be helpful or harmful to neurons, and that excess quinolinic acid can interfere with neural transmission in circuits known to be involved in depressive symptoms. The purpose of this study was to test the efficacy of IDO1 inhibitors, IDO1A and IDO1B in the CSD model paradigm in C57Bl/6J male mice. The mice were exposed to chronic stress by aggressor mice (CD-1 retired breeders) for period of 15 days. Starting from day 14, mice were subjected open field (OF), contextual fear conditioning (CFC), and the active avoidance (AA) tests to monitor stress related changes in behavior compared to the control mice. The compounds were administered once-a-day starting from CSD day 13. In a separate experiment, the control and defeated mice were tested in the sucrose preference test (SPT). Following 15 days of CSD, the mice displayed clear and robust depressive-like phenotypes. These included: decreased sucrose preference, reduced activity and increased immobility in OF, increased freezing behavior in the CFC test, and impaired avoidance behavior in the AA assay. Moreover, treatment with IDO1B significantly decreased freezing in CFC test compared to vehicle treated CSD mice. Finally, post-mortem samples can be used to validate the target of interest, for example induction of IDO1, microglia activation, and tryptophan catabolite presence following IDO1 inhibition. In conclusion, the multiple endpoints of the CSD model provide a comprehensive model of depression in which the next generation anti-depressant can be assessed.

Title: Antidepressant actions of deep brain stimulation are augmented by dopamine reuptake inhibition

Authors: *R. P. KALE[1], A. Z. KOUZANI[2], K. WALDER[3], M. BERK[3], S. J. TYE[1];
[1]Mayo Clin., Rochester, MN; [2]Sch. of Engin., [3]Sch. of Hlth., Deakin Univ., Waurn Ponds, Australia

Abstract: The mechanisms underlying treatment resistant depression (TRD) and manic switch are yet to be fully understood. A diminished plasticity response is suggested to be a neuroprogressive adaptation to treatment resistance in TRD, and may be alleviated by DBS. TRD can be induced in rodents through a stress-hormone challenge using adrenocorticotropic hormone (ACTH). TRD is often characterized by lower psychomotor activity, alterations in metabolism, reduced motivation, anhedonia, passivity and decreased positive affect. Modulation of dopamine sensitivity within the cortico-mesolimbic system, particularly the nucleus accumbens (NAc) and medial forebrain bundle (mfb), mediate coping behaviors in response to stress. This study aims to quantify antidepressant actions of NAc and mfb DBS in ACTH-pretreated animals, alone and in interaction with dopamine reuptake inhibition. TRD was induced in male Wistar rats via ACTH treatment (ACTH-(1-24); i.p. 100µg/day) in combination with social isolation (2 weeks). A control group was similarly isolated and treated with saline (i.p. 0.9%/day). ACTH and saline treated rats were further divided into 2 main groups: 1) receiving the dopamine reuptake inhibitor GBR12909 (GBR) daily during the second treatment week; and 2) GBR naive. Within these two group, animals received either ACTH+NAc DBS, ACTH+mfb DBS, ACTH, or Saline. Chronic DBS (7 days) was administered to the NAc or mfb via bilateral bipolar twisted electrodes secured to back-mounted DBS devices. Home cage activity counts were obtained for all rats using infrared beam motion detectors throughout the experiment. The open field test (OFT) was run each day of the second week, 40 minutes post-GBR and 80 minutes post-ACTH injections. Forced swim test (FST) was conducted on the last day of the protocol and animals were humanely euthanized. Total homecage activity was significantly increased in the ACTH+GBR group compared to ACTH group ($p<.01$) and other GBR groups ($p<.05$). OFT locomotor activity (day 14) was decreased in the ACTH+GBR group compared to NAc+GBR ($p<.01$) and Saline+GBR ($p<.05$) groups, but not the mfb+GBR group. FST immobility (day 15) was significantly reduced for all GBR treated animals ($p<<0.05$). NAc DBS and mfb DBS also reduced FST immobility ($p<0.05$) relative to ACTH-pretreated animals. This work confirms the therapeutic potential of NAc and mfb DBS and suggests augmentation of transient dopamine dynamics through blockade of dopamine reuptake may enhance therapeutic

outcomes. The observed increased locomotor and circadian activity underscores the pathways and mechanisms whereby this interaction might increase risk of development of a mania-like profile.

Title: Hypothalamic pituitary adrenal-axis hyperactivity in depression co-morbid with obesity in experimental mice

Authors: *Y. KURHE, R. MAHESH;
Birla Inst. of Technol. & Science, Pilani, Pilani, India

Abstract: Several studies have explained the hyperactivity of hypothalamic adrenal axis in depression and obesity [1]. The present study investigates i) obesity risks the depressive behavior in mice [2] ii) corticosteroids as a pathological links for depression co-morbid with obesity [3]. Swiss albino mice were fed with high fat diet (HFD) for 14 weeks. Sucrose preference test (SPT) and forced swim test (FST) were performed in obese mice. Biochemical estimations including plasma glucose, corticosteroids and brain oxidative stress marker malonaldehyde (MDA) and anti-oxidant reduced glutathione (GSH) concentrations were performed. Results showed severe depressive behavior in HFD mice compared to normal pellet diet (NPD) fed animals as shown by reduced sucrose consumption in SPT, increased immobility time in FST (Table 1), increased plasma glucose and corticosteroids, increased brain MDA and decreased GSH (Table 2) concentration in HFD mice compared to NPD mice. The unchanged locomotor score in HFD mice compared to NPD fed mice, ruled out false positive results in FST. Present study demonstrates that obesity heightens the risk of depression in obese mice. Obesity is a stressful abnormal condition with raised oxidative stress and HPA axis hyperactivity causing abnormal corticosteroids to worsen depression by dysregulation of glucose [4]. The depressive behavior was severe in HFD mice as compared to NPD mice where HPA axis hyperactivity could play a crucial role in depression co-morbid with obesity. [1] Asensio C, et al. Title: Disturbed inhibition in the hippocampus underlying decreased sensitivity to reward in depression

Authors: *K. HENNINGSEN[1], U. BØLCHO[2], M. M. HOLM[2], I. VIDA[3], O. WIBORG[1]; [1]Translational Neuropsychiatry Unit, Aarhus Univ., Risskov, Denmark; [2]Dept. of Biomedicine, Aarhus Univ., Aarhus, Denmark; [3]Inst. of Integrative Neuroanatomy, Berlin, Germany

Abstract: Anhedonia is defined as a decrease in sensitivity to normally rewarding stimuli. It is one of the core symptoms of depression and a common symptom in response to psychostimulant withdrawal. We have previously shown that rats with an anhedonic-like response to chronic mild stress (CMS) have an impaired hippocampal GABAergic system. This was illustrated by a decreased number of spontaneous inhibitory postsynaptic currents and an increased paired pulse facilitation in granule cells of the dentate gyrus. In this study, we have used an amphetamine withdrawal paradigm to induce an anhedonic-like condition in rats. The anhedonic-like state is measured as a decrease in sucrose consumption. In this study we aim to investigate the excitatory/inhibitory balance of rats exposed to amphetamine withdrawal using extra- and intracellular electrophysiological recording techniques. Preliminary results show that in response to amphetamine withdrawal, rats show a decrease in sucrose consumption peaking on day five, following withdrawal. Moreover, extracellular recordings indicate that amphetamine withdrawal is associated with an impaired hippocampal inhibitory system. On going studies are conducted to further delineate the functional origin of the impaired inhibition seen in our preliminary studies.

Abstract: One third of depressed patients are unresponsive to antidepressant drugs, constituting a population known as treatment resistant depression (TRD). Ketamine is the only drug showing clinical efficacy in TRD patients. Decreased neuronal microtubule dynamics has been associated with the pathogenesis and treatment of depression and might represent a potential biomarker in TRD. The endogenous ‘depressed’ Wistar Kyoto (WKY) rat, unresponsive to selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, was used as a model of TRD to investigate

microtubular proteins as a biomarker. Male WKY rats (6-8 weeks; n=8 per group) were administered either fluoxetine (10 mg/kg i.p.), ketamine (5 mg/kg i.p.) or saline (1 ml/kg i.p.). Immobility, defined as depressive-like behaviour, was tested in the forced swimming test (FST) 30 minutes and 7 days post-administration and compared with Sprague-Dawley (SD) rats (6-8 weeks; n=8). Plasma was isolated 24 hours and 8 days post-administration; medial prefrontal cortex (mPFC) and dentate gyrus (DG) were isolated 8 days post-administration. Expression of acetylated alpha-tubulin (Acet-Tub; marker of stable microtubules) was measured as a central (brain regions) and peripheral (plasma) marker of microtubule dynamics by infrared Western Blotting. WKY rats show increased immobility in FST compared with SD rats. Ketamine produced a rapid (30 minute) and long-lasting efficacy (7 day) whereas fluoxetine elicited no effects. Plasma Acet-Tub was approx. 100% higher in WKY compared to SD rats at each time point. Importantly, fluoxetine augmented Acet-Tub overexpression in WKY rats 24 hour post-administration, ketamine had no significant effect. Neither drug significantly altered Acet-Tub expression 8 day post-administration. The observed overexpression of plasma Acet-Tub in WKY rats as well as its pharmacological modulation were similar to the alterations of microtubule dynamics identified in the brain. WKY rats represent a model of TRD responding to acute ketamine and not fluoxetine in the FST. WKY rats overexpressed plasma Acet-Tub consistent with decreased neuronal microtubule dynamics. Importantly, acute fluoxetine increased the overexpression of plasma Acet-Tub in WKY rats, an effect previously demonstrated in Lister-hooded rat hippocampus (Bianchi et al., 2009, Synapse 63:359-364), while ketamine had no effects. Thus, analysis of microtubule dynamics may represent a potential biomarker of disease progression in TRD. Transpharmation Ireland is currently analysing microtubule dynamics in plasma samples from TRD patients to explore translational and clinical relevance of its preclinical discovery.

Title: Evaluation of antidepressant-related assays sensitive to clinical relevant doses of ketamine

Authors: *C. MOMBEREAU[1], T. BRUUN[1], J. PRENDERVILLE[3], J. ROUINE[3], L. BADOLO[2], M. BIANCHI[3];

Abstract: The non-competitive NMDA antagonist ketamine has been shown to elicit a rapid and long-lasting antidepressant effects in treatment resistant depressed subjects and in preclinical models. However, discrepancies have been observed between the plasmatic concentration of clinically effective infusion and the doses routinely used in rodent limiting the translatability between these species. Indeed, both Zarate (2012) and Zhao (2012) estimated a maximal plasmatic concentration (Cmax) of 200 ng/ml after iv infusion of the sub-anesthetic dose of 0.5 mg/kg for 40 min in human whereas we estimate a Cmax of 2000-10000ng/ml after injection of the routinely used 10-30 mg/kg in rodents. This observation raise the possibility that the antidepressant-like effects of ketamine observed in preclinical models could be mediated by off-target effects such as engagement of opioids, dopamine or nicotinic receptors. In the present study, we attempt to evaluate the sensitivity of different animal models/behavioral paradigms to detect antidepressant-like effects of clinical relevant doses of ketamine such as tail suspension, forced swim test and novelty suppressed feeding test in mice and rats. Both rapid and long-lasting effects of ketamine were investigated testing the animals 30 min as well as 24h after drugs administration. Antidepressant-like effects of ketamine were observed in mice in both the tail-suspension test as well as novelty suppressed feeding at respectively 30 and 10 mg/kg with estimated plasmatic concentration of 1000-3000ng/ml. In Wistar Kyoto rats, considered as model of endogenous depression resistant to antidepressant treatment with Selective Serotonin Reuptake Inhibitors (SSRI), we observed that 3 and 5 mg/kg were able to induced fast and prolonged antidepressant like response in the forced swim test corresponding to plasmatic concentration of 100 and 200 ng/ml. Consequently, we identify the Wistar Kyoto rats as one of the most optimal model since we observed both fast and prolonged effect of ketamine at clinical relevant doses. Consequently, we will consider this model as a most appropriate entry-point in order to assess antidepressant properties of novel agent acting on NMDA receptor as well as investigate biological substrate mediating these effects. Title: From synapses to depression and back: plasticity of excitatory drive in cortico-mesolimbic synapses

Authors: *M. D. KVARTA[1], J. FISCHELL[2], N. HESSELGRAVE[2], T. LEGATES[2], A. VAN DYKE[2], S. THOMPSON[2];
[2]Physiol., [1]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: A pathological weakening of excitatory synaptic transmission between multiple brain regions is induced by chronic stress and may underlie the induction of depression-related behavioral changes, such as anhedonia. Here we propose a model of multi-synaptic involvement of cortico-mesolimbic circuitry in depressive-like behavior. In this model, drive from the hippocampus (HC) and prefrontal cortex to the nucleus accumbens (NAc) is dampened by pro-depressive forces, while opposing drive from the lateral habenula is overactive, ultimately resulting in decreased dopamine release from the ventral tegmental area. Using field recordings, we show this defective circuitry contributing to anhedonia can be extrinsic to the NAc by weakening upstream synapses within CA1 of the HC following four different chronic stress models that generate a depressive-like neurobehavioral phenotype with construct, face, and predictive validity: unpredictable stress, restraint stress, multimodal stress, and exogenous CORT administration. This weakening is driven by a loss of GluA1-mediated AMPAR signaling at distal apical dendrites in the temporoammonic-CA1 (TA-CA1) pathway, and is reversed by monoaminergic antidepressant treatment. Induction of a depressive-like state characterized by anhedonia can also occur via changes intrinsic to the NAc, by weakening synapses onto NAc medium spiny neurons innervated by excitatory HC inputs. Our hypothesis predicts that restoring excitatory drive in this series of synapses will restore the normal affective state, and we show chronic administration of fluoxetine exerts this action. We predicted that negative allosteric

modulation of GABA receptors should also restore excitatory drive. Using behavioral, electrophysiological, and biochemical methods, two such compounds that target α5 subunit-containing GABA-A receptors, L-655,708 and MRK-016, promoted synchronous oscillatory activity between the HC and NAc, restored excitatory strength at TA-CA1 synapses, and restored normative behavior in social interaction and sucrose preference tests following a chronic stress paradigm, all within 24 hours of treatment. These data support an excitatory synapse hypothesis model in which depressive-like behavior is promoted by perturbing cortico-mesolimbic circuitry, and suggests novel therapeutic approaches that may be capable of rapid antidepressant effects by restoring pathologically weakened synapses within the circuit.

Title: Effects of bacterial translocation and intestinal decontamination on the inflammatory response induced by a depression model in rats

Authors: D. MARTIN-HERNANDEZ[1,2,3], A. G. BRIS[1], K. S. MACDOWELL[1,2,3], A. SAYD[1,2,3], S. R. MAUS[1,2,3], B. GARCIA-BUENO[1,2,3], J. L. M. MADRIGAL[1,2,3], L. ALOU[1], M. L. GOMEZ-LUS[1], J. C. LEZA[1,2,3], *J. R. CASO[1,2,3];

Abstract: Background and purpose: there is a pressing need to identify new pharmacological targets that can result in improved tools for the treatment of the major depression disorder (MDD). Recent studies suggested that MDD is accompanied by an increased intestinal

permeability which would be related to the inflammatory pathophysiology of the disease through bacterial translocation. Thus, we aimed to evaluate if the exposure of rats to a depression model (CMS: chronic mild stress) induced an inflammatory response, both in prefrontal cortex (PFC) and colon, and to test the effects of an intestinal decontamination protocol on both structures checking the possible bacterial translocation contribution to the inflammation. Material and methods: male Wistar rats (n=8/group) were used: a control group, a CMS group and a CMS group with intestinal decontamination (CMS+ATB). Intestinal decontamination protocol was based on oral administration of antibiotics, using antibiotics without direct anti-inflammatory actions. The behavior was analyzed by means of the Forced Swim Test (FST) and the Sucrose Intake Test (SIT). The presence of bacteria in mesenteric lymph nodes (MLNs), liver, spleen and blood was evaluated as well as the LPS plasma levels. To study the possible intestinal dysfunction caused by CMS exposure, we measured mRNA or protein levels of COX-2, iNOS, IgA, CCL28, ZO-1, occludine and M1-M2 polarization factors like t-bet and STAT3. In the brain, we studied the mRNA and/or protein levels of TLR-4, phosphorylated (activated) forms of MAPK p38, ERK1/2 and JNK, dual-specificity phosphatases (DUSPs) (MKP-1, PAC-1, MKP-3) and nuclear expression of AP-1, Nrf2 and PPAR-gamma. Results: the FST and the SIT indicate a depressive-like phenotype after CMS but not in the FST for the CMS+ATB group. There is a presence of bacteria in the MLNs, liver and spleen in the CMS experimental group but not in the CMS+ATB group. The CMS induces an intestinal dysfunction that is partially restored by intestinal decontamination. In the PFC, the pro-/anti- inflammatory dysbalance detected after CMS is partially restored in the CMS+ATB group. Conclusion: our data point out to a role of the intestinal bacteria in the pathophysiology of depression at intestinal and brain levels through MAPK pathways since intestinal decontamination restore some of the CMS effects. These results are in agreement with previous data showing that external stressors to the brain, such as the LPS from bacteria, could activate innate immune receptors aggravating the stress- induced neuroinflammation and the oxidative/nitrosative damage.

Title: Ketamine reduces prefrontal kynurenine levels in an animal model of treatment resistant depression

Authors: J. B. PRICE[1], L. SCHWIELER[3], M. FRYE[1], C. SELLGREN[3], S. ERHARDT[3], *S. J. TYE[2];

Abstract: Ketamine is a rapid acting antidepressant, effective in a subset of patients with treatment-resistant depression. We have previously demonstrated that treatment response to ketamine is associated with elevated proinflammatory C-reactive protein levels in plasma of antidepressant resistant rats pre-treated with adrenocorticotopic hormone (ACTH). The present study aimed to extend this model through combinatorial administration of ACTH and lipopolysaccharide (LPS) and determine the relationship between ketamine response in these animals and levels of kynurenines in the prefrontal cortex (PFC). In this protocol, rats were administered ACTH (100ug/day over 14 days) and LPS (750-1250 ug/kg over three days). Rats were subjected to sucrose preference test every other day throughout the protocol, as well as open field test and forced swim test. Results demonstrate that ketamine (10mg/kg) reduced immobility during the forced swim test in rats previously injected with LPS in combination with ACTH by a mean of 78.5 seconds ($p<.0001$; $n=8$). Validity of results was corroborated by the open field test, which indicated that immobility while swimming was not due to pre-existing motor deficit. Following behavioral tests, animals were humanely euthanized and brains were frozen on dry ice. The PFC was dissected and high performance liquid chromatography was performed to examine changes in kynurenic acid and kynurenine. Levels of kynurenic acid were significantly reduced in the PFC of animals pre-treated with ACTH+LPS following ketamine administration ($p<.01$; $n=10$). However, no difference was observed between ketamine responders ($n=7$) and non-responders ($n=3$) in this effect. Similarly, levels of kynurenine were significantly reduced in the PFC of animals pre-treated with ACTH+LPS following ketamine administration ($p<.01$; $n=5$) in animals deemed ‘responders’ only. These results suggest that ketamine is an effective antidepressant in an inflammation- and chronic stress-based depression model and indicate it functionally reduces prefrontal kynurenine levels in these animals.

Title: A molecular target connecting obesity and anxiety/depression

Authors: *Z. T. QIN[1,3], X. ZHOU[3], C. CHANG[3], A. HARI[3], A. F. R. STEWART[2,4], H.-H. CHEN[1,3];

Abstract: Emerging evidence implicates a bidirectional link between obesity and anxiety/depression. However, the mechanism remains a mystery in the diseased brain. Abnormal endocannabinoid signaling and dysfunction of hypothalamus-pituitary-adrenal axis (HPA) axis are believed to lead to obesity and depression. Inhibition of protein tyrosine phosphatase 1B (PTP1B) suppresses appetite and restores the glucose and lipid metabolism. Our study (Neuron, 2015) shows that PTP1B inhibition also attenuates stress-induced suppression of eCB signaling and anxiety. This study will focus on whether and how PTP1B-sensitive pathways are associated in this bidirectional link of obesity and depression in the HPA axis. Biochemical, electrophysiological and behavioral assessment will provide the evidence under genetic or pharmacological manipulation in the high-fat diet induced obese mice and other obese/diabetic animal models. The discoveries will suggest potential therapeutic targets to treat both metabolic and emotional disorders.

Title: The antidepressant potential of tumor necrosis factor (TNF) alpha antagonists

Authors: *K. BRYMER, J. BOTTERILL, M. MITCHELL, H. CARUNCHO, L. KALYNCHUK;
Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Exposure to stressors frequently precedes the onset of depression in human patients. Accordingly, many preclinical rodent models of depression make use of chronic exposure to stress or glucocorticoids to induce a depressive phenotype. Furthermore, chronic exposure to stress promotes the release of cytokines, which in turn exacerbate the stress response and disrupt cognition. Prominent among these is the cytokine TNF-alpha, which is preferentially expressed in the hippocampus and pre-frontal cortex. We hypothesized that treating chronically-stressed rats with drugs that block the action of TNF-alpha could have antidepressant effects. In this experiment, we examined the effect of repeated corticosterone (CORT) treatment and concurrent TNF-alpha antagonism (i.e., with Enbrel) on cross-modal memory and forced-swim test (FST) behavior. Additionally, we examined object-location and object-in-place memory--tasks that are dependent on the hippocampus and pre-frontal cortex, respectively. Previous work in our lab has demonstrated that repeated CORT injections induce deficits in both object-location and object-in-place memory, however no research has examined CORT's effects on cross-modal memory. Rats received either 21 days of daily CORT injections (40 mg/kg) or vehicle injections, in addition to semi-weekly injections of Enbrel (0.8 mg/kg) or vehicle, with behavioral testing commencing on day 22. CORT increased immobility in the FST and impaired both object-location and object-in-place memory. These effects were also reversed by concurrent treatment with Enbrel. CORT also produced mild impairments in cross-modal memory, and these mild impairments were also reversed by Enbrel. These novel results show that the TNF-alpha antagonist Enbrel can have antidepressant effects in a preclinical animal model of depression. We suggest that this may occur through a restoration of function in the hippocampus and prefrontal cortex.

Title: Ketamine modulates the dopamine system in zebrafish(danio rerio) larvae

Authors: *S. F. ALI, B. L. ROBINSON, M. DUMAS, E. CUEVAS, M. G. PAULE, J. KANUNGO;
Neurochemistry Lab, Div. of Neurotoxicology, Natl. Ctr. Toxicological Res/Fda, Jefferson, AR

Abstract: Ketamine, an antagonist of the N-methyl-d-aspartate (NMDA)-type glutamate receptors, is a pediatric anesthetic. Ketamine reduces tyrosine hydroxylase (TH) levels in mammals. A number of studies show that ketamine is neurotoxic in mammals and zebrafish. In mammals, ketamine is known to modulate the dopaminergic system. Since zebrafish embryos and larvae are an ideal model system in which to assess drug toxicities, we measured the levels of dopamine (DA) and its metabolites, 3, 4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), in zebrafish larvae exposed to various doses of ketamine using HPLC/EC. Ketamine, at doses equivalent to human sub-anesthetic doses (0.1 - 0.3 mM in water), did not produce significant changes in the DA, DOPAC and HVA levels in 2-day old larvae treated for 20 h. In these larvae, TH mRNA expression remained unchanged compared to that in controls. However, 2 mM ketamine (internal exposure equivalent to the lower range of the human anesthetic dose) significantly reduced DA but not DOPAC level indicating that DA synthesis was adversely affected. Quantitative real-time polymerase chain reaction (qRT-PCR) analysis showed that, in these larvae, TH mRNA expression was significantly reduced. These results indicate that ketamine's dose-dependent effects on dopamine synthesis and TH transcription differentiate its sub-anesthetic and anesthetic doses and may be correlated with ketamine-induced neurotoxicity observed in the zebrafish early life stages.

Title: Behavioral interactions between nmda receptor antagonists and antidepressants in rats

Authors: *J. A. TEMPLE, K. A. TRUJILLO, A. ROCHA, T. ZAFAR;
California State Univ. San Marcos, San Marcos, CA

Abstract: A primary pharmacological action of traditional antidepressants is to block reuptake of monoamines, however, many patients are resistant to these medications. Desipramine is a tricyclic antidepressant medication and acts by blocking norepinephrine reuptake. Ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist, has been shown to have promising antidepressant effects in humans, including individuals resistant to currently available medications. However, because ketamine produces significant side-effects and is abused by some individuals, it is unlikely to replace traditional antidepressants. It is therefore important to better understand ketamine's antidepressant effects and develop alternatives. Past work in our laboratory, and others, has demonstrated that the combination of an NMDA receptor antagonist with a traditional antidepressant produces a profound increase in the locomotor stimulant effect of the NMDA antagonist. This suggests a strong neurochemical interaction between classical antidepressants and NMDA receptor antagonists. In the present study we examined the locomotor effects of ketamine in combination with desipramine (DMI) in Sprague Dawley rats. We hypothesized that a combination of ketamine and DMI would produce a stimulation of activity greater than either drug alone. Ketamine alone produced a short-lived stimulation of locomotor activity at both 10 mg/kg and 30 mg/kg. DMI (2.5 mg/kg) alone produced a slight locomotor depression compared to the saline control group and mildly inhibited the locomotor stimulant effect of ketamine at both doses. It is currently unclear why the combination produced effects different from those seen with other NMDA receptor antagonists, such as MK-801. We are investigating potential explanation for these unexpected results.

Title: Lack of effects of ketamine on the mTOR pathway in rats

Authors: S. POPP[1], M. M. VAN GAALEN[2], A. BESPALOV[1], *B. BEHL[1];
[1]AbbVie Deutschland GmbH & Co.KG, Ludwigshafen, Germany; [2]Encepharm, Goettingen, Germany

Abstract: A single dose of ketamine produces a robust antidepressant response within hours after infusion that lasts for a week or even longer in some patients. Recently, Li et al. (Science, 239: 959-64, 2010) suggested that the rapid antidepressant effects of ketamine are mediated by activation of the mTOR pathway associated with a rapid and sustained elevation of synapse-associated proteins and spine numbers in the prefrontal cortex (PFC). We attempted to reproduce these results following the methods described in the Li paper. We subjected male Sprague-Dawley rats to a forced swim test and assessed the effects of ketamine on both the mTor pathway and the latency to immobility as a measure of antidepressant-like effects. After a single i.p. application of 10 or 30 mg/kg, ketamine did not influence levels of phosphorylated forms of mTOR, p70S6K and S6 ribosomal protein in the prefrontal cortex (1 h post-injection) or synaptic proteins (Synapsin I, PSD95 and GluR1), the translation of which is controlled by the mTOR pathway (3 h post-injection). Meanwhile, ketamine produced a dose-dependent increase in latency to immobility in the rat forced swim test, an effect that could be dissociated from the ability of ketamine to enhance locomotor activity in the open field. To further validate the protocols used to assess changes in the mTor pathway, we demonstrated that rapamycin (10 or 25 mg/kg i.p.) administered for 8 days strongly inhibited the phosphorylation of the S6 ribosomal protein. Thus, despite using the protocol maximally close to that described by Li et al. as well as trying multiple variations of this protocol we were unable to reproduce previously published activation of the mTOR pathway by ketamine. *Disclosures: All authors are/were employees of AbbVie. Title: Different classes of antidepressants produce divergent effects in the open space swimming test in the mouse

Authors: *V. CASTAGNÉ, C. LANDEMAINE, V. LÉON;
Porsolt S.A.S., Le Genest-saint-Isle, France

Abstract: The open space swimming test (OSST) is considered a potential model for the assessment of chronic treatment with antidepressants and it is based on the use of repeated sessions of forced swimming. During the OSST, mice progressively develop a passive behavior (observed as low distance swum and long duration of immobility), which stabilizes with the repetition of swimming sessions. The present study evaluated the effects of different classes of antidepressants in the OSST. Male NMRI mice were submitted to 15-minutes swimming sessions during which their behavior was video recorded. The distance swum and the time spent immobile were analyzed by video-tracking during test sessions. Swimming sessions were performed daily from Day 1 to Day 5 in order to induce a stable passive behavior in animals before any pharmacological treatment. Thereafter, swimming sessions were performed at 3 or 4 days intervals. Daily intraperitoneal treatments were administered starting on Day 8 and continued until the end of the experiments. During the first swimming sessions, mice progressively developed a passive behavior, as reflected in shorter distance swum and a longer duration of immobility on Day 5, as compared with Day 1. Thereafter, passive behavior remains stable in vehicle control mice. Antidepressants acting mainly on norepinephrine (NE) neurotransmission such as imipramine or desipramine reverse this passive behavior. In particular, imipramine (30 mg/kg i.p.) clearly increases the distance swum and decreases the duration of immobility ($p < 0.001$ on all testing days). In contrast, Serotonin Selective Reuptake Inhibitors (SSRIs) such as fluoxetine and escitalopram, aggravate the passivity of the animals. Several experiments confirmed these observations after both acute and chronic treatment with the different classes of substances. Finally, mice initially treated with escitalopram for a period of 2 weeks and then treated with desipramine for an equivalent period display a biphasic change in passive behavior (an increase induced by escitalopram followed by a decrease in passivity induced by desipramine, as compared with vehicle controls). The OSST and the forced swimming test (FST) therefore seem able to detect opposite effects of different classes of antidepressants in the mouse. Our data suggest that the repeated but predictable swimming stress during OSST induces a passive behavior which can be either reversed or further accentuated by substances increasing NE or 5-HT neurotransmission, respectively. In contrast, all classes of antidepressants tend to reverse the passive behavior induced by the acute but non-controllable swimming stress in the FST.

Title: Sex differences in the abuse potential of low-dose ketamine

Authors: *K. J. SCHOEPFER[1], C. E. STRONG[1], S. K. SALAND[1], A. M. DOSSAT[1], F. JOHNSON[2], M. KABBAJ[1];
[1]Dept. of Biomed. Sci., [2]Dept. of Psychology, Florida State Univ., Tallahassee, FL

Abstract: In clinical studies, low subanesthetic doses of the noncompetitive NMDA receptor antagonist ketamine (KET) have been shown to produce rapid (within hours) and long-lasting (up to 2 weeks) antidepressant effects in treatment-resistant patients. Interestingly, more recent clinical studies have demonstrated that the antidepressant effects of ketamine can be maintained over much longer periods of time if the drug is administered repeatedly. This may be problematic because ketamine in high doses is known to have addictive properties and is recreationally abused. Therefore, more studies delving into the safety of repeated infusions of low doses of ketamine are warranted. We have recently reported that female rats are more sensitive than males to KET's antidepressant-like effects, responding to 2.5 and 5.0 mg/kg (i.p.), respectively, and therefore aimed to determine whether there are also sex differences in the addictive properties of repeated low-dose KET treatment. We thus assessed the rewarding properties of repeated low-dose KET (0, 2.5, or 5.0 mg/kg, i.p.) in adult male and female Sprague-Dawley rats. We found that regardless of sex, dose, or treatment frequency, rats did not develop a conditioned place preference for low-dose KET, suggesting repeated KET treatment at therapeutically-relevant doses is not rewarding. We also assessed behavioral sensitization to the locomotor-activating effects of KET. We found that both male and female rats sensitized, and that their responses at 2.5 and 5 mg/kg KET depended on the frequency (every other day vs. weekly) of treatment injections. The behavioral outcomes of the sensitization experiments in both sexes were consistent with changes in the expression of markers of synaptic plasticity and dendritic spine densities in the nucleus accumbens. Taken together, these findings suggest that repeated low-dose KET treatments can induce behavioral and physiological changes similar to changes induced by other drugs of abuse and high doses of ketamine. Therefore, more studies like this are

warranted to determine the safety of repeated low-dose KET treatment for treatment-resistant depression.

Title: Antidepressant activity of rose oil in Wistar Kyoto rats

Authors: *K. LOK, S.-T. LI;
Bio-X Inst., Shanghai Jiao Tong Univ., Shanghai, China

Abstract: Objective: Depression is one of the most common psychiatric disorder that results in significant consequences in many countries. Clinicians managing depressed patients face two challenges: First, some antidepressants' therapies are associated with a variety of side effects. Second, longer time are needed for some antidepressants to work effectively. Such consequences cause medication non-adherence and discontinuation. In traditional manuscripts there are many indications about the anxiolytic effects of rose oil, and toxicity rarely occurs with appropriate use of essential oils. So far, however, less scientific research have been done about antidepressant effect of essential oil, even though this is one of the most commonly used aromatherapy. The purpose of present study was to determine the effects on depression like behaviors and underlying mechanisms of inhaled rose essential oil. **Methods:** All experiments were carried out on 6 weeks old male Wistar Kyoto (WKY) rats. Rats were allowed to inhale rose essential oil's-, or its principal constituent β-Citronellol oil's vapors for 2 weeks (7 hours/day) in a special cage prior to performing the behavioral tests. Control animals were caged in the same conditions but in the absence of the tested oils. Locomotor activity of animals were measured by total distance travelled in open field test (OFT). The antidepressant activities of rose oil and β-Citronellol were assessed using the forced swim test (FST). Proteomic analysis using an isobaric tag for relative and absolute quantitation (iTRAQ) and tandem mass spectrometry was performed to identify differentially expressed proteins in the hippocampus of different groups. Then, some of the depression-related proteins were followed-up simultaneously in qRT-PCR, western blot, and immunohistochemistry assays. **Results:** No significant alterations of locomotor activity in OFT were detected in oil-inhaled WKY rats. While significantly reduced immobile time (I.T) in FST

were observed in WKY rats after rose- or β-Citronellol oil-treatments. Using the iTRAQ-approach, 26 differentially regulated proteins were identified in β-Citronellol treated WKY rats. We further analyzed the changes of protein expression levels by western blotting and immunohistochemistry methods. **Conclusion:** The results showed that inhalation of rose or β-Citronellol essential oils possess antidepressant-like effects, suggesting that it is a simple, low-risk, and cost effective interventions of depression.

Title: Potential neurophysiological signals tracing antidepressant effects of glutamate receptor antagonists

Authors: *D. NAGY[1], M. STOILJKOVIC[1], F. MENNITI[2], M. HAJOS[1];
[1]Yale Univ., New Haven, CT; [2]Mnemosyne Pharmaceuticals Inc., Providence, RI

Abstract: Ketamine is a non-competitive NMDA receptor channel blocker with rapid onset antidepressant effects. Clinical observations in depressed patients responding to ketamine suggests that efficacy results from synaptic potentiation, indexed as an increase in sensory evoked potentials, after the drug is eliminated (Cornwell et al., 2012). However, ketamine also causes a psychotomimetic response tightly linked to drug exposure. An open question is the mechanistic relationship between the 'Drug-On' psychotomimetic and 'Drug-Off' antidepressant effects. To investigate this, we compared Drug-On and Drug-Off effects of ketamine with an NR2B-selective NMDA antagonist, CP-101,606, that also has rapid onset antidepressant efficacy. Aims were 1) model ketamine-induced, Drug-Off increases in sensory evoked potentials, 2) determine whether CP-101,606 had similar effect, and 3) compare the Drug-On effects to gain insight into which of these may account for the Drug-Off effects. The effects of ketamine (5, 10 and 80 mg/kg) and CP-101,606 (2, 6.7 and 20 mg/kg, sc) were determined on auditory evoked potentials (AEPs), auditory gating and local field potentials in hippocampal CA3 and primary auditory cortex in freely-moving rats. Neurophysiological responses were analyzed at 5-30 min when drug exposures were maximal (Drug-On) and 5-6 hours, after drugs

were eliminated (Drug-Off). Ketamine Drug-On dose-dependently disrupted auditory gating and increased delta and gamma band power, and at the high dose reduced AEP amplitude in the hippocampus and cortex. Effects were attenuated or absent in Drug-Off phase. Importantly, the predicted antidepressant dose of ketamine (10 mg/kg, sc) significantly enhanced AEPs in cortex and hippocampus in the Drug-Off phase. Similar to ketamine, CP-101,606 significantly enhanced AEPs in cortex and hippocampus in Drug-Off period. However, CP-101,606 Drug-On did not disrupt auditory gating or alter gamma or delta oscillations. Our findings show that both ketamine and CP-101,606 augment AEPs during Drug-Off phase, consistent with a possible mechanism for antidepressant efficacy. CP-101,606 was distinctively different from ketamine during Drug-On phase since it did not disrupt auditory gating or alter gamma and delta oscillations. Thus, antidepressant efficacy of NMDA receptor inhibition may arise from a mechanism distinct from that causing the Drug-On effects of ketamine, which may be linked to psychotomimetic effects. Furthermore, sensory evoked potentials may serve as potential translational biomarkers of antidepressant efficacy applicable to developing drugs targeting glutamatergic neurotransmission.

Title: Comparison of variables associated with postpartum depression in adolescent and adult women with low socioeconomic status in the southeast of Mexico

Authors: *H. A. RUBIO-ZAPATA[1], D. F. ESTRELLA-CASTILLO[2], P. AGUILAR-ALONSO[3], K. B. OJEDA-TORRES[4];
[2]Rehabil., [1]Facultad De Medicina- UADY, Merida Yucatan, Mexico; [3]Chem. Sci. Fac., BUAP, Puebla, Mexico; [4]Hosp. Materno Infantil, Secretaría de Salud, Merida, Mexico

Abstract: Postpartum depression (PPD) is a pathological mood disorder that usually occurs between the first 6-8 weeks after birth, it is common to confuse the emotional disorders of pregnancy, so diagnosis may be overlooked. However diminishes the quality of life of the patient and affects the health of mother and child. Its origin is multifactorial so its incidence and prevalence vary widely. Low socioeconomic status has been reported as a risk factor for presenting PPD, which is why the objective of this study was to compare the epidemiological characteristics of adult and adolescent women with PPD treated at a public hospital for poor people in Mexico Yucatan. A comparative study involving 110 adult women and 110 adolescents randomly selected, attended by vaginal delivery in the maternity hospital in Merida, Yucatan, during July and August 2014. All participants answered the Spanish Version of the Scale Edinburgh Postnatal Depression, an epidemiological questionnaire and AMAI scale to determine socioeconomic status. No patients with difficult births or cesarean sections, or with known mental illness or treated with psychotropic drugs were included. Results: The age of adult women was 25.35 ± 4.84 years and 17.6 ± 9.9 in adolescent. The frequency of postpartum depression in adults was 21%, while in adolescents was 13%. The average value of the scale of Edinburgh was 13.19 ± 0.6 for adults and 13.77 ± 1.6 for adolescents with PPD (t-Student p = 0.67). The associations significant with DPP were: adult (chi2, p = 0.027), unemployed and adult (p = 0.001), physical abuse and adult (p= 0.02) and single-teen (P = 0.004), there was no association with the other variables: schooling, sexual abuse, parity, contraceptive use, unwanted pregnancy, unplanned pregnancy, number of sexual partners, product weight, and others. In conclusion adult women had higher frequency of PPD than adolescents. The PPD was associated with abuse, unemployment, and being single. The factors associated with PPD were different between adults and adolescents with low socioeconomic status in the southeast of Mexico

Title: Chronic treatment with antidepressants enhances dopamine D1 receptor signaling in the hippocampal dentate gyrus

Authors: *M. KUROIWA[1], T. SHUTO[1], N. SOTOGAKU[1], Y.-S. OH[2], A. NISHI[1];
[1]Kurume Univ. Sch. of Med., Kurume, Fukuoka, Japan; [2]the Rockefeller Univ., New York, NY

Abstract: Major depression is a psychiatric disorder with high lifetime prevalence. Antidepressants have been widely used to treat major depression, although the mechanisms underlying their therapeutic effects are not fully understood. Hippocampal dentate gyrus (DG) is one of target brain regions for antidepressants. Recently, chronic treatment with a selective serotonin reuptake inhibitor, fluoxetine, is reported to induce functional changes of mature granule cells in the hippocampal dentate gyrus, in addition to the facilitation of adult neurogenesis. The mature granule cells affected by chronic fluoxetine treatment show a decrease in expression of calbindin, a marker of mature granule cells, and an increase in expression of dopamine D1 receptors (Kobayashi et al., 2010). In this study, we investigated the expression profile and function of dopamine D1 receptors in the dentate gyrus after chronic antidepressant treatment. Treatment of mice with fluoxetine (15 mg/kg/day) for 14 days increased the expression of D1 receptors, but not other subtypes of dopamine receptors, in mRNA and protein levels only in the DG. Immunohistochemical analysis in Drd1a-EGFP mice revealed that the expression of D1 receptors is mainly induced in NeuN and calbindin-positive granule cells. The ability of a D1 receptor agonist, SKF81297, to phosphorylate DARPP-32 at Thr34 (PKA-site) in DG slices was enhanced in fluoxetine-treated mice. These results suggest that chronic treatment with fluoxetine induces the up-regulation of D1 receptor signaling in the DG, which may contribute to therapeutic action of antidepressants.

Title: Effect of the antidepressant agomelatine on the inflammatory response induced by lipopolysaccharide: a genome-wide study in the rat ventral hippocampus

Authors: A. C. ROSSETTI[1], M. S. PALADINI[1], G. RACAGNI[1], M. A. RIVA[1], A. CATTANEO[2,3], *R. MOLTENI[1];
[1]Univ. of Milan, Milan, Italy; [2]IRCCS Ctr. San Giovanni di Dio - Fatebenefratelli, Brescia, Italy; [3]Inst. of Psychiatry - King's Col. London, London, United Kingdom

Abstract: Growing evidence suggests that the activation of the immune/inflammatory system may be associated with depression pathogenesis and, in line with this observation, several studies mainly focused on pro-inflammatory cytokines reported that antidepressant drugs have immunoregulatory effects. However, given the complexity of the inflammatory response, which implies the integration of different mechanisms triggered by various systems, the aim of the present work was to assess the anti-inflammatory properties of the antidepressant agomelatine with an unbiased genome-wide approach by using the microarray technique. Specifically, we analysed the gene expression profile of the ventral hippocampus, a cerebral area relevant for depression, of adult rats chronically treated with the antidepressant before to receive a systemic injection of lipopolysaccharide (LPS) in comparison with animals treated with saline. To this aim, adult male Sprague-Dawley rats received agomelatine or vehicle for 21 days before being challenged with an acute injection of LPS or saline 16 h after the last drug administration. Animals were sacrificed 2 h after the immune challenge and the ventral hippocampus was dissected and processed for RNA extraction. Transcriptomic analysis was performed using Affymetrix® Array and the results were analyzed with Partek Genomics Suite and with Ingenuity Pathway Analyses software. We found that LPS administration induced the transcription of 284 genes mainly associated with pathways related to inflammation. Conversely, chronic treatment with agomelatine alone modulated 105 transcripts belonging to different pathways in saline-treated rats, like the phospolipase C and the CXCR4 pathways. Moreover, the drug was able to prevent the LPS-induced modulation of 91 genes with respect to the control group and of 52 genes with respect to animals treated only with LPS. An intersection analysis between these two lists of genes led to the identification of some transcripts induced by LPS on which agomelatine has the larger effect of normalization. In summary, by using a genome-wide approach, we have highlighted the transcriptional profile of a chronic treatment with agomelatine both at basal state -identifying genes and pathways related to the basal effects of the antidepressant- and in condition of acute inflammation - identifying genes and pathways associated to its anti-inflammatory properties. These genes/pathways might represent potential new targets for pharmacological intervention of depression associated to inflammation.

Title: Impact of vortioxetine on spontaneous and afferent-driven spike activity recorded in the rat ventral striatum/nucleus accumbens

Authors: ***S. CHAKROBORTY**[1], E. DALE[2], A. L. PEHRSON[2], C. SANCHEZ-MORILLO[2], A. R. WEST[1];
[1]Neurosci., Rosalind Franklin Univ., North Chicago, IL; [2]Lundbeck Res. USA, Inc., Paramus, NJ

Abstract: The novel antidepressant vortioxetine is currently used in the clinic to treat major depressive disorder. In addition to blocking serotonin (5-HT) reuptake via inhibition of the 5-HT transporter (SERT), vortioxetine is a $5HT_{1A}$ receptor agonist, $5HT_{1B}$ receptor partial agonist, and an antagonist at the $5HT_{1D}$, $5HT_3$, and $5HT_7$ receptors. Vortioxetine has been shown to enhance 5-HT transmission in the prefrontal cortex (PFC) and can potentially affect 5-HT signaling in other brain regions, such as the ventral striatum/nucleus accumbens (VS/NAc) which also play key roles in the control of motivated behaviors. Thus, the current study utilized both between- and within-subjects designs to examine the impact of systemic vortioxetine (0.8 mg/kg, i.v.) administration on spontaneous and PFC-evoked spike activity of electrophysiologically identified VS/NAc medium-sized spiny projection neurons (MSNs) recorded in urethane-anesthetized rats. In between-subjects studies, following vortioxetine administration (10-60 min), VS/NAc MSNs exhibited decreases in both the probability and onset latency of PFC-evoked spikes. No significant effects of vortioxetine on spontaneous firing activity were apparent. The vortioxetine-induced decrease in the onset latency of PFC-evoked spikes was also replicated in within-subjects studies in which MSNs were recorded prior to, and up to 40 minutes after, drug administration. Vortioxetine administration also induced a substantial decrease (>50%) in the magnitude of PFC-evoked spike activity observed following train stimulation of the hippocampal

fimbria as compared to pre-drug controls. Taken together, the current studies indicate that vortioxetine is likely to exert complex modulatory effects on prefrontal corticoaccumbens pathways and the responsiveness of VS/NAc MSNs to excitatory inputs from the hippocampal fimbria. Future studies assessing the impact of this multimodal serotonergic compound on PFC neuron activity and local feed-forward inhibitory processes in prefrontal corticoaccumbens pathways may reveal novel strategies for treating disorders of motivated behavior.

Title: Ketamine promotes electrophysiological and biochemical alterations in the glutamatergic transmission in the dorsal raphe

Authors: N. LLAMOSAS[1], L. PEREZ-CABALLERO[2,3], *E. BERROCOSO[2,3], L. UGEDO[1], M. TORRECILLA[1];
[1]Pharmacol., Univ. of the Basque Country UPV/EHU, Faculty of Medicine, Spain; [2]Univ. of Cadiz, Cadiz, Spain; [3]Inst. de Salud Carlos III, Ctr. de Investigación Biomédica en Red de Salud Mental (CIBERSAM), Madrid, Spain

Abstract: Evidence demonstrates that administration of glutamatergic antagonists, and particularly ketamine, exert rapid antidepressant effects. The tight interactions between glutamatergic and monoaminergic systems and the shared actions between the classical and the novel antidepressants have been well-described. This gives rise to the possibility that ketamine

could exert its antidepressant effects by acting on monoaminergic areas, such as the dorsal raphe (DR). Here, we used electrophysiological and biochemical approaches to determine whether ketamine is altering the glutamatergic transmission and the mTOR pathway in the DR, besides promoting rapid antidepressant-like behaviors. In the tail suspension test we replicated the preclinical findings showing that ketamine (30 mg/kg, i.p.) has acute (30 min) and sustained (24h) antidepressant-like effects in mice. By using whole-cell patch-clamp recordings we observed that bath perfusion of ketamine (50 μM, 10 min) increased the frequency of sEPSCs in DR neurons. In addition, the AMPA receptor antagonist 6,7-dinitroquinoxaline-2,3-dione (DNQX, 10 μM) blocked this effect, and the NMDA receptor antagonist D-2-amino-5-phosphonopentanoate (D-AP5, 50 μM) failed to increase the frequency of sEPSC, showing that the observed ketamine-induced glutamate release involves AMPA, but not NMDA receptors. Furthermore, pre-incubation of the slices with the mTOR inhibitor PP242 (2.5 μM, 40 min) attenuated the effect of ketamine on sEPSC. However, when ketamine was administered 24 hours prior to the recordings, it produced no effects either in sEPSCs or eEPSCs, pointing out a functional difference between the acute and sustained effects of this drug in the DR. Finally, western blot experiments revealed that ketamine (30 mg/kg, i.p.) did not induce acute (30 min) phosphorylation of mTOR in the DR, whereas 24 hours after the injection ketamine increased the levels of the phosphorylated-active form of mTOR. Collectively, these results identify functional actions of ketamine on the glutamatergic transmission in the DR, and also reveal that the AMPA receptor-mediated electrophysiological “rapid onset” effects, which may trigger other functional/cellular effects, are not maintained in the DR 24 hours after the administration of ketamine.

Title: Age-dependent effects of chronic electroconvulsive seizure (ECS) treatment

Authors: ***M. JAGGAR**, S. GHOSH, V. A. VAIDYA;
Tata Inst. of Fundamental Res., Mumbai, India

Abstract: Electroconvulsive seizure (ECS) treatment is a fast-acting antidepressant treatment that is often the therapy of choice for depressed patients refractory to pharmacological antidepressants, as well as in cases of geriatric depression. While preclinical studies with ECS have identified several molecular, cellular and behavioral changes that arise following repeated seizure treatments, the underlying mechanisms of action for this treatment modality remain poorly understood. In animal models, ECS evokes a robust activation of several immediate early and plasticity-associated genes, enhances monoamine turnover, increases hippocampal neurogenesis, evokes axonal sprouting and dendritic reorganization, accompanied by robust effects on mood-related behavioral tasks. However, thus far the preclinical studies have been performed in young animals and have been presumed to evoke a similar constellation of changes as animals age into middle-aged life. The primary focus of our study was to examine the age-dependent effects of ECS by comparing the molecular, neurogenic, structural and behavioral effects evoked by ECS in young (2 month) and middle-aged (12 month) adult male Sprague-Dawley rats. Behavioral studies revealed that ECS evoked antidepressant-like behavioral responses on the Forced Swim Test in both young and middle-aged animals. Molecular studies profiling gene expression in the hippocampus thus far indicate that while regulation of trophic factors (bdnf, vegfa, fgf2) and immediate-early gene (arc, c-fos, egr-1-3) expression did not differ significantly in either the nature or the extent of regulation at the two ages examined, genes associated with the formation of perineuronal nets were differentially regulated by ECS in an age-dependent manner. Specifically, the expression of ncan, vcan, hapln1 and has2 were shown to be increased by ECS in middle-aged, but not in young adult animals. Interestingly, detailed gene expression analysis of autophagy associated genes (lc3a, becn1, atg4b, ulk1) showed a significant decrease in young adults, but not in middle-aged animals. Studies are currently underway to characterize age-dependent effects of ECS on neurogenesis, gene expression, perineuronal net architecture, cell death, mitochondrial function and signaling pathways. Our results suggest that the molecular and cellular effects of ECS on the hippocampus are age-dependent. This raises the intriguing possibility that distinct temporally dependent consequences may underlie the behavioral effects of ECS at the time points studied.

Title: Sex differences in the reinforcing properties of intermittent, low-dose ketamine

Authors: *K. N. WRIGHT, C. E. STRONG, M. KABBAJ;
Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Major depressive disorder (MDD) is a chronic debilitating disease that affects twice as many women as men. While antidepressants such as fluoxetine are only effective in a portion of patients, the N-methyl-d-aspartate (NMDA) receptor antagonist ketamine can rapidly reduce depressive symptoms in most treatment-resistant individuals for MDD as well as bipolar disorder, with multiple infusions prolonging the effect. Although ketamine has therapeutic value, chronic exposure to higher doses has well-documented abuse potential and detrimental health effects. Low-dose ketamine's abuse potential has not been thoroughly assessed, a growing concern especially for women who are not only more vulnerable to developing addiction than men, but also have higher comorbidity for drug addiction and MDD. Therefore in this study, we aimed to assess whether low doses of ketamine are reinforcing and whether there are sex differences in its reinforcing properties. To do this, we utilized intravenous self-administration (100 μg/kg/infusion, with 50 maximum infusions) in male and female rats. Intact cycling females self-administered ketamine only on days when they were in proestrus (when gonadal hormones are high) or diestrus (when hormones are low, determined by daily vaginal lavage), and males self-administered ketamine once every four days. This timeframe was used to mimic clinically relevant administration and to determine how cycling E2 and P4 influence the response to ketamine in females. Male rats maintain stable self-administration of this low dose on FR1, and we are currently investigating their behavior on FR2, FR5, and progressive ratio schedules of reinforcement. Rats will also undergo extinction followed by cue-induced and drug-primed reinstatement to determine if males and females are vulnerable to relapse, a major hurdle on the path to recovery from addiction. Additionally, since there is evidence of hormonal modulation of intracellular signaling in the reward pathway with psychostimulants, we will determine whether there are sex differences in the expression of molecular targets in the nucleus accumbens that are altered by ketamine self-administration. These markers include brain-derived neurotropic factor (BDNF), glycogen synthase kinase-3 (GSK-3), and delta FosB (ΔFosB). Taken together, this study helps to characterize the safety of low-dose repeated ketamine for the treatment of MDD.

Abstract: S 47445 is a potentiator of glutamate AMPA receptors possessing procognitive, neurotrophic properties and enhancing synaptic plasticity 1,2). Here, the anxiolytic/antidepressant-like effects of S 47445 were investigated in a mouse model of anxiety/depression based on chronic corticosterone administration. The contribution of hippocampal neurogenesis in these effects was also studied. Four doses of S 47445 (0.3-1-3-10mg/kg, per os, for 4 weeks) were assessed on different anxiety- and depression-related behaviors (the elevated plus maze (EPM), open field (OF), splash test (ST), forced swim test (FST), tail suspension test (TST) and fur coat state) as well as on hippocampal neurogenesis in comparison with chronic fluoxetine treatment (18 mg/kg/day, per os, for 4 weeks), a serotonergic antidepressant. Then, the anxiety/depression model was combined with a genetic ablation of hippocampal neurogenesis (GFAP-Tk model) and the neurogenesis dependence of the behavioural effects of chronic treatment with 10mg/kg of S 47445 was studied and Brain Derived Neurotrophic Factor levels were also measured in hippocampus. S 47445 at 3 and 10mg/kg reversed corticosterone-induced depressive-like state by increasing grooming duration and decreasing the immobility duration in TST and FST, respectively. The coat state's deterioration was reversed at all tested doses. Moreover, S 47445 significantly reversed the anxiety phenotype observed in OF and EPM, at 1mg/kg and at 1, 3, 10mg/kg, respectively. Significant effects were observed with fluoxetine for all these tests, excepted for the coat state in which it was inefficient. S 47445 also demonstrated significant neurogenic effects on proliferation, survival and maturation of hippocampal newborn neurons mainly at 3 and 10mg/kg. Interestingly, at these 2 doses, it significantly corrected corticosterone-induced deficits of dendrites arborisation by increasing both dendritic lengths and number of intersections. Finally, S 47445 had anxiolytic/antidepressant-like activity specifically in the novelty suppressed feeding test requiring adult hippocampal neurogenesis. The increase in hippocampal mature BDNF levels observed at 10mg/kg is one of the mechanisms of S 47445 mediating the adult hippocampal neurogenesis's increase. Altogether, the AMPA potentiator S 47445 displays robust antidepressant-anxiolytic-like properties after chronic administration through neurogenesis dependent/independent mechanisms and neuroplastic activities. S 47445 could have promising

therapeutic potential for the treatment of major depressive disorders or generalized anxiety disorders.

Title: Combinational antidepressant effects of glutamatergic agents

Authors: J. KLINE, K. BATTANI, *L. SEMKE, V. DURIC, L.-L. YUAN;
Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA

Abstract: Accumulating evidence suggests dysregulation of glutamatergic transmission in the brain is linked with depressive disorders. Ketamine, an antagonist of a subtype of glutamate receptors, exhibits fast-acting and long-lasting antidepressant effects in humans and in animal models. However, limitations of ketamine use as a long-term treatment, particularly its dissociative/psychotomimetic effects and abuse potential, highlight the need for alternative glutamatergic agents. D-serine, an endogenous NMDA receptor co-agonist, also targets glutamate transmission and has shown therapeutic potential in preclinical models of depression. Their opposing actions on the shared target (NMDAR) and the highly overlapped molecular signature evoked by ketamine and D-serine raises the possibility that their co-administration may diminishes adverse side effects of ketamine without compromising its antidepressant effectiveness. Immediately following intraperitoneal injection (< 1 min), ketamine (10 mg/kg) altered states of consciousness and induces motor incoordination in mice. Co-administration of D-serine significantly reduced the level of motor incoordination as quantified by the number of falls induced by ketamine. However, the antidepressant effects of ketamine did not appear to be compromised by D-serine as assessed in the forced swim test. In parallel with its behavioral influences, D-serine addition did not interfere with ketamine-activated signaling pathways at the 1-hour post injection time point; it actually enhanced ketamine's effects on key synaptic proteins at the 24-hour time point. These results support the notion that ketamine and D-serine may represent a more effective combination therapy than either one alone.

Title: Cell cycle regulation of the adult hippocampal progenitor cells in depression and by antidepressants

Authors: *P. PATRICIO, A. MATEUS-PINHEIRO, A. MACHADO-SANTOS, N. ALVES, M. MORAIS, J. BESSA, N. SOUSA, L. PINTO;
Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal

Abstract: Depression is a complex and multidimensional disorder affecting around 20% of the world population. Alterations in hippocampal dendritic morphology and cell proliferation/genesis are known to be involved in the pathophysiology of depression and in the actions of antidepressants (ADs). Indeed, decreased cell genesis and dendritic atrophy were detected in the hippocampus of depressed individuals, whereas ADs treatment prevented it. Previous genome-wide studies by our group disclosed differential molecular regulation by different classes of ADs in the hippocampal dentate gyrus (hDG) of the uCMS (unpredictable chronic mild stress) rat model of depression (Patrício et al., Neuropsychopharmacology, 2015). Following this study, the cell cycle mechanisms regulating hippocampal cell proliferation and cell genesis were investigated using *in vivo* (macrodissected hDG) and *in vitro* (rat hippocampal-derived neurospheres; NSP) approaches. UCMS animals presented a slight increase in the percentage of cells in G1 phase of the cell cycle. Accordingly, these cells had decreased expression levels of cyclin D1 compared to controls, whereas fluoxetine-treated animals reversed these levels to those of controls. To better characterize these responses, we used an NSP culture. This system allowed enriching our population in hippocampal-derived progenitor cells. Dexamethasone (DEX; glucocorticoid (GC) receptor agonist; 1 μM) and corticosterone (CORT; hormone that activates both GCs and mineralocorticoid receptors; 1 μM) were applied to the NSP for 6 days, to mimic the effects of GCs elevation in the brains of depressed individuals and animal models of depression. Moreover, neurotransmitters involved in the action of monoaminergic ADs (norepinephrine and serotonin) were applied to the DEX/CORT-treated cells, in the last 4 days of culturing. PI staining was used for cell cycle distribution assessment by flow cytometry. A G1 phase arrest was detected in the DEX-treated cells. Addition of neurotransmitters to the cells partly reversed this arrest. The expression of G1 phase cyclin-dependent kinase inhibitors p21 and p27 was significantly increased in the DEX-treated cells. Interestingly, two other atypical cell cycle regulators, Cdk5 and its activator p35, were increased by DEX exposure. These results suggest a mechanism for the regulation of hDG progenitor cells proliferation upon glucocorticoids increase. Studies are now being conducted to further elucidate the role of these and other cell cycle molecules in the regulation of proliferative phenomena implicated in the pathophysiology of depression and AD treatment.

Title: Adjunctive treatment of brexpiprazole with fluoxetine can improve depression-like behaviors and dendritic changes after inflammation

Authors: M. MA[1], Q. REN[1], N. YOSHIMI[2], Y. OHGI[2], T. FUTAMURA[2], *K. HASHIMOTO[1]; [1]Chiba Univ. Ctr. Forensic Men Hlth., Chiba, Japan; [2]Otsuka Pharmaceut. Ltd, Tokushima, Japan

Abstract: Substantial clinical data support the addition of low doses of atypical antipsychotic drugs to selective serotonin reuptake inhibitors (SSRIs) to rapidly enhance the antidepressant effects in treatment-resistant patients with major depressive disorder (MDD). Brexpiprazole, a novel serotonin-dopamine activity modulator, was developed to offer efficacious and tolerable therapy for schizophrenia and adjunctive treatment of MDD. The purpose of the present study is to examine whether brexpiprazole could enhance antidepressant-like effects of the SSRI fluoxetine in depression-like behaviors and spine density in mice after the administration of lipopolysaccharide (LPS). Twenty two hours after the administration of LPS (0.5 mg/kg) or saline, vehicle, fluoxetine (10 mg/kg), brexpiprazole (0.1 mg/kg), or fluoxetine (10 mg/kg) plus brexpiprazole (0.1 mg/kg) were administered orally. Behavioral tests, including locomotion, tail suspension test (TST) and forced swimming test (FST), were performed 2-hr, 4-hr, 6-hr after drug administration, respectively. Administration of these drugs did not alter the locomotor activity in mice treated with LPS. In the TST and FST, fluoxetine or brexpiprazole alone did not alter the increased immobility time in mice treated with LPS. In contrast, combination of fluoxetine with brexpiprazole significantly decreased the increased immobility time in mice treated with LPS. Furthermore, LPS caused a reduction of spine density in prefrontal cortex (PFC), CA3 and dentate gyrus (DG) of the hippocampus, whereas LPS increased spine density in the nucleus accumbens (NAc). Although fluoxetine or brexpiprazole alone did not affect alterations in spine density in PFC, CA3, DG, and NAc after LPS administration, combination of fluoxetine with brexpiprazole significantly reversed LPS-induced alterations in the spine density in PFC, CA3, and DG. These results suggest that the combination of fluoxetine and brexpiprazole shows antidepressant-like effect in an inflammation model of depression, and that the effect may be related to enhance synaptogenesis in the PFC, CA3, and DG of hippocampus, but not NAc.

Title: Rapid sex- and hormone-dependent changes in signaling pathway activation and protein levels in the hippocampus following low-dose ketamine administration: a phosphoproteomics approach

Authors: *S. K. SALAND[1], R. K. SINGH[2], R. MERCER[2], T. T. LAM[3], K. WILCZAK[3], M. KABBAJ[1];
[1]Dept. of Biomed. Sci. & Program in Neurosci., [2]Translational Sci. Lab., Florida State Univ., Tallahassee, FL; [3]Dept. of Mol. Biophysics and Biochemistry, W.M. Keck Fndn. Biotech. Resource Lab., Col. of Medicine, Yale Univ., New Haven, CT

Abstract: Considerable sex bias in the risk for depression is well-established. Extending beyond prevalence and presentation, sex differences in antidepressant efficacy have also been identified that point to a role for gonadal hormones in moderating treatment response. Despite its clear importance, the precise nature of hormonal influence on antidepressant efficacy is unclear and understudied. We recently reported that female rats are more sensitive to the fast-acting antidepressant ketamine when compared to male rats, and that gonadal estrogen (E2) and progesterone (P4) are required for this heightened response. However, the mechanisms underlying this sex-dependent sensitivity to ketamine's antidepressant-like effects remain elusive. Therefore, a phosphoproteomics approach was used to identify ketamine-induced changes in signaling pathway activation and protein abundance within the dorsal hippocampus (dHPC) of intact adult male rats and female rats in either diestrus (low E2 and P4) or proestrus (high E2 and P4) stages of their estrous cycle. Tissue was collected 30 minutes following saline or an acute low dose (2.5 mg/kg) of ketamine that is behaviorally ineffective in male rats, after which total and TiO2-enriched phosphopeptide lysates were prepared and processed via high-resolution liquid chromatography-tandem mass spectrometry (LC-MS/MS) using the LTQ Orbitrap Velos. Collected LC-MS/MS data were processed and quantified (by label-free approach), and proteins identified with Progenesis QI software and MASCOT Search Engine,

respectively. Pathway and gene ontology analyses were utilized to determine how changes in protein abundances and patterns of protein phosphorylation could selectively be altered by low-dose ketamine in female as compared to male rats. Results revealed striking dissimilarities in the dHPC proteome and phosphoproteome of male and female rats both at baseline, and following low-dose ketamine treatment. Notably, these differences were heavily influenced by hormonal status in female rats. Together, these data suggest that both biological sex and the hormonal milieu are critical modulators of ketamine's rapid actions within this brain region, and provide greater insight into potential translational and post-translational processes underlying sex- and hormone-dependent modulation of ketamine's therapeutic effects. Immunohistochemical and functional studies are underway to identify region-specific changes in and functional relevance of identified proteins and pathways of interest.

Title: Ovarian hormones impart resilience against chronic stress and modulate the effects of fluoxetine on hippocampal plasticity

Authors: *R. MAHMOUD[1,2], S. R. WAINWRIGHT[1,2], J. A. CHAITON[1], S. E. LIEBLICH[1], L. A. M. GALEA[1,3,4];

Abstract: Depression is more prevalent in women than in men, and sex differences are reported in the ability of antidepressants to alleviate symptom of depression. These findings indicate a role for gonadal hormones in the disease pathoetiology and the mechanisms underlying antidepressant efficacy. The present study investigated the effects of long-term ovarian hormone deprivation on the development of depressive-like endophenotypes and on antidepressant efficacy in female Spague-Dawley rats. Six months following ovariectomy (OVX) or sham surgery, all rats were subjected to 6 weeks of chronic unpredictable stress (CUS); a paradigm

intended to induce depressive-like phenotypes in rodents. During the last 3 weeks of CUS, rats received daily injections of fluoxetine (FLX, 5 mg/kg) or vehicle. All rats were assessed on standard measures of anxiety-, depressive-, and anhedonia-like behaviours. Our findings demonstrate that long-term ovarian hormone deprivation increased passive behaviour in the forced swim test, increased latency to feed in the novelty suppressed feeding test, and decreased sucrose preference. Further, long-term OVX resulted in a reduced dexamethasone suppression of corticosterone release, suggesting that ovarian hormones protect against chronic stress-induced impairments in the glucocorticoid-dependent negative feedback system. Finally, although fluoxetine treatment lacked behavioural and neuroendocrine efficacy, it reduced hippocampal expression of the microglial marker Iba-1, and increased several markers of hippocampal plasticity (Ki67, BrdU, and PSA-NCAM) in a region-specific and ovarian status-dependent manner. Taken together, our findings demonstrate that ovarian hormones may impart resilience against the behavioural and neuroendocrine consequences of chronic unpredictable stress, and may modulate the effects of fluoxetine on hippocampal plasticity.

Title: New Herbal Treatment for depression and Anxiety Disorders with minimal side-effects increase BDNF level in the hippocampus

Authors: *R. DORON[1], M. FRANKO[2], R. TOLEDANO[2], S. ARMOZA[3], M. REHAVI[3]; [1]The Academic Col. Tel Aviv Jaffa/The Open Unive, Tel Aviv- Jaffa, Israel; [2]Sch. of Behavioral Sci., The Academic Col. of Tel Aviv-Yaffo, Tel Aviv-Yaffo, Israel; [3]Physiol. and Pharmacology, Sackler Fac. of Med., Tel-Aviv Univ., Tel Aviv, Israel

Abstract: Anxiety and Depression disorders are prevalent and severe diseases with deleterious impact on both patients and society. Selective serotonin reuptake inhibitors (SSRIs) were shown to be effective in treating a wide spectrum of anxiety and depression disorders. Despite their therapeutic actions, SSRIs are associated with a wide variety of side effects such as weight changes, insomnia, gastrointestinal disturbances and sexual dysfunction. Furthermore, recent studies show that their success rates are not high, reaching 50% at most. Therefore, there is a clear need to explore alternative treatments for anxiety and depression disorders. We have recently produced a novel herbal mixture for the treatment of anxiety disorder. The novel treatment displayed anxiolytic and antidepressant-like effects in treated mice previously exposed to stress. The aim of the present study was to examine whether the novel treatment induce two common side effects normally induced by the conventional treatment with the SSRI escitalopram, namely, sexual dysfunction and weight gain. Mice were treated with either: (a) herbal treatment; (b) one of the four herbal components; (c) escitalopram; or (d) control group. Following treatment, sexual behavior and weight gain were evaluated in the different groups, as well as changes in prefrontal cortex serotonin transporter levels. We have found that the novel treatment has not altered sexual behavior and did not cause a weight gain, while escitalopram did lead to these two side effects. Interestingly, serotonin transporter levels in the prefrontal cortex of the escitalopram treated group were significantly lower compared to the other treatment groups. The BDNF level in the hippocampus increase after ecitalopram and herbal treatment. These results suggest that the novel treatment may have the same behavioral anxiolytic and antidepressant efficacy as SSRIs, while causing fewer side effects, possibly due to different biological mechanisms. Further studies are now conducted in order to explore the underlying biological mechanisms through which the novel treatment lead to the behavioral anxiolytic and antidepressant effects.

Title: Long-term treatment with fluoxetine suppresses the stress response of serotonin by up-regulating dopamine D1 receptor signaling in the hippocampal dentate gyrus

Authors: Y. KAWAHARA[1], T. SHUTO[1], Y. HANADA[1], *H. KAWAHARA[2], A. NISHI[1]; [1]Pharmacol., Kurume Univ. Sch. of Medicin, Kurume, Japan; [2]Tsurumi Univ. / Sch. of Dent., Yokohama / Kanagawa, Japan

Abstract: Hippocampal serotonin (5-HT) is responsive to variety of stress and its extracellular levels are regulated by selective serotonin reuptake inhibitors (SSRIs). Long-term treatment of fluoxetine, an SSRI, has been shown to up-regulate the expression of D1 receptors in the hippocampal dentate gyrus (DG). Therefore, we investigated whether the 5-HT response to acute stress in the DG could be modulated by long-term fluoxetine treatment via mechanisms involving D1 receptors. Fluoxetine was administered for 14 days (15 mg/kg/day) and the extracellular levels of 5-HT were measured by *in vivo* microdialysis in the DG of mice using HPLC-ECD. Novelty (30 min) was applied as a stressful stimulus. In the placebo-treated group, novelty stress induced a significant increase of 5-HT to approximately 200% of basal levels. In the fluoxetine-treated group, novelty stress failed to increase 5-HT levels, but the 5-HT response to novelty stress was observed when a D1 receptor antagonist, SCH23390 (0.5 miroM), was continuously infused into the DG. Local infusion of a D1 receptor agonist SKF81297 (10 microM) which did not affect the 5-HT levels in the placebo-treated group, induced a significant decreased of the 5-HT levels in the fluoxetine-treated group. The results demonstrate that long-term treatment of fluoxetine suppresses the 5-HT response to novelty stress by up-regulating D1 receptor signaling in the DG. Such interaction of 5-HT and dopamine system may be involved in therapeutic effects of SSRIs.

Title: Ovarian hormones influence sensitivity to the antidepressant-like effect of low dose ketamine in C57BL/6 mice

Authors: *A. M. DOSSAT, K. N. WRIGHT, C. E. STRONG, M. KABBAJ;
Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Ketamine, an NMDA receptor antagonist, has shown great promise as a rapid-acting antidepressant compound. Despite the wealth of knowledge recently acquired regarding the antidepressant efficacy of ketamine, it is still not clear if there are gender differences in sensitivity to ketamine's antidepressant effects. This is a critical gap in our knowledge regarding the clinical application of this compound because it has long been established that females are twice as likely to suffer from depression as compared to males. Our group previously showed that female rats are more sensitive to the antidepressant-like effects of ketamine, an effect that was mediated by ovarian hormones. The purpose of the current study was to examine potential sex differences in sensitivity to low dose ketamine in mice, as well as clarify the contribution of ovarian hormones to this sensitivity. We used a mouse model to take advantage of the natural peaks of progesterone (P4) and estrogen (E2) that occur on distinct days. Female mice were lavaged daily for at least two cycles to determine what phase of the estrous cycle they were in. In experiment 1 females in either diestrus 1 (D1), diestrus 2 (D2), proestrus (P), estrus (E) and males were treated with 0, 1.5, or 3 mg/kg ketamine 30 min prior to a forced swim test (FST). Males and females in D1 exhibited an antidepressant-like profile to 3 mg/kg ketamine. However, females in D2 (peak of P4) displayed an antidepressant-like response to both 1.5 and 3 mg/kg ketamine. Females in P (peak of E2) displayed an antidepressant-like profile in the vehicle condition, with no additional effect of any dose of ketamine. In experiment 2 females were treated with an estrogen receptor (ER) α (PPT) or ERβ (DPN) agonist when in D1, to take advantage of the natural nadir of gonadal hormones during this estrous phase; 24 h later these animals received a subthreshold dose of ketamine (1.5 mg/kg) 30 min prior to the FST. Females in D1 did not display an antidepressant-like profile after 1.5 mg/kg ketamine, PPT, or DPN administration. However, following treatment with both PPT and DPN, females displayed a significant response to the sub-threshold dose of ketamine. These results suggest that both ERα and ERβ play a role in enhancing sensitivity to ketamine and future experiments are aimed at differentiating the functional roles of these receptor subtypes. Current research is aimed at elucidating the neural mechanism(s) underlying the enhanced sensitivity to ketamine observed in females that are simultaneously experiencing an endogenous flux of ovarian hormones, with a focus on brain-derived neurotrophic factor in the prefrontal cortex and hippocampus.

Title: Modulation of hypothalamic neurogenesis by stress and antidepressants: the relevance in energy balance regulation in depression

Authors: M. MORAIS, A. MATEUS-PINHEIRO, P. PATRÍCIO, L. PINTO, N. SOUSA, *J. BESSA;
Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal

Abstract: Major depression is associated with critical changes in appetite and body weight, which are differentially regulated by distinct classes of antidepressants (AD). The hypothalamus is the key brain region involved in energy balance regulation and has been described as a novel neurogenic region (1). However, the possible modulation of hypothalamic neurogenesis by stress and antidepressant treatment is yet to be explored. In the present study, we aimed to address this by exploring hypothalamic neurogenesis in animals submitted to chronic mild stress (CMS) and treated with the antidepressants fluoxetine and imipramine (2). These analyses were performed in the arcuate (ARC) and median eminence (ME) nuclei of the hypothalamus, neurogenic regions that have recently been implicated in energy balance regulation (3). Additionally, the relevance of the functional phenotype of these newborn neurons was assessed by the co-expression with NPY, POMC and leptin receptors. The results revealed that stress and antidepressant treatment induced significant changes in food intake and body weight gain. Animals exposed to stress presented no differences in the total food intake but revealed significant body weight loss. Treatment with AD differentially regulated these phenomena. While fluoxetine reduced total food intake and body weight gain, imipramine restored total food intake and increased body weight gain. In addition, the circadian disruption of feeding patterns in stressed animals was reversed by both AD. Regarding the impact in the brain, the results revealed that stress and AD differentially modulate hypothalamic neurogenesis in the ARC and ME nuclei. Stressed animals displayed an increase in newborn neurons in the ARC and a decrease in the ME. Interestingly, only imipramine was able to revert these neuroplastic effects. In summary, this work demonstrates that CMS and AD treatment can modulate hypothalamic neurogenesis in two different hypothalamic nuclei involved in energy homeostasis.. Furthermore, a differential effect in hypothalamic neurogenesis was observed with different classes of antidepressants. 1.Kokoeva MV, Yin H, Flier JS. Abstract: [Background] Matrix metalloproteinases (MMPs), a family of enzymes that regulate the extracellular matrix (ECM), are involved in higher-order brain function through a shedding of extracellular matrix proteins, such as growth factors. Recently, both clinical and animal studies demonstrated glial plasticity to be important for the therapeutic action of antidepressants. We previously reported that antidepressants increase glial cell line-derived neurotrophic factor (GDNF) production possibly through a shedding of the fibroblast growth factor receptor (FGFR) ligands by MMPs (Hisaoka et al., 2011). The current study clarifies the types of MMPs and cellular mechanisms that lead to GDNF production following antidepressant treatment in astroglial cells. [Methods] Rat C6 cells and primary astrocytes were used in the following experiments. We measured the level of GDNF mRNA by real-time PCR and the activity of MMP-2 and MMP-9 by gelatin-zymography. [Results] Amitriptyline (a tricyclic antidepressant)-induced GDNF mRNA expression was significantly inhibited by broad-spectrum MMP inhibitors (GM6001 and prinomastat). RT-PCR revealed that both rat C6 cells and primary astrocytes express the GM6001-sensitive MMPs, including MMP-2, 3, 9. In C6 cells, amitriptyline-induced GDNF mRNA expression was significantly and completely inhibited by a MMP-9 inhibitor or MMP-3 inhibitors, whereas a MMP-2 inhibitor had no effect. Treatment with amitriptyline increased acute and time-dependent MMP-9 activity around twofold level, but not MMP-2 activity. Amitriptyline-induced MMP-9 activation was completely blocked by MMP-3 inhibitors. Furthermore, treatment with exogenous MMP-3 or MMP-9 significantly

increased GDNF mRNA expression, but exogenous MMP-2 had no effect. In rat primary astrocytes, treatment with amitriptyline or several different classes of antidepressants also increased MMP-9 activity. [Conclusion] These results demonstrated that the MMP-3/MMP-9 cascade is crucial in amitriptyline-induced GDNF mRNA expression. Our data suggest the possible existence of a novel MMP-related target in astrocytes for antidepressants, leading to activation of GDNF production.

Title: Adiponectin is required for PPARγ-mediated effects on depression- and anxiety-related behaviors

Authors: *M. GUO[1], D. ZHAO[1], R. DING[1], M. WANG[1], X.-Y. LU[2,1];
[1]Binzhou Med. Univ. Hosp., Shandong, China; [2]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Our previous studies have shown that the levels of adiponectin, an adipocyte-derived hormone, are low in animal models of depression and adiponectin deficiency increases susceptibility to depressive-like behaviors. Rosiglitazone is a peroxisome proliferator-activated receptor gamma (PPARγ) agonist widely used for the treatment of type 2 diabetes. Rosiglitazone stimulates de novo production of adiponectin. In this study, we examined the effects of rosiglitazone on depressive- and anxiety-like behaviors and whether such effects require adiponectin. In the forced swim (FST) test, rosiglitazone was administered intraperitoneally (i.p.) 3 times within 24 h following the pretest. Rosiglitazone treatment significantly reduced immobility time in the FST, accompanied by increased plasma adiponectin levels. The antidepressant-like effect of rosiglitazone in the FST was abolished in adiponectin knockout mice. Moreover, rosiglitazone treatment in wild-type mice decreased the latency to approach and

eat a familiar food in the novelty-suppressed feeding test and increased time and entries to open arms in the elevated-plus maze test. These anxiolytic effects of rosiglitazone were also abolished in adiponectin knockout mice. Taken together, these results demonstrate that adipocyte-derived adiponectin is required for PPARγ-mediated effects on depressive- and anxiety-like behaviors.

Title: Vortioxetine increases synaptic glutamate neurotransmission without altering extrasynaptic glutamate concentrations

Authors: *A. L. PEHRSON, E. DALE, S. LEISER, C. SANCHEZ;
Lundbeck Res. USA, Paramus, NJ

Abstract: Vortioxetine is a multimodal-acting antidepressant that has shown beneficial effects on cognitive functions in clinical studies. Although it acts through purely serotonergic receptor mechanisms at clinically relevant doses (5-HT1D, 5-HT3, and 5-HT7 receptor antagonism, serotonin (5-HT) transporter inhibition, 5-HT1B receptor partial agonism and 5-HT1A receptor agonism), recent work suggests that these serotonergic actions indirectly modulate glutamate neurotransmission in a cognition-relevant way. This poster presents an overview of data suggesting that vortioxetine selectively increases synaptic glutamate neurotransmission without altering extrasynaptic glutamate, and reverses cognitive deficits induced by glutamate dysregulation. Vortioxetine and the SSRI escitalopram were compared in terms of long-term potentiation (LTP), 5-HT-mediated inhibitory postsynaptic currents (IPSCs) in hippocampal pyramidal neurons, cortical pyramidal neuron firing rates, and gamma band oscillatory power. Given vortioxetine's effects in these glutamate neurotransmission-sensitive models, cortical and hippocampal extracellular glutamate concentrations were investigated via microdialysis. Finally, vortioxetine's ability to reverse glutamate-related cognitive dysfunction was investigated using models including MK-801-induced social recognition memory deficits and subchronic PCP-induced attentional set shifting impairments.Vortioxetine significantly enhanced LTP and reduced the frequency and amplitude of 5-HT-mediated IPSCs in hippocampal pyramidal cells. Acute vortioxetine treatment also increased the firing rate of cortical pyramidal neurons [1] and enhanced gamma oscillatory power *in vivo*. The SSRI escitalopram had no effects on LTP, 5-HT

mediated IPSCs, cortical pyramidal neuron firing [1] or gamma oscillations. Despite the vortioxetine induced changes in these glutamate neurotransmission-sensitive models, no effect was found on cortical or hippocampal extracellular glutamate concentrations. Finally, vortioxetine reversed MK-801-induced memory deficits and subchronic PCP-induced impairments in attentional set shifting.These data suggest that vortioxetine, unlike the SSRI escitalopram, enhances synaptic glutamate neurotransmission in a manner that is relevant for cognitive function. However, vortioxetine's lack of effect on extracellular glutamate concentrations suggests that it selectively modulates synaptic vs. extrasynaptic glutamate neurotransmission.References: [1] Riga M, Celada P, Sanchez C, Artigas F European Neuropsychopharmacol 23:S393-4

Title: Dopamine D1 receptor activation enhances antidepressant effects of SSRI in a mouse model of depression

Authors: *T. SHUTO, M. KUROIWA, N. SOTOGAKU, A. NISHI;
Kurume Univ., Kurume, Japan

Abstract: Selective serotonin reuptake inhibitors (SSRIs) act as antidepressants by modulating monoamine system. However, the ability of SSRIs to improve symptoms of depression is limited. Chronic administration of SSRI is recently found to increase dopamine D1 receptor expression and upregulate D1R signaling in the hippocampal dentate gyrus, one of the main target brain regions of antidepressants, in C57BL/6 mice. Therefore, we performed behavioral studies to investigate the role of dopamine D1 receptors in anti-depressant action of an SSRI,

fluoxetine. Depression-like behaviors were evaluated with novelty-suppressed feeding test and tail suspension test in a chronic restraint stress mouse model of depression. Chronic treatment with fluoxetine (15 mg/kg/day, 14 days) alone showed anti-depressant effect in mice subjected to mild restraint stress (2 hr/day, 14 days), but not to strong restraint stress (4 hr/day, 28 days). However, chronic co-administration of a dopamine D1 receptor agonist, R(+)-SKF81297 (1.5 mg/kg/day), with fluoxetine showed anti-depressant effects in mice subjected to strong restraint stress. In addition, acute injection of SKF81297 at 3.0 mg/kg induced behavioral seizures only in chronically fluoxetine-treated mice, suggesting that chronic fluoxetine treatment lowered the seizure threshold for D1 receptor activation. These results suggest that activation of dopamine D1 receptor signaling in the dentate gyrus ameliorates depression-like behaviors by enhancing antidepressant effects of SSRI under SSRI-resistant stress conditions.

Abstract: The central serotonin (5-hydroxytryptamine, 5-HT) system modulates diverse physiological functions, including of regulation of sleep, rhythm, appetite, learning, memory and emotion. Dysfunction of the 5-HT system in the brain has been implicated in the etiology of the wide range of neurodevelopmental disorders, including depression, anxiety, obsessive-compulsive disorder, autism, and schizophrenia. As the rate-limiting enzyme for the synthesis of central 5-HT, TPH2 plays a pivotal role in the modulation of 5-HT neurotransmission and is thus

a promising target for the therapeutic treatment of neuropsychiatric disorders. Previously we demonstrated that the expression of the human TPH2(hTPH2) gene is strictly controlled through the NRSF-mediated negative regulation in immortalized rat serotonergic RN46A cells (a generous gift from Dr. Whittemore SR., Univ Louisville, KY). However, the mechanism by which hTPH2 gene expression is activated remains unresolved. Sequence analysis revealed an inverted CRE (5'-TAACGTCA-3') in the hTPH2 promoter (-243/-236 relative to the transcription start site). Interestingly, potential CREs were also found at corresponding positions of the mouse (-374/-367, 5'-TAACGTCA-3') and rat (-203/-196, 5'-TGACGCAT-3') TPH2 genes. This prompted us to examine how the hTPH2 gene promoter activity changes by CRE-mediated signaling pathways in RN46A cells. A 2-kb promoter region of the hTPH2 gene (-1850/+141) was cloned into pGL4-Basic (TPH2-55) and a mutant having deletion of its 5'-untranslated region (+10/+121; a region containing potential repression elements) was constructed (TPH2-100). A series of mutant constructs with nucleotide substitutions in the CRE was made. Promoter activities were assessed by transient transfections into RN46A cells. Whereas overexpression of CREB (CRE binding protein) alone showed marginal effects, overexpression of PKA-alpha (cAMP-dependent protein kinase catalytic subunit alpha) alone increased TPH2-100 promoter activity. Simultaneous overexpression of CRTC (CREB regulated transcription coactivator) in addition to PKA-alpha and CREB further enhanced TPH2-100 promoter activity. Gel mobility shift assays confirmed the CREB binding to the relevant element. These results indicate that the CRTC plays a critical role in positively regulating the hTPH2 promoter activity through associating with CREB on the inverted CRE of the hTPH2 promoter region and the subsequent 5-HT synthesis in the brain.

Title: R-ketamine: a novel rapid and long-lasting antidepressant

Authors: C. YANG[1], *Y. SHIRAYAMA[2], J.-C. ZHANG[1], Q. REN[1], M. MA[1], W. YAO[1], C. DONG[1], K. HASHIMOTO[1];
[1]Chiba Univ. Ctr. Forensic Men Hlth., Chiba, Japan; [2]Teikyo Univ. Chiba Med. Ctr., Chiba, Japan

Abstract: The NMDA receptor antagonist ketamine shows rapid and robust antidepressant effects in treatment-resistant patients with major depression and bipolar disorder, indicating that ketamine is the most attractive antidepressant. Ketamine (or RS (±)-ketamine) is a racemic mixture containing equal parts of R (-)-ketamine and S (+)-ketamine. S-ketamine has an approximately 4-fold greater affinity for the NMDA receptor than the R-isomer. Furthermore, S-ketamine shows an approximately 3-4 fold greater anesthetic potency and greater undesirable psychotomimetic side effects, compared with the R-isomer. Recently, we reported that, compared with S-ketamine, R-ketamine produced rapid and long-lasting antidepressant effects in juvenile mice exposed neonatally to dexamethasone (Zhang et al., 2014). In this study, we examined the effects of R- and S-ketamine in the social defeat stress and learned helplessness (LH) models of depression. Behavioral tests, including the tail suspension test (TST), forced swimming test (FST), and 1% sucrose preference test, were performed. Although both isomers of ketamine showed antidepressant-like effects in the social defeat stress model, R-ketamine was more potent than S-ketamine. Seven day after a single does, R-ketamine was more potent than S-ketamine. Furthermore, R-ketamine, but not showed antidepressant-like effect in the rat LH model. In the behavioral tests for side effects, S-ketamine, but not R-ketamine, caused hyperlocomotion, prepulse inhibition deficits, and rewarding effect. In conclusion, a single dose of R-ketamine produced rapid and long-lasting antidepressant effects in the social defeat stress and LH models of depression. Therefore, R-ketamine appears to be a potent and safe antidepressant relative to S-ketamine, since R-ketamine is free of psychotomimetic side effects.

Title: Alcohol access in adolescence and early adulthood does not affect sign-tracking, but augments omission contingency learning, in rats

Authors: *P. E. KALLENBERGER, N. BRIGHT, H. FISHER, M. GREER, A. LIMOGES, A. PAJSER, C. L. PICKENS;
Kansas State Univ., Manhattan, KS

Abstract: Problem: Alcohol use in humans is associated with impaired response inhibition in self-reports of every-day life and in laboratory tasks. In humans, it is difficult to determine whether alcohol consumption leads to response inhibition impairments or if the response inhibition impairments lead to increased alcohol consumption. We tested rats with previous adolescent/early adult alcohol access in a procedure where there was no requirement to press a lever associated with the delivery of food (sign-tracking task), and then assessed the rats' abilities to inhibit these responses (omission contingency task). We assessed whether alcohol consumption correlates with sign-tracking or if alcohol access might alter responses in these tasks. Methods: Rats were given access to alcohol using a chronic intermittent access procedure (24-hr access to 20% alcohol 3X per week, separated by 24-48 hr periods where no alcohol is available) or water alone for six weeks (PND 26-66). Three days after the final alcohol period, rats began food restriction, and then began sign-tracking training 10 days later. The rats received six days of sign-tracking training. Next, the rats received six days of omission contingency training. During the omission contingency sessions, one lever was paired with food only if the rat did not press the lever while it was available. Results: We did not find any significant correlations between the amount of alcohol consumed and behavior in either the sign-tracking or omission contingency task. We also did not observe any effect of prior alcohol access on sign-tracking behavior. However, we did observe a significant effect of prior alcohol access (vs. water access alone) on the rate of omission training, such that rats with prior alcohol access learned more quickly to inhibit their responding to the lever on the omission contingency. Conclusion: Our results suggest that alcohol consumption in adolescence and early adulthood can lead to faster omission contingency learning. This replicates a previous effect seen in mice given chronic intermittent exposure to alcohol via vapor chambers (DePoy et al., 2013), but it is unclear whether this effect reflects alterations in response inhibition abilities or some change in the representations that guide sign-tracking behavior. Future research will determine whether alterations in omission contingency performance occur after alcohol consumption in adulthood and also investigate the neurobiological basis of alcohol's effects.

Title: Acute ethanol exposure in adolescent female rats alters fear conditioning in an age dependent manner

Authors: J. A. TRAVIS[1], K. ISHIWARI[2], *R. SIRCAR[1,2];
[1]The City Col. of New York, New York, NY; [2]Albert Einstein Col. of Med., Bronx, NY

Abstract: Earlier, our lab and others have reported that ethanol treatment in adolescent female rat causes hippocampus-associated spatial memory deficit when tested in the hidden platform task of the Morris water maze. Adult rats did not show any such deficit. Ethanol in adolescent rats also impairs memory functions during fear conditioning. Adolescent female rats treated acutely with ethanol and subjected 30 minutes later to a couple of tone-shock pairings in the fear conditioning paradigm, showed significant disruptions specifically in the hippocampus-related contextual memory but not in the amygdala-associated cued fear paradigm. The present study was undertaken to determine the effects of ethanol on fear conditioning in younger and older adolescent rats. Thirty minutes prior to training in the fear conditioning paradigm, both young and older adolescent rats were treated with a single intraperitoneal injection of ethanol (2g/kg). Control rats received equivalent volumes of vehicle. Twenty four hours later, all rats were tested for (i) contextual fear in the same training chamber, and (ii) cued fear in a novel chamber along with exposure to tone. For each rat, freezing during contextual and cued fear conditionings were recorded. Freezing was used as a measure of memory; more freezing indicates better memory. Younger adolescent female rats treated with ethanol showed significant impairments in contextual fear. There was little effect on cued memory. On the other hand, older adolescent rats exhibited impairments in both contextual as well as cued fear conditionings. Together, these data suggest a differential behavioral effect of ethanol on memory functioning in younger vs. older adolescent rats.

Title: The long-term effects of adolescent binge alcohol exposure on anxiety behavior in male Wistar rats

Authors: *A. R. TORCASO, A. ASIMES, E. PINCETI, Y. S. RAO, C. L. SHULTS, C. K. KIM, T. R. PAK;
Cell and Mol. Physiol., Loyola Univ. Chicago, Maywood, IL

Abstract: Binge drinking during adolescence is a common occurrence which is associated with increased risk of developing alcohol dependence and other mental health disorders. Hypothalamo-pituitary-adrenal (HPA) axis dysfunction is one characteristic commonly observed in many affective disorders, including anxiety and depression. Our laboratory has previously demonstrated that adolescent binge-pattern alcohol exposure results in long-term dysfunction of the HPA axis in a Wistar rat model. However, it was not determined in those studies if the rats would exhibit increased anxiety-like behaviors, in accordance with observations based on human adolescent binge drinkers. Therefore, the current study aimed to measure anxiety behaviors in young adult male Wistar rats that had received binge-pattern alcohol treatment as adolescents with no further perturbation, and furthermore to observe the behavioral and neuroendocrine responses to a heterotypic psychological stressor in these rats. Following a week of handling, rats were exposed to an eight day binge-pattern alcohol paradigm from post-natal day (PND) 37-44, which has been previously used in our laboratory, or received water as a control. The rats were un-manipulated for three weeks, then handled again for one week prior to behavioral testing. Around PND 72, anxiety behaviors were measured using the elevated-plus maze (EPM) equipped with a video camera and tracking software. The following day, half the rats from each group (binge-treated or water-treated) were placed in a plastic restraint tube for 30 minutes, or as a control were placed individually in a new cage, then were immediately tested again in the EPM. Compared to controls, the binge-treated rats spent less time in the open arms and more time in the intersection of the four arms. Following EPM testing, the rats were euthanized by rapid decapitation, and the brain and trunk blood were collected. Plasma corticosterone (CORT)

levels were measured by ELISA. Two-way ANOVA revealed a statistically significant effect of alcohol exposure or restraint stress on CORT levels, but there was no significant interaction between the two independent variables. Taken together, these data suggest that rats with prior adolescent binge alcohol exposure not only have long-term dysfunction of the neuroendocrine response to stress, they also exhibit increased anxiety behaviors under stress.

Title: Adolescence chronic caffeine exposure increases alcohol drinking and depressive-like behavior in mice

Authors: ***D. J. HINTON**, Y. CHOI, A. OLIVEROS, C. A. VADNIE, S. CHOI, D.-S. CHOI; Mayo Clin. Col. of Med., Rochester, MN

Abstract: During adolescence, dysregulation of neurotransmitter systems could alter the maturation of brain circuits involved in reward, mood and cognitive behaviors. Caffeine is the most commonly consumed drug in the world. Despite several notable beneficial effects of acute caffeine that have been documented in adults, excessive caffeine consumption during adolescence has been shown to be associated with psychiatric disorder symptoms which include attention deficit hyperactivity disorder, anxiety, aggressiveness, sleep disturbances and addiction. Adolescent mice self-administered caffeine (1 mg/ml) for 16 weeks beginning at 4 weeks of age. We found that chronic caffeine-exposed mice showed reduced motivation to explore a novel environment compared to mice consuming water (control mice). Mice chronically consuming caffeine also had less motivation to walk on the accelerating rotarod compared to control mice. Caffeine-exposed mice buried less marbles in the marble-burying test, suggesting that chronic caffeine reduced attentive behaviors. Furthermore, caffeine consuming mice showed reduced motivation to escape the forced swim test suggesting the presence of depression-like behavior compared to control mice. In addition, caffeine consuming mice exhibited anxiety-like behavior as they spent significantly less time in the center zone of a novel open-field chamber and less

time in the open arm of the elevated plus maze compared to control mice. In Pavlovian association experiments, mice chronically consuming caffeine exhibit increased impulsive behavior to obtain a hedonic reward (20% sucrose). Finally, caffeine was removed from the diet for 1 week and mice were presented with a two-bottle choice ethanol drinking experiment. The concentration of ethanol was raised every fourth day, increasing from 3 to 6 to 10 to 15 to 20% (v/v) ethanol. Mice that were previously exposed to caffeine consumed and preferred significantly more ethanol than mice that previously only drank water. Overall, these data indicate that chronic inhibition of adenosine receptors during adolescence may contribute to increased impulsivity and ethanol consumption as well as anxiety- and depressive-like behaviors in adult mice.

Title: Adolescent ethanol exposure, pubertal timing, and novelty seeking in adulthood

Authors: *E. KIM, L. P. SPEAR;
Binghamton Univ., Binghamton, NY

Abstract: Adolescence-typical behaviors such as high novelty seeking are associated with increased risk for using drugs of abuse. Animal studies have shown that adolescent intermittent ethanol exposure (AIE) sometimes leads to retention of adolescent-like phenotypes into adulthood, perhaps increasing propensity for later alcohol use disorders. Research in humans has implicated pubertal timing in distinct behavioral outcomes, including drug/alcohol use. Given that ethanol (EtOH) may alter neural substrates underlying the timing of sexual maturation, the present study assessed whether AIE alters pubertal status, potentially contributing to the long term behavioral consequences of AIE. Male and female Sprague-Dawley rats were intubated with 4.0 g/kg of EtOH (25% v/v) (AIE), water (H20) or non-intubated (NI) every other day from postnatal (P)25-45. All rats were weighed and assessed daily until P50 for physical signs of sexual maturation (first day of vaginal opening [VO] in females and partial or complete balano

preputial skinfold separation [BPS] in males). Additional controls (CTRL) for behavioral testing were only handled on P25 and 45. On P70, all animals were given a novel object test and assessed for latency to contact, time spent sniffing and in contact with the object, as well as locomotor activity. While no differences were seen in mean age of partial BPS, AIE and H2O males completed BPS at significantly younger ages than NI males. Females in the H2O group exhibited VO at a younger age than NI females; this apparent intubation effect was reversed by EtOH, with no significant differences between AIE and NI females. In novel object testing in adulthood, NI males contacted the object more quickly than their female counterparts, a sex difference that did not reach significance in the other experimental groups. Although the novelty seeking behaviors were not affected by AIE, further analysis revealed that pubertal status predicted behavioral outcomes within treatment groups for males but not females. Delayed time to partial BPS was positively correlated with time spent sniffing in EtOH males, and object contact in EtOH and H2O treated males. Time to complete BPS was positively correlated with time spent sniffing and in contact in EtOH males only. These data further demonstrate the role of pubertal status in novelty seeking behaviors and provide evidence for the contribution of altered pubertal timing after exposure to EtOH in the later expression of novelty seeking behaviors.

Title: Concurrent ethanol-nicotine intake by peri-adolescent p rats confers resistance to extinction of intravenous nicotine self-administration in adulthood

Authors: E. A. ENGLEMAN, A. M. SENTIR, M. D. WHITE, Z. A. RODD, R. A. CHAMBERS, *R. L. BELL;
Dept. of Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Abuse of ethanol (Et) and nicotine (NIC) during adolescence appear to have deleterious long-range consequences extending into adulthood. The objective of the current study was to examine the long-range consequences of peri-adolescent (P-A) Et-NIC co-abuse in alcohol-preferring (P) rats. P-A female P rats were randomly divided into 5 drinking groups (3-drinking bottles available concurrently): Water [W--W--W (W)], 10% sucrose [W--10% S--10% S (S)], 10% sucrose + 0.07 mg/ml and 0.14 mg/ml NIC [W--0.07 mg/ml NIC & 10% S--0.14 mg/ml NIC & 10% S (NS)], 15% (v/v) Et [W--15% Et--15% Et (E)], and 0.07 mg/ml and 0.14 mg/ml NIC + 15% Et [W--0.07 mg/ml NIC & 15% Et--0.14 mg/ml NIC & 15% Et (NE)]. From post-natal day (PND) 30 to 60, rats received two scheduled 1hr access periods, during the dark cycle each day, to their respective solutions (Monday-Friday) with ad lib access to water and food. Rats in the NS and NE groups averaged 8.5 ± 1 and 7.2 ± 1 mg/ml NIC intake, respectively, per day. Et intake averaged 8.2 ± 1 and 7.1 ± 1 g/kg body weight/day for the E and NE groups, respectively. All rats were then double-housed in plastic cages with free access to food and water only until ~PND 74 when all rats were implanted with intravenous (IV) catheters. On PND 80, rats began a 3 week acquisition/maintenance phase of operant IV self-administration (IVSA) of 0.015 mg NIC/kg/infusion (FR1) - daily 2 hr sessions, 5 days/week. After 3 weeks of NIC IVSA, all rats began the 2 week extinction phase of the experiment which proceeded exactly as in the acquisition phase, except no NIC was infused after any lever press. Rats from all groups acquired the NIC IVSA behavior; however, rats in the NE P-A drinking group showed significantly greater NIC IVSA as adults than any of the other P-A drinking groups. Compared with the other groups, total responding on the active lever during the extinction phase was greater for the NE group (715 ± 114/10 sessions, mean ± SEM) compared to the W (439 ± 54), S (466 ± 44), NS (502 ± 74), and E (492 ± 51) groups [ANOVA followed by planned post-hoc tests, $p < 0.05$]. The greater resistance to extinction displayed by the NE group suggests that P-A NIC-Et co-abuse produces a unique effect by enhancing the conditioned reinforcing effects of cues associated with NIC IVSA in adulthood; whereas P-A NIC or P-A Et did not exert this effect. Thus, P-A NIC-Et may enhance the salience of environmental cues conditioned to NIC-induced effects, or vice versa, driving NIC relapse behavior in those with a genetic predisposition for alcohol-abuse and -dependence.

Title: Sex and age-dependent modulatory effects of maternal care on ethanol preference and sensitivity to ethanol-induced sedation hypnosis

Authors: *D. O. POPOOLA[1], N. M. CAMERON[2];
[1]Binghamton Univ., Endicott, NY; [2]Psychology, State Univ. of New York, Binghamton, NY

Abstract: We investigated the influence of natural variations in maternal care on ethanol consumption and sensitivity to ethanol-induced sedation. Long Evans litters were categorized into high or low licking and grooming (LG). Using a free two-bottle choice test, high and low offspring were tested for 5% v/v ethanol consumption and preference for four weeks (PND 32-57). Using the loss of righting reflex (LORR) paradigm, offspring were tested at PND 42 (mid-adolescence) for sensitivity to acute 20% v/v ethanol-induced sedation at 3.0g/kg and 3.5g/kg ethanol dose. Male offspring were also tested with LORR at 3.0g/kg or 3.5g/kg ethanol dose at PND 50 (late adolescence), and 3.0 g/kg at PND 92-95 (adulthood). Low-LG female, consumed less total fluid in general, and preferred 5% ethanol to water over the last three weeks of consumption compared to High-LG female. Maternal care didn't influence male ethanol consumption, preference, and total fluid consumption. While maternal care didn't alter sensitivity to acute ethanol-induced sedation during mid-adolescence, Low-LG male were more sensitive to ethanol-induced sedation than High-LG at all tested doses during late adolescence and adulthood. LG frequency also negatively correlated with sensitivity during late adolescence while the correlation approached ($p = 0.057$) significance in adults. Therefore, maternal care sex-dependently influences alcohol consumption, and age-dependently mediates male sensitivity to alcohol-induced sedation. This suggests that gonadal hormones play a role in the modulatory effects of maternal care on alcohol use. We are currently investigating the age-dependent effect on sensitivity in female, and also the mechanisms underlying these behavioral effects.

Title: Voluntary exercise promotes resiliency to adolescent binge ethanol-induced reductions in adult brain serotonergic neuron markers

Authors: *R. P. VETRENO, T. J. WALTER, F. T. CREWS;
Sch. of Med., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Serotonergic neurons within the raphe nucleus are linked to the regulation of sleep, mood, and other functions that mature during adolescence. Binge drinking and alcohol abuse are common in humans adolescents, and we hypothesized that adolescent binge drinking might alter the development of the serotonergic leading to long-term changes in adult neurobiology. Using a Wistar rat model of adolescent intermittent ethanol treatment (AIE; 5.0 g/kg, i.g., 2-day on/2-day off from postnatal day [P] 25 to P55) followed by maturation to adulthood (P80), we discovered that AIE treatment reduced serotonin (5-HT)-immunoreactive (+IR) staining in the dorsal raphe nucleus, hypothalamus, and amygdala, but not the medial raphe nucleus. Western blot analysis revealed a a reduction in the 5-HT synthesizing enzyme tryptophan hydroxylase 2 as well as vesicular monoamine transporter 2, which packages 5-HT into synaptic vesicles, consistent with a loss of adult serotonergic neurons following AIE. Adolescent intermittent ethanol treatment increased the number of Iba-1+IR microglia and the microglial activation marker CD11b. To determine if microglial activation could recapitulate the effect of AIE on the serotonergic system, young adult rats (P70) were treated with lipopolysaccharide (1.0 mg/kg, i.p.), and 10 days latter 5-HT+IR was reduced similar to AIE treatment. Voluntary exercise during AIE and maturation into adulthood was found to prevent both the AIE-induced loss of 5-HT+IR in the dorsal raphe nucleus as well as the increases in Iba-1+IR and CD11b+IR. Together, these data suggest that adolescent binge ethanol treatment reduces serotonin in the young adult brain, possibly through a microglial mechanism. Voluntary exercise in the form of running wheel exposure promotes resilience to the deleterious effects of AIE treatment on the serotonergic system of the dorsal raphe nucleus. Long lasting reductions in brain serotonin following adolescent binge drinking could contribute to long-term changes in brain serotonin function. (Supported by the NADIA of the NIAAA)

Title: The ontogeny of ethanol aversion

Authors: ***J. SAALFIELD**, L. SPEAR;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Rodent models have been used to investigate factors potentially contributing to the increases in ethanol intake seen during adolescence. Such studies have determined adolescents to be less sensitive to many ethanol effects than adults, particularly those ethanol effects likely serving as cues to limit intake. While there is convincing evidence from both our laboratory and others that mid-adolescents are less sensitive to ethanol-induced conditioned taste aversion (CTA) than are adults, the precise ontogeny of this aversion is unknown. Given prior evidence showing discrete developmental windows within adolescence, the current experiment examined CTA to a range of ethanol doses across ages chosen to represent pre-adolescent/juvenile (Pre: P23-25); early adolescent (Early: P28-30), mid adolescent (mid: P35-37); late adolescent (late: P42-44); “emerging adult” (emerging: P52-54), and adult (P72-74) periods. In Exp. 1, pair-housed male Sprague-Dawley rats on ad-lib food and water were given 60 min access to chocolate Boost® while separated from their cagemates in their home cages, and injected intraperitoneally immediately thereafter with 0, 0.5, 1, 1.5, 2 or 2.5 g/kg ethanol. Testing occurred 48 hours later and consisted of an identical 60 min access period to the Boost® conditioned stimulus (CS). The results revealed two age groupings, with the 3 youngest ages (pre, early and mid) displaying an attenuated sensitivity to ethanol’s aversive properties relative to the 3 older age groups (late, emerging, adult), with CTAs not emerging until 2 g/kg and 1.5 g/kg, respectively. To assess whether the relative resistance to ethanol CTA seen in this study was related to the highly palatable nature of the Boost® solution, Exp.2 was conducted similarly except that supersaccharin was used as the CS, animals were 50% water deprived the day before training and testing to ensure adequate CS intake, and only doses of 0, 1.0, 1.5, and 2.0 g/kg were examined. Early adolescents showed no CTA at any dose, whereas pre-adolescents exhibited CTA only at 2.0 g/kg. Older animals were more sensitive to ethanol CTA, with the

mid, late and emerging groups displaying reduced sensitivity (1.5 g/kg) compared to adults (1.0 g/kg). In both studies, an attenuated sensitivity to the aversive properties of ethanol was evident in adolescents relative to adults, although more pronounced age differences were evident in water deprived animals than when a highly palatable CS was given to ad libitum animals. Overall, the attenuated sensitivity to the aversive properties of ethanol was most notable early in adolescence, with the enhanced aversive sensitivity of adults reached gradually thereafter.

Title: Binge-like alcohol exposure during adolescence disrupts dopaminergic neurotransmission in the adult prefrontal cortex

Authors: *H. TRANTHAM-DAVIDSON[1], S. CENTANNI[1], L. CHANDLER[2];
[1]Neurosci., [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: The prefrontal cortex (PFC) is a brain region that is critically involved in cognitive function and inhibitory control. A, and adolescence represents a critical period of continued PFC development of this region that parallels the maturation of these its cognitive functions. This extended period of developmental plasticity is thought to renders the PFC, and its underlying circuitry, extremely especially vulnerable to environmental insult that, which may result in deficits that persist well intoproduce lasting changes that persist into adulthood. Alcohol drinking typically begins during adolescence when consumption of large quantities, in binge-like episodic patterns, is common. The present study investigated the effects of adolescent intermittent ethanol (AIE) exposure (post-natal day 28-42) by vapor inhalation on neurocircuitry in the adult medial PFC (mPFC). A primary function of dopamine (DA) in the PFC is to maximize the efficient

processing and transfer of information within the neurocircuitry that mediates decision-making. Dopamine (DA) innervation of the medial PFC (mPFC) peaks in early adolescence and then undergoes pruning and changes in DA receptor function during the transition to adulthood. These changes appear to play a critical role in the maturation of the executive function of the PFC. The present study investigated the effects of adolescent intermittent ethanol (AIE) exposure during post-natal days 28-42 by vapor inhalation on dopaminergic function in the prelimbic region of the adult PFC. Using Specifically,an adult acute slice preparation, we examined the functionality of pyramidal neuron DA receptors D1 and D2/D4 receptors of layer V pyramidal neuron in the prelimbic PFC was examined in the adult acute slice preparation. These studies revealed that AIE exposure resulted in a loss of D1 receptor modulation of pyramidal neuron intrinsic excitability and synaptic transmission, but had no effect on D2 or D4 modulationreceptor function. Interestingly, treatment with the D2 agonist eticlopride during AIE exposure period prevented the loss of D1 receptor function. In contrast, eticlopride treatment had no effect in the control air exposed rats. Taken together, these findings suggest demonstrate that binge-like alcohol exposure during early to mid adolescence compromises D1 receptor function, but co-administration of a DA D2 agonist during AIE exposure can protect against these deficits treatment with D2 agonists during alcohol exposure may be protective against these changes and result in and may prevent AIE induced deficits in the cognitive function of the PFC. improved cognitive outcomes.

Title: Biomolecularmarkers of impulsivity following adolescent alcohol-induced changes to the orbitofrontal cortex

Authors: C. R. SHORT, *M. S. MCMURRAY, J. D. ROITMAN;
Psychology, Univ. of Illinois At Chicago, Chicago, IL

Abstract: Adolescence is a developmental period that involves a significant increase in impulsive decisions and potential experimentation with drugs and alcohol. The prefrontal cortex (PFC) is thought to play a role in inhibiting impulsive choices. Because PFC undergoes continued development during adolescence, it may be sensitive to the effects of alcohol, altering

its developmental trajectory, thereby having long-term repercussions from casual abuse. In this study, a rodent model of alcohol abuse was used to investigate the effects of daily adolescent alcohol exposure on adult impulsivity and associated neurophysiology. Adolescent rats (10 per group) were injected (IP) with either a high dose of 3 mg/kg alcohol (EtOH) or saline (CONT), at the onset of the dark cycle from postnatal day 30-50. In adulthood, rats performed a probabilistic risk task. In this task, rats were presented with two levers: one lever constituting a safe option (1 pellet) and the other a risky option (3 or 0 sucrose pellets), based on a fixed probability for each session. The probability (12.5%, 33%, 50%, 67%, 75%) was varied between session to encourage risk-seeking or risk avoidance. Using this task, we found no behavioral differences between the CONT and EtOH exposed animals, with both showing generally risk-preferring behavior. Our lab has previously identified a regional impairment in the function of the orbitofrontal region of the PFC following alcohol consumption in adolescence. Thus, using qPCR, we examined mRNA levels in this region of genes thought to be involved in risk assessment, which included D1 and D2 dopaminergic receptors, α7 subunits of the nicotinic receptor, and muscarinic M1 receptors. Differential expression of these receptors has been shown to affect reward, motivation, and reinforcement in decision making and addiction studies. These findings will shed light onto the way in which adolescent alcohol intake affects decision making and in adulthood and will guide future research in finding novel treatments for the abuse of alcohol during this period.

Title: Aging increases alcohol sensitivity and eliminates circadian modulation of alcohol-induced behaviors in *Drosophila* melanogaster

Authors: *A. K. DENOBREGA, L. C. LYONS;
Biol. Science, Program of Neurosci., Florida State Univ., Tallahassee, FL

Abstract: Alcohol abuse and its physiological consequences in older adults is a serious problem given the rising elderly population and the increased physiological sensitivity to alcohol in aged

individuals. The patterns of alcohol consumption differ considerably between age groups as older individuals drink more frequently but consume fewer drinks at a time (Institute of Alcohol Studies, 2013) resulting in an underrepresentation of the extent of alcohol abuse in older adults. Although increased sensitivity to alcohol-induced motor and cognitive impairments can be observed in aged rodents as well as humans, little research has been done on the effects of acute alcohol in aged individuals (Novier et al., 2015). Compared to the neuronal complexity of mammalian systems, the simple circuitry of *Drosophila melanogaster* makes *Drosophila* a valuable model for identifying important factors and mechanisms in alcohol neurobiology (Guarnieri & Heberlein, 2003). Previously, we found that the circadian clock modulates the acute loss of motor control in flies using the loss-of-righting reflex (LoRR) assay. Flies exhibit a circadian rhythm in the LoRR with the greatest sensitivity to alcohol occurring from mid to late night (Van der Linde and Lyons, 2011). In the current research, we have extended these studies to investigate alcohol sensitivity and the role of the circadian clock in alcohol-induced behaviors in aged flies. We found that as flies age alcohol sensitivity increases and circadian regulation of alcohol sensitivity weakens. The circadian rhythm in LoRR remains significant at 10 days but disappears by 20 days of age. Interestingly, the behavior during the late subjective day when flies are normally the least sensitive to alcohol is most changed with aging. During the late subjective day, significantly less alcohol exposure is needed for LoRR in 10 day old flies compared to 3 day old flies with even shorter alcohol exposures necessary for 50% LoRR in 20 day old flies. Although age related changes in alcohol sensitivity may also be observed during the late night when flies are most sensitive to alcohol, these changes are smaller in magnitude compared to the late subjective day. These results suggest the hypothesis that the circadian clock phase specifically buffers the effects of alcohol exposure and that this influence on alcohol-induced behaviors is diminished with aging. These behavioral studies demonstrate that *Drosophila melanogaster* is a practical model system for studying the effects of alcohol in aging populations and for investigating the potential protective aspect of the circadian clock in acute alcohol use.

Title: Adolescent ethanol exposure leads to durable changes in HPA axis sensitivity to an immune stimulus at adulthood

Authors: *A. S. VORE, T. L. DOREMUS-FITZWATER, A. GANO, J. PANICCIA, T. DEAK; Binghamton Univ., Binghamton, NY

Abstract: Adolescent alcohol use comprises a significant public health concern and is often characterized by binge-like consumption patterns. While ethanol exposure in adulthood has been shown to alter several aspects of the stress response, including the Hypothalamic-Pituitary-Adrenal (Axis), few studies have examined whether binge-like ethanol exposure during adolescence results in enduring changes in HPA axis sensitivity that could persist into adulthood. In the present series of studies, therefore, male adolescent Sprague-Dawley rats were given intragastric (i.g.) intubations of ethanol (4 g/kg) or vehicle once per day for 3 consecutive days, beginning on postnatal day (P) 30 (± 1). This binge exposure was immediately followed by a 2-day period of rest/withdrawal. Rats then received one more 3-day cycle of ethanol exposure and were subsequently allowed to age normally until reaching adulthood. At P73 (± 2), separate groups of ethanol- and vehicle-exposed rats received 1 of 3 distinct stress challenges to probe HPA axis sensitivity across unique stress modalities: (i) In Exp. 1, animals were given an acute challenge of 2.5 g/kg ethanol (intraperitoneally; i.p.); (ii) In Exp. 2, rats received an acute injection of a moderate dose (50 μg/kg) of lipopolysaccharide (LPS); and (iii) In Exp. 3, a third cohort of adolescent-exposed rats was challenged with 60 min of restraint. In all experiments, a time course of tail blood samples were collected for later assessment corticosterone (CORT) concentrations, as well as other blood measures. As expected, all 3 stress challenges led to a time-dependent surge in CORT release. Whereas 2 of the adult challenges (ethanol and restraint) showed a trend for increased sensitivity following adolescent ethanol exposure, acute administration of LPS resulted in the opposite pattern: a decrease in the CORT response. Gene expression analyses of cytokines (IL-6, IL-1, and TNF alpha) from the white blood cell layer of fractionated whole blood using RT-PCR revealed that adolescent ethanol exposure led to attenuated LPS-induced increases in cytokines, with this reduction significant for IL-6 expression. These findings suggest that adolescent ethanol exposure may cause lasting alterations in HPA axis sensitivity that (a) persist into adulthood and (b) may vary depending on the nature of the challenge incurred during adulthood; and (c) that adolescent ethanol exposure may produce enduring changes in processing of antigen by the immune system and/or neuroimmune function. Future studies identifying the cellular mechanisms underlying these effects are currently under way.

Title: The effect of adolescent binge drinking on oxidative stress in the prefrontal cortex

Authors: *W. VARGAS, A. DAVE, H. N. RICHARDSON;
Dept. of Psychological and Brain Sci., Univ. of Massachusetts-Amherst, Amherst, MA

Abstract: Underage binge drinking is associated with various harmful health effects and social problems. Moreover, alcohol is the most commonly used and abused drug by adolescents. During adolescence, brain regions such as the prefrontal cortex (PFC) are still developing and thus may be more vulnerable to potentially toxic substances like alcohol. Extremely high doses of alcohol administered to animals are known to induce oxidative stress, which is an imbalance of oxidants and antioxidants in an aerobic system. The objective of the present study was to determine the effect of voluntary binge drinking on oxidative stress in gray and white matter of the PFC in young animals. Adolescent male and female Wistar rats were exposed to two weeks (postnatal days 28-42) of operant binge alcohol self-administration. After the end of the binge treatment period, brains were collected and the PFC was processed for oxidative stress assays. The 2, 7-Dicholorofluorescein and BCA protein assays were used to determine reactive oxidative species concentrations as an index of oxidative stress. Preliminary results suggest sex differences in oxidative stress levels in the PFC after alcohol, with a trend of higher levels in males compared to females. These data suggest differential sensitivity of the male and female PFC to alcohol early in adolescence in rats.

Title: Adolescent alcohol exposure suppresses the CREB signaling system in the rat amygdala during adulthood

Authors: H. ZHANG[1,2,3], D. KOKARE[1,3], E. J. KYZAR[1,2,3], T. TEPPEN[1,2,3], *S. C. PANDEY[1,2,3];
[1]Dept Psychiatry, Univ. of Illinois at Chicago, Chicago, IL; [2]Jesse Brown VA Med. Ctr., Chicago, IL; [3]Ctr. for Alcohol Res. in Epigenetics, Chicago, IL

Abstract: The cAMP-responsive element binding protein (CREB) transcription factor in the amygdala has been shown to be involved in anxiety-like and alcohol drinking behaviors. In addition, it has been shown that withdrawal from chronic ethanol treatment reduces CREB phosphorylation and CBP expression in the amygdala of adult rats and this is associated with the development of anxiety-like behaviors. In the present study, we assessed the effect of adolescent intermittent n-saline (AIS) or intermittent ethanol (AIE) exposure on CREB phosphorylation and expression of CBP and p300 in the amygdaloid structures of rats in adulthood. Rats were exposed to intermittent ethanol treatment (2 g/kg, intraperitoneal) during post-natal days (PND) 28-41, with one injection per day for two consecutive days. This was followed by 2 days without ethanol treatment for a total of 4 cycles. The rats were left undisturbed in their home cage until PND 92 without additional ethanol exposure. At this time point, brains were dissected to measure CREB and phosphorylated CREB (pCREB) protein levels and protein and mRNA levels of CBP and p300 in amygdala of AIE and AIS exposed adult rats. It was found that CREB and pCREB protein levels and mRNA and protein levels of CBP and p300 were significantly reduced in the amygdala of AIE adult as compared with AIS adult rats. While AIE rats showed a significant reduction in protein levels in the central (CeA) and medial nucleus of amygdala (MeA), protein levels of these molecular markers in the basolateral amygdala (BLA) did not change. These results indicate that AIE exposure reduces CREB signaling and related co-factors CBP and p300 expression in the CeA and MeA during adulthood that may be associated with AIE-induced anxiety and alcohol intake as previously reported by our laboratory.

Title: Adolescent intermittent ethanol alters oligodendrocytes and myelin in the prefrontal cortex of adult male rats

Authors: *W. LIU, F. T. CREWS;
Bowles Ctr. for Alcohol Studies, Univ. of North Carolina-Chapel Hill, Chapel Hill, NC

Abstract: Prefrontal cortex (PFC) and white matter development parallels maturation of cognitive control, executive functions and working memory. Binge drinking is common in adolescent humans. The current study examined the effect of adolescent intermittent binge ethanol (AIE) compared with water controls on oligodendrocytes and myelin in the prelimbic (PrL) subregion of the prefrontal cortex of adult male rats. Timed-pregnant dams (E17) were allowed to acclimate to our vivarium on (P1), litters were culled to 10 pups, weaned on P21, male weight matched and pair-housed. Two groups were treated with ethanol (AIE, 5g/kg/day, i.g., P25-P55; 2 days alcohol, 2 days off) and another two groups were given water as controls, control and AIE groups were sacrificed at P57 or P95. The impact of AIE on white matter maturation was investigated using immunohistochemistry in PrL for the following markers of oligodendrocytes and myelin; NG2 (a marker of oligodendrogenesis progenitor cells, OPCs), Olig2 (OPCs and mature oligodendrocytes), PDGF Rα (oligodendrocyte progenitor cells), Olig1 (nuclear, OPC and immature oligodendrocyte), MBP (hydrophilic myelin basic protein), dMBP (degraded myelin basic protein), MOP (Myelin oligodendrocyte glycoprotein) and PLP (highly hydrophobic transmembrane proteolipid protein). Multiple markers showed age-related changes consistent with maturation, For example, between P57 and P95, there was age-related decrease in NG2+IR (37%, $p<0.01$), Olig1+IR (30%, $p<0.05$), Olig2+IR (18%, $p<0.05$), dMBP+IR (76%, $p<0.001$) and MOG+IR (50%, $p<0.01$) expression, that contrasts with an age-related increase in PLP+IR (177%, $p<0.05$) in control group. AIE did not change many oligodendrocyte markers at P57, but did decrease PGDF Rα+IR, MBP+IR, dMBP+IR and MOG+IR at P57. At P95, AIE increased Olig2+IR (21%, $p<0.05$), MOG+IR (45%, $p<0.05$) and PLP+IR expression (151%, $p<0.01$) in the PrL, and dMBP+IR remained decreased at P95. These data are consistent with AIE indicate altering oligodendrocytes and myelin maturation leading to persistent changes in PFC. (Funded by the NADIA from NIAAA).

Title: Disruption of early stage resting state activity as a function of alcohol consumption in nonhuman primates: an MEG study

Authors: *J. R. STAPLETON-KOTLOSKI[1], J. A. ROWLAND[2,4], A. T. DAVENPORT[3], P. M. EPPERLY[3], D. P. FRIEDMAN[3], D. W. GODWIN[2], J. B. DAUNAIS[3];
[2]Neurobio. & Anat., [3]Physiol. & Pharmacol., [1]Wake Forest Univ. Sch. of Med., Winston Salem, NC; [4]W.G. "Bill" Hefner VAMC, Salisbury, NC

Abstract: Chronic alcoholism is characterized by structural damage and cognitive deficits, but when these manifest is unclear. Here we used resting state (RS) MEG to image two cohorts of nonhuman primates (NHPs) following a chronic EtOH exposure paradigm. The first study was a cross-sectional comparison of a group of vervet monkeys that had chronically self-administered EtOH (n=7) or maltodextrose (n=3) under identical operant conditions (3 month induction + 12 months daily access with average daily EtOH intakes of 1.1-3.1 g/kg). RS MEG data were beamformed with synthetic aperture magnetometry (SAM) and source series were extracted for peaks and selected ROIs. Chronic EtOH altered precuneus RS activity in an intake-dependent manner such that non-heavy drinkers exhibited similar SAM z-scores to control animals as compared to heavy drinkers. RS source series activity in chronically drinking vervets demonstrated clear power spectral reductions in all frequencies from 0-80 Hz in anterior cingulate (ACC), dorsolateral prefrontal cortex (DLPFC), hippocampus (HPC), and vermis

relative to controls. These robust decreases were detected after chronic, daily access for 15 months so it was not possible to determine when the reductions began. Data from an ongoing study in which rhesus monkeys (n=5) self-administered EtOH under identical operant conditions as the vervets described above found that RS activity is altered in a rate-dependent manner immediately after a 3-month induction phase during which all EtOH animals consume identical g/kg doses of EtOH. Relative to the naïve pre-induction RS scans, power spectral densities revealed increased power in left DLPFC, left medial orbitofrontal cortex, and bilateral ACC. While power increased for all animals in frontal regions, there was differential sensitivity in more caudal regions such as HPC or vermis such that the slowest drinker displayed increased power while the fastest drinker displayed decreased power. The link between RS activity and drinking rate is important since early drinking typographies (i.e., 'gulping' vs 'sipping') are highly predictive of subsequent daily EtOH intake in NHPs (Grant et al., 2008). Finally, other regions such as bilateral substantia nigra and amygdala exhibited decreased power following EtOH. Collectively, these data suggest that in several brain areas implicated in alcoholism functional changes occur very early in the drinking history, are regionally selective, and likely precede structural changes. RS alterations early in the drinking history may also be a non-invasive biomarker predictive of a heavy drinking phenotype.

Title: FAAH moderates neurocognitive effects of cannabis use in youth

Authors: *K. M. LISDAHL;
Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Intro: The last two decades there has been a rise in adolescent cannabis use, with 6.5% of 12th graders reporting daily use (Johnston et al., 2013). Adolescence is a sensitive period that involves significant neurodevelopmental changes in both gray and white matter (Giedd et al., 1996; Sowell et al., 2004) and drug exposure during these years is if particular concern.

Therefore, it continues to be a top public health priority to characterize the public health impact of cannabis exposure and to identify potential at-risk groups for greater neurocognitive deficits. Genetic differences may place individuals at increased risk for these cognitive effects. Two candidate genes are *FAAH*, which regulates the endogenous cannabinoid anadamide, and the CB1 receptor (*CNR1*) (Ho & Hillard, 2005). It was hypothesized that regular cannabis users who are also carriers of the *FAAH* A genotype, related to diminished endocannabinoid signaling, will demonstrate greater neurocognitive and sleep consequences. **Methods**. As part of the parent study, cognitive, substance use, sleep quality, and DNA data was collected from 83 youth (ages 18-25), including 38 regular cannabis users and 45 healthy controls. SNP genotyping was obtained for *FAAH* (rs324420) and *CNR1* (rs2180619). Exclusion criteria included independent psychiatric disorders, neurologic or major medical disorders, left-handedness, non-English speakers, history of prenatal drug exposure, intellectual disability, reading ability <80 Standard score, significant other drug use (>25 times in lifetime). **Results.** We will present a series of studies examining the independent and interactive effects of cannabis and *FAAH* genotype on neurocognition and sleep. Main effects of cannabis included reduced orbitofrontal and parietal volume, reduced prefrontal gyrification, poorer frontolimbic white matter integrity, worse problem solving/set shifting and psychomotor speed, and poorer sleep quality (*p*'s<.05). *FAAH* genotype significantly moderated the effects of cannabis on verbal retention, working memory, orbitofrontal morphology, and frontolimbic white matter integrity (*p*'s<.05). **Discussion**. These gene-by-cannabis use interactions may explain inconsistency in the literature. Other clinical and policy implications will be discussed.

Title: Onset-specific effects of regular cannabis use on brain functional systems

Authors: *F. FILBEY[1], V. MISHRA[2];
[1]Univ. of Texas At Dallas, Dallas, TX; [2]Advance MRI, Frisco, TX

Abstract: Graph theory models propose that brain regions have a pattern of functional connections that form a brain functional system. Thus, graph theory provides a more holistic understanding of brain function relative to regional activations (Bullmore & Sporns 2009). Such models have shown that functional systems are sensitive to developmental/aging effects as well as exposure to substances (e.g., decreases in modularity, efficiency). The goal of this study was to determine the interaction between these two factors on graph metrics. To that end, 128 regular cannabis users (age range: 31±7 years) were scanned using resting state functional MRI (rsfMRI). After routine preprocessing of all rsfMRI images (e.g: motion correction, band-pass filtering, etc), nodes of the network (graph) were derived by registering each brain to AAL atlas yielding 45 regions in each hemisphere. The mean time series for each region was calculated by averaging the time series of all the voxels within each region. Further, a symmetric correlation matrix of size 90x90 was generated from Pearson correlation coefficients between each pair of nodes, for each subject. Each correlation matrix was further converted into a weighted network (weights being the correlation between any two nodes) and binary network (weights of the non-zero edges in the weighted graph equated to 1). Each of such binary and weighted networks was explored for two sets of network properties: global network metrics, yielding information about the topological brain properties such as small-worldness, path length, clustering coefficient, hierarchy, modularity, efficiency etc and regional nodal metrics such as nodal efficiency, betweenness, nodal efficiency, cluster and nodal participant etc. The network properties thus obtained were compared across the cannabis users to see the difference in the brain organization due to early and late onset of regular use of cannabis. Our findings suggest that effects on functional systems as measured by graph metrics are moderated by age of onset of regular use, particularly in the default mode network (DMN), fronto-parietal network (FPN; cognitive control), salience network (SN; directed attention) and subcortical (limbic/reward) network. These findings demonstrate the presence of observable effects on brain functional systems across the lifespan that are unique to the age of onset.

Title: Comparing effects of alcohol and marijuana: An n-back fmri study in young adults

Authors: A. BYRON-ALHASSAN, T. HATCHARD, O. MIODUSZEWSKI, *A. SMITH; Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Alcohol and marijuana are the most commonly used drugs during adolescence. Within the past five years, alcohol usage has declined while marijuana usage has increased. Given this increase in marijuana use among teenagers, and the potential combination of using both alcohol and marijuana during this time when brain maturation is so vital, it is critical to understand the neurophysiological impacts of both drugs on the teen brain. The optimization of brain development can be monitored by proficiency in working memory. As usage and public opinion of drug use is often a result of the perceived risk of the substance, a comparison of the performance and neurophysiological impact of each drug during a working memory task will be of considerable relevance. The purpose of the present study was to compare the effects of alcohol with those of marijuana, on a functional magnetic resonance imaging (fMRI) working memory task, in adolescent users. **Methods** Participants were recruited from the Ottawa Prenatal Prospective Study. Ten marijuana users were compared with 14 non-users and 17 alcohol users were compared with 11 non-users. Each participant attended one imaging session on a 1.5 T Siemens Magnetom Symphony MR scanner for whole brain BOLD fMRI. A 2-back letter n-back task was used. For both drugs, BOLD activations during the working memory task, and performance (reaction time and errors) were compared to the respective control group of non-users using SMP8. **Results/Conclusions** No significant differences in performance were found between groups. fMRI analyses revealed significantly more activity in both drug groups compared to controls but the areas of increased activity during working memory were different for the 2 drugs. Alcohol users had significantly more activity in the cingulate gyrus and the right caudate nucleus, while the marijuana users engaged the middle temporal gyrus and cerebellum significantly more than controls. These findings suggest that, although both substances produce a need for additional resources to maintain successful performance, the mechanism by which they function differs. This additionally implies that, especially in the developing brain, use of both marijuana and alcohol would cause more widespread negative effects on neural processing.

Title: Extinguished environment elicits transient synaptic potentiation in the accumbens shell

Authors: *D. ROBERTS-WOLFE[1], C. GIPSON[1], A. MOTTS[2], A. SMITH[1], K. WISCHUSEN[2], M. SCOFIELD[1], P. KALIVAS[1];
[1]Neurosci., Med. Univ. of South Carolina, Charleston, SC; [2]Col. of Charleston, Charleston, SC

Abstract: Discovering mechanisms underlying inhibition of drug seeking is critical to developing new therapies for substance use disorders. Extinction training consists of animals repeatedly receiving no reinforcement for pressing a lever formerly paired with cocaine infusions. Animals successfully inhibit drug seeking when returned to the extinguished context (the operant chamber in which they underwent extinction training). This inhibition requires neuronal activity in nucleus accumbens (NA) shell and its prefrontal (infralimbic) input. Transient synaptic potentiation (tSP) in accumbens medium spiny neurons (MSNs) is a physiological correlate of behaviors requiring glutamatergic inputs into nucleus accumbens. For example, cue-induced reinstatement of drug seeking is associated with a tSP (rapid increases in AMPA:NMDA ratio and dendritic spine head diameter that normalize by the end of the reinstatement session) that requires prefrontal inputs and activation of matrix metalloproteinases (MMPs 2 and 9). As tSP is associated with behavior relying on glutamate in nucleus accumbens, and glutamate in NA shell is necessary for inhibiting drug seeking in an extinguished context, we hypothesize that exposure to an extinguished context will induce tSP in NA shell. Following 10 days of cue-paired cocaine self-administration, animals underwent 2-3 weeks of either extinction training in the same context (but without discrete cues) or home-cage abstinence. Animals were sacrificed after returning for 15 minutes to the context in which they had undergone self-administration (with or without extinction training), or sacrificed without re-exposure to the context. We used whole cell patch clamp electrophysiology to examine AMPA:NMDA ratio and diolistic labeling to image dendritic spines. Exposure to the extinguished context induced tSP in NA shell. AMPA:NMDA ratios were increased in animals re-exposed to the extinguished context relative to extinguished animals not re-exposed. Spine morphology was not affected by

re-exposure to an extinguished context. No changes were noted in NA shell as a result of cocaine self-administration or extinction training alone. The fact that 15 min of exposure to the extinguished environment increased AMPA:NMDA, but did not change spine morphology differs from tSP characterized during reinstatement in NA core, and suggests dissociable mechanisms underlying these two common measures of synaptic plasticity. Future studies will examine the role of MMPs and infralimbic inputs on tSP induced in the NAshell by an extinguished environment.

Title: Elucidating the effects of atypical dopamine uptake inhibitors on the phasic release of dopamine in mice

Authors: J. KEIGHRON, *A. H. NEWMAN, G. TANDA;
NIDA-IRP, Baltimore, MD

Abstract: Atypical dopamine uptake inhibitors, such as JHW 007, have low potential for abuse and may lead to critical discoveries in the development of treatments for psychostimulant abuse. These compounds are known to bind to the dopamine transporter with high affinity and block the pharmacological and behavioral effects of stimulant drugs of abuse, such as cocaine and methamphetamine. The objectives of this study are to explore the effects of JHW 007 and other typical and atypical dopamine uptake inhibitors on the phasic release of dopamine. We would also like to determine how these effects correlate with the previously reported behavioral and tonic dopamine level data. Fast scan cyclic voltammetry (FSCV) is an electrochemical method that allows for the study of the phasic release of dopamine both *in vivo* and *ex vivo*. In this study, phasic dopamine release in the striatum of male Swiss-Webster mice was followed both prior to, and for several hours after administration of cocaine or JHW 007 with doses ranging from 0.3 mg/kg to 32 mg/kg. This allowed us to study the effects of both drugs on the intensity, duration, and effective clearance of dopamine released during phasic events as the effects of each drug

developed. Initial results indicate that both typical and atypical inhibitors effect phasic dopamine release by two mechanisms, increasing the amount of dopamine release per event, and decreasing the rate of clearance of dopamine from the intercellular space as evident by the changes in the intensity and duration of events when inhibitors are present. When cocaine is administered these mechanisms are affected in a dose dependent manner. However, atypical inhibitors such as JHW 007 do not produce the same magnitude of effect at similar doses, and may act on these two mechanisms at different times, causing the apparent shift in the dose response curve previously reported with microdialysis. In summary, our results help provide a broader view of the role of JHW 007 and other atypical dopamine uptake inhibitors in potential treatments for stimulant abuse by elucidating the mechanisms involved in the phasic release of dopamine.

Title: Beta-arrestin 1 dependent regulation of cocaine self-administration in mice

Authors: *N. MITTAL[1], A. MINASAYAN[2], T. SCHALLERT[3], C. J. EVANS[2], W. M. WALWYN[2];
[1]Univ. of Texas At Austin, Austin, TX; [2]UCLA, Los Angeles, CA; [3]Univ. of Texas at Austin, Austin, TX

Abstract: Prolonged use of cocaine results in long lasting synaptic changes in the mesolimbic reward centers. Identification of substrates that are responsible for the induction and maintenance of such plasticity may help provide novel therapeutic targets for the treatment of substance abuse and relapse. Cocaine self-administration has been shown to abolish long term depression (LTD) in the bed nucleus of the stria terminalis (BNST), which can be rescued by blockade of the NR2B subunit of the N-Methyl-D-aspartate receptor (NMDAR). Studies have shown a similar blockade of LTD in the NAc following cocaine self-administration. We have previously shown a role of the scaffolding protein, β-arrestin 1, in modulating GPCR expression and function by regulating pathways responsible for receptor trafficking onto the cell membrane. Therefore, we

hypothesized that β- arrestin 1 may be involved in regulating cocaine-induced changes in NMDAR expression and function. We trained mice lacking β-arrestin 1 to self-administer cocaine, and measured synaptic activity from medium spiny neurons (MSNs) in the shell of the NAc, before and after cocaine self-administration. We found that mice lacking β-arrestin 1 had increased basal AMPA to NMDA ratios in the NAc as compared to the wild-type mice. Moreover, the β-arrestin 1 knockout mice were slower in both acquiring, and extinguishing cocaine self-administration. Furthermore, unlike wild-type mice, the knockout mice did not show an increase in NR2B receptor expression after the acquisition of cocaine self-administration. These findings identify a, previously unknown, role of β-arrestin 1 in regulating NMDAR function following cocaine self-administration.

Title: Examining the role of toll-like receptor 4 on nucleus accumbens synaptic physiology and drug reward behavior

Authors: *D. T. KASHIMA[1], B. A. GRUETER[2];
[2]Anesthesiol. Res., [1]Vanderbilt Univ., Nashville, TN

Abstract: Drug abuse and addiction remain significant problems in society. Drugs of abuse alter the nucleus accumbens (NAc) physiology suggesting it plays a role in a final common pathway for dependence/addiction. The NAc is made up of two types of medium spiny projection neurons (MSNs) that differentially modulate reward behavior. Neuron-mediated mechanisms of change at excitatory synapses within the NAc in response to drug experience are well-studied. However, growing evidence suggests the involvement of the brain's innate immune system in modulating reward behavior and synaptic physiology. Previous studies demonstrated that pharmacologic manipulation of toll-like receptor 4 (TLR4), a pattern-recognition molecule of the innate immune

system, attenuates cocaine-reward learning. In the brain, TLR4 is primarily associated with microglia. Microglia are phagocytes with the ability to regulate synaptic physiology through 1) physical removal of synapses during development, 2) responses to certain forms of injury, and 3) secretion of chemical factors known to mediate homeostatic plasticity. Despite these observations, mechanistic examination of how the innate immune system alters NAc synaptic physiology in relation to drug-reward behavior has not been demonstrated. We performed behavioral assays as well as cell-type specific electrophysiology on wild type and TLR4 knockout mice. We show that TLR4 knockout mice exhibit altered NAc synaptic plasticity and express an attenuation in cocaine-mediated reward learning. Additionally, we find that pharmacologic agonism of TLR4 modifies NAc MSN synaptic plasticity. These results suggest that TLR4 and the immune system may directly affect synaptic physiology to alter reward behavior.

Title: Cell type specific dysregulation of GABAergic plasticity in the Ventral Pallidum after extinction from cocaine self administration

Authors: *D. NEUHOFER[1], Y. KUPCHIK[2], P. KALIVAS[1];
[1]Neurosci., MUSC, Charleston, SC; [2]Fac. of Med., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The Ventral pallidum (VP) is the main target of the mesolimbic indirect pathway and as such integrates motivational and sensory information. It has been demonstrated that the projection from the nucleus accumbens (NAc) to the VP regulates the reinstatement of cocaine-seeking, a process which depends on normal activation of mu opioid receptors. Indeed, NAc-VP GABAergic synapses of drug-naïve animals undergo a form of presynaptic long-term depression (LTD) that is mu opioid receptor dependent. This form of plasticity is abolished in cocaine-extinguished rats due to tonic saturation of mu opioid receptors. Classically it is thought that the output from the NAc to the VP is composed exclusively of axons of medium spiny neurons

(MSNs) expressing the D2 dopamine receptor (D2-MSNs). However, we have recently shown that the VP receives significant input from D1-MSNs and that projections from the NAc to VP contain D1 mRNA, questioning this strict segregation. Here we examine whether both accumbal inputs to the VP express electrically-induced LTD and the effect of extinction of cocaine-seeking behavior on each input. Using Cre dependent expression of ChR2 in either D1 or D2 MSNs we demonstrate that while both inputs exhibit LTD in drug-naïve mice, the elimination of GABAergic LTD in cocaine-extinguished mice described previously is cell type specific. While LTD can still be elicited in D1 MSN input to the VP of cocaine extinguished mice, LTD in D2 MSN terminals is abolished. This differential effect of cocaine on plasticity may be explained by differences in signaling pathways and further research is required to identify the relevance of each of these VP afferents to the reinstatement of cocaine seeking behavior.

Title: Inherent individual differences in dopamine release are associated with variability in subsequent cocaine consumption

Authors: *J. K. SHAW, R. A. ESPAÑA;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The mesolimbic dopamine (DA) system is heavily implicated in the onset and maintenance of cocaine use and variability within this pathway is believed to underlie individual differences in vulnerability to the development of cocaine abuse and addiction. Previous work has demonstrated that rats classified as high responders to novelty acquire cocaine self-administration more readily and are characterized by both greater DA-ergic storage capacity and cocaine-induced uptake-inhibition than those identified as low responders. Despite this evidence, the direct relationship between DA neurotransmission and individual differences in cocaine self-administration has not yet been fully elucidated. To determine the relative contributions of DA release and uptake to vulnerability to use cocaine, we measured baseline DA release and uptake dynamics in the striatum of anesthetized rats using fast scan cyclic voltammetry prior to any

behavioral testing. Following recovery, the rats were provided access to cocaine-associated levers and the time to acquire, consumption of, and motivation for cocaine using fixed ratio-1 and within-subject threshold schedules of reinforcement was measured. Preliminary results suggest a strong relationship between baseline DA release and cocaine consumption while uptake did not appear to be strongly associated with any behavioral measure, potentially implicating DA reserve pools in vulnerability to cocaine use disorders. These data suggest that individual differences in cocaine self-administration may be associated with inherent variability in the mesolimbic DA system. The current findings may aid in further development of targeted pharmacotherapies to treat cocaine addiction.

Title: PCAF regulates the acetylation of Sigma-1 receptor chaperones

Authors: *Y. YASUI[1], T.-P. SU[2];
[1]NIH/NIDA, Baltimore, MD; [2]NIDA, NIH, Baltimore, MD

Abstract: Sigma-1 receptors (Sig-1Rs) are endoplasmic reticulum (ER) chaperon proteins that are implicated in various neurological disorders. Sig-1Rs have received attention because of the specific involvement in drug abuse. Since antagonizing Sig-1Rs diminishes cocaine-induced behavioral responses, Sig-1Rs are expected to be a potential therapeutic target of cocaine abuse. Sig-1Rs predominantly reside at the mitochondria-apposing ER subdomain (the mitochondria-associated ER membrane, MAM) but can translocate to other compartments of the cell under stimulation with cocaine. We previously showed that cocaine-induced translocation of Sig-1Rs, which intensifies the Sig-1R interaction with Kv1.2 potassium channel, plays a substantial role in behavioral and neuronal responses to cocaine in mice. Thus, the dynamic shift of the subcellular distribution is a critical step for Sig-1Rs to execute their functions at remote sites other than the MAM. However, the detailed mechanism on how the translocation is initiated is largely unknown. We found that Sig-1Rs interact with lysine acetyltransferases, p300/CBP-associated factor (PCAF) and GCN5. The interaction between Sig-1Rs and PCAF possibly occurs at the ER and the ER-Golgi intermediate compartment, and is intensified with cocaine treatment. It has been reported that acetylation of membrane proteins in the ER lumen regulates the protein

translocation at the early secretory segment of the translocation pathway. We therefore hypothesized that PCAF and GCN5 may acetylate Sig-1Rs and the acetylation of Sig-1Rs may be related to the Sig-1R's translocation. We found that the acetylation level of Sig-1Rs is increased by overexpression of PCAF and decreased by knockdown of PCAF. We also found that cocaine intensifies the interaction between PCAF and Sig-1Rs. However, paradoxically, cocaine does not affect the acetylation level of Sig-1Rs. We examined whether the PCAF expression level may affect the subcellular distribution of Sig-1Rs by density gradient centrifugation, and found that overexpression or knockdown of PCAF did not significantly changed the distribution pattern of Sig-1Rs. Together, our data show that Sig-1Rs are acetylated and PCAF regulates the Sig-1R acetylation level. Although cocaine affects the interaction between Sig-1Rs and PCAF, PCAF-induced acetylation of Sig-1Rs may not be the underlying mechanism whereby cocaine causes the translocation of Sig-1Rs.

Title: Synapse-specific deconstruction of endocannabinoid signaling in the nucleus accumbens shell

Authors: *B. D. TURNER[1,2], E. DELPIRE[3,4], B. GRUETER[3,4];
[1]Vanderbilt Univ. Med. Ctr., Nashville, TN; [2]Vanderbilt Brain Inst., [3]Anesthesiol., [4]Mol. Physiol. and Biophysics, Vanderbilt Univ., Nashville, TN

Abstract: Aberrant glutamatergic transmission within the nucleus accumbens shell (NAcSh) is heavily implicated in the development and reinstatement of drug-induced addiction-like behaviors. Integration of glutamatergic input from the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA) by NAcSh medium spiny neurons is thought to encode stimulus salience and direct associative learning processes. Moreover, long-lasting adaptations at these synapses have been repeatedly linked to drug self-administration and the incubation of drug craving in rodent models of addiction. Extensive investigation has highlighted NAcSh post-synaptic plasticity mechanisms as highly-penetrant molecular mediators of maladaptive

associative-learning pathologies. However, less is known regarding presynaptic regulatory mechanisms and their contribution to drug-induced remodeling of reward circuitry function. Presynaptic regulation in the NAc via endocannabinoids (eCBs) and the cannabinoid type-1 receptors have been correlated with non-contingent drug exposure and self-administration behaviors. However, how the eCB system functions at discrete synapses remains unknown. Here, we utilize whole-cell electrophysiology, transgenic D1tdTom marker mice, pharmacology, and optogenetics to examine how the eCB system controls glutamatergic input onto NAcSh medium spiny neurons. We have found that eCB plasticity induced by low-frequency stimulation is cell-type specific. Future studies will examine how this plasticity is affected by psychostimulant exposure and abstinence with the aim of developing novel addiction therapeutics.

Title: Cocaine and Stress disrupt mGluR/SK inhibition on dopamine neurons of the VTA

Authors: *J. PARRILLA-CARRERO, E. POTAPENKO, A. RIEGEL;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Both environmental stressors and drugs of abuse cause enduring cellular adaptations in the ventral tegmental area (VTA) which contribute to addiction. In rats with a history of cocaine use, stressors promote relapse of drug seeking by enhancing corticotrophin-releasing factor (CRF) signaling in the VTA. One potential mechanism by which stress and drugs of abuse overlap is the induction of CRF-dependent plasticity at glutamatergic synapses. The interaction between stress, drugs of abuse, CRF, and glutamate in the VTA, however, remains poorly understood. Aside from promoting excitatory signaling via ionotropic receptors, glutamate also recruits inhibition in VTA neurons via the activation of postsynaptic metabotropic glutamate receptors (mGluRs), mGluRs mobilize intracellular calcium stores to activate inhibitory sK channels. This Ca2+-dependent signaling is potentiated by CRF. Here, using whole cell patch

clamp electrophysiology recordings from VTA neurons, we investigated mGluR - sK channel inhibition after single and repeated exposure to the ecologically valid stressor TMT (a component of fox odor), or repeated exposure to cocaine. Single TMT exposure facilitated mGluR - SK currents, an adaption normalized by either the CRF receptor 1 (CRF-R1) antagonist CP-156254 or the CRF receptor 2 (CRF-R2) antagonist K41498. However, repeated TMT exposure weakened the evoked mGluR - SK current, a condition that was unabated by blockade of CRF-R2. In addition, repeated TMT exposure significantly increased the frequency of spontaneous miniature outward currents (SMOCs). These SMOCs were observed prior to synaptic stimulation, persisted in the presences of TTX, and were blocked by either depletion of intracellular calcium stores with CPA, or by the irreversible sK channel blocker apamin. Activation of sK channels may be enhance due to dysregulated calcium leak from intracellular stores. Interestingly, repeated administration of cocaine (IP) with 7-14 days of withdrawal resulted in similar increases in SMOCs. We propose that cocaine as well as stress, alters mGluR inhibition in DA neurons through impairment of intracellular Ca2+ signaling.

Title: Cocaine mediated molecular regulation of mitochondrial dynamics in nucleus accumbens projection neuron subtypes

Authors: *R. CHANDRA[1], C. FRANCIS[1], M. ENGELN[1], A. AMGALAN[1], L. JENSEN[1], P. KONKALMATT[2], A. GANCARZ[3], S. GOLDEN[4], D. DIETZ[3], G. TURECKI[5], S. RUSSO[4], M. LOBO[1];

Abstract: Altered brain energy homeostasis is a hallmark adaptation occurring in the cocaine-addicted brain. This includes alterations in glucose metabolism, glutamate homeostasis, and oxidative stress. Recent studies demonstrate that mitochondria dysfunction is associated with psychiatric disorders. However, mitochondrial dynamics have not been thoroughly addressed in cocaine abuse. Our data demonstrate that genes important for mitochondria biogenesis and function are upregulated in nucleus accumbens (NAc) of rodents that self-administer cocaine (FR1 schedule, 1mg/kg/infusion) and in postmortem NAc of cocaine dependent individuals. We next examined mitochondrial biogenesis and function genes in the two NAc projection medium spiny neuron (MSN) subtypes, those enriched in dopamine D1 vs. D2 receptors. Using the RiboTag methodology, we observe an up-regulation of ribosome-associated mRNA of many mitochondrial biogenesis and function genes in D1-MSNs but a decrease in D2-MSNs after repeated cocaine (7 days, 20 mg/kg). We have generated a Cre inducible adeno-associated virus (AAV)-double inverted floxed open reading frame (DIO)-mito-dsRed to label mitochondria in D1-MSNs and D2-MSNs using D1-Cre and D2-Cre mouse lines. This will allow us to examine mitochondrial volume and number in MSN subtypes after repeated cocaine exposure. Additionally, we have developed an AAV-DIO to overexpress peroxisome proliferator-activated receptor-gamma coactivator-1α (Pgc1α), a transcriptional coactivator of mitochondrial biogenesis and function genes. Overexpression of Pgc1α in NAc D1-MSNs enhanced cocaine conditioned place preference and cocaine-induced locomotion, while Pgc1α expression in D2-MSNs reduced these behaviors. Another gene we are pursuing is dynamin-related protein 1 (Drp1), a GTPase that directly binds to the outer mitochondrial membrane to promote mitochondria division hence it plays an important role in generating new mitochondria. We find that the active form of Drp1 protein is increased in NAc and the Drp1 gene is increased in D1-MSNs but reduced in D2-MSNs after repeated cocaine (7 days, 20mg/kg). We are developing Cre-inducible AAVs for wildtype, constitutively active, and a dominant-negative Drp1 so we can test Drp1 function in MSN subtypes in cocaine-related behaviors. Collectively, our findings demonstrate altered molecular mechanisms governing mitochondrial dynamics in the two MSN subtypes with cocaine exposure.

Title: Cocaine self-administration and cue-reinstatement disrupt Kv7 (KCNQ) channel inhibition in the prefrontal cortex

Authors: *W. BUCHTA, A. RIEGEL;
Dept. of Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: In human cocaine addicts, re-exposure to drug-paired cues induces hyperactivity in the prefrontal cortex (PFC) that precipitates drug-craving and relapse. While the underlying mechanisms are unknown, they likely involve cellular adaptations in intrinsic ion channel signaling. For example, pyramidal cells in the PFC normally display robust spike-frequency adaptation (accommodation) that limits repetitive neuronal firing. This firing pattern is mediated in part by Kv7 (KCNQ) K+ channels, which are activate at subthreshold potentials, are non-inactivating, and are sensitive to inhibition by multiple neuromodulators known to be released in response to cues. Therefore, using whole cell patch clamp electrophysiology we recorded from L5 pyramidal cells in the prelimbic (PL) PFC of rats after a history of chronic cocaine self-administration and extinction training, with or without re-exposure to cocaine-paired cues and investigated Kv7 channel function. After cocaine self-administration and extinction, cells demonstrated (a priori) hyperexcitable firing rates, loss of spike accommodation, and reduced Kv7 channel inhibition. These adaptations could be normalized by acute blockade of dopamine D1 receptors, inhibition of PKA, depletion of intracellular Ca2+, or stabilization of Kv7 ion channels directly with retigabine. This suggests that excessive dopamine D1 receptor signaling disrupts Kv7 channel function. Re-exposing rats to cocaine-paired cues for 30min further enhanced neuronal excitability, involving calcium-store dependent desensitization of Kv7 channel activity. These cellular adaptations may contribute to cue-induced drug seeking, since *in vivo* infusion of retigabine into the PFC prior to cue-induced reinstatement testing blocked cocaine-seeking behavior. Taken together these data suggest that chronic cocaine experience enhances cue-induced PFC excitability by disrupting intrinsic Kv7 channel mediated spike accommodation, resulting in repetitive neuronal firing in response to depolarizing (excitatory) inputs. This neuroadaptation may underlie the enhanced saliency of drug-related cues that trigger relapse in cocaine addicts.

Title: Dynamic changes in nucleus accumbens miR-495 expression across cocaine self-administration and reinstatement

Authors: *R. M. BASTLE[1], N. S. PENTKOWSKI[1], P. R. KUFAHL[2], N. A. PEARTREE[2], T. CHAUDHURY[1], C. D. SMITH[1], R. J. OLIVER[3], N. I. PERRONE-BIZZOZERO[3], J. L. NEISEWANDER[1];
[1]Sch. of Life Sci., [2]Dept. of Psychology, Arizona State Univ., Tempe, AZ; [3]Dept. of Neurosciences, Univ. of New Mexico, Albuquerque, NM

Abstract: We previously found that the microRNA miR-495 is highly expressed in the striatum, targets several addiction-related genes (ARGs), and is downregulated in the nucleus accumbens (NAc) 1 h following both acute and sensitizing cocaine injection regimens. We then found that miR-495 overexpression in the NAc shell (NAcSh) decreases ARG expression, cocaine self-administration (SA) under a progressive ratio schedule of reinforcement, and responding during extinction and reinstatement. These findings suggest miR-495 regulates genes that are involved in motivation for cocaine. Here, we sought to characterize changes in NAc miR-495 expression across different lengths of cocaine SA, and following cue and cocaine-primed reinstatement. Adult, male Sprague-Dawley rats were trained to lever press for cocaine (1.0 mg/kg/0.1ml, IV) under a variable ratio (VR) 5 schedule of reinforcement. Control rats received yoked saline infusions. Rats were sacrificed 1 h following either the 1st (i.e., Day 1 group) or the 22nd SA session that either followed a 1- or 21-d abstinence period (i.e., Day 22 or Relapse group, respectively). Total RNA was isolated from NAc tissue and miR-495 expression was measured using qRT-PCR. We found that miR-495 levels were significantly increased in the Day 1 and Day 22 SA groups in the NAcSh compared to saline controls, but no change was found in the NAcSh of the Relapse group or between any groups in the NAc core. A separate group of rats underwent SA training (0.75 mg/kg/0.1ml, IV; VR5), followed by daily extinction sessions, and then were either tested for cue or cocaine-primed reinstatement. For cocaine-primed

reinstatement, cocaine- and saline-trained rats received either a cocaine (15 mg/kg, IP) or saline injection on test day. Rats were sacrificed immediately following the 90-min test session. We found no change in NAc miR-495 expression following cue reinstatement, but did find a significant decrease following a cocaine-prime on test day, regardless of whether rats were trained with cocaine or saline. This latter effect is consistent with our previous findings where experimenter-delivered cocaine downregulates NAc miR-495 expression. In contrast, self-administered cocaine upregulates miR-495 levels, specifically in the NAcSh. This effect only occurs during SA acquisition and maintenance, suggesting miR-495 increases in the early stages of acquiring cocaine abuse-related behavior, but not in later stages. Given that miR-495 targets several ARGs and increasing its expression in the NAcSh suppresses motivation for cocaine, the blunted increase in miR-495 during relapse may contribute to neuroadaptations underlying cocaine dependence.

Title: The neuronal RNA-binding protein HuD interacts with Argonaute proteins and GW182 proteins in an RNA-dependent manner relieving miRNA-mediated repression

Authors: A. S. GARDINER, M. DELL'ORCO, *N. PERRONE-BIZZOZERO; Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM

Abstract: The RNA stability factor HuD is an RNA-binding protein that binds specific U-rich sequences in the 3'UTR of target mRNAs. This interaction serves to stabilize mRNAs, allowing for increased translation of the targets. MicroRNAs (miRNAs) also bind specific sequences in the 3'UTR of target mRNAs, but unlike HuD, this interaction most often results in decreased translation through silencing or degradation. MiRNAs function in the context of the RNA-

induced silencing complex (RISC), which includes Argonaute (Ago) proteins. Ago proteins interact with GW182 proteins, which are required for miRNA-mediated gene silencing. GW182 proteins accumulate in GW-bodies, also known as P-bodies, which are sites for mRNA degradation. mRNAs may also be stored in P-bodies, in the cell body as well as in neuronal processes, until they are needed. Previously, we reported that HuD and miR-495 have many target mRNAs in common, as the miR-495 seed sequence is complementary to the HuD GU-rich binding motif and that many of these common targets are implicated in drug addiction (Gardiner et al. 2013; SfN Poster 350.10). Thus, HuD and miR-495 compete for the binding and regulation of addiction-related genes such as BDNF and CAMK2a, which are enriched in shared binding-sites in their 3'UTRs. Interestingly, when HuD was transfected into HeLa cells that were previously subjected to miR-495-mediated repression, reporter constructs showed robust derepression. However, the opposite did not occur when miR-495 was added to cells previously treated with HuD. Here we show that in the mouse striatum, a region important for addiction-related processes, HuD interacts with Ago proteins and that this interaction is in part RNA-mediated. We also show that HuD interacts with the P-body marker GW182. In addition, HuD colocalizes with GW182 in neuroblastoma cells treated with hydrogen peroxide. These findings suggest a mechanism by which HuD may "rescue" mRNAs from miRNA-mediated repression in P-bodies, allowing for increased translation. Furthermore, since HuD is expressed in the nucleus accumbens and regulated by cocaine, HuD-mediated target derepression may be involved in the post-transcriptional control of gene expression during the establishment of addiction-related behaviors.

Title: Neuronal rna-binding protein hud regulates addiction-related target mrnas, structural plasticity, and cocaine addiction-related behaviors

Authors: ***R. J. OLIVER, JR**, A. S. GARDINER, J. L. BRIGMAN, A. M. ALLAN, N. I. PERRONE-BIZZOZERO;
Dept. of Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM

Abstract: Post-transcriptional mechanisms play an important role in nervous system development and function, however, very little is known about their role in the etiology of substance use disorders. RNA binding proteins (RBPs) provide one such regulatory mechanism in post-transcriptional regulation. HuD is a neuronal specific RBP that associates with the 3'UTR of specific mRNAs containing AU-rich instability elements (AREs). Through association with these regions, HuD stabilizes mRNA transcripts protecting them from degradation. We found that HuD targets include those that have been implicated in addiction, including CaMKIIa, Bdnf, Mef2c, and Arc. Additionally, HuD (ELAVL4) itself was found within the KARG suggesting it may play a role in this disorder. Using a dual luciferase expression system, we demonstrated that the Camk2a, Arc, and the long and short 3' UTR variants of BDNF transcripts (Bdnf-L, Bdnf-S) are direct targets of HuD. Confirming this, we found that mice overexpressing neuronal specific HuD (HuD OE; Camk2a-myc-ELAVL4/Npb; Bolognani et al., 2006) had increased mRNA expression of targets such as CaMKIIα and Bdnf, especially within the Nucleus Accumbens (NAc). Increased protein expression of these targets was also found within this region. Since many HuD targets have roles in structural plasticity of neurons, specifically within the NAc, we were interested in the role that HuD may play in this phenomenon. We found that HuD OE animals had increased percentage of immature thin spines, with a decrease in intermediate stubby spines within NAc neurons. However, there were no differences in the percentage of mature mushroom spines. Next, we were interested in the translation of these molecular and structural alterations to behavior. We found that HuD OE mice are more sensitive to the acute locomotor stimulatory actions of 7.5 mg/kg cocaine compared to wild type (WT) littermates. Although their initial response to cocaine was elevated, the animals did not exhibit sensitization to cocaine suggesting a ceiling effect of drug-induced locomotor activity. In a conditioned place preference model, we found that HuD OE spend more time in the cocaine (15 mg/kg) associated chamber compared to WT littermates. Finally, this effect may be limited to drug associated cues, as HuD OE and WT animals did not show a difference in their acquisition or extinction of appetitive behavior. However, upon exposure food-paired cues, HuD OE animals show increased reinstatement behavior. Together, these results suggest that HuD may play a role in addiction-related alterations in gene expression, plasticity, and behavior.

Abstract: Variations in cadherin-catenin adhesion complex genes are associated with multivariate drug use, however the role of these proteins in drug-mediated synaptic plasticity has not been defined. Here we demonstrate that classical cadherins N-cadherin, R-cadherin, and cadherins -7, -8, and -11 are expressed in dopaminergic (DA) and non-dopaminergic neurons of the VTA and that N-cadherin is localized to both excitatory and inhibitory synapses being formed onto these DA neurons. Inhibiting intercellular N-cadherin interactions abolished spike-timing dependent plasticity in the VTA, indicating that cadherins are important mediators of synapse plasticity in this region. Using immuno electron microscopy we demonstrate that following cocaine-mediated conditioned place preference (CPP), cadherin and GluA1 are significantly recruited to the synaptic membrane of excitatory synapses being formed onto dopaminergic neurons. This is reversed following extinction of CPP. Moreover, stabilizing cadherin at the membrane using a transgenic mouse model significantly attenuates cocaine-mediated CPP. These results show that cadherins play an important role in synaptic plasticity in the VTA and may be involved in structural changes at synapses caused by cocaine use.

Title: Phasic neuronal activity in the anterior cingulate cortex robustly differentiates water and cocaine cues in rhesus macaque monkeys

Authors: J. T. MORRA[1], E. BAEG[2], H. P. JEDEMA[3], *C. W. BRADBERRY[3,4];
[1]Psychiatry, Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA; [2]Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci. at Sungkyunkwan Univ., Suwon, Korea, Republic of; [3]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [4]VA Pittsburgh Hlth. Services, Pittsburgh, PA

Abstract: Prior studies in rodents suggest that cues associated with natural rewards, such as food and water, are represented by phasic activity in a common, overlapping subpopulation of neurons in the ventral striatum. Conversely, phasic cocaine cue encoding has been shown to manifest in a parallel, largely non-overlapping ensemble of neurons in that region. Though these electrophysiological studies have substantiated parallel processing of motivationally salient cues in the rodent ventral striatum, the topography of encoding of drug vs non-drug reward is less well characterized in the primate brain. Rodent functional imaging data implicate a broad tapestry of brain reward circuitry in the differentiation of cocaine and natural reward cues, including the dorsal striatum and medial prefrontal cortex. In primates, both orbitofrontal and anterior cingulate cortex have been shown to selectively encode distinct non-drug rewards. The purpose of the current study was to extend electrophysiological differentiation of cocaine versus non-drug reward associated cues to a broader neuroanatomical framework in the non-human primate brain. We simultaneously recorded multiple single units in the ventral and dorsal striatum, as well as the anterior cingulate and orbitofrontal cortices of rhesus monkeys during both water and cocaine self-administration blocks within the same sessions. We identified differential encoding of water and cocaine cues across all brain regions. However, we found that neurons in the anterior cingulate cortex distinguish cocaine from water cue conditions more robustly than neurons in the other regions of interest. These data implicate the anterior cingulate cortex as a structure of particular importance in the differentiation of drug and non-drug reward.

Title: Cocaine evokes microvesicle release by activating sigma-1 receptor and ARF6

Authors: *Y. NAKAMURA[1], S.-Y. TSAI[1], Y. LI[2], D.-T. LIN[2], T.-P. SU[1];
[1]Cell. Pathobiology Section, Integrative Neurosci. Res. Br., [2]Optical Imaging Core, NIDA IRP CORE FACILITIES, NIDA IRP, Baltimore, MD

Abstract: The sigma-1 receptor (Sig-1R) is known to function as a chaperone and has been implicated in many central nerve system disorders including depression, neuropathic pain and drug addiction. We reported previously that the Sig-1R can translocate (e.g., from mitochondrion-associated endoplasmic reticulum membrane to the endoplasmic reticulum network and plasma membrane) after the agonist stimulation and shapes therefore neuronal and behavioral responses to cocaine which is a Sig-1R agonist (Kourrich et al., Cell, 2013). Given that a recent clinical study demonstrated that Sig-1Rs are present in the plasma and that the concentration of Sig-1Rs increased following the treatment of antidepressants including fluvoxamine which is a Sig-1R agonist (Shimizu H et al., Neuropsychiatr Dis Treat. 2013), we previously examined the possibility that cocaine may cause Sig-1Rs to translocate into extracellular space in the form of extracellular vesicles that may represent a new route of shaping neuroplasticity induced by cocaine. Thus, our previous study showed that Sig-1Rs were found in the isolated microvesicles following a 30 min treatment of cocaine and that the extracellular Sig-1R level increased in a cocaine dose-dependent manner (0.1, 1 and 10 μM). Furthermore, pre-treatment with BD1063, a specific Sig-1R antagonist, completely inhibited the cocaine-evoked release of microvesicles containing Sig-1R (Nakamura et al., SfN 2014). However, the mechanisms underlying cocaine-induced microvesicle release are still unknown. The present study examined the effect of cocaine on the activity of ADP-ribosylation factor 6 (ARF6) which is a small GTP-binding proteins and is known to be an important signaling molecule to regulate microvesicle release and membrane trafficking. Indeed, cocaine stimulation increased an active form of ARF6 (ARF6-GTP). Those results indicate that the activation of Sig-1R by cocaine in causing microvesicle release may involve ARF6. Title: Opposite regulation of cannabinoid CB1 and CB2 receptors in the prefrontal cortex of rats treated with cocaine during early adolescence

Authors: *J. GARCIA-FUSTER, R. GARCIA-CABRERIZO;
IUNICS. Univ. of the Balearic Islands, Palma de Mallorca, Spain

Abstract: The endocannabionoids function as retrograde lipid messengers through the activation of inhibitory CB1 and CB2 receptors. CB1 is highly expressed in the cerebral cortex and other limbic areas of the brain reward circuitry, while CB2 is less abundant and is mainly associated with inflammatory processes mediated by microglia. The endocannabinoid system is implicated in the neurobiology of cocaine addiction, even though the literature shows inconsistent findings in how chronic cocaine regulates CB1 and CB2 receptors in the brain. Given that adolescence represents a critical moment for shaping adult behavior and may predispose to disease vulnerability later in life, this study evaluated: (1) the basal regulation of cannabinoid CB1 and CB2 receptors in several brain regions (i.e., prefrontal cortex, PFC and hippocampus, HC) during the course of adolescence (post-natal day PND 40, PND 47, PND 54) as compared to adulthood (PND 61), and (2) the regulation of brain CB1 and CB2 receptors by a sensitizing regimen of chronic cocaine (15 mg/kg, 7 d, i.p.) during different windows of adolescence vulnerability (early PND 33-39, mid PND 40-46, late PND 47-53). Control rats received 7 consecutive days of saline (0.9% NaCl, i.p., 1 ml/kg) at the indicated windows of adolescence. CB1 and CB2 receptor protein levels were evaluated in the PFC and HC by western blot analysis with specific and validated antibodies 24 h after the last treatment dose (PND 40, PND 47, PND 54). The results demonstrated a dynamic and opposite basal modulation of CB1 and CB2 receptors during the course of adolescence. In particular, CB1 receptor levels were increased while CB2 receptors were decreased in adolescence as compared to adulthood with asymptotes values around mid adolescence (PND 47) both in PFC (CB1: +45±22, $p<0.05$; CB2: -24±6%, $p<0.05$) and HC (CB1: +53±23, $p<0.05$; CB2: -20±8%, $p<0.05$). Interestingly, chronic cocaine only regulated CB1 (+55±10%, $p<0.05$) and CB2 (-25±10%, $p<0.05$) receptors when it was administered during early adolescence and only in the PFC. These results identified a period of vulnerability during early adolescence at which cocaine dysregulated the activation of CB receptors in the PFC. Further studies are evaluating whether these changes are transient or can interfere in the normal program of brain development and have enduring consequences beyond that age period and into adulthood.

Title: Role of hevin in the neuroplasticity of cocaine addiction

Authors: *V. F. VIALOU, R. MONGRÉDIEN, A. ORRICO, A. ERDOZAIN;
INSERM, Paris, France

Abstract: Exposure to addictive drugs can result in maladaptive alterations in neural circuit function, which underlie the addicted phenotype. While alteration in synaptic plasticity in corticoaccumbens circuit has long been caracterized as a core factor in addiction, extracellular matrix proteolysis has recently been implicated in mediating addiction. The focus of my research is on a matricellular protein called Hevin that is expressed in the nucleus accumbens and has been shown to play a role during development on synpatogenesis. We first performed double fluorescent *in situ* hybridization to characterize hevin expression in nucleus accumbens in the adult mouse brain. We could confirm hevin expression in specific cell types: neurons and astrocytes. We then quantified hevin protein levels in the nucleus accumbens after acute or chronic cocaine administration. Hevin was upregulated only by chronic cocaine. In order to evaluate its orle in sensitivity to cocaine, we used viral-mediated gene transfer into nucleus accumbens to overexpress hevin. We also used the complementary approach to downregulate hevin expression via the expression of shRNA directed against hevin. Finally, we used hevin knock-out mice. After hevin manipulation, we subjected the mice to conditioned place-preference. We show here that viral overexpression of hevin in the entire NAc decreases cocaine's rewarding effect. Surprisingly, downregulation or lack of hevin also decreases cocaine's rewarding effect. This points to a complex role of hevin in the neuronal plasticity associated to the adaptation to drugs of abuse. Alterations in spine morphology and numbers are key features of chronic exposure to cocaine and might mediate the cognitive impairments and mood disturbances of various diseases. My preliminary studies show that hevin in NAc basally increased spine density and this effect was potentiated after repeated cocaine. This is in accordance with its synaptogenic role at excitatory synapse in neuronal cultures and *in vivo* in optic tectum. We are currently testing the effects of hevin upregulation in specific neuronal subtypes. Long-term alterations in the nucleus accumbens contribute to the behavioral abnormalities observed after cocaine administration. We identified hevin as a key player of

cocaine's rewarding effects. Alteration in hevin's level alter cocaine sensitivity but increases spine number. Together these experiments will provide better understanding of the role of hevin in the pathophysiology of drug addiction.

Title: Enhanced sensitivity to repeated cocaine increases perineuronal net staining in the adult rat medial prefrontal cortex

Authors: *M. SLAKER, B. A. SORG;
Washington State Univ., Vancouver, WA

Abstract: Perineuronal nets (PNNs) are unique structures of extracellular matrix in the central nervous system. Within the medial prefrontal cortex, PNNs surround the soma and proximal dendrites of parvalbumin (PV)-containing, GABAergic interneurons. The appearance of PNNs during development coincides with the closure of critical periods, during which time external stimuli influence development of neuronal circuits. Cocaine is a psychomotor stimulant that increases locomotor activity in rats; after repeated cocaine exposure, rats become sensitized to cocaine and display an enhanced locomotor response. We sought to determine the effect of cocaine exposure on PNNs within the medial prefrontal cortex. We hypothesized that exposure to a strong external stimulus (cocaine) during adulthood would increase the intensity of PNNs within the prefrontal cortex. To test this, we exposed adult, male rats to 1 or 5 days of cocaine (15 mg/kg, i.p.) and locomotor activity was measured each day to assess sensitization. Two hours following the last injection, rats were sacrificed and the prefrontal cortex was assessed for PNN intensity. Preliminary results suggest that 2 hr following the last cocaine injection, PNN intensity was increased in the prelimbic region of the prefrontal cortex but was unaffected in the infralimbic or medial orbitofrontal regions. This increased intensity was positively correlated with sensitized locomotor activity, suggesting that PNN intensity in the prelimbic region may serve as a functional read-out of cocaine-induced motivational behavior. In addition to PNNs, we

also analyzed PV expression. These results demonstrate that exposure to cocaine increases PNN intensity within the prelimbic region of the prefrontal cortex and suggest that repeated cocaine may render the medial prefrontal cortex resistant to normal physiological stimuli.

Title: Emergence of endocytosis-dependent mglur1-ltd at nucleus accumbens synapses during withdrawal from cocaine self-administration

Authors: *A. F. SCHEYER[1], M. E. WOLF[2], K. Y. TSENG[3];
[1]Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]Neurosci., [3]Cell. and Mol. Pharmacol., Rosalind Franklin Univ., North Chicago, IL

Abstract: Extended-access cocaine self-administration induces a progressive enhancement of cocaine craving during withdrawal termed “incubation of craving”. Rats evaluated after >1 month of withdrawal (“incubated rats”) display alterations in signaling at medium spiny neuron (MSN) synapses of the nucleus accumbens (NAc), including elevated levels of Ca2+-permeable AMPA receptors (CP-AMPARS) and a transition in group I metabotropic glutamate receptor (mGluR)-mediated synaptic depression from mGluR5- to mGluR1-dependent. To determine the time-course over which these adaptations appear and further characterize the emergent form of mGluR1-mediated synaptic depression, we conducted whole-cell patch-clamp recordings in NAc core MSN of “incubated rats” at multiple time-points during withdrawal. Elevated synaptic contributions from CP-AMPARs, as well as the loss of mGluR5- and gain of mGluR1-mediated synaptic depression, were not detected between 7 and 25 days of withdrawal, but were present following at least 35 days. Furthermore, the previously identified mGluR1-mediated suppression of the EPSC was found to be a form of long-term depression (mGluR1-LTD). We also investigated the mechanism underlying this mGluR1-LTD by conducting recordings in the presence of dynamin inhibitory peptide or pep2-EVKI, which disrupt endocytosis and PICK1

regulation of calcium-impermeable AMPAR (CI-AMPAR) trafficking, respectively. Together, our results indicate that mGluR1-LTD involves a non-obligatory swap of CP-AMPARs and CI-AMPARs mediated by dynamin-dependent internalization and PICK1-dependent insertion. Together, these results elucidate the time-course for the emergence of multiple adaptations during withdrawal, in addition to the mechanisms underlying mGluR1-LTD at NAc MSN synapses after the "incubation" of cocaine-craving.

Title: Effect of naltrexone on neural response to risky decision making

Authors: P. T. KORTHUIS[1], L. DENNIS[1], R. LISOWSKI[1], D. SCHWARTZ[1], B. TREMBLAY[1], V. WILSON[1], *W. F. HOFFMAN[2,1];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Mental Hlth. Div. P35C, Portland VA Med. Ctr., Portland, OR

Abstract: Introduction: Persons who use methamphetamines (MA) often engage in risky decision-making. Naltrexone blocks opioid mu receptors in the reward pathway that may modulate impulsivity. We assessed the effect of naltrexone on impulsivity and its neural correlates in MA dependence. **Methods:** We evaluated 42 MA-dependent participants on a probability-delay discounting (PDD) fMRI task before and 3 weeks after randomization to extended-release naltrexone (XR-NTX 380mg) or placebo injection. The PDD asks participants

to choose between an immediate, certain monetary reward and alternative reward of varying magnitude, time to receipt, and odds against winning. We calculated area under the curve (AUC) for delay and probability. AFNI amplitude modulated regression identified brain regions whose BOLD response scaled with the size of the reward characteristic. Linear mixed models assessed within subject (time) by group main effects and interaction (voxel threshold p=0.01; cluster threshold familywise $\alpha<0.05$). **Results:** Participants were similar by treatment group (Table). Performance on the PDD did not differ between groups over time, but probability AUC decreased for XR-NTX group, suggesting decreased impulsivity. fMRI analysis found significant treatment by time interaction clusters for probability and delay (Figure). Cluster voxels were less responsive to stimulus in the NTX group, but unchanged for placebo.

Table: Comparison of demographic and discounting measures between groups before and after XR-NTX injection.

	Demographics			PDD			
				Delay		Probability*	
	Age (SD)	% Male	Education (SD)	pre	post	pre	post
XR-NTX (19)	39.3 ± 10.6	76.0	12.6 ± 2.04	0.61 ± 0.25	0.61 ± 0.24	0.36 ± 0.25	0.31 ± 0.26
Placebo (23)	36.7 ± 9.53	70.4	12.5 ± 0.77	0.47 ± 0.24	0.50 ± 0.21	0.34 ± 0.19	0.26 ± 0.12

*Significant main effect of visit ($F(1,40) = 5.7$, $p = 0.021$).

Conclusions: In this sample, XR-NTX decreased sensitivity to delay and probability in behaviorally relevant brain regions. The PDD may be useful for studying the neural basis of behavioral response to other substance use disorder treatments.

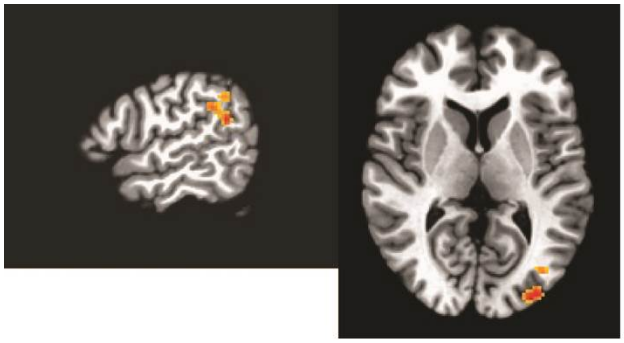

Figure: Regions with significant group x time interaction terms. Left, right inferior parietal lobule for the AM regressor associated with probability; right, occipito-parietal junction for the AM regressor associated with delay.

Title: Imaging of cerebral glucose metabolism in methamphetamine dependence with and without psychosis compared to normal controls: a PET study

Authors: D. VULETIC[1], J. WARWICK[2], T. MOALOSI[2], J. ZEEVAART[3], *P. DUPONT[4], D. STEIN[1];
[1]Dept. of Psychiatry, Univ. of Cape Town, Cape Town, South Africa; [2]Dept. of Nuclear Med., Stellenbosch Univ., Cape Town, South Africa; [3]Nuclear Energy Corp. of South Africa (NECSA), Johannesburg, South Africa; [4]Lab. for Cognitive Neurol., KU LEUVEN, Leuven, Belgium

Abstract: Objective: Methamphetamine dependence may lead to a range of psychiatric and medical symptoms, including psychotic symptoms. However, there are few PET data that include patients with methamphetamine dependence who do and do not have psychosis. We used positron emission tomography (PET) with [18F]fluorodeoxyglucose (FDG) to investigate the neurocircuitry of methamphetamine dependence with and without psychotic symptoms. Methods: Resting brain glucose metabolism was measured with FDG-PET using a Philips Gemini PET-CT scanner in three groups: ten patients with methamphetamine dependence, twelve patients with a history of methamphetamine induced psychotic disorder (both these groups of participants were abstinent for a minimum of one week), and eleven normal controls. After normalization for whole brain counts, warping to MNI (Montreal Neurological Institute) and smoothing with a 12mm Gaussian kernel, we performed a voxel based ANOVA using SPM8. The significance threshold was set at FWE corrected $p < 0.05$. Results: In the methamphetamine dependence group with no psychosis, significantly decreased glucose metabolism was seen in the anterior right cingulum compared to the control group ($x=14, y=42, z=12$, $T=5.23$, FWE corrected $p=0.02$, cluster size=1067). No significant differences were seen between the other group comparisons. Conclusion: Lower metabolism in the cingulum in methamphetamine dependence is consistent with previous reports showing decreased activity

in this region in recently abstinent patients. Such decreased metabolism has been suggested to contribute to impaired cognitive and emotional processes in these patients. The lack of findings in those patients with a history of psychosis is contrary to expectations, and may reflect normalization by antipsychotic treatment.

Title: Differential effects of Methamphetamine and Modafinil on the mRNA levels of dopamine and glutamate receptors and voltage-gated Ca^{2+} channels in the mouse prefrontal cortex

Authors: *V. BISAGNO[1], B. GONZALEZ[2], J. CADET[3], E. GARCIA-RILL[4], F. J. URBANO[5]; [1]ININFA-CONICET, Buenos Aires, CABA, Argentina; [2]ININFA-(UBA-CONICET), Buenos Aires, Argentina; [3]Mol. Neuropsychiatry Res. Br., NIDA-NIH, Baltimore, MD; [4]Ctr. for Translational Neurosci., UAMS, Little Rock, AR; [5]IFIBYNE (UBA-CONICET), Buenos Aires, Argentina

Abstract: Abuse of methamphetamine (METH) can induce cognitive dysfunctions in humans and animal models. On the other hand, the psychostimulant Modafinil (which shares with METH the property of being also a DAT blocker) is prescribed as a cognitive enhancer. We have previously demonstrated that Modafinil can attenuate METH-induced deficits in visual memory and improve ERK signaling in the medial prefrontal cortex (mPFC). We have also reported that METH blunted calcium currents in mPFC pyramidal neurons and decreased excitatory transmission through D1/D5 receptor mechanisms. Interestingly, SCH23390 (D1/D5 antagonist) alone was able to produce similar detrimental effects on mPFC physiology. Our studies suggest inverted-U-shaped dopamine (DA) actions in mPFC: low levels of DA are beneficial (i.e.

moderate Modafinil actions), high levels are detrimental (massive dopamine release by METH). In order to unveil other potential differences in the actions of METH and Modafnil, we evaluated mRNA expression of glutamate and DA receptors subunits and voltage-gated Ca2+ channels (Cav) induced by METH (acute and chronic, 1 mg/kg) and Modafinil (acute, 90 mg/kg) in the mouse mPFC. We found that METH and Modafinil differ in their effects on mPFC as follows: (a) for DA receptors, METH decreased Drd1 mRNA while Modafinil did not; (b) Modafinil increased the expression of Drd2, METH did not; (c) for the P/Q type Cacna1a (Cav2.1), Modafinil increased its expression while METH did not show any acute effect but produced increased expression after chronic treatment; (d) for L type Cav1.3 Cacna1d, only METH showed reduced expression. On the other hand, glutamate receptor subunits mRNA AMPA Gria1 and Gria2 were increased for both psychostimulants whereas NMDA subunit Grin1 was significantly increased after acute Modafnil but only after chronic METH treatment. Western blot analysis also revealed that both drugs decreased CaMKII phosphorylation in the mPFC. In normal physiological conditions DA levels in the mPFC need to be precisely tuned to maximize signal/noise ratios. Our results support the idea that DA tuning may involve decreasing synaptic transmission (by effects on Ca currents and glutamate transmission) in cortico-cortical and cortico-subcortical networks. These mechanisms appear to be negatively impacted by toxic psychostimulants like METH to contribute to the mPFC hypofunction observed in METH addicts. Thus, some of the beneficial effects of Modafnil might be related to differential effects on DA/glutamate in the mPFC.

Title: Simultaneous determination of the effects of methamphetamine on GABA, glutamate and monoamines by microdialysis in the prefrontal cortex and hippocampus of rats

Authors: *S. C. CHEETHAM, H. ROWLEY, L. PINDER, R. KULKARNI, D. HEAL; RenaSci Ltd, Nottingham, United Kingdom

Abstract: Methamphetamine is a highly abused drug with complex pharmacological actions in the brain. Intracerebral microdialysis in freely-moving rats can provide valuable insights in such

cases, but it is often limited by the number of neurotransmitters that can be measured in each sample. We have used *in vivo* microdialysis to investigate methamphetamine's effects simultaneously on GABA, glutamate (GLU), dopamine (DA), noradrenaline (NA) and 5 HT in the prefrontal cortex (PFC) and hippocampus (HIP). Under gaseous anaesthesia, 4.0 mm microdialysis probes were stereotaxically implanted into the PFC (coordinates relative to bregma: AP +3.4 mm; ML +/-0.8 mm; DV 5.0 mm relative to dura) and HIP (AP -5.3 mm; ML +/-4.8 mm; DV -7.5 mm) of male, Wistar rats (250-350g; n=5). Dialysate samples were collected at 15 min intervals for 2 hr. GABA and GLU were analysed by UHPLC with electrochemical detection (ECD) and DA, NA, 5 HT by HPLC ECD using Antec ALEXYS™ systems. Methamphetamine (3.0 mg/kg) was dosed by intraperitoneal injection. Mean basal (T=0 min) extracellular concentrations of neurotransmitters (monoamines in fmol/5µl; amino acids in amol/1.5µl) were: PFC: DA = 3.47 ± 1.00, NA = 4.99 ± 1.98, 5 HT = 0.48 ± 0.07, GABA = 3.6 ± 2.0 and GLU = 496 ± 83; HIP: DA = 1.07 ± 0.12, NA = 3.82 ± 0.92, 5 HT = 0.12 ± 0.02, GABA = 2.4 ± 0.7 and GLU = 354 ± 27. Compared with pre-intervention baseline values, methamphetamine (3.0 mg/kg) produced rapid neurotransmitter changes that peaked 30-45min after dosing. In PFC, there were increases in DA (533%, $p<0.001$), NA (408%, $p<0.001$), 5 HT (1500%, $p<0.001$), GABA (452%, $p<0.05$) and a decrease in GLU (-56%, $p<0.001$). In HIP the same pattern of effects was observed, but the changes in monoamines were much greater with increases in DA (1781%, $p<0.001$), NA (765%, $p<0.001$), 5 HT (11,058%, $p<0.001$), GABA (451%, $p<0.01$) and a decrease in GLU (31%, $p<0.01$). The results reveal that methamphetamine produced large increases in DA and NA in PFC and HIP, but surprisingly its greatest effect was to potentiate 5 HT efflux in these regions. The increases in extracellular monoamines were accompanied by concomitant reductions in GLU and increases in GABA in both regions. It is most likely that that the decreased excitatory and enhanced inhibitory amino acid neurotransmitter efflux in PFC and HIP were homeostatic responses to attenuate the pharmacological effects of methamphetamine. The marked increases of 5 HT in both brain regions may also have been part of this response.

Title: Changes in cortico-striatal neuroplasticity following methamphetamine

Authors: *D. MISHRA, J. PENA BRAVO, S. M. GHEE, C. R. BERINI, A. LAVIN, C. M. REICHEL;
Dept. of Neurosciences Res., Med. Univ. of South Carolina, Charleston, SC

Abstract: Methamphetamine (meth) abuse induces changes in the prefrontal cortex (PFC) and nucleus accumbens (NAc), which exert inhibitory control over maladaptive behaviors like drug over-consumption and mediates reward-related behaviors, respectively. Hence, meth-induced functional impairment of these two regions may increase abuse vulnerability. Here, we describe changes in cortico-striatal neuroplasticity following a contingent and non-contingent meth administration protocol. In Experiment 1, rats were given 4 non-contingent i.p. injections of 4 mg/kg meth or saline at 2 hr intervals in one day. Rats were killed 7 days later and whole-cell patch clamp recordings were performed in the dorsomedial PFC (dmPFC) and field potentials in the NAc core (NAcc) of the same animals. In the dmPFC, meth increased the AMPA/NMDA ratio in meth groups compared to controls indicating potentiated state of deep-layer PFC pyramidal neurons. In the NAcc we observed a significant paired pulse depression (indicating a higher neurotransmitter release probability) in meth group when compared to controls. Also, input/output curves revealed an overall decrease in synaptic strength of meth rats. In Experiment 2, rats received one-hour meth self-administration (SA) sessions for 7 days, followed by 14 days of six-hour long access sessions and yoked saline controls. Meth was delivered IV on an FR1 schedule at a volume of 20 μg/50 μl infusion and rats were killed 7 days after discontinuation of meth. In the dmPFC, AMPA/NMDA ratio was unaffected in meth SA rats when compared to controls although, only n=2 rats have been recorded so far. In the NAcc, we assessed long term depression (LTD) and potentiation (LTP) to understand the synaptic strength using low frequency (5Hz, 900 times) and high frequency (100Hz, 4 times) stimulation protocols. Meth SA caused a loss of LTP and significantly lessened the degree of LTD induction compared to the controls. Combined, our findings indicate changes in synaptic neurotransmission in both the dmPFC and NAcc following contingent and non-contingent meth. The relationship between meth pharmacology alone or combined with behavior output has yet to be defined. Additional questions need to determine how these maladaptive consequences impact glutamate release, reuptake, and relapse to meth-seeking behavior.

Title: Chronic methamphetamine exposure decreases neural activation in hypothalamic-pituitary-adrenal axis associated brain regions in a sex-specific manner

Authors: J. JACOBSKIND, *D. G. ZULOAGA;
Univ. at Albany, Albany, NY

Abstract: Sex differences in the abuse and consequences of methamphetamine (MA) have been reported in both humans and rodents, with females showing a more rapid spiral into addiction. One mechanism through which MA may contribute to these sex differences is by differentially activating the hypothalamic-pituitary-adrenal (HPA) axis. Our previous studies indicate that females show elevated MA-induced glucocorticoid release and altered activation of HPA axis associated brain regions following an acute exposure. However, little is known about potential sex specific effects of chronic MA on activation of HPA axis associated brain regions. In this study we administered MA (5 mg/kg) or saline to C57BL/6J mice for 10 consecutive days. Ten days after the chronic treatment period, mice were injected with a final dose of MA (5 mg/kg) or saline. Two hours later brain tissue was collected and immunohistochemically labeled for detection of the immediate early gene c-Fos in HPA-axis associated brain regions (paraventricular nucleus of the hypothalamus (PVH), central amygdala (CeA), basolateral amygdala (BLA), lateral amygdala (LA), bed nucleus of the stria terminalis (BNST), and medial amygdala (MeA)). Final injection with MA increased the number of c-Fos positive cells in all investigated regions, except the MeA. Chronic exposure to MA reduced c-Fos in the PVH, BNST, CeA, and the BLA and in three of these areas (BNST, CeA, and LA) this reduction was greater in males. In the PVH, final injection with MA increased c-Fos to a greater extent in females compared to males regardless of whether they had previously been exposed to MA. Together our findings demonstrate that chronic MA can suppress subsequent activation of HPA axis associated brain regions and in select regions this suppression is sex specific. In turn, these changes may contribute to sex differences in MA abuse patterns reported in humans and rodents.

Title: Microinjection of CART Peptide 55-102 into the nucleus accumbens blocks amphetamine-induced locomotor activity by regulating Akt-GSK3β signaling pathway

Authors: B. CHO[1], W. KIM[1], *J.-H. KIM[2,1];
[1]Yonsei Univ. Coll. Med., Brain Korea 21 Plus Projects for Med. Sci., Seoul, Korea, Republic of; [2]Yonsei Univ. Coll Med., Seoul, Korea, Republic of

Abstract: It has been previously shown that psychostimulants-induced locomotor activity are significantly attenuated by microinjections of cocaine- and amphetamine- regulated transcript (CART) 55-102 peptide into the nucleus accumbens (NAcc), suggesting that CART peptides exert an antagonistic effect on the generation of locomotion by these drugs in this site. In order to further identify what signal pathway might be involved in this process, we examined, in the present study, the effect of CART 55-102 on amphetamine (AMPH)-induced decreases of GSK3β and Akt phosphorylation levels in the NAcc tissues obtained from the rats which were given systemic injections of either saline or AMPH (1 mg/kg, i.p.) following microinjections of either saline or CART 55-102 (2.5 μg/0.5μl/side) into this site. Accumbal CART 55-102 recovered the decreases of GSK3β and Akt phosphorylation back to saline levels. These results suggest that CART 55-102 peptide in the NAcc may play a compensatory inhibitory role in AMPH-induced locomotor activity by recovering the Akt-GSK3β signaling pathway modified by AMPH.

Title: Exploration of mTOR signaling in the ventral striatum during the development of methamphetamine sensitization

Authors: *S.-H. HUANG, L.-M. LEE, J.-C. CHEN;
Physiol. and Pharmacology, Sch. of Med., Chang-Gung Univ., Taoyuan City, Taiwan

Abstract: Behavioral sensitization to abused drug simulates human addicts that encode an array of obscure behaviors, however the molecular mechanism remains largely unclear. There are several cellular pathways may participate the progress of behavioral sensitization, and in this study we focus on change of mammalian target of rapamycin (mTOR) complex and down-stream regulator(s) in methamphetamine (METH) sensitized mice. Previous studies indicate that mTOR and its down-stream signals are important translation regulators in determining the neuroplasticity at synapse, however its impact on the progress of drug abuse is unclear. The aim of this study is to identify the role of mTOR signals in the development of METH sensitization in designated brain area. To this end, B6 mice were treated with daily METH (2 mg/kg, i.p.) for consecutive 8 days followed by behavioral monitoring. The results show that in METH sensitized mice, levels of total and phospho- mTOR/S2448 as well as its substrate phospho-p70S6K increased progressively along with daily METH injections in the ventral striatum, but not in dorsal striatum. The change of total mTOR could be also observed in a synaptosomal preparation from ventral striatum in METH-sensitized mice, suggesting a synaptic mTOR alteration. To examine the impact of mTOR up-regulation on METH sensitization, we co-administered mTOR inhibitor, rapamycin during daily METH injections and found mTOR inhibition significantly suppressed the degree of METH sensitization at behavioral initiation, but not expression stage. Further, via mTOR shRNA injection at ventral striatum, we confirm that decrease in mTOR expression suppressed behavioral sensitization to METH. These results suggest striatal mTOR plays an important role on initiation of METH sensitization.

Title: Genome-wide DNA hydroxymethylation patterns in the rat nucleus accumbens consequent to methamphetamine self-administration

Authors: *J. L. CADET[1], S. JAYANTHI[1], A. GODINO[1], I. KRASNOVA[1], M. T. MCCOY[1], B. LADENHEIM[1], O. TORRES[1], R. LEE[2];
[1]Mol. Neuropsychiat Br., NIH/NIDA, Baltimore, MD; [2]Psychiatry, Johns Hopkins Med. Institutions, Baltimore, MD

Abstract: In animal models of methamphetamine addiction, rats learn to self-administer the drug and accelerate their intake over time. However, these self-administration (SA) models do not include adverse psychosocial consequences that are embodied in the diagnostic criteria of substance use disorders. Indeed, adverse outcomes are relevant factors that can promote abstinence in humans. Here, we studied the genome-wide DNA hydroxymethylation consequences of suppression of drug seeking by repeated foot-shocks (punishment). Rats were trained to self-administer methamphetamine for 9 h per day for 20 days. Reward delivery was paired with a tone-light cue sequence. Subsequently, 50% of the lever-presses were punished by mild foot-shock for 10 days for one methamphetamine SA group whereas lever-presses were not punished for another methamphetamine SA group. Shock intensity (0.18-0.36 mA, 0.5 sec) was gradually increased over time. Response-contingent punishment suppressed extended-access methamphetamine taking in some rats (Punishment-sensitive, PS) whereas other rats were punishment-resistant (PR) and continued to press for methamphetamine at a high level. Rats were euthanized at 2 hours after the last self-administration session and brain regions were collected for further molecular experiments. Tissues from the nucleus accumbens (NAc) were used to identify differentially hydroxymethylated regions by using hydroxymethylated DNA immunoprecipitation followed by whole genome sequencing (hMeDIP-Seq). Our study identified several differentially hydroxymethylated regions in the NAc of methamphetamine self-administering rats. Several classes of genes showed differential DNA hydroxymethylation in rats that showed the PR compared to the PS phenotype. These included genes involved in epigenetic regulation (DNA methyl-transferase1-associated protein 1 and Sin3A), genes that code for protein phosphatases (protein phosphatase 1, regulatory subunit 12A), and several microRNAs (miRNA 146a). In comparison to the PS group, the PR phenotype also showed increased DNA hydroxymethylation at long interspersed nuclear elements (LINE), with these differences being potentially responsible for genomic instability and consequent altered gene expression in the PR rats. These observations are consistent with our previous suggestions that methamphetamine SA is associated with diverse molecular modifications in the brain. Our findings support the idea of developing specific epigenetic agents in order to expand the therapeutic armamentarium against methamphetamine addiction.

Title: Efficacy of a tetanus-toxoid succinyl-methamphetamine vaccine differs between male and female mice

Authors: *T. A. KOSTEN[1,2,4], C. N. HAILE[1,2,4], K. J. WINOSKE[1], E. D. LYKISSA[5], N. NAIDU[5], B. M. KINSEY[3,4], R. ARORA[3,4], F. M. ORSON[4,3], T. R. KOSTEN[2,4]; [1]Psychology, Univ. of Houston, Houston, TX; [2]Psychiatry, [3]Immunol. Abstract: Background: We previously reported that the behavioral effects of cocaine and response to an anti-cocaine vaccine significantly differed between male and female mice. Here we assessed potential sex differences in response to methamphetamine (MA). We also determined whether the efficacy of a vaccine targeting MA would show sex-dependent effects. The anti-MA vaccine was constructed of tetanus-toxoid linked to succinyl-methamphetamine (TT-SMA), absorbed with aluminum hydroxide, and administered with the adjuvant E6020, a Toll-like receptor-4 agonist. Methods: Locomotor activity was compared between male and female mice (BALB/c) following administration of various doses of MA (1-4mg/kg) in 90-min sessions. Separate groups of male and female mice, vaccinated with TT-SMA and boosted 3-weeks later, were employed to determine plasma anti-MA antibody concentrations at several time points across a 12-week period. Vaccinated and non-vaccinated female mice were administered MA (2.0mg/kg) and locomotor activity assessed. Brain levels were also evaluated in vaccinated and non-vaccinated mice 30-min following MA administration to assess whether the vaccine effectively decreased the ability of MA to cross the blood-brain barrier. Results: MA elicited greater locomotor activity in female compared to male mice at all doses tested (p's<0.05). Following vaccination, antibody levels increased after a boost at week 3 in both male and female mice; however, the increase was greater in female mice ($p<0.05$). Female mice vaccinated with SMA-TT showed attenuated MA-induced locomotor activation (2.0mg/kg; $p<0.05$) and significantly lower brain levels of MA compared to non-vaccinated female mice ($p<0.001$). Conclusions: Results suggest female mice are more sensitive to the locomotor activating effects of MA and to the immunogenicity of the TT-SMA vaccine. That the vaccine attenuated

MA-induced locomotor activation is likely due to slowing MA brain penetration and supports the future development of this vaccine construct for the treatment of MA addiction, particularly in female addicts.

Title: Methamphetamine reward: contribution of toll-like receptor 4 and proinflammatory mediators

Authors: *T. J. FABISIAK[1], A. L. NORTHCUTT[1], K. T. BROWN[1], M. C. WINKLER[1], T. A. COCHRAN[1], M. E. HAAS[1], X. WANG[1], J. AMAT[1], S. F. MAIER[1], K. C. RICE[2], R. K. BACHTELL[1], M. R. HUTCHINSON[3,4], L. R. WATKINS[1];

Council Ctr. of Excellence for Nanoscale BioPhotonics, Adelaide, Australia; [4]Discipline of Physiol., Univ. of Adelaide Sch. of Med. Sci., Adelaide, Australia

Abstract: Drug reward has long been attributed to neuronal responses, chiefly within the mesolimbic dopamine (DA) pathway. Recent evidence suggests that glial activation within the brain is also required for drug reward. Morphine and cocaine activate glial Toll-Like Receptor 4 (TLR4), resulting in proinflammatory, neuroexcitatory signaling. TLR4 is an innate immune pattern recognition receptor, expressed principally on microglia in the CNS. TLR4 appears to recognize morphine and cocaine as xenobiotics (i.e., substances foreign to the brain), triggering

CNS glial signaling, akin to the immune responses elicited by bacteria. The ensuing proinflammatory cascade can have neuroexcitatory consequences. In the case of morphine or cocaine, blockade of TLR4; 1) prevents induction of CNS immune activation, 2) suppresses conditioned place preference (CPP), 3) blocks drug-induced DA increases within the nucleus accumbens (NAc) and 4) attenuates drug self administration. These findings indicate that drug-induced proinflammatory CNS glial signaling is necessary for drug reward and reinforcement. Methamphetamine (METH) is thought to exert its rewarding effects via reversal of DA transporters in the mesolimbic DA pathway. Repeated METH use is also associated with neurotoxicity. There are indications that CNS glial activation may contribute to METH's rewarding and neurotoxic effects. However, the mechanism by which METH triggers a CNS glial response is unknown. Here, we show that METH can bind to TLR4 to initiate glial reactivity. Systemic METH TLR4-dependently induces upregulation of proinflammatory markers in the brain, notably within the ventral tegmental area (VTA). Systemic TLR4 antagonism also attenuates METH CPP and METH-induced increases of DA within the NAc. We recently demonstrated that the rewarding effects of cocaine are dependent on IL1β signaling within the VTA. METH also initiates CNS glial responses within the VTA. However, intra-VTA mRNA is upregulated for IL6 but not IL1β at the timepoints tested. Studies are currently underway to investigate whether METH-induced NAc DA increases and METH self-administration are dependent on intra-VTA IL6 signaling. Interestingly, IL6 has been linked to METH neurotoxicity, suggesting a role for METH-induced CNS glial signaling underlying both reinforcement and neurotoxicity. Our data suggest that METH-activation of TLR4 contributes to its rewarding effects, as well as implicating a possible mechanism underlying neurotoxicity. These findings provide further support for the xenobiotic hypothesis, and indicate that TLR4 may be a promising target for pharmacological intervention to treat drug abuse.

Title: Alpha-synuclein elevation shapes dopamine neurotransmission via a DAT dependent mechanism

Authors: *K. SAHA[1], B. BUTLER[1], M. LIN[1], R. STEGER[1], J. COLEMAN[2], B. GIASSON[1], T. E. GOLDE[1], H. KHOSHBOUEI[1];

Abstract: Alpha-synuclein is a small cytosolic protein enriched in the presynaptic terminals. Although its physiological function remains unknown, alpha-synuclein has been implicated in a number of pathological conditions coined synucleinopathies, which include Parkinson's disease. Though, the neuroprotective and/or neurotoxic effects of endogenous levels of alpha-synuclein is debated, it is clear that pathological levels of alpha-synuclein negatively affects the activity of dopaminergic neurons, albeit with less understood mechanism. Here we examined whether overexpression of wild-type alpha-synuclein influences the activity of dopamine neurons by measuring the spontaneous firing activity and action potential morphology of dopamine neurons. Electrophysiological results revealed that alpha-synuclein elevation decreases the frequency of spontaneous firing of dopamine neurons, increases action potential half-width and reduces afterhyperpolarization (AHP) magnitude. Alpha-synuclein overexpression enhances the action potential half-amplitude following amphetamine (AMPH) exposure compared to neurons expressing physiological levels of alpha-synuclein. We used GCaMP6, a highly sensitive calcium sensor, to study calcium dynamics in the neuronal cell bodies and processes when alpha-synuclein is overexpressed. In the absence of stimulation, as compared to control neurons containing endogenous alpha-synuclein levels, alpha-synuclein over-expression increased calcium spike amplitude and decreased spike frequency in neuronal cell bodies, but not in the neuronal process. Since activation of dopamine transporter (DAT) has been shown to increase intracellular calcium, we asked whether alpha-synuclein regulation of intracellular calcium is DAT dependent. We found alpha-synuclein regulation of calcium mobilization in the cell body and neuronal processes was blocked by inhibition of dopamine transporter; whereas, amphetamine activation of DAT further enhanced the calcium spike amplitude in both the neuronal cell bodies and processes that overexpressed alpha-synuclein. These preliminary data suggest alpha-synuclein elevation uniquely impacts dopamine neurotransmission via a DAT-dependent mechanism.

Title: Preferential enhancement of MDMA-induced accumbens 5-HT over DA levels is amplified by 5-HT2C receptor antagonism

Authors: *C. L. DUVAUCHELLE[1], W. T. MADDOX[2], M. E. REVERON[1];
[1]Pharmacol. & Toxicology, [2]Psychology, Univ. of Texas, Austin, TX

Abstract: Actions on serotonin (5-HT) and dopamine (DA) systems underlie unique behavioral and neurochemical responses induced by 3, 4-methylenedioxymethamphetamine (MDMA or "Ecstasy"). 5-HT receptors can modulate 5-HT and DA function, but their specific role in MDMA-induced effects are yet to be determined. This study was conducted to investigate the effects of 5-HT2c receptor antagonism on MDMA-induced changes in nucleus accumbens (NAcc) extracellular 5-HT and DA levels, locomotor activity and spontaneous behaviors. During a 2-h *in vivo* microdialysis test session, MDMA-naïve rats were treated with either saline (0.2 ml) or the 5-HT2C selective antagonist, SB 242084 (1.0 mg/kg, i.v.) 30-min prior to a self-administered infusion of MDMA (3.0 mg/kg, i.v.) or saline (0.1 ml). Saline pretreated rats showed pronounced increases in NAcc extracellular 5-HT (approx 5-fold) and DA (approx 2-fold) after MDMA administration. Pretreatment with SB 242084 resulted in significantly enhanced extracellular NAcc 5-HT (approx 9.5-fold) and behaviors associated with serotonin syndrome (e.g., low body posture, forelimb and hindlimb treading) after MDMA injection. MDMA-stimulated NAcc DA and locomotor activity was comparable in SB 242084 and saline pretreated animals and SB 242084 alone did not alter NAcc 5-HT, DA or behavioral activities prior to MDMA administration or after saline injection. Our findings indicate that 5HT2C receptor antagonism in combination with MDMA preferentially amplifies MDMA-induced NAcc 5-HT neuronal and behavioral responses compared to NAcc DA and DA-mediated effects.

Title: PKC-b inhibitors attenuate amphetamine and cocaine stimulated dopamine release

Authors: ***A. G. ZESTOS**[1], S. MIKELMAN[2], R. T. KENNEDY[1], M. E. GNEGY[2];
[1]Chem., [2]Pharmacol., Univ. of Michigan, Ann Arbor, MI

Abstract: Amphetamine abuse afflicts over 13 million people, and there is currently no universally accepted treatment for amphetamine addiction. Amphetamine serves as a substrate for the dopamine transporter (DAT) and reverses the transporter to cause dopamine efflux in addition to inhibiting the vesicular monoamine transporter (VMAT) to promote dopamine exocytosis. Activation of protein kinase Cb enhances extracellular dopamine in the presence of amphetamine by enhancing the reverse transport of dopamine and internalizing the D2 autoreceptor. We previously demonstrated that PKCb inhibitors block amphetamine-stimulated dopamine efflux in rat striatum *in vitro*. In this study, we utilized *in vivo* microdialysis in live, behaving rats to assess the effect of the PKCb inhibitors enzastaurin and ruboxistaurin on amphetamine-stimulated increases in monoamines and their metabolites. A 30 min perfusion of the nucleus accumbens core with 1 uM enzastaurin or 1 uM ruboxistaurin reduced amphetamine-stimulated efflux of dopamine and its metabolite 3-methoxytyramine by approximately 50%. The inhibitors also significantly reduced extracellular levels of norepinephrine and its metabolite normetanephrine after amphetamine. The stimulation of locomotor behavior by amphetamine, measured simultaneously with the analytes, was comparably reduced by the PKCb inhibitors. Ruboxistaurin also attenuated cocaine stimulated extracellular dopamine, a process that would not be dependent upon DAT reversal. In order to see if this process was D2 autoreceptor mediated, we examined the effect of ruboxistaurin on cocaine activation when D2 receptors were blocked with raclopride. The inhibitory effect of ruboxistaurin was reduced in the presence of

cocaine and raclopride, suggesting that ruboxistaurin action involved D2 autoreceptors. Using a stable isotope label retrodialysis procedure, we determined that ruboxistaurin had no effect on basal levels of dopamine, norepinephrine, glutamate, or GABA. Our results support the utility of using PKCb inhibitors to reduce the effects of amphetamine and cocaine.

Title: Amphetamine sensitization requires dopamine neuron glutamate cotransmission

Authors: *S. MINGOTE[1], N. CHUHMA[1], A. KALMBACH[1], A.-C. SIENA[1], B. INBAR[2], H. MOORE[2], S. RAYPORT[1];
[1]NYSPI Dept Mol. Therapeut., Columbia University/New York State Psychiatric Inst., NEW YORK, NY; [2]Integrative Neurosci., Columbia University/New York State Psychiatric Inst., New York, NY

Abstract: Increased activity of dopamine (DA) neurons projecting to the nucleus accumbens (NAc) shell is thought to mediate the initial reinforcing effects of abused drugs such as amphetamine (Covey et al., TINS, 2014). Mesoaccumbal DA neurons are distinguished by showing the highest incidence of glutamate (GLU) cotransmission; however it is not clear whether DA neuron GLU cotransmission is involved in the development of drug-induced responses. Transgenic approaches have abrogated GLU cotransmission by conditional knock out of the vesicular GLU transporter VGLUT2 in DA neurons; VGLUT2 cKO mice show a reduced response to amphetamine, but this could be due to reduced DA or GLU release (Birgner et al., PNAS, 2010), as VGLUT2 cKO mice also have reduced DA neuron numbers, DA content and release (Hnasko et al., Neuron, 2010; Fortin et al., JNS, 2012). To address the role of DA neuron GLU cotransmission specifically, we targeted GLS1, which encodes the GLU synthetic enzyme

glutaminase that mediates glutamate recycling and is important for maintaining GLU neurotransmission at fast firing frequencies. Unlike VGLUT2 cKO mice, GLS1 cHet mice (with a conditional heterozygous deletion of GLS1 in DA neurons) showed no alteration in DA content, DA release or DA neuron number. This allowed us to focus on the contribution of high frequency DA neuron GLU cotransmission, specifically during burst firing. We have recently shown that stimulation of DA neurons at burst firing frequencies can drive cholinergic interneurons (ChIs) in the NAc shell to burst fire, and that after a single dose of amphetamine, these DA neuron excitatory connections undergo a dramatic drug-induced plasticity (Chuhma et al., Neuron, 2014). We have now found, in DAT- IREScre::Ai32 mice and recording in ChIs, that photostimulation of DA neuron terminals elicits GLU cotransmission that shows more rapid frequency dependent attenuation in GLS1 cHet (triple mutant) mice. Consistent with the overall lack of impact on DA transmission, GLS1 cHet mice showed no motor impairments measured on the rotarod, nor an altered dose-response curve for amphetamine-induced locomotion. Strikingly, GLS1 cHet mice did not show sensitization to repeated amphetamine. Thus, DA neuron GLU transmission at burst firing frequencies appears to underlie the development of drug-induced behaviors.

Title: Phosphorylation by PKC of the GluA1 subunit of the AMPA receptor in the nucleus accumbens is required for the expression of amphetamine sensitization

Authors: *V. KONDEV, D. LI, N. BUBULA, P. VEZINA;
The Univ. of Chicago, Chicago, IL

Abstract: Two experiments assessed the contribution of PKC phosphorylation in the nucleus accumbens (NAcc) to the expression of locomotor sensitization by amphetamine. PKC constitutes a family of serine-threonine kinases that can be classified into three main isozyme subgroups with numerous substrates in the central nervous system. Some of these substrates

especially in the NAcc could play a role in the expression of sensitization by amphetamine. In the first experiment, rats in different groups were exposed to 5 injections of amphetamine (1.5 mg/kg, IP; 1 injection every other day) and three weeks later, challenged with saline or amphetamine (1.0 mg/kg, IP). NAcc tissues were harvested 30 minutes later and PKC activity determined with a PepTag non-radioactive PKC assay using PLSRTLSVAAK as peptide substrate or pNeurogranin(S36) as a postsynaptic endogenous substrate. In both cases, amphetamine exposure did not affect basal PKC activity but did enhance activity levels observed following the amphetamine challenge, suggesting a role for this kinase in the expression of locomotor sensitization by amphetamine. To further characterize this role, a second experiment assessed the need for phosphorylation by PKC of the S816-S818 residues of the GluA1 subunit of AMPA receptors in the NAcc. Phosphorylation of these residues is known to facilitate GluA1 insertion into the plasma membrane which in turn can enhance glutamatergic transmission and amphetamine-induced locomotion. Rats in different groups were exposed to saline and amphetamine as above. One week later, they were infected in the NAcc with lentivirus bearing GFP or the serine-alanine mutant GluA1(S816A-S818A) and two weeks after that tested for their locomotor response to NAcc amphetamine (2.5μg/side). Preventing GluA1 phosphorylation with the serine-alanine mutant blocked expression of the sensitized locomotor response to NAcc amphetamine normally observed in amphetamine exposed rats. Together, these results support the need for NAcc PKC in the expression of behavioral sensitization by amphetamine and highlight the importance of NAcc AMPA receptor regulation by PKC in generation of the sensitized response.

Title: Exposure to amphetamine enhances AMPA receptor phosphorylation by CaMKII without increasing cell surface expression

Authors: *Q. WANG[1,2], D. LI[1,3], N. BUBULA[1], M. CAMPIONI[3], D. S. MCGEHEE[2], P. VEZINA[1];
[1]Psychiatry, [2]Dept. of anesthesia and critical care, Univ. of Chicago, Chicago, IL; [3]Gladstone institute, university of california, San francisco, CA

Abstract: While exposure to either cocaine or amphetamine leads to various manifestations of sensitization, only exposure to cocaine has been found to produce long-lasting increases in basal cell surface and synaptic AMPA receptor (AMPAR) levels in rat forebrain. This led us to further characterize changes in AMPAR expression in the nucleus accumbens (NAcc) long after amphetamine exposure. In a first series of experiments using the BS3 cross-linking approach, no difference between saline and amphetamine exposed rats was found in the cell surface expression of either GluA1 or GluA2 AMPAR subunits. This finding was supported in a second experiment showing no difference between these two groups in the amplitude of AMPAR-mediated mEPSCs recorded in NAcc slices. This finding was again confirmed in a third experiment showing no effect of amphetamine exposure in GluA1 and GluA2 levels observed either in whole cell lysate or in the PSD of NAcc neurons subjected to subcellular fractionation and Western blot assays. On the other hand and extending previous findings obtained in whole cell lysates, we found in a fourth experiment conducted in PSD fractions of NAcc shell tissues that exposure to amphetamine produces a long-lasting increase in pGluA1(S831), a CaMKII residue. This increase in GluA1 phosphorylation was accompanied by a significant and long-lasting increase in levels of CaMKIIα, but not CaMKIIβ, in PSD fractions of the NAcc shell. This enrichment of CaMKIIα in the PSD may provide one mechanism for the enduring increase in pGluA1(S831) which in turn can contribute to the enhanced behavioral responding to amphetamine and NAcc AMPA observed in sensitized rats. Finally, in an effort to delineate a mechanism underlying the increase in PSD CaMKIIα, a fifth experiment using immunoprecipitation assessed the effect of amphetamine exposure on changes in protein coupling in the PSD. Interestingly, previous exposure to amphetamine was found to modestly increase the coupling of CaMKIIα to PSD-95 but to significantly decrease CaMKIIα/NR2b and increase NR2b/PSD95 coupling. Overall, these results reveal significant changes in protein interactions in the PSD of NAcc medium spiny neurons that are well positioned to influence AMPAR mediated signaling underlying the expression of behavioral sensitization by amphetamine. Some of the changes observed in protein coupling in the PSD are surprising given the need for increased CaMKIIα/NR2b coupling in the expression of LTP. The decrease in CaMKIIα/NR2b coupling observed in the present experiments likely characterizes a basal interactive state between these two proteins in periods removed from amphetamine challenge.

Title: Amphetamine modulates Nurr1 and NF-kB p65 expression in the rat Ventral Tegmental Area

Authors: *C. ARREDONDO, M. P. GONZÁLEZ, M. E. ANDRÉS, K. GYSLING;
P. Catholic Univ. Chile, Santiago, Chile

Abstract: Psychostimulants are drugs with high consumption rates worldwide, resulting in a major public health problem. The rewarding and addictive effects of drugs of abuse are produced by increased dopaminergic neurotransmission in the ventral midbrain area and its target nuclei. Nurr1 is a nuclear receptor essential for the development and survive of midbrain dopaminergic neurons. This transcription factor regulates the expression of key genes of the dopaminergic phenotype as tyrosine hydroxylase (TH) and dopamine transporter. It is well known that repeated consumption of drugs of abuse causes long-lasting changes in dopaminergic neurons. The evidence also points to abused drugs as triggers of inflammatory processes and damage in the brain. Exposure to cocaine and methamphetamine alters the transcription factor NF-kB levels in PC12 cells. Interestingly, Nurr1 and NFkB-p65 interact to regulate inflammatory genes in response to lipopolysaccharide (LPS) in microglia and astrocytes. The objective of this work was to study the changes in Nurr1, NFkB-p65 and TH expression in the rat midbrain region, after an acute and chronic exposure to amphetamine. Male Sprague-Dawley rats weighing about 280g were injected with amphetamine (1.5 mg/kg) acutely or every day during fourteen days (chronic). Our data show that Nurr1 and NFkB-p65 co-localize in TH-positive cells in the rat ventral tegmental area. Nurr1, TH and NFkB-p65 expression was assessed by Western blots of ventral midbrain total protein extracts. Acute amphetamine treatment induced an increase in Nurr1, TH and NFkB-p65 protein levels. Chronic amphetamine treatment decreased Nurr1 and NFkB-p65 protein levels, but TH was unchanged compared to saline-treated rats. Our results show that Nurr1 in midbrain dopaminergic neurons responds in a different way to acute or chronic amphetamine treatment and suggest that Nurr1 and NFkB-p65 could mediate a common response to amphetamine

Autònoma de Barcelona (UAB),, Barcelona, Spain; [4]Howard Univ., College of Medicine, Pharmacology, WA

Abstract: The C-terminal domain of the heavy chain of tetanus toxin (Hc-TeTx) is a nontoxic peptide with demonstrated *in vitro* and *in vivo* neuroprotective effects against striatal dopaminergic damage induced by MPP+ (1-methyl-4-phenylpyridinium) and 6-hydoxydopamine, suggesting its possible therapeutic potential in Parkinson's disease. Methamphetamine (METH), a widely abused psychostimulant, has selective dopaminergic neurotoxicity in rodents, monkeys and humans. This study was undertaken to determine whether Hc-TeTx might also protect against METH-induced dopaminergic neurotoxicity and the consequent motor impairment. For this purpose, we treated mice with a toxic regimen of METH (4 mg/kg, 3 consecutive i.p. injections, 3h apart) followed by 3 injections of 40 ug/kg of Hc-TeTx into grastrocnemius muscle at 1h, 24h and 48h post METH treatment. We found that Hc-TeTx significantly reduced the loss of dopaminergic markers tyrosine hydroxylase (TH) and dopamine transporter (DAT) and the accompanying increases in silver staining (a well established degeneration marker) induced by METH in the striatum at 3 and 7 days after METH

treatment. Moreover, Hc-TeTx prevented the increase of neuronal nitric oxide synthase (nNOS), but did not affect microglia activation induced by METH. Stereological neuronal count in the substantia nigra indicated loss of TH-positive neurons after METH that was not significantly affected by Hc-TeTx. Importantly, impairment in motor behaviors on days 1 and 3 post METH treatment, were significantly reduced by Hc-TeTx. Here we demonstrate that Hc-TeTx can provide significant protection against METH-induced neurotoxicity and motor impairment. Thus, Hc-TeTx fragment may represent a potential therapeutic drug for METH-abusers.

Title: Antisense-mediated downregulation of xCT reduces basal glutamate in the NA and alters post-synaptic AMPA receptor subunit expression

Authors: *A. L. LACROSSE[1], M. A. GORDON[2], B. S. JACKSON[2], L. A. KNACKSTEDT[2]; [1]Psychology, [2]Univ. of Florida, Gainesville, FL

Abstract: Ceftriaxone is a beta-lactam antibiotic which increases the expression and function of the glutamate transporter GLT-1 and of system xC-, which exchanges extracellular cysteine for intracellular glutamate. Basal glutamate levels in the NA (NA) are largely controlled by system xC-, and a decrease in its activity is a contributing cause of the altered glutamate homeostasis observed in this brain region following cocaine self-administration in rats. The catalytic subunit of xC- is xCT, and we have demonstrated that expression of xCT and GLT-1 is decreased in the NA core following cocaine self-administration. We have also shown that ceftriaxone attenuates cue- and cocaine-primed reinstatement while restoring levels of both xCT and GLT-1 in the NA core. At this time it is not known if alterations in both transport systems mediate the altered synaptic plasticity in the NA after cocaine self-administration. Here we used a morpholino antisense strategy to decrease the expression of xCT protein and examined basal levels of glutamate and GluA1 and GluA2 expression. We found that xCT antisense infusion into the NA significantly decreased basal glutamate. We also found an increase in NA GluA1 expression in

cocaine self-administering rats and no change in GluA2 expression. In ceftriaxone-treated rats infused with xCT antisense in the NA, this increase in GluA1 was potentiated. These data support the importance of xCT expression in maintaining basal glutamate in the nucleus accumbens and point to basal glutamate levels as a key mediator of post-synaptic AMPA receptor alterations.

Title: Role of the ribosomal protein S6 phosphorylation in the mouse brain

Authors: *A. BIEVER[1], E. PUIGHERMANAL[1], V. PASCOLI[2], O. MEYUHAS[3], C. LÜSCHER[2], E. VALJENT[1];
[1]Inst. De Génomique Fonctionnelle, Montpellier, France; [2]Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland; [3]The Inst. for Med. Research–Israel-Canada, Jerusalem, Israel

Abstract: The 40S subunit ribosomal protein S6 (rpS6) has attracted much attention over the last four decades since it is the first ribosomal protein shown to undergo inducible phosphorylation upon a wide variety of stimuli. However, despite the profound elucidation of the respective kinases and extracellular stimuli triggering phospho-rpS6, little is known about the physiological role of its phosphorylation. In this study, we aimed to characterize the functional relevance of the *in vivo* rpS6 phosphorylation in the brain. For this purpose, we performed a behavioral characterization of rpS6P-/- knock-in mice, in which all phosphorylatable serine residues are substituted by alanines. Interestingly, these mice display a reduced locomotor response to d-amphetamine, which markedly increases phospho-rpS6 in the striatum of wild-type mice. Moreover, they show impaired synaptic plasticity of GABAergic medium-sized spiny neurons in the nucleus accumbens. Finally, since rpS6 phosphorylation has been widely correlated with changes in protein synthesis, we performed polysome profile and puromycin incorporation analyses in rpS6P-/- knock-in as well as in wild-type mice treated with d-amphetamine. Intriguingly, we found no differences in global translational rates in the striatum, hippocampus and frontal cortex. Altogether, our results indicate that neither basal nor drug-induced transient rpS6 phosphorylation correlate with changes in overall mRNA translation. Nevertheless, despite

the lack of causal relationship between both events, rpS6 phosphorylation plays an important role in striatal plasticity and behavioral responses.

Title: Predicting treatment outcome in prescription opiate dependence using functional near infrared spectroscopy (fnir)

Authors: ***A. HUHN**[1], S. C. BUNCE[2], D. STANKOSKI[2], J. HARRIS[2], E. BIXLER[2], R. E. MEYER[2];
[2]Psychiatry, [1]Penn State Col. of Med., Hershey, PA

Abstract: Aims: Growing evidence for a neuroadaptive model underlying long-term vulnerability to relapse in opiate dependence is largely based on animal research; little is known about its predictive capability concerning risk of relapse in clinical populations. The period directly following opiate withdrawal is marked by heightened CNS response to drug-related stimuli, diminished pleasure from natural rewards, increased stress response and irritability. The current study utilizes a cue reactivity paradigm coupled with fNIR to test the hypothesis that recently withdrawn prescription opiate dependent patients (RWP) in a residential setting would show reduced response to natural rewards and heightened response to drug-related stimuli. To date, relapse information has been gathered from a subset of patients, allowing us to examine the predictive value of this data. Methods: RWP (n=11) and healthy controls (HC; n=8) were evaluated using fNIR as they viewed hedonically positive (food), socially-relevant positive, drug related, or neutral stimuli. RWPs data was collected in a residential treatment facility, 10-14 days after withdrawal. T-tests and Pearson's correlations were used to compare fNIR response across groups. Results: RWPS showed reduced bilateral response to natural reward stimuli in the dorsolateral PFC (DLPFC) relative to HC ($p<.05$). Outcome data were available from a subgroup of RWP (n=8) that had either relapsed (n=4) or remained abstinent (n=4) for a period of three months following discharge from residential treatment. Relapse was associated with increased

activation in the right DLPFC ($p<.05$) in response to food and drug stimuli, and decreased activation ($p<.01$) in bilateral DLPFC and ventromedial PFC in response to socially rewarding stimuli. Responses to drug stimuli and socially rewarding were negatively correlated ($r=-.727$; $p=.041$) Conclusion: Consistent with previous studies, these data suggest RWPs display differential CNS responses to natural reward cues relative to HCs. Importantly, these preliminary data suggest that CNS responses in the PFC may serve as a biomarker to predict treatment outcome; this has the potential to be a powerful tool for clinicians (e.g., as an objective measure of vulnerability to relapse to guide treatment planning). These data demonstrate the feasibility of using fNIR, a relatively low-cost neuroimaging tool, in translational care.

Title: Functional magnetic resonance imaging measures of network connectivity related to incorrect responses predict completion of substance abuse treatment

Authors: *V. R. STEELE[1], E. D. CLAUS[2], B. C. FINK[3], J. M. MAURER[1], M. R. ARBABSHIRANI[2], V. RAO[2], V. D. CALHOUN[1], K. A. KIEHL[1];
[1]The Mind Res. Network; Univ. of New Mexico, Albuquerque, NM; [2]The Mind Res. Network, Albuquerque, NM; [3]Dept. of Psychiatry, Univ. of New Mexico, Albuquerque, NM

Abstract: US nationwide estimates indicate at least two-thirds of prisoners have a history of substance abuse or dependence. Tailoring substance abuse treatment to specific needs of incarcerated individuals could improve effectiveness of treating substance dependence and preventing drug abuse relapse. The purpose of the present study was to test the hypothesis that pre-treatment functional connectivity measures of error processing would predict which individuals would or would not complete a 12-week cognitive behavioral substance abuse

treatment program. Adult incarcerated participants (N = 139; Females = 89) who volunteered for substance abuse treatment performed a response inhibition (Go/NoGo) functional magnetic resonance imaging (fMRI) task. Independent component analysis (ICA) was performed to identify networks related to false alarms elicited during the Go/NoGo task. Functional network connectivity measures of ICs related to false alarms were used to classify individuals who completed (N = 107; Females = 75) and discontinued (N = 32; Females = 14) treatment. A support-vector machine (SVM) classifier with a double input symmetric relevance feature selection step was used to identify two functional network connections that predicted treatment completion and discontinuation. For cross-validation, a nested 5-fold SVM with a radial basis function kernel was used to produce an overall accuracy of 81% while also identifying 81% of individuals who completed and 78% who prematurely discontinued treatment. Increased connectivity between the rostral anterior cingulate cortex (RACC) and striatal regions was measured in the completed group compared to the discontinued group. Increased connectivity between the caudal anterior cingulate cortex (CACC) and temporal regions (including insula) was measured in the discontinued group compared to the discontinued group. These findings support previous event-related potential (ERP) effects highlighting deficiencies in error-monitoring and post-error response adjustments in individuals who prematurely discontinue treatment. Cross-modal similarities suggest future treatments could be refined by targeting error-monitoring and post-error response adjustment in at-risk individuals, which could lead to more favorable long-term outcomes.

Cagliari, CAGLIARI, Italy; [4]Dept. of Life and Envrn. Sci., Univ. of Cagliari, Cagliari, Italy; [6]Inst. of Translational Pharmacology, UO Cagliari, [5]Italian Natl. Res. Council, Pula (Cagliari), Italy; [7]Chem. and Pharm., Univ. of Sassari, Sassari, Italy; [8]Sanjivani_College_of_Pharmaceutical_Education_Research, Kopargaon, India, Kopargaon, India

Abstract: The standardized roots extract of Withania somnifera Dunal, a medicinal plant mostly used for its anti-inflammatory properties, has been shown to interact with a number of morphine and ethanol central effects. Thus, it has been shown that Withania prevents ethanol withdrawal-induced anxiety, potentiates ethanol-induced anxiolysis and prevents development of tolerance to the analgesic effects of morphine. In addition, we also reported that chronic administration of WSE prevents the loss of dendritic spines that takes place in the nucleus accumbens shell upon morphine withdrawal in morphine-dependent rats. As an extension of these observations, the aim of our work was investigating further the effects of Withania somnifera roots extract (WSE) on morphine-elicited conditioned place preference (CPP) and ethanol-elicited place conditioning (both preference (CPP) and aversion (CPA)) and on motivation for drinking ethanol by operant self-administration (SA) paradigms. To this end, in morphine CPP experiments male CD-1 mice underwent backward conditioning (CPP) whereas in ethanol conditioning experiments mice underwent both backward and forward (CPA) conditioning; the effects of WSE (50 and 100 mg/kg) were evaluated on acquisition and expression of both morphine- and ethanol-elicited conditioning. In self-administration experiments male Wistar rats were trained to self-administer ethanol (10%) by nose-poking and the effects of WSE (25 - 75 mg/kg) were evaluated on acquisition and maintenance of ethanol self-administration, on ethanol breakpoint under a progressive-ratio schedule of reinforcement, on ethanol deprivation effect and on reinstatement of seeking behaviours. The results of these experiments confirmed 1) that under appropriate experimental conditions, morphine and ethanol elicit place conditioning; 2) that the administration of WSE dose-dependently impairs both the acquisition and the expression of morphine-elicited CPP and of ethanol-elicited CPP and CPA; 3) that WSE reduces acquisition, maintenance and breakpoint of ethanol self-administration as well as the deprivation effect and reinstatement of ethanol-seeking behaviour. Although further studies are required to investigate in detail the mechanism(s) by which WSE interferes with the motivational properties of morphine and ethanol, these results provide strong support to the suggestion that the use of WSE could represent an interesting phytotherapeutic approach.

Title: Dezocine and buprenorphine reduces withdrawal syndrome in a morphine dependent rat model

Authors: *R. LIU[1], F.-X. WU[1], C.-H. CHUN-HUA XI[1], X.-P. HUANG[3], J. MA[2], W. YU[4], B. ROTH[3];
[1]Dept. of Anesthesiol. and Critical Care, [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of North Carolina Chapel Hill Med. Sch., Chapel Hill, NC; [4]Eastern Hepatobiliary Hosp., shanghai, China

Abstract: Opioid dependence continues to be a major public health issue without optimal therapeutic. Based on our recent discovery of the unique pharmacological profile of dezocine as a non-addictive opioid, a partial mu agonist and kappa antagonist, similar to that of buprenorphine, we hypothesized that dezocine could be used to manage opioid dependence. In the present study, the effects of dezocine and buprenorphine on morphine withdrawal syndrome were compared in a rat morphine dependence model. Daily intraperitoneal injection of dezocine markedly reduced morphine withdrawal syndrome similar to that of buprenorphine. Astrocyte activation in nucleus accumbens after opioid exposure was observed in the morphine dependent rats, and such astrocyte activation was significantly inhibited in the presence of dezocine and buprenorphine. The molecular target profiling for both dezocine and buprenorphine was performed. Dezocine interact with sigma 1 receptor, while buprenorphine has no interaction with sigma 1 receptor. These findings suggested that dezocine could be an alternative medication for opioid addiction management similar to that of buprenorphine. The advantage of dezocine over buprenorphine for opioid dependence management is proposed.

Title: Characterizing molecular mechanisms of adolescent cue exposure therapy in animal models of addiction and anxiety

Authors: *I. ZBUKVIC, D. GANELLA, C. BYE, C. PERRY, H. MADSEN, A. LAWRENCE, J. KIM;
The Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia

Abstract: Substance abuse and anxiety disorders represent two of the most common mental illnesses worldwide, with onset most often occurring during adolescence. Treatment for these disorders frequently involves cue exposure therapy (CET), based on the principle of cue extinction. This type of learning is known to involve dopamine signaling in the prefrontal cortex (PFC), a system undergoing dramatic alterations during adolescence. These changes may result in a deficit in cue extinction learning, which would explain adolescent resistance to treatment such as CET in the clinical setting. The present study aimed to characterize CET in adolescent versus adult rats using a cocaine self-administration paradigm and a fear conditioning paradigm. In the first study, adolescent and adult rats were trained to lever press for cocaine (3mg/kg/infusion) over 10-12 days, where cocaine infusions were paired with a light cue. Once stable self-administration was established, rats received 7 daily lever extinction sessions, where lever pressing had no programmed consequences. The following day rats underwent a single cue extinction session designed to model CET consisting of 120 cue-alone presentations, or remained in their home cages. Cue extinction significantly reduced cue-induced reinstatement next day in adult but not adolescent rats ($p<.05$). We then measured changes in dopamine receptor mRNA expression in the PFC and the striatum following cocaine-associated cue extinction. In the second study, adolescent and adult rats were fear conditioned using 3 tone-footshock pairings. The next day rats underwent a single cue extinction session designed to model CET consisting of 30 presentations of the tone in absence of the footshock. Cue extinction significantly reduced reinstatement of conditioned fear the next day in adult rats only ($p<.05$). We then measured changes in dopamine receptor mRNA expression in the PFC and the amygdala following cue extinction.

Title: Effect of environmental enrichment on glutamate concentrations in the hippocampus and prefrontal cortex in mice exposed to toluene

Authors: *N. PAEZ-MARTINEZ[1,2], R. SOLIS-GUILLEN[1], S. MONTES-LOPEZ[3];
[1]Inst. Politecnico Nacional, Mexico City, Mexico; [2]Direccion de Neurociencias, Inst. Nacional de Psiquiatria, Mexico City, Mexico; [3]Neuroquimica, Inst. Nacional de Neurologia y Neurocirugia, Mexico City, Mexico

Abstract: Inhalants are substances widely used as recreational drugs. These are easy to obtain in legal, relatively inexpensive and common household products (paint thinner, markers, felt pens, spray paints and glues, among others) and toluene is the main chemical compound present in most of them. Previous studies have shown that toluene produces memory impairment and environmental enrichment reverse these responses; however, there are limited research regarding the mechanisms involved in such effects. Therefore, in the first part of this study we evaluated the changes on glutamate in the hippocampus and prefrontal cortex (areas associated with memory impairments) in mice exposed to toluene. In the second part we evaluated the effect of environmental enrichment on glutamate concentrations in mice with history of toluene exposure. To fulfill both objectives young male mice were exposed to toluene during four weeks. In a group of animals the brains areas were dissected out and glutamate concentrations analyzed by HPLC. Another group of mice were exposed to toluene and afterwards they were housed either on environmental enrichment or on standard conditions. Evaluation of glutamate was also conducted after 4 weeks of housing treatment. Results showed that toluene did not significantly modify glutamate content in either of the areas evaluated. Similarly, environmental enrichment did not produced alterations on glutamate concentrations in both areas. Results may suggest that glutamate changes may not be associated with memory alterations after toluene exposure; likewise glutamate alterations may not be responsible for the reversal of memory detriments after environmental enrichment.

Title: Retrieval-dependent changes in craving and alcohol-memory following reappraisal in high-risk drinkers: a model for reconsolidation-based cognitive therapy?

Authors: *S. K. KAMBOJ, T. HON, R. K. DAS;
Univ. Col. London, London, United Kingdom

Abstract: Introduction: Reconsolidation is implicated in the strengthening and modification of long-term memories. 'Reappraisal' is an emotion regulation procedure used in cognitive behavioural therapy, which aims to modify 'dysfunctional thoughts' so that their meaning is less threatening or more adaptive. Here we examine whether retrieval procedures designed to destabilise alcohol memories can alter accessibility of alcohol-related thoughts, craving, attentional bias and drinking behaviour. Methods: On Day 1 participants either retrieved alcohol-related memories using one of two retrieval procedures - Value Prediction-Error (n=15) or Omission Prediction-Error (n=16) - or did not retrieve alcohol memories (Control; n=16). After this, participants identified six dysfunctional alcohol-related thoughts, which related to their reasons for drinking excessively. They then generated alternative, more balanced thoughts (reappraisals) for each of the six unhelpful thoughts. Memory for these reappraisals and general access to alcohol related memories (alcohol fluency) was assessed at the end of Day 1 and again one week later (Day 8). Alcohol craving and drinking behaviour (over the previous 7 days) were also assessed on both days, and attentional bias (eye movements) on Day 8. Results: The Omission Prediction-Error group showed a reduction in fluency for positive alcohol-related words on Day 8, along with a reduced current desire to drink (purposefulness-craving). Conclusions: This preliminary study employs an emotion regulation strategy commonly used in cognitive therapy (reappraisal) in the context of memory retrieval procedures designed to cause memories to become unstable and susceptible to modification (reconsolidation). We found preliminary evidence that omitting an expected reward during retrieval (Omission Prediction-Error) prior to generating new, adaptive appraisals related to moderate drinking, resulted in reductions in accessibility of positive alcohol-related words. These findings have implications for the development of psychological treatments through the incorporation of behavioural neuroscience findings.

Title: Preclinical studies of a passive vaccine against heroin

Authors: ***I. BOGEN**, A. M. S. KVELLO, J. MØRLAND, J. M. ANDERSEN;
Norwegian Inst. of Publ Hlth., Oslo, Norway

Abstract: Passive immunization with monoclonal antibodies is currently being studied as an alternative treatment strategy for drug overdose and addiction. The aim of such antibody therapy is to sequester the active drug in the blood and thereby prevent the psychoactive substance from entering the brain and exert its effects. The acute effects of heroin are mainly caused by its first metabolite, 6-monoacetylmorphine (6-MAM), which is rapidly formed in the blood before crossing the blood-brain-barrier and binding to brain opioid receptors. In a recently published study, we reported that a monoclonal antibody specific to 6-MAM (anti 6-MAM mAb) reduces acute heroin-induced effects in mice (Bogen et al., 2014). The aim of the present study was to characterize the time course of the interference of the antibody with heroin effects and to assess μ-opioid receptor binding after heroin injection in mAb-treated animals and controls. Furthermore, we wanted to elucidate the efficacy of the antibody upon repeated heroin injections. Mice were pretreated with anti-6-MAM mAb (10 mg/kg) or saline, followed by one or several injections of heroin (2.5 μmol/kg). Immediately after the last heroin injection, the behavioral drug effect was assessed in a locomotor activity test, which may be used as a measure of the psychostimulatory effects of opioids. Blood and brain levels of opioids were quantified by LC-MSMS. A radioligand assay employing [3H]DAMGO was used to examine μ-opioid receptor binding *ex vivo*, comparing mAb treated animals and controls. The behavioral effects of heroin, measured as locomotor activity, were reduced by approximately 60% in mAb-treated animals compared to controls. The brain levels of 6-MAM were reduced by 27, 32 and 60% in mAb-treated animals when measured 5, 10 and 25 minutes after heroin administration, respectively. Furthermore, a single dose of anti-6-MAM mAb reduced the brain concentration of 6-MAM by approximately 60% even after daily repeated heroin injections for three consecutive days. We found a 36% increase in available μ-opioid receptors in the brains of mAb-treated mice

compared to controls, indicating decreased levels of opioids in these animals. The results from the current study confirm that anti-6-MAM mAb treatment reduces the acute behavioral effects of heroin by blocking the entry of 6-MAM to the brain. Moreover, our results indicate that anti-6-MAM mAb reduces heroin-induced effects even after repeated drug exposure.

Title: The effects of N-Acetylcysteine on corticostriatal resting-state functional connectivity mediate nicotine withdrawal symptoms and may help prevent relapse

Authors: *B. FROELIGER[1], P. A. MCCONNELL[2], P. W. KALIVAS[1], K. M. GRAY[1]; [1]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [2]Neurosci., Med. Univesity of South Carolina, Charleston, SC

Abstract: BACKGROUND: Chronic exposure to drugs of abuse disrupts corticostriatal glutamate transmission, which in turn meditates drug seeking. In animal models, N-acetylcysteine normalizes dysregulated frontostriatal glutamatergic neurotransmission and prevents reinstated drug seeking; however, the effects of N-Acetylcysteine on human corticostriatal circuitry function and preventing smoking relapse is unknown. METHODS: The present study examined the effects of N-Acetylcysteine on corticostriatal resting-state functional connectivity (rsFC), nicotine withdrawal symptoms and maintaining abstinence. Healthy adult smokers (N=16; mean (SD) age 36.5±11.9; cigs/day 15.8±6.1; yrs/smoking 15.7±8.9) were randomized to a double-blind course of 2400 mg N-Acetylcysteine (1200 mg b.i.d.) or placebo over the course of 3 ½ days of monetary-incentivized smoking abstinence. On each abstinent day, measures of mood and craving were collected digitally, and participants attended a lab visit in order to assess smoking (i.e., expired-air carbon monoxide [CO]). On day 4, participants underwent fMRI scanning. A demographically-matched nonsmoker control-group (N=16) was

scanned once for comparison. RESULTS: As compared to placebo (n=8), smokers in the N-Acetylcysteine group (n=8) maintained abstinence, reported less craving and higher positive affect (PA) (all p's <.01), and concomitantly exhibited stronger frontostriatal and weaker visuostriatal rsFC [p<.05; FWE]). Frontostriatal rsFC was negatively correlated with CO and fully mediated the relationship between craving and PA. Finally, no differences in rsFC or affect were found between the N-Acetylcysteine group and nonsmokers. CONCLUSIONS: Taken together, these findings suggest that N-Acetylcysteine may normalize dysregulated corticostriatal connectivity, help to restructure reward processing, and reduce vulnerability to relapse after quitting smoking.

Abstract: Background: The effects of the hallucinogen D-lysergic diethilamide (LSD) are described as a "mystical experiences", "sensory journeys", pseudo-hallucinations, affective changes, enhancement of past memories. It was firstly synthetized in 1938 by A. Hofmann, but its mechanism of action has not yet completely elucidated. It is well known that LSD interacts with the serotonin (5-HT) system binding to 5-HT1 and 5-HT2 receptors (Peroutka and Solomon, 1973), decreasing the activity of 5-HT neurons in the Dorsal Raphe Nucleus (DRN) (Trulson and Jacobs, 1979) and increasing the firing rate of cortical neurons in the somatosensory cortex in rats (Marek and Aghajanian, 1996). However, little is known of its potential interactions with the dopamine (DA) neurons of the Ventral Tegmental Area (VTA). In this study, we first evaluated the effects of LSD on DA neuron activity in the parabrachial nucleus of VTA, and second, we compared these effects to those produced on 5-HT neurons in the DRN. Third, we pretreated rats with p-chlorophenylalanine (PCPA), an inhibitor of 5-HT synthesis, to test whether the effects of LSD on DA neurons are mediated by the 5-HT system. Methods: Using *in vivo* electrophysiology, we studied the effects of cumulative doses of LSD (10-90 ug/kg, i.v.) on DRN 5-HT and VTA DA neurons in Sprague Dawley male adult rats. A second group of rats was pretreated with PCPA (350 mg/kg, i.p.) 48-h and 24-h before VTA DA recordings. Results: LSD induced a significant decrease of DRN 5-HT firing activity at the dose of 10 ug/kg, and switched off the firing at 20 ug/kg (n=6). These doses did not affect DA neuronal activity. At the dose of 60 ug/kg, LSD decreased DA firing activity (vehicle: 2.42 ± 0.95 Hz; LSD 60 ug/kg: 1.44 ± 0.61 Hz, n=6), while at 90 ug/kg it completely shut down VTA DA activity ($p<0.05$ versus vehicle, n=6). Notably, the injection of cumulative doses of the selective D2 antagonist haloperidol (0.05-15 mg/kg, i.v.) was able to reinstate the activity of DA neurons (1.53 ± 1.23 Hz, $p<0.05$, n=6). In PCPA-pretreated rats, LSD decreased the activity of VTA DA neurons similarly to non-treated rats (vehicle: 2.04 ± 0.64 Hz; LSD 60 ug/kg: 0.40 ± 0.29 Hz, $p< 0.05$, n=4), but in this case, haloperidol (0.05-0.25 mg/kg, i.v.) was not able to reinstate DA neuronal activity. Discussion: These results suggest that LSD modifies the DA system independently from the 5-HT system and D2 receptors. Furthermore, it confirms that the 5-HT system plays an inhibitory role on VTA DA neurons through the modulation of D2 receptor.

Title: Cognitive behavioral therapy normalized abnormal neural circuits at resting state in Internet gaming disorder

Authors: *Y. YAO[1], J. ZHANG[1], C.-S. R. LI[3], L. LIU[2], L. WANG[1], B. LIU[1], S. MA[1], X. FANG[2];

Abstract: Internet gaming disorder (IGD) has become a serious mental health issue worldwide. Developing effective interventions for IGD and evaluating the benefits of these interventions are of great significance. Evidence suggests that IGD is associated with altered brain structures and functions, thus investigating neurobiological abnormalities of IGD would advance our understanding of its underlying mechanism and provide information to develop more tailored interventions. Resting-state fMRI offers an effective way to measure intrinsic brain activities without the burden of specific tasks, and has been used as an objective measure to assess the effects of interventions in IGD. The aims of this study were to identify regional abnormalities and related altered neural circuits in IGD during resting-state, and how cognitive behavioral therapy (CBT) takes effect at circuits level. Forty-one young adults with IGD and 19 age- and sex-matched healthy controls (HCs) were recruited, and their resting-state fMRI data were collected. Twenty-three IGD subjects (IGDs) participated in a group CBT once a week lasting for six weeks, and were scanned before and after the intervention. The remaining 18 IGDs did not receive an intervention, but were similarly scanned at the same time points. We firstly compared amplitude of low frequency fluctuation (ALFF) between 41 IGDs and 19 HCs before intervention, and found that IGDs showed decreased ALFF in the posterior cingulate cortex (PCC) and frontal pole. We further examined alteration in resting-state functional connectivity (rsFC) of these two regions using seed-based correlation analysis, and found that IGDs exhibited increased rsFC between PCC and dorsolateral prefrontal cortex. Finally, we examined the effects of CBT on rsFC in IGD. Compared with IGDs who did not receive intervention, IGDs receiving CBT demonstrated significantly reduced interactions between PCC and precentral gyrus, and between frontal pole and hippocampus/parahippocampus. These findings suggest that IGD is associated with abnormal spontaneous activity and maladaptive interactions between regions within default mode network (DMN) and executive cognitive network (ECN). Furthermore, CBT

may exert its effect by reducing the interactions between ECN and DMN, and between regions in ECN and components in reward system.

Abstract: Cocaine is a commonly abused psychostimulant that causes alterations to the mesocorticolimbic circuitry and addiction-related behaviors. Females have been shown to be more vulnerable to the effects of cocaine than males. Taurine is an essential amino acid that displays several neuropsychopharmacological roles such as neuromodulator, neurotrophic, and osmomodulatory roles. Previous data from our laboratory shows that males and females form a preference to cocaine but pre-treatment of taurine attenuates cocaine preference to non-significant levels. The objective of the present study is to determine if exposure to taurine will

reduce cocaine preference in gonadectomized (GDX) male and female subjects and elucidate whether gonadal hormones affect taurine's efficacy and potential for cocaine treatment. Males and females were run in two cohorts (n = 36; n=9/treatment group). The cohorts were divided into four groups. The first group are injected with taurine pretreatment and taurine+cocaine coadministration treatment (pre-tau/coc+tau), the second group is exposed to taurine pretreatment and cocaine+saline coadministration treatment (pre-tau/coc+sal), the third group also received the taurine pretreatment and taurine+saline coadministration treatment (pre-tau/tau+sal), and the fourth group is saline-pretreatment and cocaine+saline coadministration treatment (pre-sal/coc+sal). The rats are pretreated with taurine (100mg/kg) or saline (intraperitoneal) for two weeks before undergoing a ten-day conditioned place preference (CPP) behavioral paradigm where a context will be paired with a drug stimulus (taurine or cocaine). GDX males acquired cocaine preference, and taurine inhibited cocaine reward under all conditions. GDX did not acquire a preference to taurine. Although GDX-females do not form a cocaine-preference, interestingly, GDX-females did acquire a preference to the taurine-paired chamber ($p<0.0064$). These results suggest taurine is potentially a good candidate for cocaine addiction but further research will need to elucidate how hormones modulates taurine's efficacy since GDX-females seem to be sensitive to the effects of taurine. Cocaine-induced behaviors can persist for years even after abstinence and the best form of treatment is still being elucidated.

Title: Putative dopamine agonist KB220Z enhances resting state brain reward circuit functional connectivity

Authors: K. BLUM[1], *M. FEBO[1], R. D. BADGAIYAN[2], P. D. PEREZ[1], L. M. COLON-PEREZ[1], P. K. THANOS[3], C. F. FERRIS[4], P. KULKARNI[4], J. GIORDANO[5], M. S. GOLD[1]; [1]Psychiatry Dept., Univ. of Florida, Gainesville, FL; [2]Psychiatry, Univ. of Minnesota, Minneapolis, MN; [3]Psychology, SUNY Stonybrook, Stony Brook, NY; [4]Psychology, Northeastern Univ., Boston, MA; [5]Dept. of Holistic Med., Natl. Inst. of Holistic Addiction Studies, North Miami Beach, FL

Abstract: Dopaminergic reward dysfunction in addictive behaviors is well supported in the literature. Several lines of evidence support the notion that alterations in synchronous neural activity between brain regions subserving reward and various cognitive functions, may significantly contribute to substance-related disorders. An electronic rat atlas was used to evaluate resting state functional connectivity in brain reward circuitry. This study presents the first strong evidence showing that a putative dopamine agonist nutraceutical (KB220Z) significantly activates, above placebo, seed regions of interest including the left nucleus accumbens, cingulate gyrus, anterior thalamic nuclei, hippocampus, pre-limbic and infra-limbic loci. This response induced by KB220Z demonstrates significant functional connectivity, increased brain volume recruitment and enhanced dopaminergic functionality across the brain reward circuitry. This robust yet selective response implies clinical relevance.

Title: Food craving in morbid obesity: influence on biological variables and bariatric surgery outcomes

Authors: *J. R. MUÑOZ-RODRÍGUEZ[1], F. POLO[1], L. BEATO[1], J. MARTÍN[1], C. GONZÁLEZ-MARTÍN[2], E. SEGURA[1], G. CASAS[1], A. LEÓN[1], E. SALAS[1], L. F. ALGUACIL[2];
[1]Translational Res. Unit, Univ. Gen. Hosp. of Ciudad Real, Ciudad Real, Spain; [2]CEU San Pablo Univ., Boadilla, Madrid, Spain

Abstract: It has been recently estimated that 20% of obese subjects are suffering from food addiction. These subjects may represent a specific endophehotype of obesity from both diagnostic and prognostic points of view. To further define this endophenotype, we have comparatively studied a broad set of biomarkers in morbid obese patients with high and low food cravings. Besides, we have compared the evolution of these biomarkers in both groups one year after bariatric surgery treatment. 23 morbid obese patients (BMI>40; 16 females and 7 males aged 44±3 years) and a group of normoweight controls (18,5>BMI<25) matched by sex and age were recruited. Patients were administered with the Spanish version of the State and Trait Food Cravings Questionnaire, trait scale, in order for them to be subdivided into two groups according to their craving scores: high food craving (HFC, with "loss of control" dimension score ≥15, n=13) and low food craving (LFC, with "loss of control" dimension score <15, n=10). Serum samples were obtained from all subjects to quantify clinical routine parameters and biomarkers of renal and liver function, metabolism and inflammation, as well as hormones and neuropeptides of interest. Quantifications were repeated one year after bariatric surgery (gastric bypass). Routine parameters were determined by conventional clinical tests while hormones and neuropeptides were determined by ELISA. Statistics was performed in SPSS v19.0 using two-way repeated-measures ANOVA with "craving" (LFC, HFC) and "treatment" (pre-surgery, post-surgery) as independent variables and Bonferroni post hoc for multiple comparisons. Data analysis revealed that carbohydrate metabolism was differentially affected in HFC and LFC subjects, the latter exhibiting higher values of HOMA-1%β and 2%β along the study. Bariatric surgery was effective to decrease body mass indexes and correct many biochemical and

metabolic alterations to a similar extent in both HFC and LFC patients; however, the magnitude of change in total cholesterol, LDL, HOMA-2%β, Mg and Fe only achieved statistical significance in HFC subjects. By contrast, patients of the LFC group were the only to exhibit a partial recovery of ghrelin and vitamin D1 levels post-surgery, and were resistant to BDNF downregulation below control values. These results together with complementary data from proteomics and metabolomics performed in our laboratory strongly suggest that morbid obese patients have different metabolic profiles and different response to bariatric surgery depending on their food cravings, thus supporting the importance of further progressing in the definition of an "addictive" endophenotype of obesity.

Title: Metabolism of L-tetrahydropalmatine (L-THP) in rats and *in vitro* effects of its major metabolites on dopamine receptors

Authors: P. HUANG[1], I. ABDALLAH[2], J. LIU[3], W. HEDRICH[2], D. Y. LEE[3], H. HASSAN[2], *L.-Y. LIU-CHEN[1];
[1]Ctr. for Substance Abuse Res., Temple Univ. Sch. Med., Philadelphia, PA; [2]Dept. of Pharmaceut. Sci., Univ. of Maryland Sch. of Pharm., Baltimore, MD; [3]Bio-Organic and Natural Products Lab., McLean Hospital, Harvard Med. Sch., Belmont, MA

Abstract: L-THP is currently in a clinical trial for treatment of cocaine addiction in the US. Here we reported its metabolism in rats and the *in vitro* pharmacology of its major metabolites. Following i.p. injection, L-THP was immediately absorbed into the blood and appeared in the brain. Metabolism of L-THP occurred rapidly with L-corydalmine (L-CD) and L-corypalmine (L-CP) as the two major metabolites, which peaked in the plasma at 15 min after i.p. injection.

Following 30 mg/kg i.p. injection of L-THP, the plasma and brain levels were in the order of L-THP > L-CD > L-CP at all time points examined (from 15 min to 24 h). After 10 mg/kg i.p. injection, the plasma and brain levels were in the same order at two time points examined (30 min and 4 h). L-THP appeared to have first-order metabolism with a $T_{1/2}$ of about 2 h. The receptor binding and functional properties of L-CD, L-CP and L-THP on dopamine receptors were characterized using cell lines stably expressing each of the five human dopamine receptors (DR). [^{3}H]SCH23390 binding and stimulation of adenylyl cyclase were used to examine the effects on D1R or D5R, and [^{3}H]N-methyl-spiperone binding and [^{35}S]GTPγS binding assays were for D2R, D3R or D4R. L-CD, L-CP and L-THP showed similar affinity for D1R (K_i, 107-199 nM) and for D5R (K_i, 242-313 nM). The K_i values of L-CP to D2R and D3R were 42.4 and 262 nM, respectively, and of L-CD to D2R was 533 nM. The following interactions had low affinity (K_i >1 μM): L-THP with D2R and D3R; L-CD with D3R; L-THP, L-CD and L-CP with D4R. For D1R and D5R, compared with dopamine, both L-CD and L-CP were partial agonists, with lower efficacies for D5R. For D2R and D3R, neither activated the receptors and exhibited antagonist activities. At the D2 receptor, L-CP and L-CD at 1 μM shifted the dose-response curve of DA to the right and increased the EC_{50} value of DA by 15- and 5.8- fold, respectively. L-CP also reduced the E_{max} value of DA significantly. At the D3 receptor, L-CP and L-CD at 1 μM shifted the dose-response curve of DA to the right and increased the EC_{50} value of DA by 7.9- and 6.2-fold, respectively without changing the E_{max} value of DA. Thus, both L-CD and L-CP are D1R and D5R partial agonists and D2R and D3R antagonists, with lower potencies at D2R and D3R. The effects of L-THP on DR-mediated signaling are currently under investigation.

Title: Dopamine D2 receptors as peripheral biomarkers for brain dopamine levels and as targets for modulating brain dopamine

Authors: *S. C. STEFFENSEN[1], E. Y. JANG[1], H. J. PARK[1], B. GARCIA[1], G. F. BURTON[1], S. H. BURNETT[1], J. G. LEE[2], C. H. YANG[2];
[1]Brigham Young Univ., Provo, UT; [2]Daegu Haany Univ., Daegu, Korea, Republic of

Abstract: Dopamine (DA) D2 autoreceptor (D2R) expression in the midbrain and striatum is a well-known biomarker for brain DA levels. Markers of D2R expression are not only detectable in the brain, but are also expressed in peripheral tissues, including blood, where DA appears to play a pivotal role in mediating communication between the nervous and immune systems. The aim of this study was to evaluate the expression of D2Rs on WBCs following exposure to DA and D2R agonists/antagonists, and to correlate expression with DA release in the nucleus accumbens (NAc) of the striatum, as well as locomotor and self-administration behavior. Using fluorescent flow cytometry and immunohistochemistry, D2Rs were expressed in WBCs in mice, rats and humans. However, their expression in rats was mostly limited to activated monocytes, which was the focus of this study. D2R expression in monocytes decreased at 2 hrs by 50% following administration of the centrally-acting D2R antagonist eticlopride (1.0 mg/kg IV) and increased at 2 hrs by 75% following administration of the centrally-acting D2R agonist quinpirole (0.1 mg/kg IV). However, D2R expression in the NAc exhibited opposite effects at 2 hrs to those in the blood. Concomitantly, using fast-scan cyclic voltammetry (FSCV), phasic DA release in the NAc was markedly enhanced 320% by eticlopride and reduced 76% by quinpirole with an onset in minutes and duration of 2 hrs. Surprisingly, intravenous administration of DA (0.1-3.0 mg/kg) enhanced DA release 2000% in the NAc with a lag of 20 min. This marked increase in DA release was not due to the blood pressure enhancing effects of DA via alpha adrenergic receptors. Intravenous DA resulted in complex behavioral effects depending upon dose, which included freezing at higher doses and activation at lower doses. Preliminary immunohistochemical studies have revealed expression of D2Rs in brain microglia after IV DA injection. These findings suggest that DAergic drugs not only yield rapid changes in brain D2 receptor expression, but elicit changes in peripheral D2 receptor expression that appear to be inversely correlated. In addition, activation of peripheral D2Rs may be a potential therapeutic target to raise brain DA levels. These results have significant clinical potential as changes in peripheral D2 receptor expression could be monitored as biomarkers of brain DA and used for the treatment of addiction as well as other diseases involving DA including Parkinson's disease.

Title: Prefrontal cortical correlates of inhibitory control in patients with alcohol use disorders

Authors: *J. D. HARRIS[1], A. HUHN[1], E. DENEKE[2], H. AYAZ[3], R. MEYER[1], S. BUNCE[1]; [1]Psychiatry, Pennsylvania State Univ., Hershey, PA; [2]Res., Caron Treatment Centers, Wernersville, PA; [3]Biomed. Engin., Drexel Univ., Philadelpia, PA

Abstract: Alcohol use disorders have devastating effects to individuals' well-being and to public health at large. One key feature of alcohol use disorders is loss of control, which is related to impulsivity and deficits inhibitory control. Recent neuroimaging studies suggest that deficits in inhibitory control and related executive functions are mediated by dysfunction of the prefrontal cortex (PFC). Prefrontal cortical dysregulation is also hypothesized to mediate severity of alcohol dependence and increase relapse vulnerability following discharge from residential treatment. This study employs clinically applicable neuroimaging technology, functional near-infrared spectroscopy (fNIRS), to examine PFC function in patients with alcohol use disorders while performing a neuroimaging adaptation of the word-color Stroop paradigm. Incongruent minus neutral conditions were selected for the contrast of interest. Stimuli were presented a in block design, with 300ms stimulus presentation and 1300ms interstimulus interval. A subjective measure of inhibitory control was assessed using the Barratt Impulsivity Scale (BIS-11). Patients' task-related PFC activity over right inferior frontal gyrus (rIFG) correlated with BIS scores ($r(35) = 0.60$, $p = 0.001$). Of note, this relationship was found for patients, but not control participants ($r(14) = -0.15$, $p = 0.61$). Importantly, rIFG has been demonstrated in tasks related to inhibition. These data demonstrates the relationship between self-reported impulsivity, and underlying prefrontal cortical activity in patients with alcohol use disorders. Furthermore, this investigation demonstrates a cost-effective, objective brain based biomarker of impulsivity that may provide relevant data to help improve alcoholism treatment efficacy. The ongoing study is evaluating the utility of these data in the prediction of treatment outcome.

Title: Reinforcing and neurochemical effects differentiate modafinil from methylphenidate in their interactions with cocaine

Authors: *G. TANDA[1], M. MEREU[1], T. HIRANITA[2], L. CHEN[1], J. LOPEZ[1], M. COGGIANO[1], J. QUARTERMAN[1], A. H. NEWMAN[3,1], J. KATZ[2];
[1]Medication Develop. Program, NIDA, Baltimore, MD; [2]Psychobiology Section, Natl. Inst. on Drug Abuse, Baltimore, MD; [3]Medicinal Chem. Section, Natl. institute on Drug Abuse, Baltimore, MD

Abstract: Modafinil (MOD) and methylphenidate are FDA-approved as a wakefulness-promoting agent, or for attention deficit disorder, respectively. They share with cocaine inhibition of dopamine (DA) reuptake by blockade of the DA-transporter, and have been tested in clinical studies as medications to treat cocaine-dependence. Non-medical use of MOD and methylphenidate as "smart drugs," in order to increase cognitive performance, especially by students, has been described. This population is also at risk for abuse of illicit stimulants, like cocaine. Interactions of MOD and cocaine have not yet been fully described, and information about the potential adverse effects of MOD in combination with an abused psychostimulant like cocaine is of public health importance. In the present study MOD (0.1-10 mg/kg iv) failed to maintain self-administration behavior in rats, whereas methylphenidate self-administration was maintained at doses equal to those for cocaine self-administration (0.1-1 mg/kg iv). However, pretreatments with MOD (10-32 mg/kg ip) or methylphenidate (1-10 mg/kg ip) potentiated cocaine self-administration, shifting the dose-effect curves to the left. Cocaine, at self-administered doses also produced dose-related stimulation of DA in the nucleus accumbens shell, a brain area involved in the reinforcing effects of drugs. Methylphenidate enhanced this stimulation whereas MOD was without significant effects. In summary, MOD has a unique stimulant profile compared to cocaine and methylphenidate. The results suggest MOD may enhance cocaine-induced reinforcing effects. However, there are no clinical reports of abuse of modafinil alone or in combination with psychostimulants; thus, it remains to be seen if the recreational use of "smart drugs" such as MOD will lead to the abuse of illicit substances. Recent clinical studies report positive therapeutic outcomes of MOD treatment in cocaine addicted subjects. The results herein support that at the very least MOD may decrease cocaine consumption, if not entirely achieve abstinence. In the absence of any approved medication for this patient population, it seems that a medication that appears to have no addictive liability on its own, but could reduce cocaine use would be of interest.

Title: Is high fructose corn syrup as addictive as oxycodone? A study of dual intravenous and intraoral self-administration, extinction and reinstatement in rats

Authors: M. MINHAS, *F. LERI;
Psychology, Univ. Guelph, Guelph, ON, Canada

Abstract: Introduction: It is reported that highly palatable food can engender “addictive-like” patterns of consumption. Furthermore, there is substantial evidence in animals that palatable food activates brain reward centers in ways that closely resemble the action of drugs of abuse. These similarities suggest that "addiction" can develop to food. The current study investigated the hypothesis that sugar can be addictive as drugs of abuse by studying the self-administration (SA) of sugar and drugs in the same animals. Methods: Male, Sprague-Dawley rats were implanted with both intra-oral (IO) and intravenous (IV) cannulas and allowed to self-administer IO infusions of high fructose corn syrup (HFCS; 8, 25, 50%) and IV infusions of oxycodone (0.05, 0.1, and 0.2 mg/kg/inf) of 16 alternating days for 3 hrs/day. After a 4-day abstinence period, animals were tested in extinction conditions by presenting simultaneously both HFCS- and oxycodone-paired levers in the absence of the reinforcers. Extinction was followed by tests of priming-induced reinstatement. Results: Preliminary findings indicate that the pattern of SA for HFCS (50%) and oxycodone (0.1 mg/kg/inf) was similar either in the presence, or in the absence, of the reinforcers. Experimenter-administered injections of HFCS (50%; IO) or oxycodone (0.1 mg/kg; IV) reinstated responding that was specific to the levers previously associated with their self-administration. Conclusions: These findings indicate that high fructose corn syrup and oxycodone engender similar patterns of consumption and seeking in the same animal. Importantly, however, priming with one reinforcer does not induce seeking of the other. Funded by NSERC

Title: Effect of bupropion and naltrexone on hedonic responses in laboratory rats

Authors: ***A. LEVY**[1], S. DANIELS[2], A. FLYNN[2], R. HUDSON[2], T. HORMAN[2], A. CHISHOLM[2], F. LERI[2];
[1]Psychology, [2]Univ. of Guelph, Guelph, ON, Canada

Abstract: Introduction: One defining feature of anhedonia is impaired reactivity to rewarding stimuli. We have been investigating two sub-processes of reward reactivity: set-point and primed-seeking. In this study, we attempted a pharmacological validation of these constructs by administering a bupropion (BUP; monoamine reuptake inhibitor) and naltrexone (NTX; opioid antagonist) alone, or in combination as employed to alleviate symptoms of depression in obese individuals. Methods and results: In animals trained to self-administer intraoral infusions of sugar in operant chambers on fixed ratio 1 schedules of reinforcement (measure of set-point seeking), acute or chronic administration of BUP+NTX reduced responding. Both acute and chronic NTX alone reduced sugar self-administration while BUP alone had no effect compared to vehicle. On a progressive ratio schedule (measure of primed-seeking), acute BUP+NTX and BUP alone enhanced sugar self-administration compared to vehicle and NTX alone. Similar effects were observed following chronic administration. In animals self-administering sugar from a sipper tube in home cages, chronic administration of combination BUP+NTX reduced both sugar and food intake. Alone, NTX also reduced sugar consumption without altering food intake; however, BUP did not affect either food or sugar consumption. Conclusions: These findings suggest that set-point and primed seeking can be pharmacologically dissociated. The former is primarily dependent on reward “satiety” and is enhanced by anorexic drugs like BUP and NTX. The latter is primarily dependent on reward “anticipation”, and is enhanced by monoamine activation, but only after acute administration. In combination, BUP and NTX act synergistically to increase reward satiety and primed-seeking.

Title: Exploring the anhedonic component of naltrexone precipitated high fructose corn syrup withdrawal

Authors: *S. DANIELS, P. MARSHALL, F. LERI;
Univ. of Guelph, Guelph, ON, Canada

Abstract: The affective component of withdrawal is a core feature of addiction. Negative emotional states last long after substance use has ceased, leaving individuals vulnerable to relapse even when physical symptoms have subsided. It has been suggested that withdrawal from sugars produces a set of somatic symptoms resembling those of opiate drugs. However, whether the affective component of withdrawal relates to consumption of sugars remains unknown. Therefore, the current study determined whether naltrexone (NTX) could precipitates conditioned place avoidance (CPA) in laboratory rats receiving acute or chronic pre-exposure to a HFCS solution. To interpret the findings, the same experiments were repeated in rats pre-exposed to acute or chronic heroin. In different experiments, animals received: intragastric acute administration of high fructose corn syrup (HFCS; 0.5, 1 or 2 g/kg); drank 0% or 50% solutions of HFCS in their home cages for 22 days (food restricted and non-food restricted); received acute subcutaneous (SC) injections 2 mg/kg heroin; or were implanted (SC) with osmotic mini-pumps releasing 3.5 mg/kg/day heroin. Following pre-treatments, animals were tested on CPA induced by NTX (1 or 3 mg/kg, SC). HFCS pre-exposure did not significantly amplify CPA induced by NTX. Food restricted rats with increased HFCS consumption demonstrated NTX-induced CPA not seen in animals given 0% HFCS, yet no significant interaction was observed. NTX-induced CPA with acute infusions of HFCS at higher but not lower doses, yet effects were not significantly different from 0% HFCS. Animals given acute and chronic heroin pre-exposure showed a NTX-induced CPA that was significantly different from control animals. These results fail to support the hypothesis that an opioid antagonist can precipitate similar affective withdrawal states following pre-exposure to sugars and opiates.

Title: The role of the central endocannabinoid system in anhedonia

Authors: *D. HAYNES, C. L. LIMEBEER, L. A. PARKER, F. LERI;
Psychology, The Univ. of Guelph, Guelph, ON, Canada

Abstract: Recent evidence has implicated the endocannabinoid system, particularly the centrally-abundant cannabinoid receptor type 1 (CB1 receptor), in hedonic processing as well as anhedonia, the inability to experience pleasure. CB1 inverse agonists in particular have been shown to elicit typical anhedonic pathology in both humans and animals when administered chronically, with studies of the latter showing suppression of palatable food consumption, hedonic taste response to highly palatable flavours, and operant responding for a palatable food reward, indicative of an anhedonic state. However, the majority of these findings originate from studies employing systemic administration, which has been shown to elicit nausea alongside anhedonia. Recent research indicates that direct administration to the lateral ventricles eliminates this nausea component while appearing to preserve the anhedonic component. The present study sought to determine whether chronic intracerebroventricular (ICV) administration of CB1 inverse agonist AM251 is capable of inducing a persistent anhedonic state and to examine the role of the central CB1 receptor in anhedonia. Naïve male Sprague-Dawley rats received direct, chronic infusion of AM251 or vehicle via subcutaneous osmotic minipump into the right lateral ventricle, or underwent sham surgery. Hedonic capacity was assessed via changes in ad libitum consumption of a sweet, highly-palatable solution (high-fructose corn syrup; HFCS), as well as hedonic taste response to an intraoral infusion of HFCS. Preliminary results revealed a trend indicating persistent suppression of HFCS consumption by ICV AM251, consistent with an anhedonic state. However, there did not appear to be any significant difference in taste reactivity to HFCS. Final results will be presented at the meeting.

Title: The influence of polyunsaturated fat diets on brain membrane lipid composition, leptin responsiveness and predisposition to anhedonia

Authors: *M. FERNANDES, D. MUTCH, F. LERI;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Introduction: Dietary fat intake and the subsequent changes in brain membrane fatty acid composition have been implicated in the development of and susceptibility to some mental illnesses. Consistent with that, polyunsaturated fatty acids (PUFAs) differently affect depression-related behaviors: Omega-3 (n-3) PUFAs are known to reduce depression, while elevated intake of foods rich in Omega-6 (n-6) PUFAs are associated with an increase in the incidence of depressive disorders. Notably, it is well known that dietary lipid composition affects sensitivity to peripheral hormones, including leptin - PUFAs consumption promotes peripheral, but not central, leptin resistance. In addition, the localization of the leptin receptor in limbic structures implicated in the control of mood and emotion, such as the hippocampus, cortex and amygdala, suggest a potential role for leptin in hedonic behaviors. Providing further connection between mood disorders and adiposity signals, a number of reports suggested that leptin has antidepressant-like properties. Therefore, we hypothesize that long-term intake of n-3 or n-6 PUFA-rich diets will differentially modulate anhedonic behaviors by altering brain membrane lipid composition and leptin responsiveness in Sprague-Dawley rats. Methods: Sprague-Dawley rats fed an omega-3 or omega-6 PUFA-diet for 4 weeks will be euthanized and brain tissue will be collected for brain membrane lipid composition analyses (gas chromatography), endocannabinoid-system metabolites (liquid chromatography-mass spectrometry) and assessment of leptin signaling in the brain (western blotting). Epididymal and inguinal fat pads were removed from the above-mentioned rats and used for adipose tissue organ culture (ATOC), a well characterized technique that has been used to determine changes in adipose tissue metabolism and gene expression. A different cohort of rats maintained in the same dietary

condition was tested for anhedonic-like behaviors. Conclusion: These studies will provide valuable and novel information on the involvement of peripheral signals, such as fatty acids and leptin, in the pathophysiology of anhedonia and associated conditions, such as depression, obesity and substance dependence.

Title: What about the cue? Modulation of cue value in the augmentation of heroin seeking in chronically food restricted rats

Authors: ***F. SEDKI**[1], L. MAYERS[2], P. MARTONE[2], U. SHALEV[2];
[1]CSBN, [2]Concordia Univ., Montreal, QC, Canada

Abstract: Disruptions in energy balance can largely affect motivated behaviours. For example, dietary restriction can increase drug intake in humans and rodents alike. Recently, we reported augmented heroin seeking in chronically food restricted rats under withdrawal. However, the underlying motivational mechanisms that drive this effect remain unclear. It is possible that exposure to caloric restriction may enhance the incentive salience attributed to drug-associated cues, and in turn augment drug seeking. Thus, we investigated the effect of food restriction on heroin seeking under a progressive ratio schedule of reinforcement, and on the acquisition of a new operant response reinforced solely by heroin-associated cues. Male Long-Evans rats were trained to self-administer heroin, by way of lever responses, for 10 days in operant conditioning chambers. Heroin infusions were associated with a complex light/tone stimulus. Next, rats were moved to the animal colony and maintained on free access to food (Sated group) or subjected to 14 days of mild chronic food restriction (FDR group), which sustained their body weight at 90% of their baseline weight. On day 14, rats underwent a 3 h heroin-seeking test under extinction conditions in the operant conditioning chambers. Exp.1: Rats were exposed to a progressive ratio

schedule of reinforcement driven solely by the heroin-associated cue. Exp. 2: The value of the cue was assessed by training the rats on a novel nose-poke response reinforced solely by the heroin-associated cues. Rats were tested across 3 sessions separated by 5 days each. Rats in the Sated and FDR groups demonstrated a robust increase in lever responding during the progressive ratio procedure, however no differences were observed between groups (Exp. 1). When exposed to a novel nose-poke procedure, rats in the FDR group acquired the novel behaviour at a greater rate compared to the Sated group. Furthermore, the enhanced acquisition of this novel behaviour persisted across multiple trials. Thus, while we did not observe differences in a progressive ratio task driven by cues alone, the value of a previously heroin-associated cue is enhanced by food restriction, and this augmented value is sustained across multiple tests.

Title: Blocking D1 receptors in the nucleus accumbens core but not shell decreases the augmentation of heroin seeking induced by chronic food restriction in the rat

Authors: *T. M. D'CUNHA, D. RIZZO, G. MOURRA, M. RUSSO, F. SEDKI, U. SHALEV; Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Dieting or chronic food restriction and drug craving during abstinence increases the risk to relapse in human addicts. Recently, we demonstrated that chronic food restriction during withdrawal augments heroin seeking in rats with a history of heroin self-administration. Moreover, this prolonged restriction increases extracellular dopamine levels in the nucleus accumbens (NAc) core and shell during a heroin-seeking test. Thus, we expect that blocking dopamine transmission in the NAc core or shell will reverse the augmentation of heroin seeking induced by chronic food restriction. Here, rats were trained to self-administer heroin for 10 days in operant conditioning chambers. Next, rats were moved to the animal colony for 14 days of

withdrawal during which they were given either unrestricted access to food or subjected to a mild chronic food restriction to reduce their body weight to approximately 90% of their baseline weight. On day 14 of withdrawal rats were returned to the operant conditioning chambers for a 3 h heroin-seeking test under extinction conditions. Rats were administered the selective dopamine D1 receptor antagonist SCH 39166 into the NAc shell (0.0, 12.5, 25.0, 50.0 ng/side) or the NAc core (0.0, 12.5, 25.0 ng/side) prior to testing. As expected, food restriction significantly augmented heroin seeking compared to the sated rats. SCH 39166 administration (25.0 & 50.0 ng/side) into the NAc shell decreased cue-induced heroin seeking in both the food restricted and sated groups. In contrast, SCH 39166 (12.5 & 25.0 ng/side) in the NAc core selectively decreased the augmentation of heroin seeking in the food restricted group. These results suggest that cue-induced heroin seeking following withdrawal may be mediated by D1 receptor activation in the NAc shell, while the augmentation of heroin seeking induced by chronic food restriction may be specifically dependent on D1 receptor activation in the NAc core.

Title: Alternating access to a highly palatable diet and amphetamine sensitivity

Authors: *C. F. MOORE[1,2], V. SABINO[1], P. COTTONE[1];
[1]Lab. of Addictive Disorders, Departments of Pharmacol. and Psychiatry, [2]Grad. Program for Neurosci., Boston Univ., Boston, MA

Abstract: Eating disorders and certain forms of obesity are associated with mesolimbic dopaminergic reward dysfunction. Overeating of diets rich in sugar and fat alter dopamine neurotransmission in the nucleus accumbens, likely contributing to the persistence of excessive intake. Amphetamine-like drugs, which act in the mesolimbic pathway to enhance the release of dopamine, also confer long-lasting neuroadaptations. However, it is not yet known if a history of

disordered eating can alter sensitivity to these drugs. In this study, we investigated the effects of palatable food diet alternation on sensitivity to amphetamine challenges and amphetamine self-administration. Ad libitum diet alternation occurred for 5 weeks prior to any testing. One group was provided a chow diet 7 days a week, and a second group was provided chow 5 days a week followed by 2 days of access to a highly palatable, chocolate flavored, high-sucrose diet. While continuing diet alternation, we measured locomotor activity following an amphetamine challenge to test sensitivity during the 2 days of access to the palatable diet as well as when animals were withdrawn from palatable food. Following this within-subject amphetamine administration schedule, animals were allowed to self-administer amphetamine in water in the home cage. Rats withdrawn from intermittent access to palatable food exhibited pronounced hypophagia of the otherwise acceptable standard diet and overeating of palatable food upon renewed access. Further analysis is being conducted to understand how a history of overconsumption of palatable food might sensitize the mesolimbic pathway to the stimulatory effects of amphetamine-like drugs, and whether this may be augmented during periods of palatable food withdrawal.

Title: Discriminative stimulus effects of naltrexone in rats with limited access to sucrose, saccharin, or water

Authors: J. L. HERRMANN[1], J. M. WARNER[1], C. C. THAI[1], *E. M. DE ROACH[1], K. A. TWAROSKI[1], A. J. STAUB[1], A. C. VIRNIG[1], A. S. LEVINE[2], D. C. JEWETT[1];
[1]Univ. of Wisconsin - Eau Claire, Eau Claire, WI; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: In most operant discrimination paradigms, large doses of naltrexone (NTX) are typically required to establish NTX as a discriminative stimulus in opioid-naïve subjects. Chronic, but limited access to sucrose increases endorphin function in rats. We attempted to establish NTX as a discriminative stimulus in rats given limited access to sucrose, saccharin, or water. Rats were trained to lever press and were given access to sucrose (25% or 32%), saccharin (0.1%) or water for 12 hours a day for two weeks. Rats were then given daily injections of either

saline or NTX (3.2 mg/kg, 15 min PT) 1 hour after access to the solution. After the training session subjects were returned to their home cage for the remainder of the 12 hour-access period. Water was available for all subjects for the other 12 hours. In rats with 12 hours access to sucrose, NTX was reliability discriminated from saline in a mean of 72 sessions (Md = 63, range 27-135 sessions). No significant differences in acquisition of the NTX-saline discrimination or initial NTX dose-effect functions were noted between sucrose concentrations. NTX failed to serve as a discriminative stimulus in rats given access to saccharin or water solutions. These results provide further support for the notion that chronic sucrose consumption increases endogenous endorphin function.

Title: Influence of the ovarian cycle and estradiol in frustration stress-induced binge-like palatable food consumption in female rats with a history of food restriction

Authors: *M. V. MICIONI DI BONAVENTURA[1], T. A. LUTZ[2], A. ROMANO[3], C. D'ADDARIO[4], L. ASARIAN[2], C. CIFANI[1];
[1]Univ. of Camerino, Sch. of Pharmacy, Pharmacol. Unit, Camerino, Italy; [2]Inst. of Vet. Physiol. and Ctr. for Integrated Human Physiol., Univ. of Zurich, Zurich, Switzerland; [3]Dept. of Physiol. and Pharmacol., Sapienza Univ. of Rome, Rome, Italy; [4]Fac. of Biosci. and Technol. for Food, Agr. and Envrn., Univ. of Teramo, Teramo, Italy

Abstract: Eating disorders show marked gender differences [1] and several epidemiologic studies suggest that binge eating episodes are more common in females than in males [2]. To further investigate the mechanisms underlying this sex difference, we used an animal model first

described by Cifani et al. [3], in which binge eating is evoked in female rats by food restriction followed by frustration stress (15 min exposure to the sight of the palatable food). We aimed to determine whether binge eating behavior varies across the estrus cycle and is influenced by estradiol in ovariectomized (OVX) rats. Finally, using immunocytochemistry, we quantified the activation of extracellular signal regulated kinase (ERK) signaling pathway in OVX rats treated with estradiol or oil vehicle, in basolateral (BLA) and the central (CeA) nuclei of the amygdala, paraventricular nucleus of hypothalamus (PVN) and arcuate nucleus (ARC). Restricted and stressed non-estrus rats showed binge eating behavior in comparison to the control not restricted and not stressed rats. This response was not present in restricted and stressed rats in estrus, and in OVX rats treated with estradiol. This lack of binge eating behavior was accompanied by a significant decrease in ERK phosphorylation in ARC, PVN and in the CeA, but not in BLA, in comparison to non-estrous rats and to not restricted and not stressed animals. Our behavioral findings show that binge eating does not occur during the estrous phase. Because this was recapitulated in OVX rats treated with estradiol, we propose that the inhibitory effect of estradiol on eating is partly responsible for the lack of bingeing. These findings are consistent with reports in women with bulimia nervosa [4], in whom the binge frequency decreased during the follicular phase, a time of the menstrual cycle when eating is also lowest. These results extend our previous findings and increase the validity of our model, such that it can be used in translational studies of the mechanism of binge eating behavior. Title: Changes of leptin and insulin plasma levels during different phases of morphine dependence in rats

Authors: T. HAVLICKOVA, P. JERABEK, P. POTMESIL, *M. SUSTKOVA;
Dep. Pharmacology, Third Fac. of Med. Charles Univ. in Prague, Charles Univ. In Prague, Praha, Czech Republic

Abstract: Aims: An increasing number of studies over the past few years have explored relationship between appetite regulating hormones (including leptin and insulin), eating disorders and drug addiction with the hope of finding new therapeutic approach to addiction. So far, in the opioid addiction these relationships have been rarely investigated. The aim of our study was to monitor changes in plasma levels of leptin and insulin in various stages of morphine dependence in the rat model. Establishing of suspected correlations would suggest the participation of these hormones in the mechanisms of morphine addiction and thus support the idea of the possible use of these mechanisms in the development of new drugs for the treatment of opioid dependence. Methods: Blood samples were collected from the tail vein repeatedly five times: within the opioid group (11 rat males) (i) baseline sample, (ii) on the last day of repeated morphine (MO) administration before the last dose injection (MO was applied once daily in increasing doses 10, 20, 20, 40, 40 mg / kg s.c.), (iii) the third day of the spontaneous abstinence (during the somatic withdrawal symptoms), (iv) on the 10^{th}-12^{th} day of abstinence before the challenge MO (10 mg/kg) dose and (v) 1 hour after this challenge dose. Within the control group (6 rats) saline was applied repeatedly and MO challenge/acute dose (10 mg/kg) was administered on the last experimental day. Leptin and insulin were subsequently determined in the plasma using multi-ELISA. Results: In comparison with the control group and its own baseline values within the opioid group the levels of insulin and leptin were significantly decreased during the repeated MO administration and also during the MO withdrawal symptoms. These low plasma levels returned to the basal values during the long-term abstinence in case of leptin and insulin levels even significantly exceeded the baseline concentrations. Challenge MO dose during abstinence (as well as acute MO dose in the control group) induced a decrease of both peptides plasma levels. Conclusion: In both anorexigenic hormones plasma levels were found similar significant changes in the MO-dependence rat model, which indicate participation of both peptides in opioid dependence mechanisms. Thus further investigation into the role of leptin and insulin systems in opioid dependence is warranted.

Title: Food-cue responses in amygdalo-cortical axons are modulated by hunger state

Authors: *C. R. BURGESS[1,2], R. N. RAMESH[1,2], K. M. LEVANDOWSKI[1], X. WANG[1], M. MINNIG[1], M. L. ANDERMANN[1,2];
[1]Endocrinol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Harvard Univ., Boston, MA

Abstract: Hunger can selectively enhance attention to food-associated cues. In modern society, where food cues are ubiquitous, this can lead to increased food intake and adverse health effects. Human neuroimaging studies demonstrate hunger-specific modulation of neural activity in temporal cortex when viewing pictures of food cues, however, the neural mechanisms that underlie this bias to motivationally relevant stimuli are unclear. We used rabies tracing techniques to demonstrate strong reciprocal excitatory connections between temporal cortex and the lateral nucleus of the amygdala. Using two-photon microscopy, we imaged calcium activity in amygdala projections to temporal cortex in head-fixed mice performing a Go-NoGo task. We imaged the same amygdala axons across days to investigate how changes in hunger state would affect amygdala feedback to cortex. Amygdala responses to visual stimuli showed selectivity for salient visual cues and were modulated by hunger state. Specifically, we saw reduced activity in response to food cues when mice were sated. We propose that the lateral and basolateral amygdala, through reciprocal connections with temporal cortex, may bias attention to motivationally relevant environmental stimuli based on internal state.

Unit, Univ. of Camerino, Camerino, Italy; [4]Dept. of Physiol. and Pharmacol., Sapienza Univ. of Rome, Rome, Italy; [5]Univ. of Rome, Campus Bio-Medico, Rome, Italy

Abstract: Satisfactory treatments for eating disorders, such as binge eating disorder and bulimia nervosa, are not available at present. Using a well-characterized animal model of binge eating, we investigated the epigenetic regulation of the adenosine A2A receptor (A2AAR) and dopamine D2 receptor (D2R) gene. The animal model included four groups (rats fed normally, and then stressed or not, rats exposed to cycles of restriction/refeeding, and then stressed or not). Gene expression analysis carried out on the amygdala complex of restricted and stressed rats revealed a significant increase of A2AAR and D2R mRNA when compared to non-stressed and non-restricted rats. Administration of the A2AAR agonist (VT 7) induced in restricted and stressed rats a significant increase of A2AAR and D2R mRNA levels when compared to vehicle group, whereas a significant decrease in rats pre-treated with the A2AAR antagonist (ANR 94) was observed. Pyrosequencing analysis revealed a significant reduction of the % of DNA methylation at A2AAR promoter region in restricted and stressed rats compared to the non-stressed and non-restricted animals. We did not find any difference in D2R DNA methylation among different groups. Significant changes in the DNA methylation status of A2AAR promoter were found in restricted and stressed rats after administration of VT 7 or ANR 94. We observed a decrease of DNA methylation in VT 7 treated rats and a hypermethylation in ANR 94 rats with respect to the vehicle group. The increase in A2AAR mRNA observed in restricted and stressed rats could be due to a compensatory mechanism to counteract the effect of binge eating, suggesting that the A2AAR activation, inducing receptor gene up-regulation, could be relevant to reduce food consumption. We here demonstrated for the first time the epigenetic regulation of A2AAR in an animal model of binge eating.

Title: Metabotropic glutamate receptors 2,3 modulate addiction to fat food intake in mice

Authors: ***A. CAMACHO**, L. MONTALVO, C. VEGA HERRERA;
Univ. Autónoma De Nuevo León, Nuevo León, Mexico

Abstract: Introduction: Obesity is a health problem worldwide. It has been proposed that obesity development results of addictive consumption of energy-dense palatable foods. Drug addiction establishment requires changes in synaptic plasticity in the reward system involving the expression of 2.3 metabotropic glutamate receptors (mGlur 2,3), N-methyl-D-aspartate receptors, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor and dopamine D2 receptors. We determine whether modulation of mGlur 2,3 prevents fat food addiction. Material and Methods: We used conditioned place preference (CPP) test to determine fat food addiction. mGluR2,3 and dopamine D2 receptors was determine by western blot in the nucleus accumbens (Nac). To determine if the role of mGlur2,3 on preference for fat food consumption in mice we intraperitoneally administered mGlur2,3 agonist LY379268. We evaluated the effect of LY379268 on behavior and fat food addiction using CPP test. Results: Mice showed that fat food exposure results in positive CPP score during the test. The preference for fatty food intake correlates with decrease in rGlum2,3 protein levels in the Nac of addicted mice. Addicted mice showed no change in body weight, plasma or blood glucose, insulin and leptin, relative to control mice. Of importance, the administration of the mGlur2,3 agonist LY379268 seems to modulate preference for fatty food intake compared to vehicle administration. Conclusions: Our data suggest that the function of mGlur2,3 is relevant and potentially adaptable to prevent addiction to appetizing food.

Title: Binge-like eating as an addiction-like disorder: novel findings from an operant model in rats

Authors: *C. HICKS, C. VELÁZQUEZ-SÁNCHEZ, J. W. SANTOS, K. L. SMITH, A. FERRAGUD, V. SABINO, P. COTTONE;
Pharmacol. and Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA

Abstract: Binge eating disorder is characterized by excessive consumption of highly palatable food within short periods of time accompanied by loss of control over eating. Extensive evidence provides support for the consideration of binge eating disorder as an addiction-like disorder. In this study, we wanted to determine whether rats undergoing an operant binge-like eating procedure could develop maladaptive forms of conditioned feeding behaviors. We also wanted to determine whether the binge eating procedure could alter dopamine D2 receptor (D2R) levels in key brain regions implicated in drug and natural reward processing. For this purpose, we trained male rats to self-administer either a sugary, highly palatable diet ("Palatable" rats) or a chow diet ("Chow" rats) for 1 hour a day. After escalation and stabilization of palatable food intake, we tested Chow and Palatable rats in (a) a conditioned place preference test, (b) a second-order schedule of reinforcement and (c) a cue-induced suppression of feeding test. In the conditioned place preference task, Palatable rats spent significantly more time in the compartment that was previously paired with the palatable food, compared to Chow controls. Furthermore, in the second-order schedule of reinforcement task, Palatable rats exhibited active lever responding 4- to 6-fold higher than Chow control rats. In addition, in the cue-induced suppression of feeding test, although Chow control subjects reduced responding by 32% in the presence of the conditioned punishment, Palatable rats persevered in responding despite the aversive cue. Finally, following exposure to the palatable diet, binge-eating rats showed reduced D2R levels in prefronto-cortical regions of the brain. These results further characterize this animal model of

binge-like eating and provide additional evidence for the addictive properties of highly palatable food.

Abstract: The ultimate goal of our studies is to find chemicals that help people quit smoking. Zebrafish larvae allow the screening of large number of chemical compounds in simple neurobehavioral assays and could represent a potential model for the initial identification of pharmacotherapeutics for smoking cessation treatment. In mammals, serotonin receptors of type 2a (htr2a) and 2c (htr2c) have been implicated in regulating different states of tobacco dependence, thus representing potential targets for treating tobacco dependence. Unclear is how nicotine functions in larval zebrafish compared to rodents and if serotonin receptors are involved in nicotine-induced behavior in zebrafish larvae in a similar way as in rodents. To develop a model of nicotine function and htr function in nicotine-induced behavior in zebrafish larvae a locomotion-based assay for has been used. Expression of htrs was detected using *in situ* hybridization, immunocytochemistry, or RT-PCR. Chemicals such as varenicline, the active chemical used for treating smoking cessation, reduces the acute nicotine-induced locomotor response without detrimental effects in larval zebrafish. A potential role of htrs in regulating nicotine-induced locomotor behavior was measured by pretreating larval zebrafish with selected htr2a and htr2c agonists and antagonists. The htr2c agonist lorcaserin showed the most effective reduction of nicotine-induced locomotor behavior with the least detrimental effects of all tested

agonists and antagonists. In contrast, tested htr2a agonists did not seem to change the acute nicotine response significantly. Exposure to nicotine before pretreatment with htr agonists and antagonists, changes the outcome of neurobehavioral experiments. To rule out detrimental effects of tested chemicals, acute mustard oil-induced locomotor responses were measured. Pharmacological characterization of zebrafish serotonin receptors will indicate functional similarities with mice serotonin receptors. In summary, the project further supports a role of serotonin receptors in nicotine-induced behavior in larval zebrafish and shows that the activation of htr2c receptors in zebrafish reduces the nicotine-induced motor behavior.

Title: Exploring a putative protein:protein interaction between the serotonin (5-HT) 5-HT2A receptor (5-HT2AR) and 5-HT2CR

Authors: ***C. E. MCALLISTER**[1], N. C. ANASTASIO[2,1], S. J. STUTZ[1], R. M. HARTLEY[1], L. H. FINK[1], B. FONGANG[3], A. KUDLICKI[3], S. R. GILBERTSON[4,1], Y.-C. CHEN[4], H. NEELANKANTAN[1], C. S. WATSON[3,1], F. G. MOELLER[5], K. A. CUNNINGHAM[2,1];

Abstract: The serotonin (5-HT) 5-HT2A receptor (5-HT2AR) and 5-HT2CR play important roles in behavior and physiology. We have recently demonstrated that knockdown of 5-HT2CR following microinjection of 5-HT2CR shRNA into the rat medial prefrontal cortex (mPFC) evokes a behavioral phenotype characterized by increased motor impulsivity and elevated reactivity to cues associated with cocaine self-administration. The 5-HT2CR knockdown in mPFC also resulted in upregulation of 5-HT2AR protein in the mPFC and a leftward shift in potency of systemic M100907 to suppress motor impulsivity, suggesting a functional disruption of local 5-HT2AR:5-HT2CR balance. Furthermore, co-immunoprecipitation studies suggested that a protein:protein interaction exists between 5-HT2AR and 5-HT2CR in mPFC. In the present study, we employed immunohistochemistry, proximity ligation assay (PLA), and luciferase complementation assay (LCA) technologies in either live cells and/or rat brain, as well as the in silico direct coupling analysis (DCA), to test the hypothesis that a protein:protein interaction occurs between the 5-HT2AR and 5-HT2CR. In immunohistochemical analyses, we found that 5-HT2AR and 5-HT2CR protein co-localized within the same cells in rat mPFC. In the PLA (Duolink), we found that native, unmodified proteins are in close proximity (<45 nm) in mPFC. In the DCA (which examines the co-evolution of residues in over 100 species), we identified candidate pairs of amino acid residues that are predicted to be in direct functional contact, most notably between the extracellular N-terminus domains of the two proteins. The LCA is being employed to test the hypothesis that the N-terminal domains are the primary points of interaction between the two receptors. In the LCA, two complementary luciferase N- (NLuc) and C-terminus (CLuc) fragments, which have no activity on their own, are fused to the two receptor proteins of interest, respectively. In the presence of the substrate D-luciferin, association of the two proteins brings the inactive fragments into close proximity to reconstitute the enzyme activity. We are co-expressing 5-HT2AR-NLuc (or CLuc) and 5-HT2CR-CLuc (or NLuc), expressed on the N-or C-terminus in mammalian cells to demonstrate the formation of a protein:protein interaction between the 5-HT2AR and 5-HT2CR in live cells. We will treat the cells with a peptide which is predicted by the DCA to disrupt the interaction and impact cellular signaling. To date, our findings suggest that 5-HT2AR:5-HT2CR protein interaction may provide a new neurobiological mechanism underlying behavior and a possible target for novel pharmacotherapuetics, such as heterobivalent ligands.

Title: Serotonin (5-HT) 5-HT_{2A} receptors in the medial prefrontal cortex regulate cue reactivity following prolonged forced abstinence from cocaine self-administration

Authors: *H. NEELAKANTAN[1], N. C. ANASTASIO[1,2], R. G. FOX[1], S. J. STUTZ[1], K. A. CUNNINGHAM[1,2];
[1]Ctr. for Addiction Res., [2]Pharmacol. and Toxicology, Univ. of Texas Med. Br. Galveston, Galveston, TX

Abstract: An intensification of craving in humans and reactivity to drug-associated cues in rodents occurs during abstinence while elevation of cue reactivity ("incubation") is observed in rats exposed to prolonged periods of forced abstinence from cocaine self-administration. Incubation in rodents has been linked to time-dependent neuronal plasticity in the medial prefrontal cortex (mPFC). The mPFC expresses the serotonin (5-HT) 5-HT_{2A} receptor (5-HT_{2A}R) and blockade of the mPFC 5-HT_{2A}R suppresses cue reactivity. We have demonstrated that membrane expression of the 5-HT_{2A}R protein in the mPFC predicts levels of cue reactivity [lever presses reinforced by the discrete cue complex (e.g., stimulus light, pump tone)] following cocaine self-administration in rats. With regard to incubation, we found that expression of the 5-HT_{2A}R is elevated in membrane extracts of the mPFC on Day 30 *vs.* Day 1 of forced abstinence from cocaine self-administration. This observation prompted us to test the hypothesis that rats will be more sensitive to the effects of a selective 5-HT_{2A}R antagonist (M100907) to suppress cue reactivity on Day 30 *vs.* Day 1 of forced abstinence. Rats were trained to self-administer cocaine for 14 days (0.75 mg/kg/inf, FR5) and the effects of M100907 (0.03-0.3 mg/kg, i.p.) on cue reactivity were measured on Day 1 and Day 30 of forced abstinence. Cue reactivity was significantly elevated on Day 30 *vs.* Day 1 of forced abstinence. Pharmacological analysis revealed that all doses of M100907 (0.03-0.3 mg/kg) significantly ($p<0.05$) suppressed cue reactivity during prolonged (Day 30), but not early abstinence (Day 1). These data suggest that the elevated expression of membrane 5-HT_{2A}R protein in the mPFC on Day 30 may contribute mechanistically to the time-dependent incubation of cue reactivity following forced abstinence.

Mechanistically linking 5-HT_{2A}R regulatory mechanisms to time-dependent incubation phenomena will have direct clinical implications in developing 5-HT_{2A}R-targeted therapeutics to minimize vulnerability to relapse in cocaine use disorder.

Abstract: A feature of multiple neuropsychiatric disorders is motor impulsivity. Recent studies have implicated 5-HT system in medial prefrontal cortex (mPFC) in mediating individual differences in motor impulsivity, notably the 5-HT_{2A}R and 5-HT_{2C}R. We investigated the

hypothesis that differences in the ratio of 5-HT_{2A}R:5-HT_{2C}R in mPFC would predict the individual level of motor impulsivity. Native protein levels of the 5-HT_{2A}R and the 5-HT_{2C}R predicted the intensity of motor impulsivity and the 5-HT_{2A}R:5-HT_{2C}R ratio in mPFC tracked with levels of premature responses in individual outbred rats. The possibility that the 5-HT_{2A}R and 5-HT_{2C}R act in concert to control motor impulsivity is supported by the observation that high motor impulsivity associated with a diminished mPFC synaptosomal 5-HT_{2A}R:5-HT_{2C}R protein interaction. We infer that there is an interactive relationship between the mPFC 5-HT_{2A}R and 5-HT_{2C}R, and that a 5-HT_{2A}R:5-HT_{2C}R imbalance may be a functionally-relevant mechanism underlying motor impulsivity. Based on these findings, we propose that correcting this imbalance and stabilizing the 5-HT_{2A}R:5-HT_{2C}R protein interaction utilizing a ligand with dual action as a selective 5-HT_{2A}R antagonist (e.g., M100907)/5-HT_{2C}R agonist (e.g., WAY163909) presents a promising and novel pharmacotherapeutic strategy for treatment of brain disorders in which motor impulsivity is implicated. We identified benign tether locations on M100907 and WAY163909 and used click chemistry to synthesize a series of M100907:WAY163909 heterobivalent ligands. We employed quantitative live cell assays to measure two types of signaling evoked by ligand activation, Ca_i^{++} release and phosphorylation of $ERK_{1/2}$. In the 5-HT_{2A}R-CHO-K1 cell line, the heterobivalent ligand inhibited 5-HT-induced Ca_i^{++} release with IC_{50}s ranging from 125-210 nM. In the 5-HT_{2C}R-CHO-K1 cell line, the heterobivalent ligands demonstrated no intrinsic activity, however, in the dual expressing 5-HT_{2A+2C}R-CHO-K1 cell line, the heterobivalent ligands inhibited 5-HT-induced Ca_i^{++} release with IC_{50}s between 438-725 nM. Interestingly, the heterobivalent ligands appear to act as partial agonists given their ability to phosphorylate $ERK_{1/2}$ in the 5-HT_{2A+2C}R-CHO-K1 cell line, demonstrating a novel pharmacological profile *in vitro*. Extensive behavioral analyses are currently underway to evaluate our novel heterobivalent molecules *in vivo*. These data provide the first profile of heterobivalent 5-HT_{2A}R antagonist/5-HT_{2C}R agonist ligands which will be useful as neuroprobes and potentially useful to develop treatment strategies for brain disorders in which impulsivity is a factor.

Title: Dynamic regulation of synaptosomal serotonin (5-HT) 5-HT_{2C} receptor (5-HT_{2C}R) expression following acute cocaine administration

Authors: *S. E. SWINFORD-JACKSON[1], N. C. ANASTASIO[1,2], C. A. SOTO[1], R. M. HARTLEY[1], C. S. WATSON[3], K. A. CUNNINGHAM[1,2];
[1]Ctr. for Addiction Res., [2]Dept. of Pharmacol. and Toxicology, [3]Dept. of Biochem. and Mol. Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Activation of the 5-HT_{2C}R in the medial prefrontal cortex (mPFC) regulates cocaine-seeking assessed in the cocaine self-administration/forced abstinence assay in rats. The functional impact of 5-HT_{2C}R activation is mechanistically controlled by a complement of factors, including subcellular localization of the receptor. Previous studies indicate that the 5-HT_{2C}R is poised to influence the synaptosomal milieu in the mPFC and interfaces in a functionally-coordinated manner with synaptic proteins to promote or inhibit receptor readiness and subsequent signaling capacity. We previously demonstrated that synaptosomal 5-HT_{2C}R expression in the mPFC on Day 30 of forced abstinence is lower than on Day 1, suggesting that regulation of the 5-HT_{2C}R in mPFC may be a mediator of elevated cue-elicited cocaine-seeking in late abstinence from cocaine self-administration. Interestingly, the levels of 5-HT_{2C}R expression in the synaptosomal compartment of the mPFC of naïve rats mirrors those assessed at Day 30; levels observed at Day 1 are significantly elevated relative to naïves. These data suggest that 5-HT_{2C}R protein expression, and perhaps subcellular localization of the receptor, are responsive to the pharmacological environment consequent to recent self-administration of cocaine and/or acute withdrawal. In the present study, we tested the hypothesis that acute pretreatment with or withdrawal from non-contingent cocaine will increase synaptosomal 5-HT_{2C}R expression in a time-dependent manner. Male Sprague-Dawley rats were injected with saline (0.9%; i.p.) or cocaine (15 mg/kg; i.p.) 15 min or 24 hrs prior to sacrifice and mPFC harvest. Crude synaptosomal protein was extracted from the mPFC and 5-HT_{2C}R protein expression was measured using a novel medium-throughput 96-well plate immunoassay adapted

for use with brain tissue in our laboratory. The plate immunoassay is highly reliable, reproducible and amenable to assaying multiple conditions in the same experiment. We found that synaptosomal 5-HT_{2C}R expression in mPFC was elevated 15 min following cocaine vs. saline administration; analyses at 24 hrs of withdrawal are in progress. Ongoing experiments are exploring the association of the 5-HT_{2C}R with synaptic protein partners (e.g. G proteins vs. β-arrestins) which regulate its trafficking and function. Understanding the dynamic regulation of 5-HT_{2C}R expression following acute cocaine administration is a critical first step toward exploring the effects of chronic cocaine-taking and withdrawal on 5-HT_{2C}R expression, which will ultimately inform the development of effective pharmacotherapeutics to treat cocaine use disorder.

Title: Individual differences in impulsive action in rats are governed by cortical N-methyl-D-aspartate receptor (NMDAR) tone

Authors: *C. KREBS, N. ANASTASIO;
UTMB, Galveston, TX

Abstract: Impulsivity is a complex, multifaceted trait broadly defined as action without sufficient foresight; high inherent impulsivity may increase the likelihood that drug use escalates into dependence and relapse. Glutamate neurotransmission within the medial prefrontal cortex (mPFC) may critically regulate the cognitive and/or behavioral dimensions underlying impulsivity. The N-methyl-D-aspartate receptor (NMDAR) is a member of the ionotropic glutamate receptor family and is composed of multiple subunits including GluN1 and GluN2A-D. Noncompetitive antagonism of the NMDAR and selective antagonism of the GluN2B subunit

enhances impulsivity in animal models. Here, we tested the hypothesis that differences in NMDAR subunit composition and signaling deficits within the mPFC mediate high inherent impulsivity, and that pharmacological potentiation of NMDAR signaling attenuates high inherent impulsivity. Outbred male Sprague Dawley rats were identified as high (HI) or low (LI) impulsive using the one-choice serial reaction time (1-CSRT) task. In this task, nose-pokes after presentation of a visual stimulus resulted in food pellet delivery. Nose-pokes before presentation of the visual stimulus (i.e., premature responses) indexed impulsive action. A quartile split based on the number of premature responses was used to identify HI or LI rats. Following phenotypic identification, mPFC synaptosomal protein was extracted from a cohort of HI and LI rats to assess NMDAR composition via immunoblotting. A separate cohort of HI and LI rats were trained to criterion on the 1-CSRT task, and on test days, pretreated with vehicle (saline, 1 ml/kg; i.p.) or D-cycloserine (DCS; agonist at strychnine-insensitive glycine site of NMDAR; 1-50 mg/kg, i.p.). Performance on the 1-CSRT task was rapidly acquired and allowed stable identification of HI and LI rats; premature responses in HI rats remained significantly higher than LI rats across 70 training days ($p<0.001$). HI rats had lower mPFC GluN1 and GluN2A synaptosomal protein expression compared to LI rats ($p<0.05$). No difference in GluN2B levels was detected between HI and LI rats. Select doses of DCS decreased premature responses relative to saline administration in HI, but not LI, rats ($p<0.05$). Taken together, inherent impulsive action may be critically driven by dysregulation of mPFC GluN1/GluN2A signaling and selective potentiation of NMDAR function may rescue high inherent impulsive action. Increased understanding of the neurobiology underlying inherent differences in impulsivity may aid development of pharmacotherapies that target drug dependence, relapse, and other disorders characterized by impulsivity.

Abstract: Eating is essential for life, but repeated consumption of large amounts of food in a brief period (i.e., bingeing) can alter the reward value of food and food-related cues and fuel binge-eating cycles. Impulsivity, a predisposition toward rapid unplanned reactions to stimuli, is one of the multifaceted determinants underlying the etiology of dysregulated eating, its pathogenesis, and treatment outcomes. The medial prefrontal cortex (mPFC) is a major neural director of reward-driven behavior, impulse control and integration of internal states with environmental cues. Compromised signaling between the mPFC and nucleus accumbens (NAc) are thought to underlie the cognitive inability to withhold prepotent responses (impulsive action) and binge intake of high fat food. We propose that strategies to directly activate this circuit would indicate that the ventral infralimbic (IL)-nucleus accumbens shell (NAcSh) pathway plays a putative suppressive role ("Stop") in impulsive action and binge eating. We employed a dual viral vector technology that allows for the targeted and isolated modulation of IL mPFC neurons that project to the NAcSh via a Cre-loxP system. A Cre-dependent viral vector based "double-floxed" inverted open reading frame (DIO) switch system expresses an engineered Gq-DREADD which only binds clozapine-N-oxide (CNO). In the presence of Cre, the loxP sites are excised and the transgene is inverted into the sense direction and expressed from the hSyn promoter. An AAV DIO construct that contains an inverted version of Gq DREADD (hM3D)-mCherry or mCherry alone was infused into the IL mPFC. A canine adenovirus-2 (CAV)-Cre axonal retrograde viral vector was infused into the NAcSh of the same rat; stable transgene expression in IL mPFC occurred only at the site of DIO vector infusions thus restricting expression to cortical neurons that project to the NAcSh. Activation of the circuit with DIO-hM3D-mCherry AAV in the presence of CNO significantly suppressed impulsive action in the 1-choice serial reaction time task ($p<0.05$); no differences in task acquisition, accuracy, omissions or additional task parameters were observed. The DIO-hM3D-mCherry-AAV in the presence of CNO significantly decreased binge intake for high fat food ($p<0.05$). These data indicate that impulsive action and binge eating reciprocally interact at the level of an imbalance in homeostasis within the corticoaccumbens circuit. Through addressing a fundamental gap in our knowledge of how the neural aspects of impulsivity relate to binge eating, we hope to develop pharmacological strategies to minimize binge eating and enhance clinical practice for disorders of overeating.

Title: Programming of dopaminergic neurons by neonatal sex hormone exposure: Effects on dopamine content and tyrosine hydroxylase expression in adult male rats

Authors: P. ESPINOSA, R. A. SILVA, R. RIQUELME, L. F. GONZALEZ, N. K. SANGUINETTI, F. C. VENEGAS, G. CRUZ, G. M. RENARD, P. R. MOYA, *R. SOTOMAYOR-ZÁRATE;
Univ. de Valparaiso, Valparaiso, Chile

Abstract: We sought to determine the long-term changes produced by neonatal sex hormone administration on the functioning of midbrain dopaminergic neurons in adult male rats. Sprague-Dawley rats were injected subcutaneously at postnatal day 1 and were assigned to the following experimental groups: TP (testosterone propionate 1.0 mg/50μL); DHT (dihydrotestosterone 1.0mg/50μL); EV (estradiol valerate 0.1 mg/50μL) and control (sesame oil 50μL). At postnatal day 60, neurochemical studies were performed to determine dopamine content in substantia nigra-ventral tegmental area and dopamine release in nucleus accumbens. Behavioral (basal and amphetamine-induced locomotor activity) and molecular (mRNA expression of tyrosine hydroxylase) studies were also performed. We found increased dopamine content in substantia nigra-ventral tegmental area of TP and EV rats favoring dopamine release in nucleus accumbens. However, neonatal exposure to DHT, a non-aromatizable androgen, did not affect midbrain dopaminergic neurons. Correspondingly, the levels of tyrosine hydroxylase mRNA were significantly increased in TP and EV rats, but not in DHT and control rats. Our results suggest a mechanism involving increased tyrosine hydroxylase expression through aromatization of testosterone to estradiol in substantia nigra-ventral tegmental area.

Title: Embryonic methamphetamine exposure inhibits methamphetamine cue conditioning and reduces dopamine tissue levels in adult wild-type *C. elegans*

Authors: S. N. KATNER[1], E. A. ENGLEMAN[1], *B. S. NEAL-BELIVEAU[2];
[1]Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Psychology, IUPUI, Indianapolis, IN

Abstract: Methamphetamine (MAP) addiction is a serious and costly disorder leading to thousands of deaths and costing billions of dollars annually. A disturbing outcome of MAP addiction is the uncontrolled embryonic exposure to this drug and the effects on brain development and behavioral consequences later in life. Although studies have begun to provide important information about some aspects of the neurobiology of MAP addiction, very little research has focused on these developmental issues and few good developmental models are available. *C. elegans* is an excellent model organism to study the neurobiological consequences of embryonic MAP exposure. It has a well studied and described neuroanatomical system, along with a short generation time for fast generation of data at a fraction of the cost of many other organisms. The objective of the current study was to determine the long-term behavioral and neurochemical effects of embryonic MAP exposure in *C. elegans*. Wild-type N2 worms were embryonically-exposed to 50 μM MAP or vehicle. Using classical conditioning, embryonically-exposed worms were conditioned to MAP (17 and 500 μM) as adults in the presence of either sodium (Na^+) or chloride (Cl^-) ions as conditioned stimuli (CS+/CS-). Following conditioning, a preference test was performed by placing worms in 6-well test plates spotted with the CS+ and CS- at opposite ends of each well. A food conditioning experiment was also performed to determine if embryonic MAP exposure affected food conditioning behavior. For the neurochemical experiments, adult worms that were embryonically-exposed to MAP were analyzed for dopamine (DA) content using high performance liquid chromatography. Pairing an ion with 17 and 500 μM MAP significantly increased the preference for that ion (CS+) by 181 ±

15 % and 176 ± 18 % of controls, respectively, in worms that were *not* pre-exposed to MAP. However, worms embryonically-exposed to MAP did not exhibit significant drug cue conditioning. The inability of MAP-exposed worms to condition to MAP was not associated with deficits in food conditioning, as MAP-exposed worms exhibited a significant cue preference associated with food. Furthermore, embryonic MAP exposure reduced DA levels by 28 to 37% of baseline levels in adult *C. elegans*, which could be a key mechanism contributing to the long-term effects of embryonic MAP exposure. Overall, these data suggest that embryonic MAP exposure selectively reduces the reinforcing properties of MAP in adult *C. elegans,* which may be driven in part by concomitant decreases in DA levels. *Supported by DA035468(EAE).*

Title: Role of serotonin and dopamine neurotransmission in psychosis-like behaviors induced by toluene

Authors: *M. T. RIVERA-GARCÍA, C. LÓPEZ-RUBALCAVA, S. L. CRUZ;
Cinvestav, México, Mexico

Abstract: Toluene-based products are commonly misused by inhalation for recreational purposes. Toluene has hallucinogenic effects, exacerbates psychosis symptoms in patients, and induces psychosis-like behaviors in rats. Among several molecular targets, toluene acts as a non-competitive NMDA receptor antagonist and alters serotonin (5-HT) and dopamine (DA) levels, but there are few studies analyzing the relationship between neurochemical changes and toluene-induced psychotomimetic actions. The present study examines the involvement of D_2 and 5-$HT_{2A/2C}$ receptors in changes in brain 5-HT and DA levels and psychosis-like behaviors produced by toluene. Male Wistar rats were exposed to toluene (4000 and 8000 ppm) for 30 min in a static exposure chamber. The $5HT_{2A/2C}$ mediated head-twitch response (Htr) was analyzed during toluene exposure. Immediately after, the striatum and prefrontal cortex were dissected and

analyzed by HPLC for DA and 5-HT contents. Independent groups of animals were evaluated in prepulse inhibition (PPI) or social interaction tests after toluene inhalation. In order to study the role of D_2 and 5-$HT_{2A/2C}$ receptors in toluene's effects, other groups of animals were pretreated (-20 min) with ketanserine (2 mg/kg) or haloperidol (1 mg/kg), exposed to toluene and tested in different trials. Toluene concentration-dependently increased DA and 5-HT contents in both brain areas. Haloperidol (1 mg/kg) and ketanserine (2 mg/kg) significantly reduced these effects. Toluene also induced a deficit in PPI, which was completely prevented by haloperidol and significantly blocked by ketanserine. Toluene-treated animals reduced contact behaviors with partners in social interaction test, and this effect was partially blocked by ketanserine, but not by haloperidol. Finally, toluene increased Htr in a concentration-dependent manner, this behavior was blocked equally by $5HT_{2A/2C}$ and D_2 receptor antagonism. Our results show that antipsychotic drugs can prevent some neurochemical and behavioral effects produced by toluene.

Title: Differential effects of translin deletion on behavioral and biochemical responses to cocaine and amphetamine

Authors: X. FU[1], M. NIWA[1], D. FUKUDOME[1], Y. CHERN[2], J. CADET[3], A. SAWA[1], *J. M. BARABAN[1];

Abstract: To help define the role of the microRNA system in regulating neuronal signaling, we have studied the impact of translin deletion on the dopamine system. Translin and its partner protein, trax, form an RNAse complex that mediates degradation of microRNAs (Asada et al., Cell Reports, 2014). Accordingly, we have used translin KO mice to assess the role of the microRNA system in dopamine signaling. We have found that the classic ability of cocaine to

increase open field exploration is markedly inhibited in these mice. Furthermore, the ability of cocaine to increase nucleus accumbens dopamine levels as monitored by microdialysis is severely compromised. Accordingly, these findings suggest that elevated microRNA levels caused by translin deletion impair dopamine release from mesolimbic dopamine neurons. In contrast, the locomotor response to amphetamine is increased in these mice, while the ability of amphetamine to elevate dopamine levels in the nucleus accumbens is normal. These findings indicate that the enhanced locomotor response to amphetamine is due to post-synaptic supersensitivity to dopamine, which may be secondary to reduced dopamine tone. Current studies are aimed at assessing whether reinstatement of translin expression in VTA dopamine neurons is sufficient to rescue these phenotypes. In summary, these findings suggest that inhibition of the translin/trax complex provides a novel means of decreasing dopamine tone and may have therapeutic potential by promoting resilience in the face of chronic stress.

Title: Involvement of orexin-2 receptors within the ventral tegmental area in development of morphine sensitization induced by lateral hypothalamus stimulation in rats

Authors: *Y. RAZAVI[1,2], F. SADEGHZADEH[2], A.-H. PIRASTEH[2], A. HAGHPARAST[2]; [1]Cell. and Mol. Res. Ctr., Tehran, Iran, Islamic Republic of; [2]Neurosci. Res. Ctr., Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: Orexin plays a crucial role in drug-seeking behavior. The lateral hypothalamus (LH) is a central region that produces orexin, and its projections to the ventral tegmental area (VTA) play an important role in antinociception. In this study, we investigated the role of LH stimulation and the involvement of the orexin-2 receptor (Ox2r) within the VTA in the development of morphine sensitization on the tail-flick test. In all animals, cannulae were implanted unilaterally into the LH and VTA to inject different doses of carbachol (62.5, 125 and 250 nM/0.5 µl saline) as a cholinergic agonist and TCS (1, 10 and 20 nM/0.3 µl DMSO) as a selective Ox2r receptor antagonist for three consecutive days (sensitization period). These drugs were injected five min before administration of an ineffective dose of morphine (0.5 mg/kg; sc)

during the sensitization period. The five days later, on the test day, tail-flick tests were performed before and after the injection of an ineffective dose of morphine (1 mg/kg; sc), The results revealed that concurrent intra-LH administration of carbachol (250 nmol/0.5 µl saline) and an ineffective dose of morphine (0.5 mg/kg) significantly induce antinociceptive effect. Additionally, the blockade of Ox2r in the VTA by TCS, can attenuate effect of analgesiometer and represented as maximal possible effects (%MPE) induced by concurrent administration of carbachol and an ineffective dose of morphine. Our findings suggest that LH stimulation potentiates the effect of an ineffective dose of morphine, and induces morphine sensitization. It seems that the chemical stimulation of LH potentiates sensitization to morphine through the orexinergic system in the VTA in rats.

Title: Physical and emotional stress alter voluntary morphine consumption ventral tegmental area gene expression

Authors: S. E. COOPER[1], M. KECHNER[1], *M. S. MAZEI[2];
[1]Neurosci., [2]Physiol., Michigan State Univ., East Lansing, MI

Abstract: There is significant co-morbidity of mood disorders and drug dependence, but the mechanisms contributing to this co-morbidity are not well understood. Preclinical models of mood disorders typically employ chronic stress to elicit depressive-like behaviors. Here, we used physical chronic social defeat stress (CSDS), as well as a modified version, emotional CSDS, to investigate changes in morphine reward and to identify potential molecular mediators of stress susceptibility and reward. We subjected male mice to standard 10-day physical or emotional CSDS and assessed social interaction (SI) on day 11 followed by voluntary morphine consumption using a two-bottle choice assay. Both physical and emotional CSDS decrease SI

score on day 11, with physical stress eliciting more robust social avoidance than emotional stress. Physical and emotional CSDS also significantly increase morphine preference and there is a significant negative correlation between SI score and morphine preference. Given that CSDS induces long-lasting changes in SI, we examined whether changes in morphine reward persist. We observed a similar significant negative correlation between SI score and morphine consumption 14 days after the last defeat. Next, we determined whether morphine preference was also altered during emotional CSDS. Contrary to results following stress, mice undergoing emotional CSDS showed a trend for decreased morphine preference compared to controls. Finally, we wanted to determine whether individual differences in morphine preference could predict susceptibility to CSDS. We found that morphine preference (determined 14 days prior to stress) did not predict susceptibility to CSDS. Combined, these data suggest that CSDS differentially affects morphine reward, depending on when consumption is measured. Given the importance of the ventral tegmental area (VTA) in both CSDS and drug reward, we are currently investigating drug- and CSDS-induced changes in VTA gene expression as potential mediators of these behavioral effects. One promising candidate is serum- and glucocorticoid-regulated kinase 1 (SGK1) as we have found that chronic morphine and physical and emotional CSDS significantly increase SGK1 gene expression in the VTA. We also have preliminary data suggesting that SGK1.1, a brain-specific isoform of SGK1 known to influence neuronal excitability, exhibits a positive correlation with SI score. The decreased expression of SGK1.1 in susceptible mice could contribute to VTA activity changes that influence CSDS susceptibility. Current studies are investigating the role of SGK1, as well as other novel molecules, in drug- and stress-induced changes in the VTA.

Title: Cannabinoid reward and aversion in the posterior ventral tegmental area is differentially mediated through dopamine projections to the basolateral amygdala or nucleus accumbens shell

Authors: *T. AHMAD[1], S. R. LAVIOLETTE[2];
[1]Dept. of Anat. and Cell Biol., [2]Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: The mammalian ventral tegmental area (VTA), is a critical neural region responsible for mediating both rewarding and aversion related behavioural processing and cannabinoids are known to modulate the activity of dopamine (DA) neuronal populations within the VTA. In addition to its well-established DAergic projections to the nucleus accumbens (NAc), the VTA also has functional projections to the prefrontal cortex (PFC) and basolateral amygdala (BLA). Importantly, cannabinoid CB1R transmission strongly modulates the emotional valence of both rewarding and aversive experiences (Ahmad et al., 2013; Laviolette and Grace, 2006). In terms of cannabinoid-related motivational effects, several studies have reported a functional dissociation between the posterior region of the VTA (PVTA), and the anterior region of the VTA (AVTA). For example, cannabinoid receptor activation via THC administration in the PVTA produces rewarding behavioural effects (Zangen et. al., 2006). In contrast, THC was found to have no motivational effects when infused into the AVTA region. Since the PVTA sends DAergic projections to both the BLA and NAc, we wanted to further investigate the possible mechanisms by which cannabinoid reward effects are processed through VTA DAergic outputs. Using an unbiased conditioned place preference (CPP) procedure combined with behavioural pharmacology, we administered either a CB1 agonist (WIN-55,212-2) or antagonist (AM 251) into the PVTA or AVTA of Sprague-Dawley rats. CB1R activation in the PVTA with WIN 55,212-2 (50-500ng) produced a dose-dependent cannabinoid reward CPP, while blockade of CB1R with AM 251 (50-500ng) produced a dose-dependent aversion. Interestingly, when WIN 55,212-2 and AM 251 were micro-infused in the AVTA, no cannabinoid reward or aversion effects were observed. To examine the PVTA-BLA and PVTA-NAc pathways, we used the broad spectrum DA receptor antagonist α-flupenthixol to block DA transmission in either the NAc or BLA. Intra-BLA micro-infusions of α-flu (1μg), blocked the earlier observed cannabinoid reward CPP, but not the cannabinoid antagonist-related aversion. Conversely, intra-NAs micro-infusions of α-flu (1μg), blocked the aversion observed with intra-VTA CB1 antagonist administration, but not the rewarding effects of intra-VTA WIN-55. Thus, our findings demonstrate a functional dissociation between VTA DA outputs to either the NAc or BLA. Furthermore, while the rewarding effects of intra-VTA CB1 activation depend upon a VTA>BLA pathway, the aversive effects of CB1 receptor blockade depend upon VTA DA outputs to the NAc.

Title: Stress acutely promotes calcium-dependent glutamatergic synaptic plasticity in the VTA via differential actions of CRF and norepinephrine

Authors: *J. TOVAR-DÍAZ, M. POMRENZE, H. MORIKAWA;
Waggoner Ctr. for Alcohol and Addiction Res., The Univ. of Texas At Austin, Austin, TX

Abstract: Stressful life experiences are a well-known risk factor for the development of addiction. Addiction is driven, in part, by powerful and enduring memories of sensory cues experienced during drug intake. Addictive drugs are thought to hijack synaptic plasticity mechanisms in key brain circuits involved in reward learning, especially the mesolimbic dopaminergic system that originates in the ventral tegmental area (VTA). Glutamatergic inputs activating NMDA receptors (NMDARs) drive dopamine neuron burst firing. Therefore, long-term potentiation of (LTP) of NMDAR-mediated transmission in the VTA may contribute to the increased motivational valence of drug-associated cues. In this study, we tested the hypothesis that stress acutely enhances the induction of NMDAR LTP via rapid, short-term actions of corticotropin-releasing factor (CRF) and norepinephrine (NE), the two key mediators of acute stress responses in the CNS. Mechanistically, LTP induction requires burst-evoked Ca^{2+} signals amplified by preceding activation of the metabotropic glutamate receptor (mGluR)-inositol triphosphate (IP_3) pathway. Using rat VTA slices, we first examined how CRF and NE regulate this Ca^{2+} signal amplification process. We found that bath application of CRF, while having no effect by itself, significantly enhanced facilitation of burst-evoked Ca^{2+} signals caused by direct photolytic application of IP_3 into the cytosol. In contrast, NE or the α_1-adrenergic receptor agonist phenylephrine (Phe), increased burst-evoked Ca^{2+} signals by themselves, as α_1-adrenergic receptors are coupled to IP_3 generation. Furthermore, Phe-induced Ca^{2+} signal facilitation was augmented by co-application of CRF. As a consequence, CRF and Phe differentially promoted NMDAR LTP induction, via facilitation of IP_3 effect and generation of IP_3, respectively, in a cooperative manner. Finally, we found that single and transient exposure to social defeat stress before conditioning resulted in enhanced acquisition of cocaine-conditioned place preference. These results suggest that stress acutely promotes learning of the motivational valence of drug-associated cues via CRF/NE-induced enhancement of glutamatergic synaptic plasticity in the VTA.

Title: Investigation of biochemical changes induced by chronic morphine and stress in the ventral tegmental area

Authors: *S. KASKA[1], R. BRUNK[2], M. KECHNER[2], M. S. MAZEI-ROBISON[3];
[1]Pharmacol. and Toxicology, [2]Neurosci. Program, [3]Neurosci. Program and Physiol. Dept., Michigan State Univ., East Lansing, MI

Abstract: Drug addiction and depression are two co-morbid diseases that have a significant health and financial burden on society. Increasing evidence suggests that dysfunction of the mesolimbic dopamine (DA) pathway could underlie this co-morbidity. We are investigating the biochemical mechanisms that drive changes in the morphology of ventral tegmental area (VTA) DA neurons induced by chronic morphine and chronic social defeat stress (CSDS). Our previous work demonstrated that exposure to chronic opiates decreases VTA DA neuron soma size in rodents and that this change is dependent on mammalian target of rapamycin complex 2 (TORC2) signaling. Moreover, decreased soma size and TORC2 signaling correlates to changes in opiate reward, highlighting the importance of understanding this process. Preliminary evidence from our lab suggests that mice that are susceptible to CSDS also have a significant decrease in VTA DA soma size. Given these similar alterations in VTA DA soma size, we are seeking to identify the molecular mechanisms. One promising candidate is the Rac1 pathway, which is a well-known mediator of actin cytoskeleton remodeling. Rac1 activity has also recently been linked with TORC2 signaling, as knockout of the TORC2 constituent protein Rictor decreased Rac1 signaling and hippocampal spine density (Huang et al. 2013). Given that chronic morphine decreases TORC2 signaling in the VTA, we are currently determining whether Rac1 activity is also decreased. We have performed western blot analysis on micro-dissected VTA tissue from mice exposed to chronic morphine or CSDS and find a significant decrease in the phosphorylation of cofilin, a protein involved in severing actin filaments, which is downstream of Rac1. We are now examining molecules upstream of cofilin to determine if exposure to

chronic morphine or stress similarly alters activity of these proteins. Additionally, in order to evaluate whether changes in VTA TORC2 signaling are sufficient to alter Rac1 activity, we are conducting western blot analysis of VTA tissue from mice with knockout or viral-mediated overexpression of Rictor. These studies will determine whether decreasing or increasing VTA TORC2 signaling decreases or increases Rac1 signaling, respectively. Thus, the ultimate aim of these studies is to establish the molecular mechanisms underlying VTA DA structural plasticity in the hopes of identifying potential novel targets for therapeutic intervention in drug addiction and depression.

Title: Acute morphine administration induces a partly reversible long term depression of inhibitory synaptic transmission onto dopaminergic ventral tegmental area neurons

Authors: M. E. AUTHEMENT, *F. S. NUGENT;
Pharmacol., Uniformed Services Univ., Bethesda, MD

Abstract: Dopaminergic neurons in the ventral tegmental area (VTA) play an essential role in mediating the acute effects of drugs of abuse. Furthermore, synaptic abnormalities in the VTA following consumption of drugs of abuse likely promote addiction. Our laboratory previously found that a single injection of morphine is sufficient to impair the induction of GABAergic synaptic plasticity onto dopaminergic VTA neurons 24 hours after injection. Here we report that a single morphine injection per se induces a long term depression (LTD) of GABAergic transmission onto dopaminergic VTA neurons. This morphine-induced LTD is present both presynaptically and postsynaptically as evidenced by a decrease in both amplitude and frequency of miniature inhibitory postsynaptic currents (mIPSCs). We then attempted to recover these abnormalities using CL-994, a class I histone deacetylase (HDAC) inhibitor that we recently

demonstrated could recover synaptic abnormalities in the VTA induced by an episode of early life stress. A two hour incubation of rat midbrain slices in Cl-994 managed to recover mIPSC amplitudes to normal levels. These results suggest that the acute effects of morphine administration may in part be mediated by epigenetic mechanisms, namely histone deacetylation.

Title: Blockade of connexin-36-expressing gap junctions in the ventral tegmental area prevents opiate withdrawal aversions in opiate-dependent animals

Authors: *G. MAAL-BARED, M. PATEL, M. CHWALEK, D. VAN DER KOOY;
Univ. of Toronto, Toronto, ON, Canada

Abstract: The ventral tegmental area (VTA) is crucial for reward seeking and seems to promote both adaptive and maladaptive behaviors such as foraging and drug seeking. The animal's prior exposure to the substance dictates which VTA efferents mediate the behavior. Descending projections to the tegmental pedunculopontine nucleus (TPP) are necessary for morphine conditioned place preferences (mCPP) in opiate-naïve but not opiate-dependent animals, whereas ascending mesoaccumbal dopamine (DA) outputs are necessary for mCPP in dependent but not naïve animals. This switch in neural substrates is due to changes in the conductance of GABAA receptors on VTA GABA neurons that renders half the GABA neurons hyperexcitable to GABAA agonists. Preliminary evidence suggests this is due to increased intracellular chloride concentrations and, subsequently, chloride efflux and depolarization upon GABAA activation. A possible mechanism by which this occurs is the downregulation of the potassium chloride cotransporter, KCC2, which normally expels chloride ions from the cell. VTA infusions of a KCC2 blocker promote the aforementioned GABA changes and also cause a switch in the substrate underlying mCPP such that the naïve reward is mediated by accumbal DA activity, suggesting that inverted chloride gradients are important for the switch to an opiate-dependent state. VTA GABA cells form a network of electrically-coupled cells that fire synchronously. This pattern of activity is mediated by connexin-36 (Cx36)-expressing gap junctions, which

permit rapid ion transfer between cells. Given that corticotegmental glutamate enhances Cx36 coupling and KCC2 downregulation, we hypothesized that electrical synaptic communication within the GABA population may contribute to the switch to an opiate-dependent state. Indeed, we found that Cx36 blockade reverts opiate-dependent rats to a TPP-dependent, naïve-like state. Furthermore, dependent rats did not avoid a withdrawal-paired compartment when conditioning sessions were preceded by VTA infusions of the Cx36 blocker, mefloquine. By contrast, these rats still exhibited somatic withdrawal signs such as tremors, head-shakes and scratches despite mefloquine administration. These experiments strongly suggest that Cx36-expressing gap junctions are necessary for both the switch to an opiate-dependent state as well as the experience of withdrawal aversions. Due to the non-specific effects of mefloquine, we currently are utilizing mice with a floxed Cx36 gene to verify that the switch in the neural substrate mediating mCPP and the block of opiate-withdrawal aversions are due to Cx36 blockade rather than other effects of the drug.

Title: Failure of nicotine exposure during the peripubertal period to induce sensitization to the administration of cocaine to the adult female rat

Authors: B. A. MCMILLEN[1], C. T. PERRY[2], G. R. WOODS[2], H. L. WILLIAMS[1], *D. A. TAYLOR[1];
[2]Pharmacol. & Toxicology, [1]Brody Sch. Med. 6S-10, Greenville, NC

Abstract: There is strong concern that the use of nicotine, either as tobacco or electronic cigarettes, early in adolescence may lead to later use of other drugs of abuse by the adult. Administration of nicotine, 0.4 mg/kg i.p. as the base, to male rats from postnatal days (PD) 35 - 44 results in adults that show enhanced reward like responses to nicotine itself, cocaine and diazepam when testing begins at PD 80 (Adriani et al, J Neurosci 2003; McMillen et al, Eur J Pharmacol 2005; James-Walke et al Neurotox Teratol 2007). The nicotine exposure also caused a long-term increase in the expression of Fos-B that forms an important gene regulatory protein. These studies and several others were all done with male rats or male mice as subjects. An

important issue is whether or not the same phenomenon can be demonstrated in female rodents. 36 female Sprague-Dawley rats were purchased from Charles River Labs for this study and housed under standard conditions in pairs. Beginning on PD 35, tails were marked, the animals weighed and 0.4 mg/kg nicotine hydrogen tartrate (dose as free base) or 0.9% saline injected i.p. for 10 days. Beginning on PD 80, the rats were put into a conditioned place preference (CPP) apparatus for 15 min: days 1, 2, and 3--free exploration; days 4, 6, 8, 10--injection of vehicle or drug and confinement to the least preferred side; days 5, 7, 9, 11--injection of saline and confinement to the preferred side; day 12_free exploration. On days 3 and 12, the movement of the rats was observed with the total number of chamber entries (frequency as a measure of overall activity) and the time spent on each side of the apparatus recorded (as a measure of the reward effect). The frequency of entries for the vehicle-exposed/vehicle-treated rats was 38 ±13. Neither exposure to nicotine nor treatment with 0, 1.0 or 3.0 cocaine-HCl (dose as the base and dissolved in citrate buffer) altered the overall activity of the rats. The change in time spent on the least preferred side did not show a significant effect by 3-way ANOVA, $F(2,2,31) = 2.35$, $p > 0.05$. The only group to show a significant change from pre-treatment to post-treatment by a paired t-test was for the nicotine-exposed/3.0 cocaine group, 220 ±22 to 340 ±32 seconds. However, this change was not different from the corresponding vehicle-exposed group. These data suggest that the female rat does not exhibit a peripubetal nicotine-induced heterologous sensitization to drugs of abuse as reported repeatedly to occur with the male rat. (CTP and GRW were participants in the High School Medical Research Program of Pitt County Schools)

Title: Inhibition of nicotine-induced expression of ΔFosB in the molecular cell layer of the hippocampus dentate gyrus by minocycline in the peripubertal rat

Authors: P. S. NAGCHOWDHURI[1], K. T. LANE[2], *B. A. MCMILLEN[1];
[1]Pharmacol & Toxicol, [2]Pharmacol. & Toxicology, East Carolina Univ., Greenville, NC

Abstract: Nicotine use during adolescence is considered to be a ‘gateway’ that leads to the brain’s sensitization to other illicit substances in the future. Psychoactive drugs such as nicotine

are known to induce the expression of the transcription factor ΔFosB that facilitates this sensitization process. A previous study from our laboratory showed that a once daily, 10-day administration of nicotine that bracketed the onset of puberty in male rats, postnatal days (PD) 35 - 44, at an intraperitoneal (i.p.) dose of 0.4 mg/kg induced the expression of ΔFosB in selected memory and reward subset areas of the rat brain. Further this expression persisted into adulthood (PND 80), especially in the nucleus accumbens (NAc) and dentate gyrus of hippocampus (DG) (Soderstrom et al. Psychopharmacol 2007). Our long-term goal is to extend the previous study by elucidating the role of microglia in this sensitization process *in vivo*. Our hypothesis is that there is a linkage between microglia activation and ΔFosB induction. In this study, minocycline, a lipophilic tetracycline antibiotic commonly used to suppress the activation of microglia *in vivo*, was injected into periadolescent male Sprague Dawley (SD) rats prior to nicotine administration to assess the impact of microglia activation on ΔFosB induction by nicotine. Male rats received once daily injections from PD 35 - 44 and were divided into four treatment groups: Vehicle, 0.4 mg/kg nicotine; 30 mg/kg minocycline and minocycline 30 min before nicotine. Similar to the report by Soderstrom and colleagues, 0.4 mg/kg i.p. of nicotine-bitartrate (all drugs dosed as free base) once daily from PD 35 - 44 increased the density ΔFosB immuno-labeled neuronal neuclei in the DG from the control by 39% ($F_{3,9} = 6.94$, $p=0.01$; Dunnett's t-test $p < 0.05$). Minocycline-HCl pretreatment 30 minutes prior to each dose of nicotine at a dose of 30 mg/kg i.p. changed the density of ΔFosB labeled nuclei by 24% compared to control and was not significantly different from control ($p>0.05$, Dunnett's t-test). The nicotine treatment group appeared to have fewer ramified microglia (non-activated) than did either the control or minocycline plus nicotine groups although this result did not reach significance due to the small number of animals ($N = 3$ per cell, $F_{3,8} = 0.881$). Thus, minocycline pre-treatment reduces the ability of nicotine to increase the expression of ΔFosB in the DG and may be due to the reduction in microglial activation produced by this drug. This study will further analyze the effect of minocycline on ΔFosB induction in the NAc, prefrontal cortex (PFC), and the ventral tegmental area (VTA).

Title: An analysis of the interaction of methylphenidate and nicotine in adolescent rats: Effects on BDNF

Authors: *E. D. CUMMINS, K. K. LEEDY, D. J. PETERSON, S. K. KIRBY, L. J. HERNANDEZ, R. W. BROWN;
East TN State Univ., Johnson City, TN

Abstract: This study was designed to analyze the interaction of adolescent exposure to methylphenidate (MPH; trade name: Ritalin) on nicotine sensitization and conditioned place preference (CPP) in rats. MPH is the most commonly prescribed medication for Attention Deficit-Hyperactivity Disorder (ADHD) which is diagnosed in 3-5% of adolescents in the United States. There are several studies that have shown adolescent MPH exposure may alter plasticity of the brain's dopamine reward system and cause an increased susceptibility to drug abuse. In the present study, rats were treated ip with 1 mg/kg MPH or saline using a "school day" regimen of five days on, two days off, from postnatal day (P)28-50. A 1 mg/kg dose of MPH has been shown to result in brain plasma levels equivalent to clinical dosing in humans. During the final two weeks of MPH treatment, animals were either behaviorally sensitized to nicotine (0.5 mg/kg free base) or saline for 12 days, or conditioned to nicotine or saline using the CPP behavioral paradigm. Behavioral sensitization is a test of the activating effects of drugs which is typically mediated by the brain's dopamine system. CPP is a test of the associative value of rewarding drugs. In addition, three days after behavioral sensitization was complete, animals were analyzed for stress behavior using the forced swim stress behavioral test. During behavioral sensitization and CPP, MPH was always given in the morning, whereas behavioral testing with nicotine was performed later in the day. For forced swim stress, animals were tested in a drug free state. Animals were tested with nicotine 6 h after MPH treatment, equivalent of six drug half lives because the half life of MPH is 1 h. For sensitization, animals were treated with either nicotine or saline 10 min before placement into a square locomotor arena (30 cm/side) and activity measured. For CPP, a pre-test was given to determine preference in a three chamber shuttle box, and animals were always conditioned with nicotine against their natural preference. Behavioral results revealed that adolescent pre-exposure to MPH reduced nicotine behavioral sensitization in female but not male rats during the first week of testing. However, MPH enhanced nicotine CPP in both adolescent male and female rats. Interesting, animals administered MPH demonstrated a significantly decreased latency to immobility in the forced swim stress behavioral test. Brain tissue was taken after CPP and will be analyzed for Brain-derived neurotrophic factor (BDNF), which is known to play a critical role in synaptic maintenance and growth. Implications towards the influence of MPH on nicotine use and its application will be discussed.

Title: Locus coeruleus neuronal firing directly correlates with behavioral response to acute and chronic doses of methylphenidate (ritalin) in adolescent rats

Authors: N. KHARAS[1], C. REYES-VASQUEZ[2], *J. ARONOWSKI[3], N. DAFNY[1];

Abstract: Attention deficit hyperactivity disorder (ADHD) is the most common disorder diagnosed in adolescents (ages 8-15) in the United States. ADHD is a behavioral disorder characterized by increased inattention, hyperactivity, and impulsivity. Currently, Methylphenidate (MPD), also known as Ritalin, is the most effective method to treat adolescents with ADHD. The objective of this study is to evaluate the behavioral and neuronal changes induced by acute and chronic MPD administration. Specifically, there is a lack of knowledge of the changes in norepinephrine (NE) in response to MPD. Thus neuronal firing was recorded from locus coeruleus (LC), the main site of NE synthesis in the CNS, while simultaneously observing locomotor activity in freely moving adolescent rats. Adolescent rats were chosen to mimic the age group correlate in humans most affected by the disease. Also, in light of personalized medicine each rat was evaluated individually in addition to studying them as a group. Following acute dose of MPD, all rats showed an increase in locomotor activity and increase in LC neuronal firing. However, upon the chronic dose of MPD, individual rats either showed an increase or decrease in their locomotor and LC neuronal activity as compared to the acute dose in a dose dependent manner; these rats were labeled as sensitized and tolerant respectively. Neuronal firing in LC directly corresponded with the changes observed in behavioral locomotor activity. This study shows the role of LC in acute and chronic doses of MPD. Furthermore, the study indicates that there is a relationship between the LC neuronal responses and behavioral expression upon exposure to MPD. Neuroadaptations of sensitization or tolerance have shown to be key factors in drug response, dependence and addiction. Observing individual rodents and being able to predict their neuroadaptation to psychostimulant drugs such as MPD could

eventually create a platform for predicting the sensitivity and likelihood of abuse in individual patients allowing for tailored treatments and application in the future of personalized medicine.

Title: Methylphenidate modulates dorsal raphe neuronal activity: behavioral and neuronal recordings from adolescent rats

Authors: H. WHITT[1], C. REYES-VASQUEZ[2], N. KHARAS[1], *N. DAFNY[1];
[1]Univ. Texas Med. Sch., Houston, TX; [2]Univ. Nacional Autonoma de Mexico, Mexico City, Mexico

Abstract: Methylphenidate (MPD) is one of the most widely prescribed psychostimulants for the treatment of attention deficit hyperactive disorder (ADHD) in children and adults. MPD binds to presynaptic catecholamine transporters in the CNS and prevents reuptake of norepinephrine and dopamine from the synaptic cleft. Unlike the psychostimulants cocaine and amphetamine, MPD does not exhibit direct actions on the serotonin transporter. Studies investigating MPD tend to focus on its effects on the CNS dopamine circuit, however there is evidence suggesting that MPD affects the serotonergic system as well. This study aimed to investigate the role of the dorsal raphe, a major source of serotonergic innervation in the mammalian brain, in the response to acute and chronic MPD exposure. The hypothesis of the study is 1) the dorsal raphe (DR) participates in MPD action, 2) the same chronic MPD dose in some adolescent animals will elicit behavioral sensitization and in others behavioral tolerance and 3) the DR neuronal activity recorded from adolescent animals expressing behavioral sensitization to chronic MPD will have a significantly different response to MPD exposure than those DR neurons recorded from animals expressing behavioral tolerance to chronic MPD. Freely behaving animals previously implanted bilaterally with permanent electrodes were used. Behavioral and DR electrophysiological activity were concomitantly recorded following acute and chronic MPD exposure using an open field assay and a wireless recording system over 10 experimental days.

Four groups of animals were used: one control group (saline) and three experimental groups treated with 0.6, 2.5, and 10.0 mg/kg MPD respectively. The animals received daily MPD or saline injections on experimental days 1-6, followed by 3 washout days and MPD rechallenge dose on experimental day (ED)10. The same chronic dose of MPD resulted in either behavioral sensitization or tolerance. DR neurons responded to acute MPD in a dose dependent manner. Neuronal activity recorded from the DR units of rats expressing behavioral sensitization to chronic MPD exposure exhibited a significantly ($p < .05$) different response to MPD rechallenge on ED10 compared to the DR neuronal activity recorded from animals that expressed behavioral tolerance to chronic MPD. This correlation between behavioral response and DR neuronal activity following chronic MPD exposure indicates that the DR is involved at least in part in the acute effects of MPD as well as the chronic effects of MPD (expression of sensitization and tolerance) in adolescent rats. The study confirms our hypothesis.

Title: Medial prefrontal cortex electrophysiological and behavioral recordings following acute and chronic methylphenidate exposure in freely behaving adolescent SD rats

Authors: C. CLAUSSEN[1], C. CANNON[1], *P. DASH[2], N. DAFNY[1];
[1]Univ. of Texas Med. Sch., Houston, TX; [2]Univ. Texas Med. Sch., Houston, TX

Abstract: Methylphenidate (MPD), a drug often prescribed for the treatment of attention-deficit hyperactivity disorder, has a potential for abuse and misuse. The prefrontal cortex is one of many areas of the brain that responds to MPD. Most of the MPD studies have been completed in adult subjects while most of the users were adolescent. The objective of this study is to investigate the acute and chronic dose response characteristics of MPD on prefrontal cortex (PFC) neuronal activity recorded in freely behaving adolescent rats. The experiment lasted for 10 consecutive days after the recovery from implanting 4 permanent semi microelectrodes in the PFC. Four groups of animals were used: saline (control), 0.6, 2.5, and 10 mg/kg MPD groups. On experimental day 1 (ED1), baseline recording (concomitant neuronal and behavioral) was

obtained following either a saline (control), 0.6, 2.5, or 10 mg/kg MPD doses. On ED2 to ED6 each group was injected with their assigned dose (saline, 0.6, 2.5, or 10 mg/kg MPD). ED7 to ED9 were washout days. On ED10, behavioral and neuronal recordings were resumed as on ED1 following saline and MPD exposure. Acute MPD was found to elicit a dose response increase of animals' locomotor activity. Rechallenge with MPD at ED10 compared to the effect of MPD at ED1 showed no significant differences. When the animals were divided into two groups based on their individual responses to chronic MPD exposure, some animals expressed behavioral tolerance and others sensitization to all three MPD groups. Electrophysiologically, a dose response characteristic for acute and chronic MPD exposure was observed. With increasing MPD doses, more PFC units responded by changing their firing rate from 36%, 63%, and 78% PFC units responded for the acute MPD exposure at ED1 to 48%, 69%, and 82% of the units following chronic exposure at ED10 to 0.6, 2.5, and 10.0 mg/kg MPD, respectively. The neuronal responses to MPD recorded from animals expressing behavioral tolerance were significantly different compared to the neuronal population responses recorded from animals expressing behavioral sensitization to repetitive MPD exposure. The majority of the PFC units recorded from animals expressing behavioral tolerance responded to the drug predominately by decreasing their firing rates, whereas those PFC units recorded from the behaviorally sensitized animals mainly showed an increase in their firing rates. The possible mechanisms are discussed.

Title: Chronic adolescent exposure to THC and induced anxiety changes behaviour in adult rats

Authors: ***A. C. WEEKS**, M. BOUDREAULT, K. NORRIS, J. ANDREWS, N. LANDRY, C. LALONDE, B. WEEGAR, A. STILLAR, M. J. SAARI;
Nipissing Univ., North Bay, ON, ON, Canada

Abstract: The legalization and increased use of cannabis and its main constituent Δ9-tetrahydrocannabinol (THC), as a recreational and medicinal drug, has enhanced research interest related to the potential interactions of cannabis use and other psychological conditions.

For example, adults and adolescents often report using cannabis as a way of coping with stress and anxiety. While the effects of marijuana use on the adult brain are fairly well understood, less is known about chronic use during adolescence. This study assessed anxiety levels and social interaction after an isolation stressor event and chronic adolescent phase injections of THC in rats. Four experimental groups included: isolation/THC, no isolation/THC, isolation/vehicle, and no isolation/vehicle. Following one week in the housing condition (isolation or social housing), daily THC or vehicle injections were carried out for 15 days starting at post-natal day 43 (see Fig. 1). An open field test was completed after the isolation period, but before injections, to assess initial anxiety levels. Following the injections, a withdrawal period, and a maturation delay, an elevated zero maze and a social interaction task were used to assess anxiety related behavioural changes. The behavioural results from the zero maze indicated that chronic adolescent THC administration following isolation-induced stress caused adult rats to spend less time in the closed regions during the first minute in the maze. For the social interaction task, there was a main effect of the drug where animals treated with THC were found to groom other rats significantly less often. These results suggest that using cannabis during adolescence changes the response to anxiety provoking situations. Following the behavioural tests, the rats were perfused for confocal microscopy. Pilot data from this analysis related to changes in synaptic protein levels in the amygdalar subregions of these animals will be presented. Figure 1

Title: Adolescent cannabinoid administration causes oxidative stress

Authors: *S. MUKHERJEE[1], T. HWANG[2], S. PAWAR[3], A. AROUMOUGAME[3], S. GHOSE[1];
[1]Dept. of Psychiatry, [2]Dept. of Clin. Sci., [3]Dept. of Radiation Oncology, UT Southwestern Med. Ctr., Dallas, TX

Abstract: Adolescent cannabis use (ACU) is an environmental risk factor repeatedly implicated in the pathophysiology of schizophrenia. The mechanism by which ACU might predispose the brain to schizophrenia is unknown. One plausible hypothesis is that the use of cannabis during a period of brain maturation leads to persistent neural changes that lead to the development of schizophrenia. Further, there is evidence that individuals with schizophrenia and a history of ACU (S-ACU+) compared to schizophrenia without a history of ACU (S-ACU-) exhibit distinct clinical profile in terms of onset of illness, severity of psychosis and cognitive function. Based on our preliminary cell culture studies demonstrating that acute administration of cannabinoid agonists induce oxidative stress, we hypothesized that ACU induces oxidative stress in the developing brain to predispose to schizophrenia. To investigate this hypothesis, we assembled a human post mortem cohort of DLPFC (BA 9) tissue from cases of schizophrenia and matched controls, each divided into those with and without ACU (n=10 per group). Whole transcriptome sequencing of DLPFC region was conducted in these cases. Our preliminary analyses reveal significant differences in oxidative stress pathways between the two schizophrenia groups. RT-PCR analyses of selected genes in this pathway recapitulated transcriptome sequencing results. Further bioinformatic analyses and molecular characterization of DLPFC at the mRNA and protein level and cellular localization studies of gene expression changes are ongoing.

Title: Determining the ontogeny of working memory, and the effects of cannabinoid self-administration, in adolescent rats

Authors: *E. K. KIRSCHMANN, M. W. POLLOCK, V. NAGARAJAN, M. M. TORREGROSSA;
Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Adolescence is characterized by risky behaviors like drug-taking, and marijuana (Cannabis sativa) use is widespread. Importantly, the neurobiological consequences of chronic cannabis use are not yet well-known. Adolescence is a period of neurodevelopment in the prefrontal cortex (PFC), a key regulator of cognition and inhibitory control, and thus there is potential for adolescent cannabis use to cause long-term effects on cognitive function. Though some rodent and primate research has shown evidence of cognitive deficits after experimenter-administered cannabinoids during adolescence, it remains unknown whether similar deficits occur in a model of drug use and addiction - cannabinoid self-administration. In order to understand what effects cannabinoid self-administration has on cognition, we first identified the critical period for the ontogeny of working memory performance in adolescents. We then established intravenous self-administration of the synthetic cannabinoid agonist WIN55,212-2 (WIN) in a short-access (2hr) paradigm in male rats and examined the long-term effects of cannabinoid self-administration during adolescence on working memory performance. Adolescent (starting on postnatal day 28; p28; n=12) and adult (>p70; n=8) male rats were trained on a delayed-match-to-sample working memory task, and performance was compared daily. Adolescent performance in the working memory task was consistently worse than adults at long delays up to p46, and did not reliably overlap adult performance until late adolescence (p51). Accurate performance on the task was dependent on activity in the prelimbic PFC in adults. Separate groups of rats were trained to self-administer WIN (n=12) or sucrose (controls; n=11) in daily 2-hr sessions during adolescence (p38-49). Working memory training began in adulthood (p87-94), and testing continued daily until p118. Short-access WIN self-administration during adolescence did not substantially impair working memory performance in adulthood. Taken together, our findings suggest that working memory becomes adult-like in late-adolescence; and adolescent short-access cannabinoid self-administration does not cause

substantial impairments in long-term cognitive function. Ongoing studies will determine whether: 1) developmental changes in GABAergic signaling are associated with developmental improvements in working memory, and 2) long-access (6hr) WIN self-administration during adolescence impairs working memory.

Title: Chronic nicotine exposure during adolescence alters the rewarding properties of the cannabinoid agonist CP 55,940 in young adult male rats

Authors: A. D. HARDIN, M. J. STONE, Z. R. HARMONY, G. J. KAPLAN, *C. A. CRAWFORD;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Adolescent exposure to nicotine alters the behavioral response to a number of addictive drugs in rodents. Specifically, adolescent nicotine treatment potentiates the reinforcing value of both cocaine and alcohol, and decreases the aversive properties of cocaine. More recently, a number of studies have demonstrated that adolescent exposure to nicotine alters the functioning of cannabinoid systems. For example, adolescent nicotine treatment enhances the unconditioned response to cannabinoid agonists, and increases the density of cannabinoid receptors. Whether chronic nicotine exposure starting in adolescence alters the rewarding properties of cannabinoid agonists (e.g., CP 55,940) has not been determined. To this end, we exposed rats to nicotine from early adolescence until adulthood and then assessed CP 55,940-induced conditioned place preference (CPP). Male Sprague-Dawley rats were given daily nicotine injections (0, 0.16, 0.32, or 0.64 mg/kg, sc) starting on postnatal day (PD) 31 and continuing for 42 consecutive days (i.e., throughout the course of the experiment). On PD 60, cannabinoid-induced CPP was assessed using a 10-day biased procedure, consisting of 1 preconditioning day, 10 conditioning days, and 1 test day. Rats were pre-exposed to CP 55,940 (0, 10, 20, or 30 μg/kg, ip) on the preconditioning day. During the conditioning phase, rats

received alternating daily treatments of saline or the same dose of CP 55,940 (0, 10, 20, or 30 μg/kg) that was administered on the preconditioning day. Among saline-pretreated rats, only 30 μg/kg CP 55,940 was able to induce CPP. In contrast, rats pretreated with 0.32 mg/kg nicotine exhibited a statistically significant CPP when a substantially lower dose of CP 55,940 (10 μg/kg) was used. These findings suggest that exposure to nicotine during adolescence enhances the rewarding value of a low dose of a cannabinoid agonist.

Title: Female adolescent morphine exposure causes transgenerational effects on metabolism

Authors: *F. M. VASSOLER, C. WYSE, A. KUBEREK, K. HUYNH, G. WIDMER, E. M. BYRNES;
Dept. of Biomed. Sci., Tufts Univ. Cummings Sch. of Vet. Med., North Grafton, MA

Abstract: Opiate use is a growing epidemic affecting young populations. Utilizing a rodent model, we have observed changes in gene expression related to metabolism within hypothalamic nuclei in offspring of females exposed to morphine during adolescence. These findings indicate that adolescent exposure to morphine may cause transgenerational effects on metabolism. Additionally, there is a reported connection between opiate exposure and increased intake of high sucrose foods. Therefore, we hypothesize that disruption of the endogenous opioid system during a critical developmental period might cause long term changes in metabolism that extend into future generations. To test this, morphine was administered to female Sprague Dawley rats for 10 days during adolescence (P30-P39) using an increasing dosing regimen (5-25 mg/kg, s.c.). Control animals received matched saline injections. Then, animals remained in their home cage, drug free, until adulthood (after P60) at which point they were introduced to drug-naïve colony males. The offspring (F1 animals) were placed on one of three diets at P30: control, high fat, or

high sucrose. The animals remained on the diet for 40 days and were weighed weekly. On P70 fasting glucose levels were measured. Fecal samples were collected just prior to being placed on the new diets and following 6 weeks on the diet for microbiota DNA sequencing. We found that among the male offspring, there was a main effect of maternal opiate history on weight gain with Mor-F1 animals gaining significantly more weight than Sal-F1 animals. Post hoc analyses revealed that there was a significant increase in weight gain in Mor-F1 animals on the high fat diet. There was no significant effect in female offspring. However, there was a trend towards an increase in weight gain in the Mor-F1 females compared to the Sal-F1 females fed a high sucrose diet. Analysis of fasting glucose levels revealed a main effect of maternal opiate history in the male offspring with significantly increased blood glucose levels in Mor-F1 males following a high fat diet as well as a high sucrose diet. While there was no significant effect in females, there was a trend observed again in the high sucrose diet of increased fasting glucose levels in Mor-F1 females. Analysis of the microbiome is ongoing. The data provide evidence of a shift in metabolic functioning in offspring of females exposed to morphine during adolescence. The direction of the shift indicates the possibility that Mor-F1 animals have an increased propensity towards metabolic syndrome.

Title: Contribution of MRGPRB4-expressing sensory neurons to the socio-environmental effect on opioid dependence and reward in adolescent mice

Authors: M. BATES, M. A. EMERY, P. J. WELLMAN, *S. EITAN;
Dept of Psychology, Behavioral & Cell. Neurosci Program, Texas A&M Univ., College Station, TX

Abstract: Drug abuse is strongly influenced by socio-environmental factors. Social support (or lack thereof) is reported as a factor that may affect the propensity to escalate from episodic use of opioids to dependence and abuse. Our recent studies demonstrated that social environment

(i.e., housing conditions) influence the development of morphine dependence and reward in adolescent mice. More specifically, our previous studies show that being housed with drug-naïve animals has a protective effect on the severity of somatic withdrawal symptoms upon cessation of drug administration, as well as the likelihood of developing, and maintaining, morphine reward. However, the physiological mechanisms of this effect are unknown. Thus, the objective of this study was to advance our understanding of the mechanisms mediating the socio-environmental effect on the development of morphine dependence and reward. Massage-like stroking (grooming) is a form of supportive social interaction in rodents. This supportive social interaction was recently suggested to be, at least partially, mediated by peripheral dorsal root ganglia sensory neurons expressing the G-protein coupled receptor MRGPRB4. It was shown that pharmacogenetic activation of MRGPRB4+ neurons induces conditioned place preference in adolescent mice, indicating that this activation is reinforcing. Because social grooming in mice may act as a form of social support, we chose to examine if pharmacogenetic manipulation of the sensation resulting from grooming is mediating the social housing effect on morphine dependence and reward. In this study, we used DREADD technology to activate/silence sensory MRGPRB4-expressing neurons in awake, freely moving animals. This was done in order to stimulate or block the 'sensation of social support' from social grooming. We tested how manipulating the activity of sensory MRGPRB4-expressing neurons affected the development of morphine dependence and reward in animals housed in different social environments (i.e., housed with drug-naïve animals vs. housed only with morphine-treated animals). We found that MRGPRB4-expressing neurons are involved in mediating the environmental (housing) effect on the severity of somatic withdrawal symptoms upon cessation of drug administration. These results suggest that sensation of social support, resulting from massage-like stroking and activation of MRGPRB4-expressing neurons, alters the development of morphine dependence in adolescents.

Title: Differences between adult and adolescent rats in locomotor sensitization to codeine

Authors: *T. ZAFAR, A. ESCOBEDO, V. ESPINOZA, A. ROCHA, K. TRUJILLO;
California State Univ. San Marcos, San Marcos, CA

Abstract: Codeine (COD) is an opioid analgesic that acts predominantly via interaction with μ-opioid receptors. Codeine mixtures sometimes referred to as "sizzurp" or "purple drank," have been increasingly abused in the hip-hop culture. Moreover, because of its broad availability, COD is often used by teens for recreational purposes. Evidence suggests that abuse of COD can lead to compulsive use and abuse. Behavioral sensitization is an increase in an effect of a drug after repeated administration. Also referred to as "reverse tolerance," sensitization is thought to be involved in the development of addiction. While there are reports of behavioral sensitization to opioids in adult rats, little has been done to elucidate sensitization in adolescents, and potential differences in sensitization between adults and adolescents. The present study examined the locomotor effects of COD following repeated administration to adolescent and adult Sprague-Dawley rats. We hypothesized that COD would induce an increase in locomotor activity across days reflective of behavioral sensitization and that adolescent rats would differ in sensitization when compared to adults. Animals received saline or COD (10 mg/kg s.c.), once daily for seven (7) days and locomotor activity was assessed each day. COD produced very little change in locomotor activity on day 1, however, activity escalated across days of treatment, reflecting the development of sensitization. Furthermore, although there were only modest differences between adolescents and adults early in treatment, there was evidence of greater sensitization in adolescents. Thus, while repeat administration of COD leads to behavioral sensitization, we found that this sensitization differs in adults and adolescents. Further research will help to determine the factors involved in COD sensitization in adults and adolescents, and may lead to better prevention and treatment for COD abuse and addiction in teenagers.

Title: Differences in ketamine-induced ultrasonic vocalizations in adult and adolescent rats: the balance between reward and aversion

Authors: *R. M. ALTAMIRANO, T. T. TOWNER, A. ESCOBEDO, K. A. TRUJILLO; California State Univ. San Marcos, San Marcos, CA

Abstract: Ketamine (KET) is a dissociative anesthetic and non-competitive NMDA receptor antagonist. Sometimes referred to as 'Special K' or 'K', KET is used at subanesthetic doses at dance clubs and raves and therefore falls into the diverse class known as club drugs. KET produces pleasurable effects in many users, but has also been reported to produce unpleasant responses in some users, including an intense dissociative response known as the 'K-Hole', which is often reported as disturbing or frightening. Although adults and teenagers have increasingly abused ketamine, little is known about differences in response at different ages. The current study examined Ultrasonic Vocalizations (USVs) in adult and adolescent Sprague-Dawley rats following administration of KET. USVs are high frequency calls made by rodents that have been found to reflect affective responses. High frequency 50 kHz USVs, are associated with pleasurable stimuli or positive affect and lower frequency 22 kHz USVs are associated with aversive stimuli or negative affect. By quantifying the number of 50 kHz and 22 kHz calls, the affective response to KET can be determined. Adolescent rats received saline or KET (30 mg/kg) at 30 days and 40 days of age, and then again when they reached adulthood at 60 days of age. Adult rats received the same treatment at 60, 70 or 90 days of age. Based on earlier work in the laboratory, it was hypothesized that adolescent rats would show a greater pleasurable response to KET (greater 50 kHz USVs) and reduced aversion (reduced 22 kHz USVs). KET induced an increase in rewarding 50 kHz USVs that was similar in adolescents and adults. In contrast, as hypothesized, adults showed a greater number of aversive 22 kHz USVs in response to KET. These results demonstrate differences between adolescents and adults in the affective response to KET. Overall, KET appears to be more appealing to younger individuals than adults (equally rewarding but less aversive), which may help to explain the use of the drug by teens at dance clubs and raves.

Title: The potential influence of 5-httlpr genotype, gender and ecstasy use on depressive symptoms in adolescent and emerging adults

Authors: *N. E. WRIGHT, K. M. LISDAHL;
Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: Objective: Lifetime ecstasy use among 12th graders is 5.6% (Johnston et al., 2015). Both ecstasy use and serotonin transporter gene (5-HTTLPR) have been associated with increased depressive symptoms (Starr et al., 2014; Matthews & Bruno, 2010). As ecstasy users frequently engage in polysubstance use (Martins, Mazzotti, & Chilcoat, 2005), a marijuana using control group is necessitated. Because gender may moderate interactions between ecstasy and 5-HTTLPR genotype (Price et al., 2013; Pardo-Lozano et al., 2012), this study examines independent and interactive effects of ecstasy use, 5-HTTLPR genotype and gender on depressive symptoms. Method: Forty-five controls (24 female, 21 male), 27 ecstasy users (9 female, 18 male), and 38 marijuana using-controls (13 female, 25 male) were balanced for 5-HTTLPR genotype (27 S carrier controls, 16 S carrier ecstasy users, 26 S carrier marijuana users). Exclusion criteria included co-morbid psychiatric and neurologic disorders (including major depressive disorder), prenatal problems, and excessive other-drug use. Multiple regressions were run to predict depressive symptoms from past year ecstasy, 5-HTTLPR status, gender, and ecstasy*5-HTTLPR and ecstasy*gender interactions, controlling for demographics and comorbid nicotine, alcohol and marijuana use. Results: Past year ecstasy use marginally predicted BDI symptoms ($p=.06$). Gender significantly predicted BDI symptoms ($p=.008$), with females experiencing more depressive symptoms. Past year ecstasy use interacted with gender to predict BDI scores ($p=.01$), with female ecstasy users demonstrating more depressive symptoms than female non-users. 5-HTTLPR genotype did not independently or interactively predict BDI symptoms ($p>.05$). Conclusions: Results demonstrated gender and ecstasy use independently and interactively predicted increased depressive symptoms in adolescents and young adults. Despite previous findings, 5-HTTLPR genotype was not associated with depressive symptoms in this sample. Therefore prevention efforts regarding ecstasy use should be aimed at young adults, particularly females, to reduce potential mental health burden. Implications and future directions will be further discussed.

Title: Alcohol enhances mephedrone-induced signs of neurotoxicity and impaired neurogenesis in adolescent CD-1 mice

Authors: *A. M. CIUDAD, L. DUART, J. CAMARASA, E. ESCUBEDO, D. PUBILL; Univ. of Barcelona, Barcelona, Spain

Abstract: Neurotoxicity of amphetamine derivatives is a matter of concern and has been subject of a great amount of studies. Recently, a new family of amphetamine derivatives under the name of cathinones, mephedrone (Meph) being the most widely consumed, broke into the illegal market. In light of the fact that around 95% of cathinone consumers have been reported to combine them with alcohol (EtOH), we sought to study the consequences of the concomitant consumption of ethanol on mephedrone-induced neurotoxicity. Adolescent (5 weeks) male Swiss-CD1 mice were treated q.i.d. with a dose of Meph 25 mg/kg and 4 doses of EtOH (2; 1.5; 1.5; 1 g/kg; obtaining a steady plasma concentration of around 1.5 g/l) each separated by 2 hours in a room with set temperature at 27ºC, emulating typical ambient conditions found in dance clubs. Several neurochemical, histological and behavioral parameters were measured. The concomitant administration of EtOH enhanced Meph-induced decreases in tryptophan hydroxylase and SERT density in the hippocampus by 2-fold 7 days post-treatment (PT). Furthermore, these decreases correlated with a 2-fold increase in lipid peroxidation, measured as concentration of malondialdehyde (MDA) 24 hours PT. In a separate treatment, animals were injected with Bromo-deoxy-Uridine (BrdU) and sacrificed 28 days PT, with the objective of measuring neurogenesis in the dentate gyrus. During this time period, animals underwent a general Morris water maze (MWM) protocol, starting on day 7 PT. MWM showed an effect of Meph treatment on multiple learning and memory parameters, which matched with a BrdU count 25% lower than that of control animals. These changes were enhanced in the Meph+EtOH group, which showed a decerease higher than 2-fold in BrdU labelling. The decrease in hippocampal neurogenesis 28 days PT in Meph-treated animals and its potentiation by EtOH could be caused by a decrease in cell proliferation, increase in cell death, or a combination of both factors. This effect was accompanied by similar decreases in serotoninergic markers, pointing to a clear enhancement of Meph-induced neurotoxicity by EtOH, which could be directly related with the increase shown in oxidative stress. These results are of special significance, since alcohol is widely co-abused with amphetamine derivatives such as mephedrone, especially during adolescence, a crucial stage in brain maturation. This is especially noteworthy, since the

hippocampus is greatly involved in learning and memory processes, and could affect normal brain development in young adults, as suggested by results obtained in the MWM paradigm.

Title: A study of the selective 5-HT2c agonists lorcaserin and CP809101 on side-effect profile, CNS penetration and functional selectivity

Authors: *G. A. HIGGINS[1,2], L. B. SILENIEKS[3], A. PATRICK[3], I. A. M. DELANNOY[3], P. J. FLETCHER[4], L. A. PARKER[5], N. J. MACLUSKY[5], L. C. SULLIVAN[6], T. A. CHAVERA[6], K. A. BERG[6];

Abstract: Clinical experience with the 5-HT2C receptor agonist lorcaserin (LOR) has identified efficacy in the treatment of obesity and smoking cessation, with a primary dose-limiting side-effect of nausea and headache. We previously reported that the highly selective 5-HT2C agonist CP809101 (CP) may induce fewer signs of malaise/nausea in rats, suggesting potential for 5-HT2C agonists with improved side-effect profiles. We have adopted three lines of enquiry to further investigate. Firstly, we examined LOR and CP in the conditioned taste reactivity model, a validated rodent test to study nausea. Secondly, we compared plasma:CSF levels of LOR and CP at doses and timepoints relevant to the in-vivo studies. Male, Sprague-Dawley rats were used for all in-vivo studies. Thirdly, we compared the signaling profiles of LOR and CP at h5-HT2C receptors to look at evidence for functional selectivity differences between these two compounds. In the taste reactivity model, LOR (1-6 mg/kg SC) produced a dose-related incidence of conditioned gaping, equivalent to lithium chloride. This effect of LOR was reversed by SB242084 (0.5 mg/kg) confirming 5-HT2C receptor involvement. CP (3-12 mg/kg SC) produced a significantly smaller incidence of gapes (Veh: 0.3+0.3; LOR 6 mg/kg: 13.1+0.3; CP 12 mg/kg: 3.9+1.5; $P<0.05$). In CHO cells stably expressing h5-HT2C receptors, both LOR and CP produced a dose related increase in IP accumulation and arachidonic acid release, consistent

with PLC and PLA2 activation respectively. ERK levels were also increased by both drugs. In each case the EC50 for CP was 5-10x greater (i.e. more potent) compared to LOR, with similar efficacy relative to 5-HT. Finally, plasma and CSF levels of LOR and CP were measured. LOR (0.3-6 mg/kg SC) produced a dose-related increase in plasma and csf concentration with a peak at 1h, and plasma:CSF ratio of 0.1-0.2. In contrast, CP had a more shallow dose-response although plasma:CSF ratio was similar to LOR. These results suggest that differences between LOR and CP on measures of nausea may be unrelated to signaling profiles at the 5-HT2C receptor, but may be reflective of CSF levels and consequent 5-HT2C receptor occupancy and activation.

Title: Serotonin receptor 2C agonists lorcaserin and CP-809101 block cue-induced reinstatement of sugar-seeking behavior in rats

Authors: *E. ALTHERR[1], L. B. SILENIEKS[2], G. A. HIGGINS[2,3], P. J. FLETCHER[5,4], W. E. PRATT[1];
[1]Wake Forest University/Dept. Psychology, Winston-Salem, NC; [2]InterVivo Solutions Inc, Toronto, ON, Canada; [3]Pharmacol., [4]Departments of Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada; [5]Biopsychology, CAMH, Toronto, ON, Canada

Abstract: A main challenge for those intending to lose weight by dieting is to resist the temptation of preferred, highly caloric foods despite continued exposure to food and with cues associated with food. Manipulations of serotonin (5-hydroxytryptamine, 5-HT) signaling have been shown to affect a variety of motivated behaviors. In particular, the 5-HT2C receptor has been implicated as a therapeutic target for weight loss, and lorcaserin (Lorquess; Belviq) has been approved for the treatment of obesity. However, although the anorectic effects of 5-HT2C receptor stimulation have been well-described, recent research has also shown that 5-HT2C

agonists reduce reinstatement of nicotine-seeking in the presence of drug cues, which suggests that lorcaserin may also aid in weight loss due to inhibition of food-seeking in the presence of food-associated cues. In these experiments, we examined the impact of lorcaserin and the highly selective 5-HT2C agonist CP-809101 on 1) cue-induced reinstatement of sugar-seeking behavior, and 2) 2-hr food intake in rats on a 22-h deprivation schedule. Male Sprague-Dawley rats (N = 12/group) were food-deprived and trained to lever press for sugar pellets in the presence of a light/tone cue (for details, see Lin & Pratt, 2013). Once trained, rats underwent daily 20-min extinction sessions in which lever presses resulted in no programmed consequences. Upon extinguishing to 10% of their pre-extinction performance, rats received two separate reinstatement sessions following drug or saline injections (counterbalanced across rats and separated by 48 hr) in which lever pressing resulted in delivery of the light/tone cue. Prior to these reinstatement tests, rats received SC injections of saline or drug (Groups 1-3: lorcaserin at 0.1, 0.3, & 0.6 mg/kg; Group 4; CP-809101 at 1 mg/kg). Lorcaserin at 0.3 and 0.6 mg/kg (but not 0.1 mg/kg) significantly blocked cue-induced reinstatement of lever pressing to the sugar-associated cues, as did the 1 mg/kg of CP-809101 (e.g., reinstatement under vehicle: 88.4± 13.4 lever presses; Lor 0.6 mg/kg: 43.2±6.5 lever presses; CP 1 mg/kg: 48.0±9.5 lever presses). Notably, these effects occurred at doses of the 5-HT2C receptor agonists that were subthreshold to the anorectic effects of the drugs, as none of the doses tested in the reinstatement paradigm affected 2-hr food intake in animals tested under a 22-hr food deprivation schedule (e.g. Veh: 21.3±0.9g, Lor 1 mg/kg: 21.2±1.3g; NS). These data suggest that the therapeutic efficacy of 5-HT2C receptor agonists may include inhibition of the appetitive aspects of food-directed motivation.

Title: The role of the 5-HT2C receptor in mediating the effects of acutely increased serotonin on incentive motivation

Authors: *C. BROWNE[1], P. J. FLETCHER[2,3,4];
[1]Univ. of Toronto/CAMH, Toronto, ON, Canada; [2]Biopsychology, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [3]Psychology, [4]Psychiatry, Univ. of Toronto, Toronto, ON, Canada

Abstract: Elevations in whole-brain serotonin (5-hydroxytryptamine; 5-HT) through systemic treatment with drugs such as d-fenfluramine or SSRIs generally inhibit reward-related behaviours. Similarly, selective activation of the 5-HT2C receptor suppresses feeding behaviour and responding for primary rewards such as food or drugs of abuse. This suggests a candidate mechanism by which 5-HT influences motivational processes through 5-HT¬2C receptors. We examined whether the 5-HT2C receptor broadly mediated the effects of 5-HT on incentive motivation based on responding for three different types of reinforcers: a primary reinforcer (saccharin), a conditioned reinforcer (CR), and a sensory reinforcer (SR). Saccharin has high intrinsic value and elicits proportionally high responding, a CR has learned value through a Pavlovian association with saccharin, and a SR presumably has some intrinsic salience allowing it to support responding. We first examined the effect of increased extracellular 5-HT with the SSRI citalopram (CIT) on responding for these reinforcers, and subsequently examined whether the selective 5-HT2C receptor antagonist SB242084 could block this effect. Lever pressing for saccharin, a CR, and a SR was examined in three separate cohorts of 12 male C57BL/6 mice, all of which were water restricted throughout testing. Responding for saccharin (0.1 ml, 0.2%) was first acquired on a fixed-ratio 1 (FR1) schedule of reinforcement and then tested on a random ratio 4 (RR4) schedule. For responding for a CR, mice first underwent 14 Pavlovian conditioning sessions wherein saccharin availability was signaled by a conditioned stimulus, forming a stimulus-reward association. Subsequently, responding for the conditioned stimulus alone (now a CR) was examined on a RR2 schedule. Responding for a SR was first acquired on an FR1 schedule and tested on a RR2 schedule. Following baseline testing for each reinforcer, the effects of CIT (10, 20 mg/kg; i.p.) on responding was first examined. Next, the ability of SB242084 (1 mg/kg) to block the effect of 10 mg/kg CIT was examined. Both 10 and 20 mg/kg CIT significantly reduced responding for all three types of reinforcers. Pre-treatment with SB242084 completely blocked the effect of CIT on responding for a CR and a SR, but did not block the effect of CIT on responding for saccharin. These results show that 5-HT regulates incentive motivation through activity at the 5-HT2C receptor. However, the ability of SB242084 to block the effects of elevated 5-HT in a reinforcer-specific manner suggests that the 5-HT2C receptor may mediate incentive motivational processes based on the type of reinforcer examined or its incentive value.

Title: Serotonin 2c receptor constitutive activity and behavior: the effect of an agonist, antagonist and inverse agonist on locomotor activity and responding for a conditioned reinforcer in mice

Authors: *C. HARVEY-LEWIS[1], C. J. BROWNE[2], G. A. HIGGINS[5,3], P. J. FLETCHER[1,2,4]; [1]Biopyschology, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [2]Dept. of Psychology, [3]Dept. of Pharmacol. and Toxicology, [4]Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [5]Intervivo Solutions, Toronto, ON, Canada

Abstract: A large literature exists on the effects of pharmacological activation of the serotonin 2c (5-HT2c) receptor on reward-related processes. However, less is known about the influence of constitutive activity of the 5-HT2c receptor on behavior. The 5-HT2c receptor can spontaneously activate intracellular signaling pathways (constitutive activity) *in vitro*; this may facilitate mesolimbic dopaminergic release *in vivo* (Deurwaerdère et al. 2004). However, no direct behavioral output of 5-HT2c receptor constitutive activity has been reported. Here, we investigate the effect of 5-HT2c receptor constitutive activity on two dopaminergic-dependent behaviors - responding for a conditioned reinforcer (CR) and locomotor activity - using a highly selective 5-HT2c agonist (CP809101), the putative 'silent' antagonist (SB242084) and putative inverse agonist (SB206553). Mice received 14days of non-contingent Pavlovian association between a CS (5s cue light and sound of dipper) and delivery of 0.1ml 0.2% saccharin. Mice were then trained on a two-lever task where active lever responses resulted in presentation of the CS (now a CR) without saccharin delivery and inactive lever responses had no consequences. Animals were treated with CP809101 (0-3mg/kg), SB242084 (0-1mg/kg) or SB206553 (0-10mg/kg) prior to testing. A second cohort was habituated to the locomotor testing apparatus for 5 days. These animals received the same dosing procedure as the first cohort. CP809101 dose-dependently decreased CR-directed responding and locomotor activity. SB242084 dose-dependently increased both measures. SB206553 had no significant effects on locomotor activity but significantly decreased CR-directed responding at the 10mg/kg. In the second phase we attempted to block these effects to test 5-HT2c specificity. Pretreatment with silent doses of SB242084 blocked the CP809101-induced decreases in locomotor activity and responding for a CR. However, SB242084 pretreatment had no effect on SB206553 induced decreases in CR-directed responding. Additionally, SB206553 pretreatment did not block CP809101- or SB242084-induced behavioral effects. The opposing behavioral effects of SB242084 and CP809101 highlight the importance of 5-HT2c receptors in motivational processes. Furthermore, the observed effects of SB242084 on locomotion and CR-directed responding provide support that endogenous tone at the 5-HT2c receptor can directly influence dopaminergic-dependent

behaviors. Unlike previous *in vivo* and *in vitro* studies, mainly in rats, we failed to find evidence for inverse agonism of 5-HT2c receptors by SB206553 suggesting a possible strain difference in its effects.

Abstract: Introduction. Parkinson's disease (PD), in which there is widespread degeneration of the catecholamine system, is characterized by both motor symptoms and impairment of both cognitive performance and executive functions. A strategy to improve both types of symptoms might be to combine dopamine D2 receptor agonism, to alleviate motor symptoms, with histamine H3 receptor antagonism, to improve cognition. The purpose of the study was to examine the cognitive effects of such a dual activity compound in the gold standard primate model of cognitive defects in PD, the so-called chronic low-dose (CLD) 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) macaque model. Methods. Cognitive performances were assessed in 3 behavioural tasks following administrations of AG-1 (0.03, 0.1 or 0.3 mg/kg). Four CLD cynomolgus macaques, displaying cognitive deficits and mild parkinsonian motor deficits, produced by chronic exposure to low doses of MPTP were tested in the Variable Delayed Response (VDR) and the Continuous Performance Task (CPT) on a touch-screen computerized system. Eight MPTP cynomolgus macaques, displaying more severe motor deficits, were tested in the Object Retrieval (OR) task. Results. In the OR task, AG-1 at 0.1 mg/kg significantly improved 1st attempt successes and correct responses by decreasing omissions compared to an optimal dose of L-DOPA. No significant overall effect of AG-1 was found on the VDR tasks. However, when performing a best dose analysis, AG-1 significantly improved the percentages of correct responses and decreased errors compared to vehicle in the VDR. In the CPT, AG-1 did

not show any positive effects. Conclusion. AG-1 improved cognitive performance of MPTP-treated monkeys in the OR and VDR tasks but not in the CPT. These results suggest the likely beneficial cognitive effects of AG-1 for patients with PD-mild cognitive impairments.

Title: Intrahippocampal injection of a small molecule RGS4/19 inhibitor has antidepressant-like effects in a mouse model

Authors: ***N. SENESE**[1], R. NEUBIG[2], J. TRAYNOR[1];
[1]Pharmacol., Univ. of Michigan, Ann Arbor, MI; [2]Michigan State Univ., East Lansing, MI

Abstract: Regulators of G-protein signaling (RGS) proteins are a large family of intracellular proteins that negatively regulate G-protein coupled receptor (GPCR) signaling to heterotrimeric G proteins. RGS proteins act as GTPase accelerating proteins (GAPs) and interact directly with active GTP-bound Gα subunits. This action enhances the hydrolysis of GTP to GDP, thus inactivating the Gα subunits and allowing reformation of the inactive Gα/β/γ-protein

heterotrimer. This allows RGS proteins to reduce both the duration and extent of GPCR signaling. We have demonstrated that mice expressing an RGS insensitive variant of Gαi2 (RGSi Gαi2; knock-in variant of Gαi2 with a single point mutation in the switch region that prevents interaction with all RGS proteins) exhibit an antidepressant-like phenotype in several behavioral tests. This phenotype is caused by increased signaling downstream of 5-HT1A receptors (5-HT1AR). In addition, we have shown in cultured hippocampal neurons that RGS19 is an effective inhibitor of 5HT1A receptor signaling. Furthermore evidence suggests that RGS4 and RGS6 are important modulators of antidepressant drug action. The present study sought to answer two questions: A) What is the location of the 5HT1ARs involved in the antidepressant-like phenotype in the RGSi Gαi2 mice and B) What information can be gained about the specific RGS proteins that are responsible for negative regulation of these 5HT1ARs. RGSi Gαi2 mutant mice show the expected antidepressant-like phenotype (reduced immobility) in the tail suspension test (TST) which is reversed by infusion of the selective 5-HT1AR antagonist WAY-100635 directly into the hippocampus. Conversely, direct hippocampal infusion of the 5-HT1AR agonist 8-OH-DPAT decreases immobility in wild type mice, and this is reversed by peripheral administration of WAY-100635. CCG-203769 is a small molecule RGS4 inhibitor with selectivity for RGS4 > RGS19 >> other RGS proteins. Intrahippocampal infusion of CCG-203769 over 3 days in wild-type mice produces a marked antidepressant-like activity in the TST. These findings identify hippocampal 5-HT1ARs specifically coupled to Gαi2 as important for the antidepressant-like effect in this phenotype and suggest RGS4 and/or RGS19 as RGS proteins that may regulate signaling through this pathway. These results identify proteins along this signaling pathway (5-HT1AR/Gαi2 complex, RGS4, RGS19) as potential targets for antidepressant medications.

Title: Behavioral effects of N,N-dialkyltryptamine hallucinogens in mice

Authors: ***L. M. KLEIN**[1], M. A. GEYER[2], A. L. HALBERSTADT[2];
[2]Psychiatry, [1]UC San Diego, San Diego, CA

Abstract: N,N-dialkyltryptamines are known to act non-selectively as agonists at 5-HT1A and 5-HT2A receptors. However, the contributions of these receptors to the behavioral effects of N,N-dialkyltryptamines are unclear. Recently, illicit sources have made available an expanded repertoire of N,N-dialkyltryptamines, including N,N-dimethyltryptamine (DMT) and homologues with one or both methyl groups extended to ethyl or propyl groups. In light of increasing use of these compounds, we investigated their behavioral pharmacology in mice. The head twitch response (HTR), a behavior mediated by 5-HT2A, is often used as a rodent proxy for hallucinogenic effects in humans. Using a head-mounted magnet and a magnetometer coil to detect head movement, we found that IP treatment with DMT (0.625-10 mg/kg), N-methyl-N-ethyltryptamine (MET; 0.625-10 mg/kg), N,N-diethyltryptamine (DET; 0.3-3 mg/kg), and N,N-dipropyltryptamine (DPT; 0.625-10 mg/kg) induced the HTR in C57Bl/6J mice, suggesting that activity at 5-HT2A contributes to the behavioral effects of these compounds. Additionally, the Behavioral Pattern Monitor (BPM) was used to assess the effects of DMT, MET, DET, and DPT on exploratory behavior. When administered at 30 mg/kg IP, all four compounds reduced locomotor activity and investigatory behavior. Since previous BPM experiments demonstrated tryptamine hallucinogens to reduce locomotor activity by activating 5-HT1A (Halberstadt et al., 2011), we assessed the contribution of 5-HT1A to these locomotor effects by comparing the effects of DMT, MET, DET, and DPT in 5-HT1A wild-type (WT) and knockout (KO) mice. Interestingly, the involvement of 5-HT1A in locomotor hypoactivity depended on the length of the N-alkyl groups. The effects of DPT were completely absent in 5-HT1A KO mice, while the effects of DET were partially attenuated in the KOs. By contrast, DMT and MET produced similar responses in WT and KO mice, and the effect of DMT was not blocked by the 5-HT1A antagonist WAY-100,635. Our findings demonstrate that the behavioral effects of N,N-dialkyltryptamines depend, at least in part, on the 5-HT2A receptor, and indicate a variable role for the 5-HT1A receptor depending on the length of the N-alkyl groups. Human clinical trials indicate subtle differences in the effects of DMT, DET, and DPT. In light of our findings, these subjective differences may result from differential interaction of these compounds with 5-HT1A. Experiments are in progress to determine the receptor(s) responsible for the effects of DMT and MET in the BPM.

Title: Sex-dependent and specie-specific effects of fluoxetine on repeated forced swimming test in rodents: translational implications

Authors: *C. LINO DE OLIVEIRA[1,2,3], I. SPEZIA[1], L. C. THEINDL[1], F. B. L. CHRISTIAN[3], J. A. CADORE[3], P. R. SUMAN[2], K. DOMINGUES[2];
[1]Univ. Federal De Santa Catarina, Florianópolis, Brazil; [2]PPG Farmacologia, Florianópolis, Brazil; [3]PPG Multicêntrico Ciências Fisiológicas, Florianópolis, Brazil

Abstract: Repeated forced swimming test (rFST) is a modified version of the Porsolt test created to provide information about gradual effects of antidepressants. rFST is based in the paradigm that the repetition of forced swimming stress may increase immobility time facilitating the detection of antidepressants in rodents. Indeed, the immobility of rats (Wistar, adult, male) in rFST decreased when they were treated once a day for 1, 7 and 14 days with fluoxetine (FLX) or imipramine in doses that were, at least, ten times lower (2.5 and 5 mg/kg) than the daily doses effective in the Porsolt test [1,2,3]. Here, we investigated if the paradigm for the rFST could be translated from male to female rats of the same strain as well as to males of other species of laboratory rodents. Female Wistar rats (adults with or without ovarian failure, n=8/group) and Swiss mice (adults, males, n=8/group) were tested in rFST during the treatment (daily, p.o. for 7 or 14 days) with FLX (1-10 mg/kg) or sucrose 10%. Male Wistar rats treated with FLX (2.5 mg/kg) or sucrose 10% comprised the “positive” control group. The rFST for rats consisted of 15 min- swimming test (pretest) followed by a 5 min-swimming test in the first (test), seventh (retest 1) and fourteenth (retest 2) day after pretest. The rFST protocol for mice was similar to that for rats except that pretest was absent. Test sessions were videotaped for posterior extraction

of duration of immobility using the software Ethowatcher. For male and female rats, different of male mice, the treatment with sucrose seemed to neutralize the influence of the repetition of the forced swimming stress on immobility revealing a possible "placebo" effect of sucrose. The immobility time of females (with or without ovarian failure) remained unchanged in the rFST during the treatment with FLX (2.5 mg/kg) whereas in males it dropped in the retest 2, as expected [2,3]. However, the immobility time of female Wistar rats and male Swiss mice increased with the chronic treatment with FLX (10 mg/kg), as compared to acute-treated group, suggesting a paradoxical effect of FLX in these animals. These data suggest that rFST paradigm may be not directly translated from male rats to female rats or to male mice. In addition, rFST may detect sexual and specie-specific styles of coping with stress and response to antidepressants. Moreover, rFST in female Wistar rats or in male Swiss mice may provide strategies to discover new antidepressants. Title: AntiParkinsonian effects of AG-1 in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated macaque model of Parkinson's disease

Authors: *A. R. CROSSMAN[1], E. Y. PIOLI[2], D. W. KO[2], Q. LI[2], E. BEZARD[2], S. HOGG[3]; [1]The Univ. of Manchester, Manchester, United Kingdom; [2]MOTAC, Manchester, United Kingdom; [3]Angita Pharmaceuticals B.V., Groningen, Netherlands

Abstract: Introduction. Parkinson's disease (PD), in which there is widespread degeneration of the catecholamine system, is characterized by motor symptoms and impairment of both cognitive performance and executive functions. A strategy to improve both types of symptoms might be to combine dopamine D2 receptor agonism, to alleviate motor symptoms, with histamine H3 receptor antagonism, to improve cognition. The purpose of the study was to examine the antiparkinsonian effects of such a compound in the gold standard primate model of PD, the so-

called MPTP macaque model. Methods. Parkinsonian symptoms were produced in 6 cynomolgus macaques by daily administration of MPTP (0.2 mg/kg, i.v.). Regular treatment with L-DOPA resulted in the development of dyskinesia. PD motor disability, dyskinesia and on-time were assessed following administration of AG-1 (0.03, 0.1, 0.3 mg/kg) in comparison to L-DOPA and pramipexole. Results. AG-1 showed a full anti-parkinsonian effect at 0.3 mg/kg with reduction of the disability, bradykinesia, posture scores and a long lasting effect of at least 10 hours. However, it induced also some dyskinesia as animals were primed. The 0.1 mg/kg dose produced a similar anti parkinsonian effect to L-DOPA. Conclusion. These results suggest the likely beneficial effects of AG-1 on motor symptoms of PD patients.

Title: Serotonin depletion eliminates sex differences with respect to contextual fear in rat

Authors: *R. PETTERSSON, M. HAGSÄTER, E. ERIKSSON;
Pharmacol., Gothenburg, Sweden

Abstract: Supporting the hypothesis that serotonin is important for upholding sex differences in behavior, we recently showed that serotonin depletion, obtained by means of the serotonin synthesis inhibitor para-chlorophenylalanine (PCPA), eliminates sex differences in anxiety-like behavior as assessed using the elevated plus maze in rat. In the present study, we compared male and female rats with respect to two other anxiety-related aspects of behavior, i.e. immobility and startle responses to sudden noise bursts, and to what extent any possible sex difference in this regard could be influenced by serotonin depletion. The two sexes differed markedly with respect to immobility after contextual conditioning induced by previous exposure to foot shocks in the sense that males displayed more immobility than females. This response was reduced by PCPA in males but not females, the result being that serotonin-depleted animals displayed no sex difference. PCPA was found to enhance startle responses in context-conditioned males and in non-conditioned females, respectively. After context conditioning males given saline, but neither females, nor PCPA-treated males, showed a negative correlation between startle and immobility, suggesting the latter behavior, when excessive, to interfere with the former. We suggest that a clear-cut sex difference in a putatively anxiety-related behavior, i.e. context-conditioned immobility, is to a large extent caused by an "anxiogenic" serotonergic influence being stronger in males than in females. The results are well in line with the theory that an important role of serotonin is to uphold certain sex differences in behavior.

Title: Role of purinergic p2x4 receptors in regulating signaling cascades and behaviors dependent upon dopamine receptor activity

Authors: *S. KHOJA[1], L. ASATRYAN[2], M. W. JAKOWEC[3], D. L. DAVIES[2];
[1]Pharmacol. and Pharmaceut. Sci., USC, Los Angeles, CA; [2]Titus Family of Clin. Pharm. and Pharmaceut. Econ. and Policy, [3]Neurol., Universityof Southern California, Los Angeles, CA

Abstract: Purinergic P2X4 receptors (P2X4Rs) are adenosine-5'-triphosphate (ATP) activated ion channels. They are expressed on multiple types of cells across the central nervous system (CNS) yet their roles in mediation of physiological responses are less explored. Previous reports link P2X4Rs to neuropathic pain, neuroendocrine effects and hippocampal synaptic plasticity. Findings from our group, using gene knockout strategy [i.e. P2X4R knockout (KO) mice] suggest that P2X4Rs play a role in sensorimotor gating, social behavior and ethanol drinking behavior. P2X4Rs may mediate these behaviors via interactions with glutamate and GABAergic systems though pre- and postsynaptic mechanisms and /or via modulation of dopamine (DA) neurotransmission. We recently found that P2X4R KO mice have altered expression of DA markers including tyrosine hydroxylase, dopamine transporter and dopamine D1, D2 receptors (D1Rs and D2Rs) in basal ganglia, implying imbalances in DA homeostasis. The current investigation tests the hypothesis that altered DA homeostasis affects signaling pathways in striatum and this underlies sensorimotor gating deficits in P2X4R KO mice. We measured phosphorylation of DA and cyclic AMP regulated phosphoprotein-32kDa (DARPP-32), cAMP response element binding protein (CREB) in striatum of P2X4R KO and WT mice using Western blotting. We also studied the responses of P2X4R KO mice to DA antagonists in prepulse inhibition (PPI) of acoustic startle, an operational measure of sensorimotor gating. In the dorsal striatum of P2X4R KO mice, DARPP-32 phosphorylation was significantly increased and the opposite effect was seen in ventral striatum. There was significant increase in CREB phosphorylation in both striatal regions of P2X4R KO mice. Sensorimotor gating deficits were rescued by D2R antagonist, raclopride but not by D1R antagonist, SCH 23390, implying DA dysregulation as a mechanism for behavioral deficit. The findings supports hypothesis that altered DA receptor expression in P2X4R KO mice dysregulates DA dependent signaling cascades and alters responses to DA antagonists. These results highlight an important role for P2X4Rs in maintaining DA homeostasis and illustrate how their deficiency induces behavioral manifestations characteristic of DA dysfunction.

Title: Attenuation of amphetamine-induced recovery from neglect with noradrenergic antagonists

Authors: *M. J. HYLIN[1], M. BRENNEMAN[2], J. CORWIN[3];
[1]Psychology, Southern Illinois Univ., Carbondale, IL; [2]Psychology, Coastal Carolina Univ., Conway, SC; [3]Psychology, Northern Illinois Univ., DeKalb, IL

Abstract: Neglect is a human neurological disorder typically produced by stroke that is characterized by an inability to attend or orient toward stimuli presented in the contralesional hemispace. Current treatments for neglect are limited in their effectiveness. Damage to the medial agranular cortex (AGm) in rodents produces severe multimodal neglect of visual, tactile, and auditory stimulation with deficits that are similar to those seen in humans. Amphetamine treatment has been shown to result in recovery from motor, visual, and spatial deficits. Recently, it has been observed that systemic injections of amphetamine produce long-lasting, relatively stable recovery from AGm-induced neglect. Prior research has indicated that treatments that affect norepinephrine produce recovery similar to that resulting from amphetamine administration, which has led to the hypothesis that amphetamine-induced recovery is due to noradrenergic mechanisms. However, no prior studies have directly tested this hypothesis. Because amphetamine results in stable and relatively permanent recovery from neglect, the purpose of the current study was to investigate whether noradrenergic receptor mechanisms are responsible for amphetamine-induced recovery from neglect. In order to block α- or β-adrenergic receptors, subjects were given an injection of a α-adrenergic antagonist (phenoxybenzamine), β-adrenergic antagonist (propranolol) or saline prior to each administration of amphetamine. Co-administration of either noradrenergic antagonist prior to amphetamine administration significantly delayed or blocked amphetamine-induced recovery. Amphetamine treatment alone induced recovery from neglect within two weeks. The results of the current study indicate that α- and β-adrenergic receptors are crucial factors in amphetamine-induced recovery from neglect in rats.

Title: Preclinical telemetric electroencephalography (EEG) and *in vivo* microdialysis to study dopaminergic hyperactivity in freely moving rats

Authors: M. SHIMASAKI, C. HOYLE, P. VOEHRINGER, *B. FERGER;
CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany

Abstract: Dopamine (DA) is a key regulator of cognition, mood, reward and movement in the human and rodent brain. The DA homeostasis is tightly controlled by the dopamine transporter (DAT), which is a target for addictive drugs including cocaine. The present study was designed to investigate the effects of cocaine in freely moving rats using telemetric electroencephalography (EEG) and *in vivo* microdialysis in the nucleus accumbens shell. Extracellular cocaine levels were measured by LC-MS-MS and dopamine levels by HPLC coupled to electrochemical detection. Behaviour was assessed by an automated motor activity system and light beam interruptions. Cocaine (5, 10 and 15 mg/kg, i.p.) dose dependently induced an increase in motor activity, which reached its maximum level after 20 min and lasted for 90 min. Almost in parallel, extracellular dopamine levels showed a peak concentration at 30 min and then returned to basal levels 120 min later. Maximum cocaine levels measured from the dialysates appeared 30 min after dosing (300 nmol/l). In addition, cocaine appeared to affect the EEG power spectrum, increasing gamma frequency band power (40-80 Hz) up to 60 min after administration, whilst causing a decrease of power in delta (0.5-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), and beta (13-40 Hz) frequencies. In conclusion, these results indicate that cocaine induces an increase in dopaminergic transmission in the nucleus accumbens shell, and as expected, produces hyperactivity. Similarly, the effect observed on the EEG frequency bands highlights a possible role in the cocaine-induced arousal behavior, which could serve as a physiological biomarker of target and pathway engagement studies in drug discovery.

Title: High dose propranolol, a beta adrenergic blocker for the control of violence and self abuse in patients with autism spectrum disorders

Authors: *E. B. LONDON;
Inst. Bas Res., Staten Island, NY

Abstract: Uncontrolled aggression (including self abuse) is a behavior which transcends diagnostic labels. This symptom is of utmost clinical importance and yet is rarely the end point of clinical trials. The antipsychotic medications, which are most frequently used, are sometimes successful however many subjects are not adequately treated and many experience unacceptable side effects to those medications. Propranolol a lipophilic beta adrenergic antagonist, has been shown in anecdotal reports dating back to the 1970's to be very successful in controlling intractable violence in various diagnoses. A retrospective chart review is presented of 46 subjects with Autism Spectrum Disorders who had violent behavior (aggression and or self abusive behaviors) which were refractory to treatments including behavioral treatment as well as at least one anti-psychotic medication. All of these behaviors were of high severity (CGI-S 5,6 or 7, markedly, severely or extremely ill) prior to the addition of the propranolol. 85% of the cases (39/46) were much or very much improved when adding propranolol to other medications which had shown some degree of success. Notably, 1) in many cases attempts to discontinue the other medications after the administration of propranolol failed; 2) only rarely did propranolol show benefit below 300 mg/day and often benefit was often not noted until reaching significantly higher doses; 3) other serious symptoms such as hyperactivity, compulsive and repetitive behaviors and mood related behaviors were often refractory to the propranolol. The mechanism of action of the high dose propranolol is not clear. Its sympatholytic properties may be responsible for this benefit; however the peripheral effects of propranolol occur at much lower doses. Central mechanisms need to be considered. One mechanism might be propranolol's blocking the reconsolidation of fearful memories as noted in PTSD. These "fearful" tracings might be consolidated routinely as subjects with ASD appear to be in a chronic hyperadrenergic state.

Abstract: The presynaptic dopamine (DA) transporter (DAT, SLC6A3) plays a critical role in clearing synaptic DA and is a direct target of psychostimulant drugs. Previously, we identified a rare, nonsynonymous SLC6A3 variant (DAT Val559) in two male siblings diagnosed with attention-deficit hyperactivity disorder (ADHD) that was previously found in subjects with bipolar disorder (BPD), and more recently has been identified in subjects with autism spectrum disorder. *In vitro* characterization of the mutant transporter revealed normal protein expression and trafficking as well as intact DA uptake. However, DAT Val559 exhibits anomalous DA efflux (ADE) and lacks amphetamine (AMPH)-stimulated DA release. To more closely link DAT dysfunction to pathogenic mechanisms underlying neuropsychiatric illness, we generated a knock-in mouse model harboring the DAT Val559 mutation (Mergy et al., PNAS 2014). In the striatum of these mice, we found elevated basal levels of extracellular DA that rose less significantly in response to amphetamine (AMPH) as compared to elevations seen in WT animals. Similarly, horizontal and vertical locomotor hyperactivity resulting from acute challenge with submaximal doses of AMPH or methylphenidate (MPH) was blunted in the DAT Val559 mice. Here we report that, in contrast to our findings with AMPH and MPH, the locomotor-stimulating actions of cocaine, as well as the ability of the drug to promote rearing and stereotypic behaviors, are completely absent in DAT Val559 mice. Though the psychomotor response to cocaine is lost in these animals, the rewarding properties of the drug remain intact as evidenced by WT levels of conditioned place preference (CPP) for cocaine. Further, we found extinction of cocaine CPP to be delayed in mice homozygous for the mutant allele. Thus, the dysfunction in DA homeostasis that results from this single DAT point mutation differentially impacts two prominent dimensions of cocaine action. Ongoing efforts seek to determine the neuroanatomical, biochemical and physiological determinants of these differential perturbations in cocaine response. Though the basis of these divergent behavioral outcomes remains unclear, the DAT Val559 mouse model appears to provide an unexpected opportunity to dissect the distinct mechanisms underlying the complex actions of cocaine, studies that may reveal further dimensions of risk for neuropsychiatric disorders linked to DA signaling dysfunction.

Title: Conditioning and sensitization of dopamine antagonist effects on open field activity

Authors: *H. S. WIRTSHAFTER[1,2], D. WIRTSHAFTER[2];
[1]MIT, Cambridge, MA; [2]Univ. of IL at Chicago, Chicago, IL

Abstract: Hyperactivity induced by dopamine agonists can be conditioned to contextual cues, and conditioning may play a role in the locomotor sensitization seen after repeated administration of these drugs. However few studies have investigated if conditioning mechanisms play a similar role in the hypoactivity induced by dopamine antagonists. We report a series of studies investigating these topics. In the first experiment, two groups of rats received four daily 10 min open field activity tests. The experimental (EXP) group received haloperidol (HAL) (0.2 mg/kg, s.c.) 30 min before testing and saline 30 min later. The control (CON) group received the injections in the reversed order. Activity remained stable in the CON animals, but declined steadily across days in the EXP rats. On day 5, all rats received saline prior to testing. In the absence of drug treatment, latency to initiate movement was significantly increased and numbers of rears decreased in the EXP as compared to the CON rats. This finding demonstrates that aspects of HAL-induced hypoactivity can be conditioned to environmental or procedural cues. The second experiment was similar to the first, but subjects in both groups received an injection of HAL prior to test day 4. Although the same drug treatments were administered on the test day, latency to initiate movement was significantly longer, and activity and rearing counts lower, in the EXP than CON animals. These results demonstrate context dependent sensitization of HAL induced hypoactivity. In the third experiment, all rats received HAL injections prior to open field tests over four days of testing. Conditioned responses to HAL were then extinguished in the EXP subjects by testing them for 4 days in the open field following saline injections. The CON animals were injected and returned to their home cages. Activity increased steadily across the four extinction tests in the EXP animals, documenting extinction of the drug response. On the final (9^{th}) day all rats were injected with HAL prior to testing. Under

these conditions activity was higher in the EXP animals, demonstrating that contextual conditioning underlies much of the sensitization seen after repeated HAL injections. These studies demonstrate that HAL-induced hypoactivity increases with repeated testing. Conditioning of the drug response to contextual or procedural cues can mediate this effect. Clinically, analogous factors may play a role in the therapeutic lag observed with neuroleptics. The ability of dopamine antagonists to produce incremental extinction-like effects on operant behavior may also be the result of similar conditioning effects.

Title: Pharmacological manipulation of the dopaminergic system: An investigation of alcohol's locomotor stimulant effect in zebrafish

Authors: *S. TRAN[1], M. NOWICKI[2], A. MURALEETHARAN[2], D. CHATTERJEE[2], R. GERLAI[1,2];
[1]Cell and Systems Biol., Univ. of Toronto, Mississauga, ON, Canada; [2]Psychology, Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Alcohol is the world's most commonly consumed drug despite its potential abuse. In humans, individual variation in how people respond to alcohol's stimulant effect has been suggested to be a risk factor for the development of alcohol addiction, yet the exact mechanism by which alcohol increases locomotor activity remains unknown. Using zebrafish, we focus on the dopaminergic system as a potential mediator for alcohol induced locomotor activity. Previous studies with zebrafish have shown that similarly to mammals, alcohol increases the total distance traveled as well as whole-brain dopamine levels and tyrosine hydroxylase activity, the rate-limiting enzyme responsible for dopamine synthesis. These studies suggest a relationship between activation of the dopaminergic system and alcohol's locomotor stimulant effect in zebrafish. Using a pharmacological approach we examine whether dopamine D1 receptor

activation and tyrosine hydroxylase phosphorylation contributes to alcohol's stimulant effect. Zebrafish exposed to 1% v/v ethanol were shown to increase the total distance traveled as well as whole-brain dopamine levels compared to controls. Pre-treatment with the D1-R antagonist (SCH-23390) or with phosphorylated tyrosine hydroxylase inhibitor (tetrahydropapaveroline) attenuated the alcohol induced increase in locomotor activity. In addition, although both pre-treatments reduced whole-brain dopamine levels, the effect of the D1-R antagonist was independent of alcohol exposure. The results suggest that in zebrafish, alcohol's locomotor stimulant effect is partially mediated through both tyrosine hydroxylase phosphorylation and dopamine D1 receptor activation, but the role of dopamine itself remains unclear. Overall, we provide support for the notion that alcohol's locomotor stimulant effect is partially mediated via the dopaminergic neurotransmitter system.

Title: Possible role of the dopamine D1 receptor in the sensorimotor gating deficits induced by high-fat diet

Authors: *C. WAKABAYASHI, T. NUMAKAWA, Y. OOSHIMA, K. HATTORI, H. KUNUGI;
Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan

Abstract: High-fat diet (HFD) has been recently reported to induce sensorimotor gating deficits, but the underlying mechanisms are not well understood. To determine whether HFD induces long-lasting deficits in sensorimotor gating and to examine the involvement of altered dopamine (DA) function. C57BL/6J mice were fed HFD for 10 weeks and then normal diet (ND) for 4

weeks. DA D2 receptor (D2R) knock out (KO) mice were also fed HFD for 10 weeks. The mice were evaluated for prepulse inhibition (PPI) of acoustic startle after HFD and the subsequent 4-week ND. We evaluated the effect of SCH23390, a D1 receptor (D1R) antagonist, on PPI and measured protein expression levels of D1R and D2R in the prefrontal cortex (PFC) and striatum in HFD mice. The concentrations of monoamines and their metabolites in the cortices of 10-week HFD or ND mice were measured using high performance liquid chromatography. Long term HFD induced PPI disruption in WT and D2R KO mice. Even after 4 weeks of subsequent ND, PPI remained to be disrupted. SCH23390 mitigated the PPI disruption. In HFD animals, D1R protein expression in the PFC was significantly decreased, while DA and its metabolites homovanillic acid (HVA) and 3,4-dihydroxyphenylacetic acid (DOPAC) levels in the cortex were increased. This is the first evidence that HFD can induce long-lasting deficits in sensorimotor gating through alteration of cortical levels of DA, HVA, and DOPAC. Our data suggest that HFD-induced PPI deficits are related to altered D1R, rather than D2R, signaling and that D1R antagonists may have therapeutic effects on the deficits.

Title: Prenatal risperidone exposure enhances prepulse inhibition of acoustic startle reflex in adult male mice

Authors: ***Y.-A. SU**[1,2,3], H. WANG[1,2,3], J.-T. LI[1,2,3], T.-M. SI[1,2,3];

Abstract: Background Psychiatric disorders are relatively common among women of childbearing age. However, the use of antipsychotics during pregnancy remains controversial. The potential embryotoxicity of the antipsychotics has to be weighed against the risk of relapse

following drug discontinuation, and the decision-making must be based on extensive research evidence. Previous animal studies indicate that prenatal exposure to antipsychotics may impair the cognitive function of adult offspring. The current study investigated whether prenatal risperidone treatment would produce long-term effects on behavior in adult male offspring. Methods All plug-positive female C57BL/6 mice were randomized two groups. Pregnant dams of both groups were exposed to risperidone at a dose of 2mg/kg body weight or vehicle (0.9% normal saline) intraperotoneally from embryonic day 6 to 16. The day of delivery was defined as postnatal day 0 (P0). Pups were reared by their biological mothers up to weaning (at P28). Only male mice were used for behavioral observations. On P75, mice were examined in the spontaneous locomotion, spatial object recognition, elevated plus maze and prepulse inhibition (PPI) of acoustic startle reflex sequentially. Results Maternal risperidone exposure from E6 to E16 reduced maternal body weight gain after the first drug administration and showed recovery on subsequent days. The data showed no significant difference in the body weight of treated offspring as compared to those of the controls. The total distance traveled in the novel environment of the open field test did not reveal any differences between two groups. Male mice offspring exposed to risperidone showed deficits in spatial object recognition when compared with control group. However, prenatally risperidone exposed mice displayed less anxiety like behavior in the elevated plus maze. In addition, the offspring of risperidone group showed significantly potentiated PPI; this effect was most striking with the two lowest prepulse intensities. Conclusion The findings of impaired spatial memory, reduced anxiety-like behavior and enhanced prepulse inhibition suggest that prenatal risperidone could produce both negative and positive long-term behavioral changes. The mechanism of risperidone's action on neurodevelopment remains to be clarified.

Title: Tyrosine hydroxylase 2 is involved in the regulation of habituation in adult zebrafish

Authors: ***S. A. SEMENOVA**, Y.-C. CHEN, P. A. J. PANULA;
Univ. of Helsinki, Helsinki, Finland

Abstract: Zebrafish has two non-allelic tyrosine hydroxylase (TH) genes, of which TH1 is more similar to its mammalian counterparts. The gene encoding tyrosine hydroxylase 2 (TH2) is primarily expressed in the hypothalamus, and the most prominent TH2 neuron groups are found close to the lateral and posterior recesses of the diencephalic ventricle, in the immediate vicinity of adult neurogenesis zones. Apart from the effect of stress on th2 gene expression in larval and adult fish, the regulation of expression of this gene and its functions in the nervous system are not completely characterized yet. We previously developed an antibody against zebrafish TH2 and used it to demonstrate that TH2 neurons of zebrafish are targeted by histaminergic and orexinergic signaling. Serotonergic and TH2 neurons were distinct, although cells of the two phenotypes were intermingled in the hypothalamic nuclei. Morpholino oligonucleotide (MO)-mediated knockdown of th2 gene expression affected the development of histaminergic and orexinergic neurons in larval zebrafish; however, the locomotor behavior of larvae was not significantly altered by MO injection. Handling or chemical stress induced prominent expression of the immediate early gene c-fos in the zebrafish hypothalamus, but very few TH2-immunopositive cells were involved in this acute response. We used the CRISPR/Cas9 approach to generate a mutant zebrafish line with a six-nucleotide deletion in exon 2 of the th2 gene. Adult male heterozygous fish appeared phenotypically normal and were fertile. Open-field behavioral test revealed altered habituation in heterozygous fish; however, changes in spatial preference evident of increased anxiety (thigmotaxis) were not detected. There was a trend towards increased interaction with own mirror image in heterozygous fish. Therefore, a role in modulation of the habituation reaction in adult zebrafish can be assigned to TH2 neurons.

Title: Antipsychotic medications induce sustained alterations in approach/avoidance learning

Authors: *N. E. VIERLING-CLAASSEN[1], A. COLLINS[2], D. BURKE[1], H. WARWICK[1], B. REGO[1], M. HILL[1], K. BATH[2], M. J. FRANK[2], C. I. MOORE[1];
[1]Neurosci., [2]Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: The most common psychiatric treatment for severe mental illness is antipsychotic (APsy) medication. APsy minimize "positive" symptoms of psychiatric disorders, including overt psychosis, but also fail to treat and may increase "negative" symptoms, such as suppressed motivation. This shortcoming is major, as the severity of negative symptoms is predictive of long-term recovery and function. Almost all APsy block 'D2' dopaminergic receptors, increasing the excitability of striatal D2 medium spiny neurons (MSNs) by removing a source of inhibition. D2 blockade leads to suppressed motivation, down regulation of behavior and eventually motor symptoms such as catalepsy. Computational models suggest a common set of interactive mechanisms giving rise to these effects: by disinhibiting the D2 "no-go" corticostriatal pathway, APsy enhance the motivational cost of action and learning from negative reward prediction errors, driving progressive avoidance learning. This combination of mechanisms – with additional interactive effects across ventral and dorsal striatum – provides a recipe for learned avolition and generation of negative symptoms. Most empirical studies focus on either the motivational or instrumental learning components of striatal dopamine function, in some cases confounding the two. We have developed a behavioral paradigm that allows us to separately assess approach/avoidance instrumental learning vs. motivation to engage in the task. Mice are cued to lick in response to the light cue that signals water availability at a single spout. 2-3.5 seconds later, one of two auditory tone cues (4KHz or 11KHz) predicts a switch in tastant delivery from water to either sucrose or quinine at the same spout. Motivation is assessed by response rate to the cue light, whereas instrumental learning is assessed by changes in responding as a function of auditory tone. Control mice (n=3) exhibited distinct responses to the two tones by day 6 (suppression for quinine-paired tone and continuation of licking for the sucrose paired tone), achieving maximum performance at 14 days. Motivation increases across days as indicated by increased trial initiation. We find that haloperidol (n=2 mice, 0.15 mg/kg) and D2 antagonist eticlopride (n=1, 0.16 mg/kg) caused learned lack of motivation while also blocking instrumental learning in response to tones, indicating a dissociation that does not simply amount to reduced behavioral output. Further, this altered behavior persists after drug exposure has ceased. Computational simulations provide alternative testable hypotheses for the mechanisms underlying these effects.

Title: The effects of acute cocaine administration on striatal monoamine levels in obesity-prone rats

Authors: *P. J. VOLLBRECHT[1], O. S. MABROUK[2], A. D. NELSON[1], R. T. KENNEDY[3], C. R. FERRARIO[1];
[1]Pharmacol., [2]Pharmcology, Chem., [3]Medicinal Chem., Univ. of Michigan, Ann Arbor, MI

Abstract: The current obesity epidemic has hastened the need to understand the neural mechanisms that contribute to over-eating and weight gain. Recent work has emphasized the importance of the mesolimbic reward pathway in aberrant eating behaviors. Enhanced striatal activation is linked to stronger food craving, greater food consumption, and difficulty losing weight in obese people. In addition, decreased striatal D2 receptor binding has been found in obese people, and consumption of fatty foods decreases D2R mRNA expression in rats. However, it is unclear to what extent pre-existing differences in striatal function may contribute. Here, we examined differences in cocaine-evoked locomotion and neurotransmitter levels in the ventral striatum of obesity-prone and -resistant rats without diet manipulation. In addition, sensitivity to the D2R agonist quinpirole was determined prior to and after exposure to a "junk-food" diet. We used microdialysis coupled with LC-MS and utilized a benzoyl chloride derivitization technique to isolate multiple neurochemicals in a single sample with high temporal resolution (3 minutes/sample). Specifically, basal and cocaine-evoked levels of monoamine neurotransmitters (dopamine, norepinephrine, and serotonin), their metabolites, as well as glutamate, GABA, acetylcholine, histamine, glutamine, glycine, aspartate, taurine, serine, adenosine, phenylalanine, glucose, and tyrosine in the ventral striatum were measured alongside locomotor activity. In addition, the inclusion of stable-radiolabeled isotopes also allowed us to calculate basal concentrations of dopamine and glutamate. Basal concentrations of monoamine neurotransmitters did not differ between groups. Consistent with our previous results, cocaine produced a stronger locomotor response in obesity-prone vs. obesity-resistant rats. Cocaine

increased dopamine and serotonin levels similarly in both groups, but resulted in elevations in norepinephrine only in obesity-prone rats. Ongoing studies are examining differences in sensitivity to NET selective blockers. Enhanced cocaine-induced locomotion in obesity-prone rats may be mediated by differences in post-synaptic transmission. Consistent with this, obesity-prone rats were less sensitive to quinpirole. This response was further suppressed by "junk-food" exposure in obesity-prone rats, whereas "junk-food" had less pronounced effects on quinpirole sensitivity in obesity-resistant rats. Together our data show that there are both pre-existing and diet-induced alterations in striatal systems of obesity-prone rats that are distinct from those found in their obesity-resistant counterparts.

Title: Direct inhibition of ventral tegmental area dopamine neurons decreases reward-seeking behavior

Authors: R. VAN ZESSEN[1], G. VAN DER PLASSE[1], *G. M. RAMAKERS[2], G. D. STUBER[3], R. A. H. ADAN[1];
[1]Translational Neurosci., [2]Brain Ctr. Rudolf Magnus, UMC Utrecht, Utrecht, Netherlands; [3]Psychiatry & Cell Biology. and Physiol., Univ. of North Carolina, Chapel Hill, NC

Abstract: Ventral Tegmental Area (VTA) dopaminergic (DA) neuronal activity plays an important role in behavioral responses to food rewards as well as the environmental cues that predict them. Over the last few years, *in vivo* optogenetic approaches have provided important insights into the involvement of VTA DA neurons during behavior. It has been established that activation of VTA DA neurons promotes behavioral activation and acts reinforcing. In direct contrast, long-term inactivation of these same neurons evokes an aversive phenotype. Although it has also been clearly established that the activity of these neurons encodes a reward-prediction error that is instrumental for associative learning, it has not been directly assessed whether this signal is necessary for reward-seeking behavior. Therefore, we used an *in vivo* optogenetic

approach to manipulate VTA DA neurons in freely moving mice during this behavior. Mice were trained on a cue-reward seeking task, where a five second cue predicted the delivery of a sucrose reward. We then inhibited the activity of VTA DA neurons during cue presentation and during reward retrieval, and found decreases in anticipatory and consumatory responses. In control experiments licking-related locomotor behavior remained unimpaired. We conclude that direct inhibition of VTA DA neurons decreases behavioral performance on cue-reward seeking tasks. We are now exploring the dynamics of associative learning and the specificity of this performance decrease.

Title: Functional dissociation between rat midbrain dopamine neuron subpopulations in the regulation of locomotor activity

Authors: L. BOEKHOUDT, A. OMRANI, E. C. WIJBRANS, M. C. M. LUIJENDIJK, I. G. WOLTERINK, *G. VAN DER PLASSE, R. A. H. ADAN;
Brain Ctr. Rudolf Magnus, Utrecht, Netherlands

Abstract: Midbrain dopamine neurons are involved in the regulation of various behaviours, ranging from locomotion and reward learning to cognitive functioning. Dysregulation of the dopamine system is associated with a variety of psychopathologies, including addiction, schizophrenia, and attention deficit/hyperactivity disorder (ADHD). However, it remains unknown if, and how, activity of midbrain dopamine neurons is directly linked to the expression of psychiatric symptoms, such as hyperactivity in ADHD. Furthermore, it is currently unidentified how the two main subpopulations of midbrain dopamine neurons, i.e. the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc), are involved in the regulation of hyperactivity. In this study, we used designer receptors exclusively activated by designer drugs (DREADD) to selectively activate midbrain dopamine neurons in either VTA or SNc, and measured the effects on home cage locomotor activity in TH::Cre rats. Activation of both

subpopulations significantly increased locomotor activity. However, whereas chemogenetic activation of SNc dopamine neurons only modestly increased locomotor activity, activation of VTA dopamine neurons induced a pronounced hyperactive phenotype. Pathway specific neuronal activation showed that, although VTA neurons projected to both the ventral and dorsomedial striatum, hyperactivity was primarily caused by VTA projections to the nucleus accumbens. In addition to hyperactivity, we also observed a disturbed feeding pattern following activation of VTA, but not SNc, dopamine neurons. These results show a clear functional dissociation between virally targeted subregions of the dopaminergic midbrain in rats, and suggest that specifically VTA dopamine neurons that project to the nucleus accumbens are involved in the regulation of hyperactive locomotion. Here we show that DREADD technology can be used to effectively manipulate dopamine specific or pathway specific neuronal subpopulations in the rat midbrain, and thereby gain insights into the dopaminergic circuitries that are involved in the regulation of behaviour, and, potentially, psychiatric symptoms.

Abstract: Background: Understanding of stimulant drug molecular action is mostly limited to animal models due to restricted timely access to relevant neural cells in humans, precluding a focus on the molecular correlates of clinical response to the drug. Methods: Drug naive children with Attention Deficit Hyperactivity Disorder (ADHD) underwent a computerized prospective assessment of medication treatment response. Prospectively documented clinical response was correlated with blood mononuclear cell (BMC) transcriptional changes before and after acute (2 hours) and sub acute (2 weeks) MPH exposure. Results: MPH induced BMC transcriptional alterations correlated with clinical response patterns, implicating molecular targets which may point to mechanistically relevant constructs. Conclusions: Prospectively quantified MPH induced improvements in sustained attention and commission errors reveal coincident short term surrogate mononuclear cell transcriptional reactivity which may point to selective underlying molecular targets of MPH response.

Title: Repeated toluene exposure does not increase activation of dopaminergic cells in the nigrostriatal pathway of adolescent mice

Authors: *J. N. LOMBARDO, S. E. BOWEN, M. L. TOMASZYCKI;
Psychology, Wayne State Univ., Detroit, MI

Abstract: Toluene, an industrial chemical found in many consumer products, is often abused for its intoxicating properties. While the neurobehavioral effects of toluene have been well studied, the mechanisms by which abused inhalants exert these effects are not well understood. Since toluene has been shown to act on catecholaminergic cells within the basal ganglia, one area of particular interest is the nigrostriatal pathway. In the present study, adolescent outbred mice (Swiss-Webster; N = 32) were exposed to 0, 1000, 2000, and 4000 ppm toluene for 30 minutes per day for seven consecutive days, after which the animals were sacrificed and brain tissue was collected. The caudate-putamen (CPu) and substantia nigra pars compacta (SNc) were then double-labeled for tyrosine hydroxylase (TH; an enzyme for dopamine synthesis) and c-Fos (a

proxy of neural activity). While none of the toluene exposures resulted in changes in c-Fos or TH expression within the SNc, the highest toluene exposure of 4000 ppm toluene increased the number of cells immunopositive for c-Fos, but not c-Fos + TH, within the CPu. Taken together, these results suggest that the neurobehavioral effects of toluene are exerted through a mechanism other than the dopaminergic nigrostriatal pathway.

Abstract: Sensory processing in the vertebrate olfactory system begins with the generation of an odor-specific pattern of glomerular activation across the surface of the main olfactory bulb (MOB). Within each glomerulus, periglomerular cells (PGCs) modulate sensory input by inhibiting sensory axon terminals, glutamatergic external tufted cells (ETCs), and the apical dendrites of principal mitral and tufted cells (M/TCs). Here, we characterize a novel circuit capable of tuning MOB sensory input by regulating interglomerular PGC activity. Specifically, we identify a class of glomerular layer-projecting deep short-axon cells (GL-dSACs) that selectively express nicotinic acetylcholine receptor subunit α2 (*chrna2*) and synaptically inhibit PGCs across multiple glomeruli. Using transgenic Chrna2-Cre mice, we show that GL-dSACs have large somata (mean diameter: 17.0 ± 1.2 μm, μ ± σ, n=6), extend 4.5 ± 1.6 (n=6) dendrites

≤200 μm within the internal plexiform layer (IPL), and project axons through the external plexiform layer (EPL) to arborize across multiple glomeruli. GL-dSACs are immunonegative for markers of EPL-projecting dSACs, and ~50% of Chrna2-Cre-labeled GL-dSACs exhibit strong $GABA_AR\alpha1$ expression. Strikingly, all glomeruli exhibit profuse innervation by GL-dSAC axons that are immunonegative for tyrosine hydroxylase, identifying GL-dSACs as a neurochemically distinct subpopulation of MOB interneurons capable of profoundly influencing glomerular activation. Consistent with such a role, optogenetic activation of GL-dSACs in acute slices bathed in NBQX and AP5 evokes monosynaptic inhibitory postsynaptic currents in PGCs. At rest, GL-dSACs exhibit highly regular spontaneous firing in both whole-cell (8.3 ± 5.6 Hz, n=33) and cell-attached recordings that is independent of spontaneous synaptic activity (5.2 ± 5.2 Hz vs. 6.5 ± 6.3 Hz, pre- vs. post-NBQX/AP5/gabazine application, n=10; p=0.12, paired t-test). Stimulation of sensory axons within individual glomeruli reliably evokes strong (200-800 pA), short-latency (4-7 ms), and short-duration (~15 ms) excitatory postsynaptic currents in GL-dSACs that trigger 1-2 action potentials and reset the spontaneous firing phase. This excitation is reliably recruited at stimulation intensities subthreshold for MC activation, suggesting that sensory input to the MOB evokes high-fidelity disynaptic excitation of GL-dSACs via ETC collaterals in the IPL. Collectively, our results thus support a model in which GL-dSACs provide rhythmic multi-glomerular disinhibitory feedback and are strategically positioned deep within the MOB to potentially integrate both intrabulbar and centrifugal input.
