Abstract: The olfactory bulb is directly connected to cortical areas, allowing an immediate relay of odor inputs for quick and reliable recognition. Its functions presumably requires highly efficient and exquisitely evolved circuits, to ensure that the information conveyed by the olfactory receptor neurons (ORNs) is cleaned and organized before it reaches the olfactory cortex. The glomerular (GL) and external plexiform (EPL) layers appear to be crucial locations to implement these functions, but their relative role is not yet understood. Using a full scale 3D computational model of the olfactory bulb (Migliore et al., 2014), taking into account several experimental findings for mitral and granule cell interactions, we have explored the basic circuits in the EPL (Migliore et al., 2015), showing the mechanisms for forming one or more glomerular units (a spatially segregated column of granule cell located below a glomerulus and with strong dendrodendritic synapses) in response to a given odor; how and to what extent the glomerular units interfere or interact with each other during learning; their computational role within the olfactory bulb microcircuit; and how their action can be formalized into a theoretical framework in which the olfactory bulb can be considered to contain “odor operators” unique to each individual. Here, we study the relative role for information processing in the olfactory bulb of 1) the inter- and intra-glomerular circuits, modulating olfactory sensory neuron inputs through the combined action of tufted and juxtaglomerular cells in the glomerular layer, and 2) the external plexiform layer circuits, acting on the output stage of the olfactory bulb through the interaction between granule and mitral cell. We found that glomerular level circuits are instrumental in transforming a potentially complex and disorganized sensory input into a contrast enhanced and normalized version, dynamically optimized to be processed and organized by the EPL circuits in terms of glomerular units that could be characteristically associated with individual odorants; EPL circuits further simplify and structure synchronized ensemble of mitral cells that appear to be optimized to code for input odors identity and concentration. This layered organization is especially important for natural odor inputs, which activate many overlapping glomeruli.

Title: Subthreshold oscillations, synchronization, and transitions between rhythms in an olfactory model

Authors: A. KARAMCHANDANI, J. N. GRAHAM, H. MENG, *H. RIECKE;
Engg. Sci. & Applied Mathematics, Northwestern Univ., Evanston, IL

Abstract: LFP recordings from the rat olfactory system show activity in β- or γ-bands (15-40 Hz and 50-100 Hz, respectively) following odor presentation. The faster γ-rhythm is generated within the olfactory bulb alone by the interplay of mitral/tufted and granule cells, while the slower β-rhythm requires the interconnectivity of the bulb with piriform cortex, most likely involving pyramidal cells. We aim to elucidate these two rhythms focusing on the role of the characteristic sub-threshold oscillations (STOs) exhibited by the mitral/tufted cells and of the two recurrent pathways involved, one within the bulb and one that also involves cortex. To investigate the role of the STOs and the dual recurrent pathways we introduce a minimal model in which the interactions between the three populations is reduced to an effective inhibitory pulse-coupling within a single population of mitral/tufted cells. The dual pathways are modeled with two types of pulses differing in their delays. The STOs arise from persistent sodium and slow potassium currents included in the Hodgkin-Huxley model. For weak coupling we reduce the system to a stochastic phase model in which the STOs are reflected in the complex interaction between the phase oscillators. For large networks with all-to-all coupling, further reduction leads to a population description in terms of a non-linear Fokker-Planck equation. We find various states differing in the clustering of the oscillator phases. For long delays, corresponding to the cortical pathway, a one-cluster state, representing nearly synchronized oscillators, dominates. For shorter delays, reflecting the intra-bulbar pathway, only states with multiple clusters and higher frequency of the population rhythm arise, resembling a γ-rhythm. In contrast to the PING mechanism for the γ-rhythm of simply spiking excitatory and inhibitory cells, where the population frequency decreases continuously with increasing propagation delay, in our model changes in the delay induce discrete transitions between the different rhythms and the population frequency of the rhythms can increase with increasing delay. We compare these theoretical results with direct numerical simulations of the single-population, spiking-neuron model, extending the results also to stronger coupling.

Title: Gamma and beta oscillations in the rat olfactory bulb define a cognitive sequence in odor discrimination

Authors: D. E. FREDERICK[1,2], *L. M. KAY[1,2];
[1]Dept. of Psychology, [2]Inst. for Mind and Biol., The Univ. of Chicago, Chicago, IL

Abstract: Gamma and beta oscillations of the local field potential (LFP) in rat and mouse olfactory systems have been associated with odor detection, discrimination and learning across a wide array of behavioral tasks within and across laboratories. Gamma oscillations and their analogs in insect systems are local phenomena, supported by the reciprocal dendrodendritic synapse between olfactory bulb (OB) granule cells and mitral/tufted cells, have been associated with discrimination of similar odors across phyla (specifically, rodents and insects). Beta oscillations require intact centrifugal input to the OB and have been linked to learning in go/no-go (GNG) tasks, and gamma oscillations have been identified as the predominant feature in a 2-alternative choice task. We tested the hypothesis that the different tasks engage either gamma or beta oscillations in rats trained in parallel to do either or both tasks. We used many different odor sets that span several orders of magnitude in theoretical vapor pressure and degrees of similarity between components to be discriminated. We show that both gamma and beta oscillations are represented in both tasks. Gamma oscillations dominate in the first 2-3 sniffs after the rat begins odor sampling, and beta oscillations begin after 200 msec of odor sampling. If rats do not sniff long enough to engage the beta oscillation mode, their performance on odor discrimination is above chance. If they sample longer, their performance improves. We falsify our hypothesis and show that task differences are a matter of degree, with oscillations of all types stronger in the GNG task during odor sampling. We also show that very fast OB gamma oscillations (~90 Hz), presumed to be associated with tufted cells, dominate early in odor sampling (first 2-3 sniffs), and that lower frequency gamma oscillations (~70 Hz), presumed to be associated with mitral cells, dominate during the later part of odor sampling (>200 msec of odor sampling). These results, combined with earlier results, suggest that this early olfactory processing network is strongly modulated by the context of the odor discrimination and the manner in which the animals are trained. However, we also show that gamma and beta oscillations, when they are

present, maintain a stable temporal relationship to odor sampling behavior and identify early and late cognitive processes in odor discrimination and identification.

Title: Granule cell excitability mediates gamma and beta oscillations in a model of the dendrodendritic microcircuit

Authors: *B. L. OSINSKI, L. M. KAY;
Inst. for Mind and Biol., Univ. of Chicago, Chicago, IL

Abstract: Odors evoke gamma (60 - 100 Hz) and beta (20 - 30 Hz) oscillations in the local field potential (LFP) of the rat olfactory bulb (OB). These oscillations arise from activity in the dendrodendritic microcircuit between excitatory mitral cells (MCs) and inhibitory granule cells (GCs). When cortical feedback inputs to the OB are blocked, beta oscillations are extinguished while gamma oscillations persist. Much of this cortical feedback targets inhibitory interneurons in the GC layer and regulates the excitability of GCs, which suggests a causal link between the emergence of beta oscillations and the GC excitability. GC dendritic spines are known to express N-methyl-D-aspartate receptors (NMDARs) and voltage-dependent calcium channels (VDCCs), both of which are sensitive to changes in GC excitability and can mediate graded inhibition onto MCs. In a biophysical model of the MC-GC dendrodendritic network we investigate how the network oscillations driven by NMDAR and VDCC mediated graded inhibition of MCs depend on GC excitability. When GC excitability is low, there is transient activation of NMDARs and VDCCs by AMPARs, which produces fast inhibitory pulses in the gamma frequency range. When GC excitability is increased, the activation of NMDARs and VDCCs is prolonged, allowing the slow decay time constants of these channels to drive beta frequency oscillations. While both NMDARs and VDCCs can drive gamma and beta oscillations, the power of beta oscillations is much higher when VDCCs alone are used. This suggests that the high power beta oscillations that have been experimentally recorded are more dependent on calcium flow through VDCCs than NMDARs.

Title: Hyperpolarization-activated currents and subthreshold resonance in granule cells of the olfactory bulb

Authors: *R. HU[1,2], K. A. FERGUSON[3], C. B. WHITEUS[3], D. H. MEIJER[3], R. C. ARANEDA[1,2];

Abstract: In sensory systems, neural circuits exhibit oscillatory dynamics driven by sensory input, extrinsic regulation, and intrinsic circuit properties. Activation and inactivation of currents, such as hyperpolarization-activated currents (I_h), are involved in generating membrane potential oscillations in neurons and contribute to network oscillatory dynamics. In the olfactory system, initial processing of odor signals occurs in the olfactory bulb (OB) and an important aspect of this processing, network synchrony, arises from the activity of reciprocal synapses between output neurons, the mitral and tufted cells (MCs herein), and inhibitory interneurons, the granule cells (GCs). Interestingly, MCs exhibit varying expression of I_h, suggesting a contribution of this current to the fidelity of information coding by MCs. In contrast, the presence of I_h in the GC population is poorly characterized. Here, using patch-clamp recordings, we show that GCs in the main OB (MOB) and accessory OB (AOB) exhibit I_h. Although maximal current for I_h varied across cells, voltage dependency was consistent in both regions (MOB: V_{half} = -105 ± 4 mV, n = 7; AOB: V_{half} = -99 ± 3 mV, n = 9). In addition, I_h in AOB and MOB GCs showed a similar sensitivity to changes in extracellular K^+ concentration, and blockage by ZD-7288 (30μM). However, loading the intracellular pipette solution with cAMP (500μM) shifted the activation curve of I_h to less negative potentials in GCs in the MOB, but not the AOB (MOB: V_{half} = -94 ± 3 mV, n =8; AOB: V_{half} = -96 ± 4 mV, n = 6). When applying the standard impedance amplitude (ZAP) protocol, we found heterogeneity across AOB and MOB

GCs in subthreshold resonance properties, with resonant cells (16/42 GCs) having resonant frequencies in the delta (1-4Hz) range. This subthreshold resonance phenotype is mediated by I_h and can be abolished by application of ZD7288. When comparing resonant and non-resonant GCs, resonant neurons tend to have lower input resistance (resonant cell mean input resistance = 1.04 ± 0.10 GΩ, non-resonant cell mean input resistance = 1.58 ± 0.15 GΩ) and larger I_h (resonant cell mean I_{max} = -176 ± 26 pA, non-resonant cell mean I_{max} = -103 ± 21 pA). These results suggest the expression of I_h and subthreshold resonance in GCs may impart unique features to odor processing in the OB and facilitate oscillatory dynamics in both the main olfactory and Vomeronasal systems.

Title: Inhibition of granule cells by adult born neurons in the olfactory bulb

Authors: P. S. VILLAR[1], A. NUNEZ-PARRA[2], K. KRAHE[1], C. EBERLY[1], *R. C. ARANEDA[1];
[1]Univ. of Maryland, College Park, MD; [2]Anschutz Med. Ctr., Univ. of Colorado, Denver, CO

Abstract: In the adult brain, thousands of newly born neurons arrive every day into the olfactory bulb (OB). These adult born inhibitory neurons, mostly granule cells (GCs), produce a continuous remodeling of the pre-existing circuits forming new synapses with other inhibitory neurons and with the main output neurons of the OB, the mitral cells (MCs). In the adults, the accessory olfactory system plays a crucial role in the expression of behaviors such as aggression and mating. Here we study the properties and functional role of newly form inhibitory synapses generated by the postnatal arrival of interneurons into in the adult accessory olfactory bulb circuit. Under voltage clamp and using low Cl internal solution GCs exhibited a low occurrence of spontaneous inhibitory postsynaptic currents (sIPSCs) (0.31 ± 0.08 Hz; n=12). In the presence of glutamate receptor blockers (APV, 100 µM; CNQX, 10 µM; LY357385 100 µM) and TTX (1 µM) the frequency of IPSCs (mIPSCs) was not significantly different (0.25± 0.04 Hz; n=12;

p>0.05). The sIPSCs were completely abolished in the presence of the GABAA receptor blocker Gabazine (10 μM). Adult born inhibitory neurons were labeled using injections of a flexed channelrhodopsin (ChR) virus in the rostral migratory stream of GAD2-Cre mice. Thirty days post-injection, LED stimulation (LEDStim) of ChR expressing neurons produced a consistent inhibition on MC's firing (control, 4.2 ± 0.8 Hz; LEDStim, 1.2 ± 0.5 Hz; n=6; P< 0.02) indicating functional integration of GCs. Under voltage-clamp, minimal LEDStim produced large evoked inhibitory postsynaptic currents (eIPSCs) in GCs (117.3 ± 15.9 pA) with a fast rise time (1.3 ± 0.0 ms) and slow decay (50.4 ± 0.0 ms). We further characterized the strength of these synapses using paired pulse LEDStim. Under control conditions the paired pulse ratio (PPR) was 0.44 ± 0.07, (n=6) and this value was increased by decreasing the extracellular Ca2+ concentration from 2 to 0.5 mM (PPR 2.2 ± 0.4). Together these results suggest that GABA release at these synapses exhibited depression. Furthermore, activation of the metabotropic GABABR with baclofen (50 μM) decreased the eIPSC amplitude (control 117.3 ± 15.9 pA; baclofen, 28 ± 4 pA) and also increased the PPR (2.2 ± 0.1; n=2). Similarly, baclofen significantly reduced the frequency of sIPSC (control 0.29 ± 0.05 Hz; baclofen 0.16 ± 0.026 Hz; p<0.002; n=6) and mIPSCs (control, 0.18 ± 0.01 Hz; 0.10 ± 0.01 Hz; p<0.02; n=6). Together these results suggest a high probability of GABA release at these synapses and a presynaptic regulation mediated by GABAB receptors.

Title: OPHN1 regulates the migration of newly generated cells in the olfactory system

Authors: A. MASET[1], L. GALLA[1], *C. LODOVICHI[2];
[1]Venetian Inst. of Mol. Med., Padova, Italy; [2]Neurosci. Inst. CNR, Neurosci. Inst. CNR and Fondazione Ricerca, Padova, Italy

Abstract: Oligophrenin1 (OPHN1), a X-linked gene associated to intellectual disability, encodes a Rho-GTPase activating protein that plays a role in the conformational rearrangements of actin

stress fibers involved in several developmental processes including axon outgrowth, dendritic maturation and cell migration. How these cellular events can affect neuronal wiring and information processing, leading to cognitive disabilities, remain to be understood. To address these questions we analyzed circuit formation and function in the olfactory system (OS) of OPHN1 ko mice. The OS is one of the few neurogenic niches in the adult mammalian brain. Everyday thousands of new neurons generated in the subventricular zone (SVZ) migrate through the rostral migratory stream (RMS) to reach the olfactory bulb (OB) where they become mature interneurons, i.e. granule cells (GCs). Using bromodeoxyuridine (BrdU), as a cell division marker we found that the number of new cells generated in the SVZ was similar in control and OPHN1 ko mice, 24 hours post injection. However the amount of new cells that reached the OB was significantly reduced in of OPHN1 ko mice, 15 days after BrdU injection. To assess whether mutation in OPHN1 could affect the migration of the new cells, we analyzed the migration process from the SVZ to the OB, in sagittal sections of the brain using double cortin (DCX), a marker of neuronal precursors and BrdU. We found that the spatial organization of neuronal precursors around the SVZ and along the RMS was deeply perturbed in OPHN1 ko mice. The new cells were not arrange in chains but tended to coalesce in clumps. Using lentiviral expressing GFP and immunostaining for DCX, we found that both the polarity and the direction of migration of the cells were strikingly disrupted in OPHN1 ko mice, respect to controls. All together our data demonstrated that the migration of adult generated cells is deeply affected in OPHN1 ko mice, resulting in a strikingly reduction of new GCs in the OB of OPHN1 ko mice. We are currently investigating how such a strikingly reduction in adult generated interneurons can affect circuit function in the olfactory bulb.

Title: Distinct physiological properties of mature adult-born neurons in the olfactory bulb of awake mice

Authors: N. FOMIN, S. FINK, Y. KOVALCHUK, Y. LIANG, *O. GARASCHUK;
Univ. of Tübingen, Physiol. 2, Tübingen, Germany

Abstract: Mammalian olfactory bulb (OB) is continuously supplied with adult-born neurons (ABCs). *In vivo* cell-attached recordings in anesthetized mice suggest that ABCs acquire odor response properties similar to that of resident cells (RCs) by 8-9 weeks of age. The odor response properties of these cells in awake animals as well as their spiking properties at rest remain, however, unclear. Here we use *in vivo* two-photon calcium imaging to study the properties of mature ABCs (mABCs, 8-19-week-old) in awake, head-restrained mice. We labeled the cells with the ratiometric FRET-based Ca2+-indicator Twitch-2B. To label mABCs, the indicator was injected into the RMS of 2-6-month-old mice, whereas RCs were labeled by direct injections into the OB of 3-4-week-old mice. In awake mice mABC's YFP/CFP ratios, which are proportional to basal Ca2+-levels, ranged from 1.7 to 5.9 (median: 2.7, interquartile range (IQR): 2.3-3.3; n=68 cells in 5 mice). Blocking action potential firing with tetrodotoxin reduced the ratios below 2, suggesting that cells with ratios above 2 (here, 93% of all mABCs) are continuously spiking. In contrast, 100% of RCs (more than 25-39-week-old) were continuously spiking in awake mice. Moreover, RCs had significantly higher YFP/CFP ratios (median: 3.6, IQR: 3.0-4.1, n=140 cells in 5 mice), indicative of the higher spiking frequencies of these cells. Odor stimulation (ethyl-tiglate, 1.67% of saturated vapor) evoked larger responses in mABCs (median amplitude: 168.13, IQR: 118.94-270.38 % ΔR/R) compared to RCs (median amplitude: 107.58, IQR: 80.03-165.74 % ΔR/R). The response variability (coefficient of variation) was significantly higher for mABCs compared to RCs. Under anesthesia, the median basal YFP/CFP ratio dropped significantly in both groups of cells (mABCs: 1.9, IQR: 1.8-2.2; RCs: 3.0, IQR: 2.5-3.6), but the fraction of continuously spiking RCs remained unchanged (98%). In contrast, we observed a significant reduction in the fraction of continuously spiking mABCs (from 93% in awake to 53% in anesthetized mice). In addition, anesthesia caused a significant increase in the median response amplitude (mABCs: 265.07, IQR: 140.02-360.85 % ΔR/R; RCs: 134.96, IQR: 90.96-174.17 % ΔR/R) and a significant decrease in the response variability for both groups of cells. Thus, long after the integration of mABCs into the OB network they still can be distinguished from RCs based on 1) lower basal Ca2+-levels and lower fraction of spiking cells, 2) higher amplitudes of odor-evoked responses 3) higher response variability in awake state and 4) a significant decrease in the fraction of continuously spiking cells under the anesthesia.

Title: Noradrenergic modulation of information processing in the male accessory olfactory bulb

Authors: *W. I. DOYLE[1,2], J. P. MEEKS[1,2];
[2]Dept. of Neurosci., [1]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: In many terrestrial mammals, the accessory olfactory system (AOS) is an olfactory system involved in the sensing and interpretation of non-volatile odorants. The first site of information processing in the AOS is the accessory olfactory bulb (AOB), a small brain region that processes incoming sensory signals from the vomeronasal organ and is also innervated by centrifugal fibers originating in the locus coeruleus. Noradrenaline (NA) is released from these projections, and is hypothesized to play important roles in AOB function. In this study we have examined the effects of NA on information processing by AOB principal neurons in *ex vivo* preparations of the male C57BL/6 and B6D2F1 AOS. This preparation allows us to study the actions of NA in the AOB in the context of carefully controlled peripheral vomeronasal stimulation with odorants. We measured neuronal responses to various vomeronasal odorants before, during, and after application of 10 μM NA. We observed many neurons that underwent significant odorant suppression following NA administration. Significant suppression was seen in responses to 7/19 (37%) of stimuli during NA application, compared to 2/17 (12%) of stimulus responses during vehicle controls ($p < 0.01$). This selective increase in the frequency of observed odorant response suppression indicates that NA-mediated inhibition does not result in global inhibition. Further support for this conclusion was gleaned from measurements of spontaneous spiking activity, which was not significantly decreased following NA application. Overall, these data suggest that NA may not act as a global source of activity suppression in the AOB, but instead may have more subtle and nuanced actions on information processing.

Title: Imaging olfactory bulb plasticity during olfactory experience

Authors: *M. W. CHU, T. KOMIYAMA;
Biol. Sci., UCSD, La Jolla, CA

Abstract: Recent studies suggest an intriguing role for the olfactory bulb as more than just a relay station from the nose to the brain: it is a place where the early processing of odor information can be modulated by experience, behavioral state and odor context, which in turn, affects olfactory perception. Here, we explore long-term changes in mitral cell odor representations in mice during two types of olfactory experience which have been shown to result in perceptual learning: passive experience, where mice are passively and repeatedly exposed to two very similar odors, and active learning, where mice are engaged in a task to discriminate between the same, two similar odors. The activity of mitral cell populations are monitored over days of these experience paradigms in awake mice using chronic 2-photon calcium imaging (Kato et al., 2012). During both types of experience, we observe a gradual sparsening in mitral cell odor responses to both odors. Furthermore, experience leads to an enhancement in the discriminability the experienced odors by mitral cell ensembles, and this enhancement is more pronounced with active learning compared to passive exposure. These results support the olfactory bulb as an important locus for olfactory perceptual learning.

Title: Neuronal mechanisms underlying mating-induced pheromonal memory in the female mouse

Authors: *Y. GAO, C. H. BUDLONG, I. G. DAVISON;
Biol., Boston Univ., Boston, MA

Abstract: Social interactions are often the source of powerful and enduring memories. In female mice, reproductive encounters drive long-lasting chemosensory imprinting in the accessory olfactory bulb (AOB), altering neural and endocrine responses to the stud male's pheromones. While changes in inhibition are strongly implicated, direct synaptic measurements of AOB plasticity remain lacking. We used whole cell recordings in acute brain slices from recently mated females to examine how mating affects inhibitory microcircuits in the AOB. Spontaneous GABA release onto AOB mitral cells (MCs) was nearly two-fold higher than in sensory-exposed or naïve controls. Mating also modulated synaptic input to AOB interneurons, increasing both the amplitude and frequency of excitatory potentials in granule cells (GCs), the presumed source of MC self-inhibition. Unexpectedly, we found that mating also strongly affected neural excitability, depolarizing GC resting membrane potential by nearly 10 mV. Finally, we tested how the firing of AOB output neurons is affected by reproductive experience. In mated females, many MCs showed strongly reduced firing when tested with repetitive stimulation to mimic repeated behavioral encounters. To investigate how plasticity correlates with neurons encoding stud male pheromones, we made targeted recordings of MCs using activity-dependent GFP labeling. Mating drove robust Fos-GFP expression in a restricted subset of MCs, whose firing rates progressively decreased to less than half that of unlabeled cells, whose responses remained stable. Taken together, our data suggest that pheromonal learning dynamically regulates the output of specific groups of AOB MCs in a way that depends on cumulative past activity. Both synaptic and intrinsic plasticity are likely to underlie mating-induced memory formation.

Title: Functional plasticity in the mouse olfactory bulb following motherhood

Authors: Y. SHLOMAI[1], A. VINOGRAD[1], D. MUKHERJEE[1], G. YUAN[2], A. CITRI[1], I. DAVISON[2], *A. MIZRAHI[1];
[1]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]Boston Univ., Boston, MA

Abstract: Motherhood is a dramatic event common across the mammalian line of descent. Motherhood is accompanied by new maternal behaviors aimed at insuring the wellbeing and survival of the offspring. Maternal behaviors are most likely associated with how specific neuronal circuits process information, but these are not well characterized. Here, we studied the functional changes in the olfactory system in mothers, focusing on the main olfactory bulb (OB) of mice. Using *in vivo* two-photon calcium imaging we show that the output of mitral cells (MCs) becomes sparse in mothers resulting in increased odor selectivity. MCs in mothers also show increased delayed temporal patterns of response. Gene profiling and slice electrophysiology show that maternal changes in MCs result from an increased inhibitory drive. To track the mechanism of circuit changes we tested two interneuron populations, parvalbumin expressing (PV) and dopaminergic interneurons. PV-expressing inhibitory interneurons but not dopaminergic neurons show more odor-evoked responses in mothers as compared to virgin mice identifying the PV neurons as a site of plasticity contributing to MCs sparsening. Moreover, MCs changes are long lasting and could be induced, in part, by the mere experience with the pups. The functional plasticity in the OB of mothers provides a novel substrate for understanding odor coding and plasticity during the maternal state.

Title: Ensemble plasticity of odor representation in populations of olfactory bulb output neurons

Authors: *Y. YAMADA[1], K. BHAUKAURALLY[1], I. RODRIGUEZ[2], A. CARLETON[1]; [1]Dept. of Basic Neurosciences, [2]Dept. of Genet. and Evolution, Univ. of Geneva, Geneva, Switzerland

Abstract: In the olfactory system, sensory neurons project their axons in a receptor-specific manner onto olfactory bulb (OB) glomeruli. At this level, sensory neurons release glutamate upon activation and excite OB output neurons (mitral and tufted cells, MCs & TCs, respectively). Odorants are known to recruit a combination of glomeruli, further evoking complex firing patterns in the population of MCs and TCs. While sensory experience can trigger functional plasticity in primary sensory neurons of the olfactory system, it remains unclear whether odor representations in output neurons are plastic. Here we performed chronic two-photon imaging in awake head-fixed mice specifically expressing the genetically encoded calcium indicators GCaMP3/GCaMP6s in MCs and TCs. We monitored fluorescence changes in response to odor applications in individual neurons, and observed either increase or decrease in fluorescence during and after odor application in both populations of output neurons. The decrease of fluorescence is consistent with a decrease of firing rate observed with electrophysiological recordings. Interestingly, repetitive odorant application over several consecutive days altered the odor representation in MCs and TCs of passively exposed animals. We observed weakening in amplitude of both excitatory and inhibitory responses. In summary, our data supports the notion that sensory experience induces ensemble plasticity in OB output neurons. Future experiments will be needed to assess whether similar ensemble plasticity may take place during olfactory discrimination learning tasks.

Title: Plasticity of mitral cell dendritic morphology in the adult zebrafish olfactory bulb following chemical deafferentation

Authors: *J. M. DICKENS, C. A. BYRD-JACOBS;
Western Michigan Univ., Kalamazoo, MI

Abstract: Repeated chemical ablation of the olfactory epithelium of adult zebrafish results in the disruption of afferent input to the olfactory bulb, causing a decrease in bulbar volume. To study this effect on a cellular level, we examined the morphology of mitral cells, the primary output neurons of the olfactory bulb. The dendritic processes and arbors of neurons are complex structures, with both their shape and synaptic connections necessary for the maintenance of neuronal structure and function. Afferent/target interactions that maintain dendritic morphology in the adult brain are not yet well understood. The hypothesis of this study was that chronic treatment of the olfactory organ with the detergent Triton X-100 would decrease the complexity of the dendritic arbors of mitral cells within the olfactory bulb. The olfactory epithelium of male and female adult fish was chronically ablated with Triton X-100 every three days for eight weeks, and mitral cells were identified using retrograde tract tracing with a fluorescent dextran applied to whole brains in culture. Unidendritic mitral cells of olfactory bulbs from unoperated control and Triton X-100-treated fish were imaged using whole-mount confocal microscopy. Dendritic length, number of dendritic tips, and dendritic tuft sizes were analyzed from five mitral cells per olfactory bulb of each fish, with five fish in the control and lesioned groups. Dendritic morphology of deafferented cells was notably affected by loss of afferent input. There was a significant difference between the total branch length of control cells and deafferented cells, with an average total length of 373.0±25.67 μm in control cells and 181.7±8.480 μm in deafferented cells ($P<0.0001$). The length of the longest dendrite of each cell was significantly shorter in deafferented cells (49.84±2.094 μm) compared to control cells (78.34±6.278 μm; $P<0.0001$). There were fewer dendritic tips in deafferented cells (9.120±0.5953) compared to control cells (14.64±0.9414; $P<0.0001$). Dendritic tuft area was significantly decreased in deafferented cells (878.0±66.67 μm^2) compared to control cells (2309±258.6 μm^2; $P<0.0001$). These results are similar to those seen following permanent removal of afferent input. Thus, afferent innervation is critical for maintenance of mitral cell dendritic morphology in the adult zebrafish. This study provides a reversible deafferentation model that will allow for future studies of dendritic plasticity following reinnervation and the potential for recovery of output neurons in the adult brain following loss of sensory input.

Title: Coding of plume dynamics in the insect olfactory system

Authors: *Z. N. ALDWORTH, M. A. STOPFER;
NIH-NICHD, Bethesda, MD

Abstract: Oscillatory synchronous activity among populations of neurons, which has been observed in diverse sensory modalities and animal phyla, has been proposed as a mechanism underlying the sparse firing of neurons. Here we investigate the roles of oscillatory dynamics in generating responses to complex odor plumes. The relatively simple olfactory system of the locust provides a useful model for investigating this mechanism. In the locust antennal lobe, odor-driven reciprocal interactions between excitatory projection neurons (PNs) and inhibitory local neurons organize PN spiking into oscillatory synchrony, and the resulting dense, rhythmic waves of spikes are transmitted to the Kenyon Cells (KCs). The KCs transform this temporally patterned, high spike rate input into a broadly distributed, very sparse format: only a small percentage of the KC population fires in response to an odor stimulus, and responsive KCs fire very few spikes. The extreme sparseness of the KC response is believed to result from two factors, membrane conductances that provide a high firing threshold, and feedback inhibition. Precisely synchronized input from PNs is thought to be necessary to overcome these factors to generate sparse and specific spiking in KCs (Perez-Orive et al, 2002). However, when trains of brief pulses of odorant, like those found in odor plumes, are delivered, some of the highest spike rates in KCs are observed during specific plume features when PN oscillatory synchrony is minimal (Brown et al, 2005). The appearance of these spikes is correlated with two forms of plasticity, sensory adaptation in olfactory receptor neurons (Ito et al, 2009), and facilitatory “fast learning” in the antennal lobe (Stopfer and Laurent, 1999; Bazhenov et al, 2006). We propose that interplay between these forms of plasticity leads to a feed-forward mechanism for driving KC firing in the absence of oscillations, thus encoding certain plume features. To test this we are making intracellular and extracellular recordings from PNs and KCs while delivering temporally varying, plume-like pulses of odor. We analyze these recordings by developing generalized linear models of both populations of neurons. Comparing predicted firing rates of the models while changing plasticity parameters will reveal the extent to which adapting and facilitating mechanisms contribute to the encoding of odor plumes.

Title: Calcium dynamics of antennal lobe local interneurons during olfactory informatiom processing

Authors: *D. FUSCA, A. PIPPOW, P. KLOPPENBURG;
Univ. of Cologne, Biocenter, Cologne, Germany

Abstract: The antennal lobe of insects constitutes the first synaptic relay and processing center of olfactory information, received from olfactory sensory neurons located on the antennae. Complex synaptic connectivity between olfactory neurons of the antennal lobe ultimately determines the spatial and temporal tuning profile of (output) projection neurons to odors. These interactions are mediated by a complex network of inhibitory and excitatory local interneurons (LNs). In the cockroach antennal lobe, we can discriminate two main LN types with distinctive physiological and morphological features: 1) Multiglomerular type I LNs generate sodium driven action potentials upon odor stimulation and exhibit GABA-like immunoreactivity. 2) Type II LNs, in which odor stimulation evokes depolarizations but no sodium driven action potentials do not express voltage dependent transient sodium currents and accordingly do not generate sodium driven action potentials. These LNs are omniglomerular and partly exhibit ChAT-like immunoreactivity (J Neurosci 29(3):716-726 (2009); J Comp Neurol 521(15):3556-3569 (2013)). The distinctive morphological and physiological characteristics of different LN types imply important consequences for their computational properties and the olfactory processing that they perform. Type I LNs expressed differential branching patterns in different glomeruli suggesting a polar organization with defined input and output regions. According to this hypothesis, the synaptic input from a defined receptive field (e.g., one or a few glomeruli) would be integrated into action potential firing that would spread to other innervated glomeruli, and provide a defined array of glomeruli with synaptic input. In this model, glomeruli could interact independently of their distance: not only nearest-neighbor glomeruli could interact, but also glomeruli that are distributed throughout the entire antennal lobe. In contrast, type II LNs have very similar branching patterns in all glomeruli, suggesting that they can receive synaptic input from all innervated glomeruli. However, during odor stimulation, synaptic input will be typically restricted to certain glomeruli, in which graded postsynaptic potentials will be generated. These potentials will spread only within the same glomerulus or to glomeruli that are electrotonically

close to the stimulated glomerulus. To test these hypotheses we combine whole-cell patch clamp recordings and calcium imaging of single local interneurons.

Title: The biogenic amine tyramine and its receptor (AmTyr1) in olfactory neuropils in the honey bee (Apis mellifera) brain

Authors: ***B. OBAYOMI**, I. SINAKEVITCH, B. H. SMITH;
SOLS, Tempe, AZ

Abstract: Biogenic amines are neuroactive compounds that are involved in a large repertoire of invertebrate and vertebrate behaviors including olfactory processing, learning and memory. We used the honey bee as a model to study the functional role and anatomical distribution of tyramine and its receptor in the olfactory network participating in odor processing. The antennal lobe of the honey bee is the anatomical and functional analog of the vertebrate olfactory bulb. The antennal lobe consists of an aglomerular neuropil that is surrounded by 160 glomeruli, where each glomerulus participates in coding a subset of odors. In our previous studies we demonstrated that each glomerulus is divided into two major areas. The cortex receives olfactory receptor inputs from axons of olfactory receptor neurons (ORNs). It contains dendrites of Projection Neurons (PNs), axons of which connect the antennal lobe to higher order processing centers. The core receives axons from local neurons (LNs) that synapse onto PNs (Sinakevitch et al., 2013). Tyramine modulates this network potentially at several points, but their precise anatomical distribution in the network has not been analyzed in detail. The present study is therefore aimed at studying the distribution of tyramine in the antennal lobe and mushroom bodies by using antibodies against tyramine and its receptor with combination of the neurobiotin tracing of neurons that are important components of the network. We found that neurons that express tyramine have particular varicose-like fibers that invade the aglomerular neuropil. We

also found that there are significant differences in the distribution of biogenic amine within a glomerulus. Tyraminergic fibers from VUM neurons are mostly located in the cortex area of glomerulus. The AmTyr1 receptor is located in the ORN processes in the glomerulus cortex. PNs also exhibited AmTyr1 in its ending in the calyces of the mushroom bodies. The distribution of tyramine and its receptor in the antennal lobe suggests that it targets different components of the network in the cortex area of glomerulus (ORNs, PNs or LNs). Our study predicts a complex role of tyramine in odor processing in the insect antennal lobe. The data could be used to unravel the neuroanatomical mechanisms of reward learning in early sensory processing.

Title: Integrate-and-fire and firing-rate models for insect olfaction

Authors: *P. B. PYZZA[1], G. KOVACIC[1], D. CAI[2,3];
[1]Mathematical Sci., Rensselaer Polytechnic Inst., Troy, NY; [2]The Ctr. for Neural Sci., Courant Inst. at New York Univ., New York, NY; [3]Shanghai Jiao Tong Univ., Shanghai, China

Abstract: The functionality of olfaction is known to be shared among a range of phyla from insects to mammals. The locust is an important animal model for studying olfaction. Experiments suggest that odors, detected through receptors on its antennas, are relayed to sensory neurons in the antennal lobe. There, they trigger a series of synchronous oscillations, followed by slow dynamical modulation of their firing rates, which slowly subside after the stimulus has been removed. I model this behavior by using a conductance-based, sparsely-coupled, Integrate-and-Fire neuronal network with fast (~2-5 ms) excitatory and both fast (~4-10 ms) and slow (~30-100 ms) inhibitory conductance responses, driven by Poisson trains of external spikes. The fast inhibitory conductance response, together with the excitation, creates the initial oscillations that are believed to be responsible for the initial detection and brief

identification of the presented odor. The slow component of the inhibitory conductance then damps the oscillations, without completely eliminating them, and aids in the creation of the slow firing rate patterns that follow yet later. The insect is conjectured to identify the odor more precisely from these slow patterns. I have further derived a coarse-grained, firing-rate model that described the overall responses of the excitatory and inhibitory neuronal populations. In the absence of the slow inhibition, the model generates fast network oscillations as seen experimentally and in my numerical simulations. They arise as an attracting limit cycle. In the full model, after the presentation of an odor, the slow inhibition rises slowly, allowing for a period such oscillations, which are then shut off by the high level of inhibition for an extended period of time, before a much slower oscillatory pattern reemerges. This pattern is the result of a balance among the three types of conductances and between the two disparate timescales. I analyze mathematically the bifurcations associated with these changes of the dynamics.

Abstract: The peripheral nervous system (PNS) in the head regions of heterobranch (opisthobranch and pulmonate) molluscs performs computations functionally like those of vertebrate olfactory bulb and pallium. It encodes incentivizing qualities of chemotactile stimuli and their topographic locations, with sensory gain set by homeostatic need. The information is used by the CNS to compute motor decisions in approach-avoidance and feeding, and for learning values of potential prey and their defenses. The PNS in *Pleurobranchaea californica* shows profuse dopaminergic, GABAergic, and serotonergic immunoreactivity, suggesting the neurotransmitters' involvements in sensory computations. We tested effects of neurotransmitters

and pharmacological blockers on the chemotactile oral veil, observing behavioral responses to stimuli and spike discharge in sensory nerves. Topical unilateral application of the D2 blocker sulpiride to the oral veil increased latencies for approach turns to appetitive stimuli and decreased sensory nerve discharge, while appetitive responses were intact on the control side. GABA applied unilaterally caused avoidance responses to appetitive stimuli on that side, while the control side remained positively responsive. The GABA blocker bicuculline caused effects like GABA. But we found that defensive acid secretion (pH ~1.5) was induced by bicuculline but blocked by GABA. Acid secretion raises appetitive thresholds and induces avoidance. Thus, GABA and bicuculline exert similar effects through different pathways. Serotonin applied to the oral veil preparation enhanced sensory nerve discharge to appetitive stimuli. These observations suggest models in which inhibitory D2 receptors and GABA act within serial disinhibitory and recurrent inhibition pathways to provide initial computations of stimulus incentive and somatotopic mapping. Serotonin release in the PNS may regulate sensory pathway gain. As PNS serotonin originates in central neurons of the feeding network, release would be a function of both feeding network activity and hunger state.

Title: Proteomic analysis of chick Nucleus Laminaris reveals potential FMRP substrates

Authors: *H. SAKANO[1], Y. WANG[2], W. S. NOBLE[1], M. J. MACCOSS[1], E. W. RUBEL[1]; [1]Univ. of Washington, Seattle, WA; [2]Florida State Univ., Tallahassee, FL

Abstract: The avian nucleus laminaris (NL) is an auditory nucleus in the brainstem that is structurally similar and functionally analogous to the mammalian medial superior olivary

nucleus (MSO) which is essential for low frequency for binaural processing. In addition, the chick NL is a useful model system for studying activity dependent dendritic plasticity, owing to the bipolar dendritic arbors that receive input from each ear and display rapid, profound and localized structural changes in response to a variety of afferent manipulations. These structural changes in dendrites are expected to involve immediate and local mechanisms such as signaling, protein modification and local translation. However, to date, the proteome of the nucleus laminaris is not known. Here we have identified 657 proteins that are expressed in the nucleus laminaris by using laser microcapture technique and tandem mass spectrometry. Gene ontology analysis reveals that many proteins are involved in mitochondria, translation, metabolism and cytoskeletal remodeling, suggestive of high metabolic demand and remodeling. Comparative analysis reveals 96 proteins that are putative substrates of FMRP (fragile X protein), which raises the possibility that these proteins are locally translated.

Title: Binaural frequency tuning and timing in neurons from the chinchilla medial superior olive

Authors: ***M. SAYLES**, P. X. JORIS;
neurosciences, KU Leuven, Leuven, Belgium

Abstract: Sensitivity to micro-second inter-aural differences in timing of sounds is critical for azimuthal localization. It emerges in specialized neurons in the medial superior olive (MSO). MSO neurons are tuned to a particular inter-aural time difference (ITD); their “best delay” (BD). How neural circuitry creates ITD tuning is a matter of debate. Many hypotheses have been

proposed. Cochlear-tuning disparities leading to neural delays by virtue of cochlear travelling-wave delay ("stereausis") have received little experimental attention in mammals. Difficulties obtaining single-unit recordings from MSO neurons have hampered progress. Previously, our laboratory examined coincidence patterns between auditory-nerve-fiber spike trains from different cochlear locations. Very small inter-aural frequency-tuning disparities accounted for the range and positive (contra-leading) bias in BDs observed experimentally. However, the disparities need to be systematically biased, with ipsi-lateral inputs tuned to higher frequencies than contra-lateral inputs. Here we test the existence of such biased disparities. Using an approach modified from Bremen and Joris (2013), we recorded from ascending MSO axons in the lateral lemniscus (LL) as they project to the dorsal nucleus of the LL (DNLL) and the midbrain, in the anesthetized chinchilla. We presented inter-aurally correlated (+1) and anti-correlated (-1) 20-kHz bandwidth noise at a range of ITDs to construct noise-delay functions. Next, we presented inter-aurally uncorrelated (0) noise, and used spike-triggered reverse correlation to estimate the impulse responses of ipsi- and contra-lateral inputs independently. We cross correlated the impulse responses to predict the noise-delay function. Typically, firing rate as a function of ITD (noise-delay function) shows a damped oscillatory pattern. From the difference between +1 and -1 noise-delay functions, the "difcor", we determined the BD. Most, but not all, BDs were within the π limit, with a bias to positive ITDs. For most units the correlation between predicted and measured noise-delay functions was very good (>0.9). However, in a few units (thought to be DNLL cells receiving MSO inputs), this prediction was poor. We found significant inter-aural frequency-tuning differences (up to 1/3 octave) in many units. These were not systematically biased toward higher-frequency tuning ipsi-laterally. We conclude that frequency tuning (and therefore, timing) disparities exist and contribute to ITD tuning in the mammalian system. However, binaural cochlear disparities in themselves cannot account for the BD distribution observed.

Title: Coincidence detection in the medial superior olive promotes responsivity to low-frequency narrowband sounds

Authors: *T. P. FRANKEN, P. X. JORIS;
KU Leuven, Leuven, Belgium

Abstract: The hearing and vocalization range of large-bodied land mammals, including humans, is geared towards low frequencies. Combined with large heads and widely separated ears, low-frequency hearing enables sound localization based on neural sensitivity to interaural timing differences (ITDs). In contrast, ultrasonic hearing is the rule in small mammals, where the brainstem circuits that process ITDs are minimal or even lacking. Curiously, some rodents are sensitive to low frequencies by virtue of dramatically enlarged middle ear spaces. These species are increasingly used as experimental models of human hearing and indeed have neurons sensitive to low-frequency ITDs. This is puzzling, since their small heads result in minuscule ITDs, which enable only coarse sound localization. We obtained *in vivo* whole-cell recordings in the medial superior olive (MSO) of the Mongolian gerbil under general anesthesia. We recorded sub- and suprathreshold responses to monaural and binaural tones over a range of frequencies, and to noise of differing bandwidths. We find that gerbil MSO neurons are surprisingly sensitive to bandwidth: they are much more responsive to low-frequency tones or narrowband noise than to wideband noise. The rate of subthreshold excitatory postsynaptic potentials (EPSPs) arriving at the neuron does not show the same sensitivity, in contrast to the correlation between EPSPs. Our findings show that the coincidence detection operation performed by MSO neurons boosts the response to low-frequency narrowband sounds. In combination with the presence of specialized bullas which increase sensitivity to low frequencies, this suggests that the MSO circuit has survival value in the detection of low-frequency sounds per se., i.e. a function which is not strictly binaural or spatial.

Title: Do non-dipole features of brainstem field potentials reveal inhibition in the medial superior olive?

Authors: *J. H. GOLDWYN[1], M. MC LAUGHLIN[2], E. VERSCHOOTEN[3], P. X. JORIS[3], J. RINZEL[4];
[1]Mathematics, Ohio State Univ., Columbus, OH; [2]Neurosci., [3]Lab. of Auditory Neurophysiol., Univ. of Leuven, Leuven, Belgium; [4]Courant Inst. of Mathematical Sci. and Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Field potentials are a potentially rich source of data for monitoring neural activity *in vivo*. Ideally, one could infer cell-level dynamics from these population-level extracellular data, but solving this inverse problem is a challenge. In recent studies, we recorded and modeled the prominent, sound-evoked field potentials in the auditory brainstem of cats (the *auditory neurophonic*), of which neurons in the medial superior olive (MSO) are the primary generators (Mc Laughlin et al 2010, Goldwyn et al 2014). Here, we formulate a biophysically-constrained and semi-analytical method for relating these field potential data to MSO activity. We make two contributions: 1) Quantitatively accurate simulations of spatio-temporal patterns of neurophonic responses to pure tones with frequencies ranging from 500 Hz to 2000 Hz, and 2) Inference of waveforms that represent putative (population-averaged) synaptic drive to MSO neurons. In our previous studies, we described the dipole-like spatial profile of the neurophonic and interpreted these data in light of the distinctive physiology and morphology of MSO neurons. In the present work, we describe consistent, frequency-dependent departures from dipole patterns apparent in some recordings in responses to stimulation of the contralateral ear. We propose a parsimonious model to account for our observations: MSO neurons receive dendritic excitation and somatic inhibition and this combination of synaptic inputs – superposition of a dendritic-based dipole and a somatic-based, effective monopole – shapes the neurophonic. We model MSO neurons as a population of passive cables. Model neurons receive a mix of excitatory and inhibitory inputs and cable theory provides the bridge between synaptic inputs, cell-level membrane potential dynamics, and extracellular voltage. We use an optimization algorithm to identify the synaptic inputs that provide the best fit between simulated and *in vivo* field potentials. We propose that the "best fit" model inputs reflect *in vivo* excitation and inhibition and thus provide insight on the elusive connection between field potential recordings and cell-level dynamics. Inhibition in the model creates a monopole-like neurophonic response and has dynamics that are consistent with known *in vitro* properties of inhibition in the MSO. The putative (population-averaged) inhibition in the model is slow relative to excitation and precedes excitation in its cycle-by-cycle

timing. However, alternative interpretations of non-dipole features of the neurophonic are possible.

Title: Adeno-associated viral transfection and optogenetic manipulation of auditory brainstem regions

Authors: ***E. MCCULLAGH**[1], S. MINKOWICZ[2], A. KLUG[1];
[1]Physiol. and Biophysics, Univ. of Colorado Anschutz, Aurora, CO; [2]Florida Gulf Coast Univ., Fort Myers, FL

Abstract: Low-frequency sound localization relies upon the difference in the times at which sound reaches the two ears (interaural time difference; ITD). Depending on the location of the sound source along the azimuth, ITDs are very small for sounds originating from or near the midline, and increase up to several hundred microseconds for sounds originating directly from one of the two sides. Thus, ITDs systematically vary with location along the azimuth, and this cue is extracted and evaluated by the auditory system during the localization process. While the medial superior olive (MSO) is the nucleus performing the actual ITD analysis, both the medial and the lateral nucleus of the trapezoid body (MNTB and LNTB, respectively) project fast and well timed monaural glycinergic inhibition to MSO neurons. Several concepts have been put forward that explain how these inhibitory inputs contribute to ITD processing in mammals. Both the MSO but also the MNTB and LNTB are deep auditory brain stem nuclei, making them difficult targets for optogenetic manipulation. Additionally, the auditory brain stem is heavily myelinated, making it challenging to deliver light to neurons in these nuclei. We have successfully transfected MSO, MNTB and LNTB neurons with inhibitory light-sensitive adeno-associated viruses (both halorhodopsin and ArchT). Once the virus has been expressed in these brain areas, we have shown that we can reduce or eliminate sound-evoked multiunit neural activity with light. Until recently, experimental manipulations that allowed for fast and reversible

activation and inactivation of MSO, MNTB, and LNTB, thus preventing direct experimental tests of the function of this circuit were not possible. Successfully transfection and manipulation of this circuit will be able to lead us forward into further investigating the processing of sound and ITDs in the auditory brainstem.

Title: Anatomical and electrophysiological properties of neural inhibition change during development and along the tonotopic axis of the mouse MNTB

Authors: O. ALBRECHT[1], E. SALCEDO[2], *A. KLUG[3];
[1]Physiol. and Biophysics, [2]Cell and Developmental Biol., Univ. of Colorado Sch. of Med., Aurora, CO; [3]Physiol. & Biophysics, Univ. of Colorado, Aurora, CO

Abstract: Auditory information processing, especially sound localization processing, requires very temporally precise neural circuits. One of these well-timed circuits is the medial nucleus of the trapezoid body (MNTB), best known for its giant excitatory inputs from the contralateral antero-ventral cochlear nucleus (AVCN), the calyces of Held. One of the MNTB's most intriguing features is that principle neurons also receive substantial inhibitory glycinergic input. We have recently shown that at least the majority of this inhibition originates from the ipsilateral ventral nucleus of the trapezoid body (VNTB). Here, we examined the developmental changes of this inhibition in the mouse and more specifically, how these changes occur in three broader tonotopic areas of MNTB (lateral = low, central = medium and medial = high frequency areas), using both anatomical and electrophysiological methods. We used an automated MATLAB algorithm to count immunolabeled GABAergic, glycinergic and "mixed" (i.e. containing both GABA and glycine) synaptic boutons and measured their size in these tonotopic areas. In electrophysiological experiments, we recorded mini-IPSCs and stimulated inhibitory inputs electrically to test for differences in the (pre)synaptic makeup between medially, centrally and laterally located MNTB neurons. We also tested for differences in postsynaptic receptor density by puffing glycine and the specific GABAA agonist muscimol onto MNTB principal neurons.

We found that shortly after hearing onset (p 14-16), profound anatomical and electrophysiological changes take place in the different frequency areas of the MNTB, which result in the establishment of a tonotopic "gradient" of inhibition that is also present in the adult animal (p 40+). For example, glycinergic boutons are larger in the most medial and the most lateral parts of the MNTB, suggesting a stronger inhibitory input for high- and low-frequency neurons. Another interesting finding is that the lateral portion of the MNTB seems to receive relatively less synaptic inputs of the "mixed" type than the central (= medium frequency) and the medial (= high frequency) areas. Finally, in terms of synaptic strength, the lateral (= low frequency) neurons show the largest IPSC amplitudes, whereas central MNTB neurons exhibit the smallest electrically elicited IPSC peaks, consistent with the anatomical results. This differential setup of inhibition along the tonotopic axis of the MNTB is suggestive of an important role this inhibition might be playing in auditory processing.

Title: Rate and temporal coding of dynamic ITD and amplitude modulation in the inferior colliculus may explain differences in psychophysical detection limits

Authors: ***N. ZUK**[1,2,4], B. DELGUTTE[1,3,2,4];
[1]Eaton-Peabody Labs., Massachusetts Eye and Ear Infirmary, Boston, MA; [2]Hlth. Sci. and Technol., [3]Res. Lab. of Electronics, MIT, Cambridge, MA; [4]Program in Speech and Hearing Biosci. and Technol., Harvard Univ., Cambridge, MA

Abstract: Humans cannot detect temporal variations in binaural cues such as interaural correlation or interaural time differences (ITD) at frequencies above 20-50 Hz where they can

still detect monaural amplitude modulation, suggesting that binaural processing is "sluggish" compared to monaural processing (Grantham & Wightman, J. Acoust. Soc. Am. 63:511; Grantham, J. Acoust. Soc. Am. 72:1178). Even so, broadband noise with a time-varying ITD remains discriminable from spatially-static noise at frequencies above 50 Hz (well above typical frequencies of natural motion), and this ability cannot be entirely explained by detection of monaural cues. In the inferior colliculus of the auditory midbrain, many neurons exhibit tuning to the frequency of both time-varying ITD and amplitude modulation in both their average firing rate and phase-locking strength. It is possible that similar biomechanisms (synaptic or channel-based) are responsible for producing such tuning. Very few studies, however, have compared tuning to time-varying ITD and time-varying amplitude in the same neurons. Here, we compared the neural coding of dynamic ITDs and diotically-presented sinusoidal amplitude modulation (SAM) by the same single units in the IC of unanesthetized rabbits. Our goal was to assess if dynamic binaural and monaural cues produce similar tuning in the IC and evaluate whether differences in tuning could account for differences in psychophysical detection. Tuning across modulation frequency was distinct for broadband noise with dynamic ITD compared to SAM with respect to both firing rate and phase-locking strength. Both the frequency of maximum phase-locking and the upper frequency limit of phase-locking were lower on average for dynamic ITD than for SAM. This finding may be a neural correlate of binaural sluggishness. While tuning of average firing rate to dynamic ITD was weak relative to SAM, median firing rates across our neuronal sample for modulation frequencies above 64 Hz deviated significantly from the average firing rate to an unmodulated stimulus presented at the center of the range of dynamic ITDs. This effect may explain the detectability of time-varying ITDs at high frequencies observed psychophysically. Overall, our results suggest that the mechanisms underlying sensitivity to time-varying binaural and monaural features are at least partly distinct and that these differences may explain the differences in psychophysical detection limits observed in humans.

Title: Emergence of hemispheric spatial tuning in the owl's auditory forebrain

Authors: *M. V. BECKERT, J. L. PENA;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Previous work has shown that the auditory forebrain structure, Field L, which is homologous to mammalian primary auditory cortex (A1), and one of its downstream nuclei that is important for sound localization, the auditory archistriatum (AAr), which is homologous to the auditory portion of the mammalian frontal eye fields (FEF), lack a topographic representation of auditory space and are organized into clusters of similarly tuned neurons. This contrasts with the topographic distribution of spatial tuning observed in the avian superior colliculus. A similar difference is observed between the superior colliculus and auditory forebrain in mammals. Unlike in the midbrain, how auditory space in encoded in the forebrain is largely unknown. We are investigating this question in the auditory forebrain of the barn owl, Tyto alba. In particular, we are studying the transition from midbrain to Field L and from Field L to AAr. We improved upon previously used techniques by utilizing tetrode recordings to directly address the existence of these clusters and gather further insight into the organization of local populations in avian cortex. Tetrode recordings were performed in anesthetized barn owls. Sound stimuli were presented dichotically through custom made earphones, varying interaural time (ITD) and level difference (ILD), or from free-field speakers to obtain tuning profile of multiple single units within a single recording site. Tuning profiles of units within these local populations were then compared to one another to assess the similarity or difference in their composition. Our results in Field L are inconsistent with the clusters hypothesis and suggest a heterogeneous organization of neuronal tunings similar to mammalian A1. Groups of neighboring neurons can be tuned to very different combinations of binaural cues. In contrast, neighboring neurons in AAr, as well as neurons from different recording sites, have very similar tunings, suggesting that AAr is far more homogeneous than Field L. Additionally, AAr neurons show a stereotypic spatial tuning and a population response consistent with the emergence of a hemispheric population responding broadly to contralateral space, as proposed for mammals.

Title: Spectro-temporal integration in sound localization as revealed by frequency-modulated tones in barn owls

Authors: *L. KETTLER, H. WAGNER;
Inst. of Biol. 2, RWTH Aachen Univ., Aachen, Germany

Abstract: We used frequency-modulated sounds to study temporal integration in sound localization in the barn owl. Two barn owls were trained to respond to a sound in which the location was specified by the interaural time difference with a head turn towards the perceived sound direction. In such a situation, barn owls turn their head towards the perceived sound source, if broadband noise is used as stimulus. If the stimulus is narrowband, so-called phantom-source localizations may occur, indicating that the barn owl perceives two images. We hypothesized that frequency-modulated sounds might lead to similar behavior as stationary sounds, if a temporal window is taken into account. We further hypothesized that the size of the temporal window may be estimated from the percentage of phantom-source localizations when the bandwidth and duration of the frequency-modulated sounds were varied. We show that indeed the phantom-source localizations mainly depend on the bandwidth but to lesser extent on the duration of the frequency-modulated sounds. The time windows derived by using a running cross-correlation model with across-frequency integration and by comparing the responses to stationary and frequency-modulated sounds varied between 2ms and 17 ms, depending on the individual owl. Thus, the binaural process underlying frequency integration is not (moderately) sluggish when frequency-modulated sounds are used as stimuli.

Title: Binaural contributions and cellular mechanisms underlying sound location sensitivity in the awake marmoset auditory cortex

Authors: *Y. WANG, X. WANG;
Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Sound localization is a crucial ability for survival, as both animals and humans can rapidly detect stimuli originating from any direction within the environment. To understand how spatial location is processed by individual auditory cortex neurons, we performed extracellular and intracellular recording experiments in awake marmosets, a highly vocal arboreal New World primate, using both free-field and dichotic stimuli. First, using extracellular recording and sounds presented through dichotic earphones, we tested to what degree the primary auditory cortex (A1) processes azimuth information. We found that most A1 neurons responded to monaural stimuli to either ear. The response to sound from the contralateral ear was overall stronger across the population. Binaural interactions were observed in the majority of neurons recorded. We found that rate-level functions can have different characteristics for the two ears, for example, being monotonic in one and non-monotonic in the other. Overall, tuning to the interaural level difference (ILD) measured dichotically was well correlated with spatial sensitivity mapped using 32 free-field speakers placed all around the animal, including spaces above, below and behind the animal. Level-dependent changes in spatial sensitivity in free-field corresponded to changes in sharpness of ILD functions at different sound intensities. The intracellular recording showed that the subthreshold inputs to A1 neurons are broadly tuned in space. This is in contrast to the spiking response recorded from the same neuron, which is more narrowly tuned to space, indicating that spatial sensitivity is actively refined at the level of single A1 neurons. Many neurons showed level-invariance and sometimes contraction with increased sound intensity. For neurons that showed expansion in spatial sensitivity at louder sound levels, the enlarged spatial receptive fields approached the extent of spatial sensitivity in the subthreshold response. The intracellular recordings also indicated that inhibition plays a role in shaping spatial receptive field. Our observations suggest that azimuth tuning in A1 arises at least partially at the cortical level through binaural interactions and further refined from its thalamic inputs.

Title: Temporal weighting of binaural cues in human auditory cortex: an fMRI study

Authors: *N. C. HIGGINS[1], S. A. MCLAUGHLIN[3], G. STECKER[2];
[1]Hearing and Speech Sci., [2]Vanderbilt Univ., Nashville, TN; [3]Univ. of Washington, Seattle, WA

Abstract: When human listeners localize sounds in space, their judgments reflect weighted combinations of the available acoustic cues. For horizontal localization, the primary cues are the interaural time (ITD) and level differences (ILD). In real world listening, these cues fluctuate over time, yet perception remains stable. That stability reflects the perceptual dominance of cues occurring at particular times in the duration of a sound: the ITD at sound onset and the ILD at onset and offset. For both cues, the middle part of the sound appears remarkably ineffective, suggesting a dissociation between perception and the physical features of the stimulus. In order to determine whether spatial processing in the human auditory cortex (hAC) reflects the perceived versus physical features of sounds, functional magnetic resonance imaging (fMRI) was used to measure activity in response to 1 s trials which varied in ITD or ILD (nine values spanning left to right) in separate runs. Each trial presented trains of 16 narrowband clicks in which the binaural cue was applied equally to all clicks (referred to as "full-cue") or only to the first click ("onset"), in which case clicks 2-16 carried zero ITD and ILD. Listeners performed a simple pitch-change detection task to ensure vigilance. Image acquisition employed a continuous event-related design (TR=2s, 3 Tesla, 2.75 x 2.75 x 3mm resolution). Data were analyzed using general linear modeling and parcellated into regions of interest corresponding to hAC using Freesurfer. Cortical responses to full-cue ILD stimuli in each hemisphere were larger for contralateral than ipsilateral ILDs, and exhibited a minimum around ILD=0. Onset ILD stimuli also elicited large responses to contralateral ILDs, but additional elevated responses near 0 dB ILD (i.e., when onset and post-onset ILDs matched) and conspicuous response minima at intermediate ILDs of +10 dB were also observed. Unlike ILD stimuli, but consistent with previous fMRI studies of ITD processing, the ITD response functions were relatively flat in both conditions, and displayed little contralateral dominance despite strong overall activation to sound. These results were used to evaluate competing models of AC population response, including topographic, opponent-channel, and three-channel models incorporating mechanisms of response adaptation, forward suppression, and lateral inhibition. Overall, the pattern of results for full-cue and onset ILD parallels the psychophysical results that perception is influenced by both stimulus onset and offset ILD cues, and provides evidence that hAC maintains sensitivity to ILD of the onset and later portions of the sound.

Title: The representation of sound azimuth in the auditory cortex of early blind humans

Authors: *K. DEREY[1], E. FORMISANO[1], G. VALENTE[1], M. ZHAN[1], R. KUPERS[2], B. DE GELDER[1];

Abstract: Early visual deprivation often leads to the development of superior sound localization abilities compared to sighted individuals3,5. The development of these enhanced spatial hearing skills can be explained by functional recruitment of the deprived visual system or by neural plasticity of the intact auditory modality, or by a combination of both. The present fMRI study investigates functional plasticity of the representation of acoustic azimuth in human auditory cortex following early visual deprivation. Methods Stimuli: Stimuli were recorded with binaural microphones in the ear canal of each participant whilst sounds were presented with a 3D sound system. This set-up maximizes the availability of spatial cues in each recording. Sounds consisted of a low (250-700Hz) or higher (600-1.400Hz) frequency modulated tone rotating smoothly in the horizontal plane around the head (full circle in 40s). Scanning: We scanned 8 EB subjects with a 3T MRI scanner. Recordings of the stimuli were presented binaurally at three intensity levels (10dB difference in between) in a passive design. Functional runs were collected using a standard EPI sequence (TR: 2000ms, 32 slices, 2mm iso-voxels). An anatomical image was obtained with a T1-weighted scan. Data of 8 sighted controls (SC) was acquired during a prior experiment with an equivalent design 2. Analysis: Functional data were preprocessed with correction for motion, slice scan time and low frequency drifts (BrainVoyager QX). We constructed a response azimuth function (RAF) per trial for each auditory responsive voxel (GLM, auditory > baseline) using a Finite Impulse Response (FIR) deconvolution. We estimated from the RAF the best azimuth position as well as the steepest slopes. Additionally, a GLM was estimated with binaural sum and difference predictors to identify spatially sensitive voxels. Results Presentation of sounds activates the auditory cortex (AC) both in EB (data of two subjects) and in SC (FDR, $q < 0.05$). RAFs indicate that azimuth tuning may be more homogeneously distributed across the azimuth in EB than in SC. Tuning width distributions of both EB and SC show 2 distinct populations, one with narrow and one with broad tuning. Finally, spatially sensitive regions appear to be located in AC as well as in occipital and parietal

regions in EB. These areas are concentrated in the AC in SC. Conclusion Our data suggests that there are both similarities (e.g. tuning width) and differences (e.g. location preference) between the cortical representation of acoustic azimuth in sighted and early-blind individuals. These differences may contribute to the enhanced auditory localization abilities observed in early blind humans.

Title: Improving binaural sensitivity in noise using a novel speech-processing algorithm

Authors: *Y. GAI, ESQ, L. M. KUJAN, J. G. CIANCIBELLO;
Biomed. Engin., St. Louis Univ., Clayton, MO

Abstract: When the environment is quiet, cochlear implants provide hearing-impaired patients with adequate speech intelligibility. However, due to those patients' degraded ability to spatially separate sound sources, speech perception quickly degrades as background noise increases. Recent psychophysical and physiological studies using sharpened envelopes have pointed toward a possible solution to the problem. Although promising, this strategy has only been tested with simple tone/noise sounds. Here we proposed a novel speech-processing algorithm that applies the concept of envelopes enhancement to any input sound, including speech. The algorithm was examined in normal-hearing listeners through headphone with noise-vocoded speech to simulate implant hearing. The measured thresholds of interaural time differences (ITDs) contained in speech envelope in quiet were on the order of a few hundred microseconds, and our algorithm significantly improved the thresholds compared with standard algorithms of cochlear implants. Speech-perception tests confirmed that the envelope sharpening did not degrade intelligibility. An unexpected finding was that, when binaurally-coherent noise was introduced, the envelope-ITD thresholds improved dramatically (from hundreds to tens of microseconds), almost as good as the thresholds of carrier-ITDs. Our finding suggest that bilateral cochlear implants may benefit from the presence of an artificial timing signal presented synchronously across the two ears.

Title: A comparison of free-field and headphone based sound localization using SoLoArc: A modular and portable, audiovisual, free-field localization device with high spatial resolution

Authors: ***J. A. WESTERBERG**[1], A. R. BALHORN[1], R. S. TYSHYNSKY[1], J. L. LOEBACH[2];
[2]Psychology, [1]St. Olaf Col., Northfield, MN

Abstract: Sound localization is often demonstrated using artificial ITD and ILD cues presented over headphones. Such tasks can be confusing, difficult for undergraduates to administer and interpret, and prone to experimental errors compared to free-field localization. Over the past 8 months we have designed and fabricated a portable audiovisual localization device. Here, we describe the construction of the SoLoArc, and present data from 3 studies, demonstrating that the device works as intended, and produces more accurate localization in the free-field azimuth compared to ILD and ITD cues presented over headphones. The device presents auditory stimuli in a 180° arc from speakers placed every 5° on the concave surface. A participant is seated at the point of convergence of the sound field, 4 feet from each speaker. An array of 73 LEDs allows the investigation of visual influence in localization tasks. The arc can be positioned for azimuth, front/back, or vertical localization. The participant's head may be fixed or freely moving. The device is interfaced to a PC using 2, 96-channel NI USB I/O devices. Matlab is used for device control allowing stimuli of any frequency and intensity to be created and delivered from each speaker independently. Preliminary tests of the device demonstrate its validity and utility. 48 undergraduates enrolled in a Sensation & Perception course completed 3 sound localization activities. Participants completed a headphone based task using ITDs as the primary cue. 440 Hz sinusoids were presented from the left and right headphones with delays ranging from 640 μsec (right ear lead) to -640 μsec (left ear lead). Sound locations were chosen from one of 4 randomized lists and participants responded by indicating an angle from where they thought the sound source emanated using a worksheet. Participants completed the same task using ILDs as the primary cue. 6000 Hz sinusoids were presented from the right and left headphones with

intensity differences ranging from +/- 21 dB between right and left ear locations. Finally, participants completed a free-field localization task using SoLoArc. Participants were presented with speaker locations from one of 8 randomized lists composed of 1000 Hz sinusoids at 70 dB, and indicated their response by pointing a laser at a metric attached to the face of the device, which was recorded by an experimenter. Regression analyses revealed that while each method was related to the ideal, β coefficients were higher for the free-field condition (β=.995) than the ILD (β=.905) or ITD conditions (β=.949). In addition to increased accuracy, participants reported that the free-field task was easier to complete and more natural and intuitive.

Title: GABAergic projections from the ventral cochlear anterior nucleus to the cochlear root neurons

Authors: *N. O. BARIONI[1], M. G. MARTINS[2], A. V. DA SILVA[3], R. G. NIETO[4], M. E. LÓPEZ GARCIA[4], J. C. HORTA JÚNIOR[2];
[1]State Univ. of São Paulo, Guarulhos, Brazil; [2]State Univ. of São Paulo, Botucatu, Brazil; [3]mUniversidade Federal do Mato Grosso do Sul, Três Lagoas, Brazil; [4]Univ. de Salamanca, Salamanca, Spain

Abstract: The cochlear root neurons (CRN) are the first in the central nervous system to receive the acoustic information. They are in connection with sensory integration centers in the brainstem, particularly the pontine caudal nucleus. The CRN are related to the the acoustic startle reflex (ASR) fundamental neural circuit. The ASR shows various modulations which are important in clinical diagnostics of psychiatric and neurodegenerative illnesses. Startle modulations are promoted by influences from several nuclei on its fundamental neural circuit. The cochlear root nucleus is the least studied nucleus of this circuit. It's afferents' origins and neurochemical identity remain unclear. Recently it was described lots of GABAergic buttons making connection with the CRN soma and dendrits, which would propose an inhibitory

modulation upon these neurons, however the source of this projections is still unknown. One possible source could be the ventral cochlear anterior nucleus (VCA), which is mainly GABAergic and indirectly projects to the CRN through a pathway composed by the inferior colliculus and ventral nucleus of trapezoid body. . Knowing VCA's GABAergic neurochemistry and due to the proximity of this nucleus to the CRN and to confirm previous tract-tracing studies that indicate afferent connection from VCA to CRN, we investigated a direct GABAergic projection from VCA to the CRN. To achieve this purpose, stereotaxic surgery with an injection of BDA (anterograde neurotracer) was performed in 3 adult Wistar rats (100 days). After 7 days, animals were perfused, the brains were collected and processed combining imunohistochemistry protocols for BDA, GABA and VGluT1. Results showed BDA labeled axon terminals in apposition with CRN soma and dendrits. Besides, confocal analisys showed a colocalization between imunolabelled GABAergic and BDA fibers and terminals. This GABAergic projection suggests an inhibitory role directly upon the CRN, probably being related to ASR modulations.

Title: Cortical circuits involved in skilled forelimb movements and tool use

Authors: *A. MAYER DE OLIVEIRA[1,3], R. E. BITTENCOURT-NACARRETE[3], J. G. FRANCA[2];
[2]IBCCF, [1]Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil; [3]Dept. of Physiol., Federal Univ. of Juiz de Fora, Juiz de Fora, Brazil

Abstract: Cebus monkeys stand out from other New World monkeys by their ability to perform fine hand movements and use tools. The posterior parietal cortex (PPC) plays a crucial role in the implementation of such behaviors working as a cortical node for visual, somatosensory and

motor integration. However, the neural substrate underpinning this function was still not fully elucidated. In the present study we described the corticocortical connectivity of different sectors of areas 5 and 7 of the PPC in the cebus monkey. After a brief electrophysiological mapping, five adult cebus monkeys were injected with fluorescent tracers at (a) hand/forearm representation of area 5 (area 5v), (b) posterior bank/border of the intraparietal sulcus (IPS), corresponding to the expected location of the anterior intraparietal area (AIP) and area PFG, and (c) area PF. After a survival of 11-14 days, animals were perfused. Retrogradely labeled neurons were plotted using a fluorescent microscope equipped with the Neurolucida system (MBF, Inc). Architectonic identification of cortical areas was performed on adjacent Nissl-stained, myelin-stained, or SMI-32 immunoreacted sections. The representation of hand/forearm in area 5v received many projections from somatosensory areas 3a, 3b, 1, 2, and S2/PV. In the PPC, labeled cells were found mainly in the anterior bank of the IPS (5d and MIP) and in area PF. In the frontal cortex, dense connectivity was observed with motor (F1) and premotor areas (F2, F4 and F5). In contrast, injections in the posterior bank/border of the IPS (in area AIP/PFG) revealed dense projections from the inferior parietal cortex (PG, PFG and PF), from area PO, and from areas of the posterior bank and caudal portion of IPS. Many labeled cells were also observed in F1 and premotor areas (mainly area F5). Area AIP/PFG was also connected with prefrontal fields, SII/PV, face representation of area 2, and higher order visual areas of the inferior temporal lobe. After injections in area PF, labeled cells were found in the anterior (face representation of area 2), posterior (5v, MIP, VIP, PFG and PG), and lateral parietal cortex (S2/PV). In the frontal lobe, area PF was densely connected with F1, F4,F5 and prefrontal fields. These results suggest that the cortical circuits involved in the somatosensory-motor integration for manual behaviors (area 5v) are segregated from the cortical circuits that are implementing the visuomotor integration (area AIP/PFG). Area 5v presents none or very weak connectivity with area AIP/PFG, while area PF is densely connected with both areas. Therefore, area PF could be playing a crucial role in the functional integration of somatomotor and visuomotor circuits.

Title: Immature corticotectal influences initiate the development of multisensory integration in the midbrain

Authors: *R. L. MILLER, B. A. ROWLAND, B. E. STEIN;
Neurobio. and Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Neonatal neurons in the cat superior colliculus (SC) develop the capability to integrate cues across sensory modalities (e.g., visual-auditory) in early postnatal life. The developmental chronology of this highly complex process is puzzling because it is axiomatic that development of cortex is delayed relative to that of the midbrain, yet development of this midbrain integrative process is known to be dependent on inputs from cortex (i.e., especially the anterior ectosylvian sulcus, AES). One possibility is that the axiom is too broad and, in this case, the corticotectal neurons in AES that are critical for this midbrain process (i.e., unisensory AES neurons) reach functional maturity sooner than expected. To examine this question, single neurons were simultaneously recorded from the SC and AES in groups of animals at different ages (4-22 weeks). The results showed that the development of SC multisensory integration begins at the time at which correlated AES-SC activity is first seen. This functional corticotectal connectivity appears to be the key to initiating the development of this midbrain process. Unexpectedly, however, a surprisingly low level of AES unisensory maturity appears to be required. Even when SC multisensory integration is effectively adult-like, the visual and auditory latencies of AES neurons are nearly twice what they will ultimately be, their responsiveness remains prolonged, response thresholds continue to be high, and their receptive fields are not yet mature. Thus, SC multisensory integration can reach an adult-like state of maturity even while relying on immature, yet functional, corticotectal inputs. Title: Modulation of vertebrate sensorimotor neural circuits by the neuropeptide, arginine vasotocin

Authors: *K. IWASAKI[1], M. SAMAHA[2], W. YAU[2], N. PEREZ[2], P. SONG[2], J. KUWADA[2]; [1]Neurosci. Grad. Program, [2]Molecular, Cellular, & Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Arginine vasotocin (*avt*) and its mammalian homolog, arginine vasopressin (*avp*), are linked to many complex behaviors including aggression and reproductive behaviors presumably by modulating neural circuits. However, how AVT/AVP regulates neural circuits is unclear. In zebrafish embryos, *avt* is expressed by neurons in the preoptic area of the diencephalon and vasotocin receptors (*avtrs*) by numerous neurons in the CNS during embryogenesis prior to any social behavior. Some of the *avtr*+ neurons in the posterior hindbrain appear to receive sensory input and likely project axons into the spinal cord at a time when embryos respond to tactile and chemical stimulation with motor responses such as swimming. *avtr* is also expressed in the mechanosensory neurons in the dorsal spinal cord. Based upon these findings we hypothesized that signaling by AVT may modulate sensorimotor circuits and thus motor responses to sensory stimulation. This hypothesis predicts that *avtr*+ neurons respond to sensory stimulation, and that increasing and decreasing AVT signaling, respectively, enhance and inhibit touch-induced swimming. The activities of neurons in the hindbrain were examined by cFos transcription as a proxy for neural activation. Neurons found in the same region of the hindbrain as the *avtr*+ neurons were found to increase cFos transcription in response to sensory stimulation of the embryo consistent with *avtr*+ neurons being responsive to sensory stimulation. Perturbation of AVT signaling by pharmacological and molecular manipulations resulted in predicted changes in mechanosensory and chemosensory induced swimming in embryos. Furthermore, photoreceptors are expressed by neurons in the preoptic region which also expresses *avt* suggesting the possibility that light may modulate the release of AVT. In fact we found that responses to tactile stimulation were enhanced in the light compared with the dark and that light enhancement required AVT signaling. These experiments suggest that AVP/AVT signaling modulates sensorimotor circuits and responses and further suggests that AVP/AVT signaling may serve a similar modulatory function in neural circuits regulating social and reproductive behaviors.

Title: Smell's melody: Brain network involved in multisensory interactions between sounds and odors

Authors: *A. GNAEDINGER[1], F. OCCELLI[2], B. GOURÉVITCH[2], C. MARTIN[1];
[1]Univ. Paris-Sud, IMNC, Orsay Cedex, France; [2]Neuro-psi, Orsay, France

Abstract: Multisensory interactions are constantly present in our everyday life and allow a unified representation of environment. Cross modal integration is often studied in multisensory associative brain regions, but recent findings suggest that most of the brain could be multisensory (A. Ghazanfar and C. Schroeder, Trends in Cognitive Sciences, 2006). Indeed, recent studies have shown that integration could also occur in primary sensory cortices, previously considered to be unimodal. This finding has modernized our view of brain organization and open new perspectives for the multisensory research field. At this time, we still don't know how the brain deals with information from different sensory systems. In this project, we want to understand whether the establishment of neuronal oscillations can functionally connect sensory regions and take part of the multisensory integration, and how this connection is built up by learning. For this, we examine changes in the cortical network involved in the acquisition of a multisensory association between a sound and an odor in rats, through the analysis of the local field potentials' oscillations. The originality of the project is to sample a large network of brain structures including primary sensory cortex (primary auditory cortex, olfactory bulb) and multimodal areas towards which converge these two senses: the piriform and perirhinal cortices. We have developed a behavioral GO/NO GO test in which the rat must combine simultaneous auditory and olfactory informations to succeed. Data and brain signals obtained in this task suggest that the power of oscillations in different frequency bands within the targeted areas and the coherence of oscillations between these areas are modified by the multisensory learning.

Title: Anatomical pathways for short-latency multisensory integration processes in primary sensory cortices A1, S1, and V1

Authors: J. U. HENSCHKE[1], T. NOESSELT[4], H. SCHEICH[2], *E. BUDINGER[3];
[1]Systems Physiol. of Learning, [2]Emeritus Group Lifelong Learning, [3]Leibniz Inst. for Neurobio. Magdeburg, Magdeburg, Germany; [4]Inst. of Psychology II, Dept. of Biol. Psychology, Otto-von-Guericke-University Magdeburg, Magdeburg, Germany

Abstract: Multisensory integration does not only recruit higher-level association cortex, but also low-level and even primary sensory cortices. Here, we will describe and quantify two types of anatomical pathways, a thalamocortical and a corticocortical that possibly underlie short-latency multisensory integration processes in the primary auditory (A1), somatosensory (S1), and visual cortex (V1). Results were obtained from Mongolian gerbils, a common model-species in neuroscience, using simultaneous injections of different retrograde tracers into A1, S1, and V1. Several auditory, visual, and somatosensory thalamic nuclei project not only to the primary sensory area of their own (matched) but also to areas of other (non-matched) modalities. The crossmodal output ratios of these nuclei, belonging to both core and noncore sensory pathways, vary between 0.4 and 63.5 % of the labeled neurons. Approximately 0.3 % of the sensory thalamic input to A1, 5.0 % to S1, and 2.1 % to V1 arise from non-matched nuclei. V1 has most crossmodal corticocortical connections, projecting strongest to S1 and receiving a similar amount of moderate inputs from A1 and S1. S1 is mainly interconnected with V1. A1 has slightly more projections to V1 than S1, but gets just faint inputs from there. Concerning the layer-specific distribution of the retrogradely labeled somata in cortex, V1 provides the most pronounced feedforward-type outputs and receives (together with S1) most pronounced feedback-type inputs. In contrast, A1 has most pronounced feedback type outputs and feedforwardtype inputs in this network. Functionally, the different sets of thalamocortical and corticocortical connections could underlie distinctive types of integration mechanisms for different modality pairings.

Title: Underestimating superadditivity in multisensory integration

Authors: *B. A. ROWLAND, A. S. DAKOS, T. R. STANFORD, B. E. STEIN;
Neurobio. & Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Multisensory neurons in the superior colliculus (SC) integrate concordant signals derived from different sensory modalities to produce enhanced responses. The quantitative framework traditionally used for reckoning the products of such multisensory integration is based on changes in the average number of impulses elicited from a neuron on a given trial. According to this simple quantification, superadditive computations (i.e., a multisensory response greater than the sum of the component unisensory responses) are only found in a minority of samples, most frequently those in which the sum of the averaged unisensory responses is less than 5 impulses. Based on summing activity over a protracted stimulus epoch, this “rule of thumb” implies that superadditive computations are represented only on the lower tail of a distribution of multisensory products, and found only when neurons are responding near their threshold. The present study questions the veracity of this inference. Two important factors must be considered in this context: 1) the moment-by-moment computations yielding the integrated multisensory products change during a neuron’s response window, and 2) interspersed with neurons that are overtly responsive to each sensory input (the typical multisensory neuron used in most studies) are many "covert" neurons which exhibit multisensory integration, but do not respond overtly to one of the component sensory inputs. To examine the impact of these two factors on multisensory integration, we evaluated the moment-by-moment products of integrating visual and auditory signals in both single neurons and multi-neuron recordings in the SC of both awake and anesthetized animals. The data show that superadditive enhancement is an exceedingly common computation in the early response window of both preparations (~100ms after stimulus onset), a period that includes the response onsets and peaks for both sensory inputs. It is rare for it not to be present. This early enhanced multisensory response proved not only to be more potent, but to be statistically more reliable. Furthermore, due to the presence of covert neurons, results from most single neuron analyses significantly underestimate the potency of multisensory enhancement within the local circuit, and do so by a multiplicative factor. Thus the emergent picture of SC multisensory integration is one in which a dynamic process produces

a wave of enhancement to the downstream neuron that is dominated by a leading edge of superadditivity.

Title: Audiovisual integration in primate dorsolateral prefrontal cortex

Authors: ***A. POREMBA**, J. BIGELOW;
Univ. of Iowa, Iowa City, IA

Abstract: Audiovisual integration underlies a wide range of adaptive behaviors in humans and other primates, including language and communication, recognizing individual conspecifics, and social decision-making. Neurobiological studies spanning the last several decades suggest audiovisual integration is enabled by convergence of auditory and visual inputs upon individual neurons at multiple sensory processing stages, and includes interactions among numerous cortical and subcortical brain regions. Among these regions is the lateral prefrontal cortex (PFC), which may be particularly important for selecting appropriate actions in response to audiovisual cues. Neurophysiological studies have concentrated on audiovisual integrative functions within the ventrolateral division of PFC (Romanski, 2012), largely because of its purported role in the ventral object-processing stream. Comparatively little is known about audiovisual integration within dorsolateral PFC, which is believed to form part of the dorsal spatial-processing stream. Motivated by neuroimaging data suggesting auditory-visual overlap in dorsolateral PFC, as well as anatomical findings revealing connections between ventrolateral and dorsolateral PFC, the current study investigated audiovisual integration in single units and local cell populations within dorsolateral PFC. Extracellular recordings were collected from three awake, behaving rhesus macaques (Macaca mulatta). Trials were initiated by maintaining central fixation for 1000 ms, after which a visual stimulus appeared centrally on a computer monitor (visual trials), or an auditory stimulus was presented through a speaker located centrally above the monitor (auditory trials), or both visual and auditory stimuli were simultaneously presented (audiovisual trials).

Stimuli included monkey faces and vocalizations, human faces and vocalizations, animal faces and vocalizations, and synthetic visual events and sounds. Each modality format and stimulus type occurred with equal frequency in pseudorandom order. Continuing fixation throughout the entire stimulus period (500 ms) was reinforced on a variable schedule (~20:1) with a calorically dense food reward. Evidence of audiovisual integration within dorsolateral PFC was obtained from units exhibiting significant evoked responses to both auditory and visual stimuli, as well as units with responses to audiovisual stimuli that differed significantly from the maximal unimodal response. The results support an expanded view of the cortical network underlying audiovisual integration, which includes both ventrolateral and dorsolateral divisions of the PFC.

Title: Acquiring the multisensory integration capability at maturity

Authors: J. XU[1], L. YU[1], B. A. ROWLAND[2], *B. E. STEIN[2];
[1]Sch. of Life Sci., East China Normal Univ., Shanghai, China; [2]Neurobio. and Anat., Wake Forest Sch. Med., Winston Salem, NC

Abstract: Cat superior colliculus (SC) neurons normally develop the ability to integrate visual-auditory information after 3-4 months of postnatal experience. Restricting visual-auditory experience by rearing them to adulthood in omnidirectional noise disrupts this developmental process (Xu et al., 2014). Prior work demonstrated that multisensory integration capabilities can be acquired later in life with intense training consisting of exposure to concordant cross-modal

cues in a darkened, quiet environment. The aim of the present study was to evaluate whether the cross-modal experience provided by a normal environment would be more effective. Following omnidirectional noise-rearing, animals (n=4) were placed in normal laboratory housing conditions. After 6 months, only 39% (24/61) of the multisensory SC neurons tested had acquired this capacity, a surprisingly low incidence compared to that found in normal controls (77%, 75/97) and dark-reared animals given the intense cross-modal exposure paradigm for 15 weeks (90%, 63/70). The noise-reared animals were then submitted to the same cross-modal exposure paradigm used in dark-reared animals. As before, a progressive increase in the incidence of neurons capable of multisensory integration was noted, and after 32,400 exposure trials (18 experimental sessions), these capabilities appeared to be fully developed. Now the incidence of neurons with multisensory integration capabilities (84%, 56/67) was no longer lower than normal or the rehabilitated dark-reared animals. These results suggest that the mature brain has not lost the capability to develop multisensory integration capabilities, but is less capable of doing so under normal conditions. Presumably, the complexity and ambiguity of cues in the rich, normal environment make it more difficult for the mature brain to extract the needed cross-modal statistics.

Title: Functional connectivity between mouse visuo-tactile area RL and cingulate cortex

Authors: S. PAPAIOANNOU[1], S. AN[1], *P. MEDINI[2];
[1]Dept. of Integrative Med. Biol., Umeå Univ., Umeå, Sweden; [2]Integrative Medial Biol. Dept., Umeå Univ., Umea, Sweden

Abstract: We have previuosly found that the mouse parietal area RL integrates visual and tactile information in mice (Olcese, Iurilli and Medini, Neuron, 2012). Anatomical work indicates that such area projects to the mouse motor cortex (Wang and Burkhalter, J Neurosci, 2011). Here we

investigate the existence of a functional connection between area RL and the prefrontal cortex of mice by a combination of extracellular and intracellular electrophysiology followed by anatomical identification of recorded neurons. Our data show robust and consistance bimodal field potential responses to unimodal and multisensory stimulation in the projection spot of area RL in the mouse frontal cortex, which are accompanied by intracellular synaptic responses in a relatively sparse population of neurons. This work will be preliminary to elucidate the circuits basis by which the multisensory input coming from RL might facilitate activation of the motor target areas in the prefrontal cortex.

Title: Comparison of dendritic spine density/size of primary auditory cortical neurons from early-deaf and hearing cats

Authors: *H. R. CLEMO[1], S. G. LOMBER[2], M. A. MEREDITH[1];
[1]Dept Anat & Neurobiol, Virginia Commonwealth U Sch. Med., Richmond, VA; [2]Brain and Mind Inst. Depts Physiol. & Psychology, Univ. Western Ontario, London, ON, Canada

Abstract: Auditory cortex is reorganized by visual/somatosensory activity following early deafness. These crossmodal inputs arise essentially from the same regions that target the auditory cortices in hearing animals, indicating that crossmodal plasticity is subserved not by the ingrowth of new projections, but by local axonal branching and synapse formation. In areas with a high degree of crossmodal plasticity, concurrent increases in dendritic spine density and diameter have been observed. In contrast, the level of crossmodal plasticity demonstrated within A1 following early deafness remains unresolved. The present study measured dendritic spine features from A1 neurons in early-deaf cats (D; ototoxic administration within the first post-natal month, confirmed by flat ABR) and hearing (H) controls. The auditory cortex of adult cats (D=

3; H=3) was incubated for Golgi-Cox staining. Reactive neurons from A1 were visualized and their dendritic spine features assessed using a light microscope (100x; oil) controlled by Neuroludica software. The overall dendritic spine density (436 dendritic segments) did not vary significantly (D=0.81 spines/μm ± 0.02 se; H=0.82 spines/μm ± 0.005 se). However, spine density significantly decreased in the granular (thalamo-recipient) layers (D=0.42 spines/μm ± 0.02 se; H=0.58 spines/μm ± 0.02 se; $p<0.0001$) but was not changed in the supra- or infragranular layers. The diameter of dendritic spine heads was measured for 3448 spines, revealing that spine heads from early-deaf (D) animals were slightly but significantly larger (D avg. = 0.63 μm ± 0.005 se) than those of their hearing (H) counterparts (H avg. = 0.61 μm ± 0.004 se; $p<0.017$). This increase in spine diameter was exhibited by neurons in the supragranular (D = 0.65 ± 0.007; H= 0.59 ± 0.005; $p<0.001$) and infragranular layers (D = 0.69 ± 0.008; H= 0.63 ± 0.005; $p<0.001$) but not granular (D = 0.44 ± 0.01; H= 0.64 ± 0.01; $p<0.001$) layers, which showed a substantial decrease. These data indicate that dendritic spines in A1 react to early hearing loss in a lamina-dependent manner. Specifically, the presumed reduction of thalamic drive to granular layers corresponds with a large reduction in spine diameter (avg. decrease of 0.2 μm), while the preservation (or perhaps enhancement) of corticocortical inputs corresponds with increased spine diameters (avg. increase of 0.06 μm) in the cortical-recipient layers. When compared with other auditory areas following deafness, these data suggest that crossmodal plasticity employs different synaptic strategies for different regions.

Title: Audiovisual integration during short-term memory in primate prefrontal cortex

Authors: *J. BIGELOW[1], A. POREMBA[2];
[1]Psychology, [2]Univ. of Iowa, Iowa City, IA

Abstract: Audiovisual integration underlies a wide range of adaptive behaviors in humans and other primates, including language and communication. Among the brain regions thought to underlie audiovisual integration is the lateral prefrontal cortex (PFC), which is specialized for

integrating and retaining sensory information in the service goal directed behaviors. Consistent with the ecological importance of audiovisual cues, behavioral studies have reported facilitated learning and enhanced memory for compound auditory-visual stimuli compared to either unimodal component. Nevertheless, neurophysiological investigations of audiovisual integration have traditionally employed passive exposure paradigms, leaving open the question of how circuits underlying audiovisual integration might interact with circuits enabling retention of information beyond periods of direct sensory stimulation. The current study investigated this question by recording neurophysiological activity within PFC during a concurrent audiovisual short-term memory task. Each trial began with a sample stimulus, followed by a retention interval (sample delay), after which a test stimulus was presented. Following a second retention interval (test delay), a button was illuminated to signal the response window. Subjects were trained to press the button following identical (match trials) but not nonidentical stimuli (nonmatch trials). Memoranda comprised sounds for auditory trials, images for visual trials, and sounds plus images for audiovisual trials. Each trial type (match, nonmatch) and modality format (auditory, visual, audiovisual) occurred equally often in pseudorandom order. Audiovisual integration was evident within stimulus periods from units exhibiting significant evoked responses on both auditory and visual trials, and units with responses on audiovisual trials that differed significantly from the maximal unimodal response. Similar forms of audiovisual integration were observed during mnemonic-related responses, including delay activity and differential responses to matching versus nonmatching test stimuli. Additional analyses revealed a dissociation among delay types, wherein inhibitory activity was most likely during sample delays where a behaviorally relevant sensory cue was predicted, excitatory activity was most likely during matching test delays where a motor response was predicted, and no change in activity was most likely during nonmatching test delays where neither event was predicted. The results reveal convergence of cross-modal and cross-temporal integration in individual units and local cell populations within PFC.

Title: A cross-modal genetic framework for the organization of sensory pathways

Authors: *D. JABAUDON, G. POUCHELON, L. FRANGEUL, L. TELLEY;
Univ. of Geneva, Geneva, Switzerland

Abstract: Modality-specific sensory inputs from the periphery are processed in parallel in distinct sensory areas of the cortex. For each sensory modality, hierarchical thalamocortical (TC) pathways involving “first-order” (FO) and “higher-order” (HO) thalamic nuclei convey information to the primary and secondary sensory cortical areas, respectively. These conserved circuit properties despite divergent peripheral origins raise the possibility that common developmental genetic programs act across sensory modalities. To explore this possibility, we used transcriptional analysis of distinct sensory TC neurons during circuit assembly. We discover that despite their affiliation to distinct sensory modalities, FO somatosensory, visual, and auditory thalamic neurons are genetically homologous. Moreover, *in vivo* modality-specific manipulation of sensory input revealed an input-dependent induction of FO genes and repression of HO genes. Together, these findings reveal a cross-modal genetic framework for the design and plasticity of sensory TC circuits, providing a unifying logic for the emergence and evolution of parallel sensory pathways.

Title: Experience dependent plasticity in adult lateral geniculate nucleus

Authors: *J. L. WHITT[1,2], H.-K. LEE[1];
[1]Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [2]Mind/Brain Inst., Baltimore, MD

Abstract: Our laboratory has recently shown that one week of visual deprivation is sufficient to reopen thalamocortical plasticity in adult mice (Petrus, 2014). This finding led us to question canonical limits of thalamic plasticity in adult animals. To test whether sensory experience alters thalamic synapses in adult animals, we preformed whole-cell electrophysiological recordings in

the lateral geniculate nucleus (LGN), medial geniculate body (MGB), and reticular thalamic nucleus (TRN) of three-month old normal reared mice and mice deprived of vision for 1 week. Using a Layer 6 (L6)-Cre mouse line (Ntsr1-Cre), we selectively expressed channelrhodopsin-2 (ChR2) in L6 of the primary visual cortex and recorded evoked excitatory synaptic transmission in the TRN and LGN. We found no change in the strength of cortico-thalamic excitation between normal and visually deprived animals. To test whether thalamic inhibitory strength is altered with sensory experience, we stereotactically injected double-floxed ChR2 (DIO-ChR2) into TRN of parvalbumin-Cre mice to measure the inhibitory synaptic transmission of reticular-thalamic synapses. We found that after visual deprivation, TRN-LGN synapses are significantly stronger and more efficient at following high frequency stimulation, while TRN-MGB inhibitory synaptic strength remains constant. These findings show that the adult thalamus exhibits experience-dependent plasticity specifically by regulating the gain of inhibitory reticular-thalamic synapses. Such plasticity is modality specific in that it is observed in the LGN, but not in the MGB, with visual deprivation. These changes will likely have functional consequences for cross-modal sensory adaptation by shifting thalamic processing towards inputs coming from spared senses.

Title: Decoding grapheme-color synesthesia using multivariate pattern analysis

Authors: *R. GOSAVI[1], E. E. MEYERING[2], N. S. ROSE[3], E. M. HUBBARD[1], B. R. POSTLE[2,3];
[1]Educational Psychology, [2]Psychology, [3]Psychiatry, Univ. of Wisconsin- Madison, Madison, WI

Abstract: Synesthesia is a condition in which the stimulation of one sensory modality evokes experiences in a second, unstimulated modality (for a review, see Simner & Hubbard, 2013). In the “grapheme-color” variant, synesthetes reliably, automatically experience a specific color when viewing a specific black-and-white symbol (with different colors associated with different symbols). Previous neuroimaging studies using univariate analyses have shown that synesthesia is associated with activity in color areas, including V4 (for reviews, see Hubbard, 2013; Rouw et

al., 2011; for a critical reveiw, see Hupe, 2015). However, these approaches are inherently unable to address a question of fundamental theoretical interest: Is the subjective experience of synesthetic color generated by the same, or different, neural processes from those that support the perception of veridical color? We have begun to address this question with multivariate pattern analysis (MVPA) by first training a linear classifier to discriminate patterns of brain activity evoked by the visual perception of four different color patches, then attempting to decode activity from separate scanning blocks, during which subjects view black-and-white images of the four letters associated with each of the four colors. Although item level decoding of color was robust for both groups, cross-category decoding was only successful for synesthetes. Finer-grained analysis of confusion matrices derived from MVPA of V1 and of V4 yielded two additional insights. First, consistent with previous studies, the neural coding of color differs qualitatively between these two regions. Second, cross-category decoding in synesthetes is markedly stronger in V4 than in V1. These findings suggest that the synesthetic experience of color may be generated by the same mechanisms that support the visual perception of color. These high-level representations of color, however, may not penetrate "backward" to primary sensory cortex.

Title: Integration of multisensory inputs by single neurons in the claustrum

Authors: ***A. M. PACKER**, T. YUAN, N. PETTIT, S. CHUN, J. Y. N. LAU, M. HAUSSER; Univ. Col. London, London, United Kingdom

Abstract: The claustrum is a long, thin, bilateral brain region lateral to striatum that is implicated in multisensory and inter-hemispheric coordination of cortical processing. Extensive anatomical work, recently confirmed by high throughput tracing techniques (Zingg et al 2014), indicate widespread connectivity between the claustrum and the cortex and highlight the need for a more thorough investigation of the claustrum's internal elements and integrative properties. For example, do individual neurons in the claustrum integrate multiple inputs, or does multimodal integration occur at the population level via connections between claustral neurons? To address this question, we have employed retrograde and anterograde tracing from mouse primary visual and motor cortex to reliably identify the claustrum in acute slices, enabling whole-cell patch-clamp recordings from confirmed claustral neurons. Recovery of cell morphology with biocytin staining allowed us to assign electrophysiological properties to morphologically-defined claustral cell types. The range of passive membrane properties, action potential waveforms, and degree of spike-frequency adaptation were consistent with previous intracellular recordings in the claustrum of anaesthetized rats. We also employed a channelrhodopsin-based mapping strategy (Petreanu, et al 2007) to activate functional inputs from defined origins onto claustral neurons. Both adapting and fast-spiking neurons received inputs from motor cortex, with strong and fast feedforward inhibition. We validated a dual-color input mapping strategy using Chronos and Chrimson (Klapoetke et al, 2014) to investigate integration of inputs from different cortical sources. Single claustral neurons exhibited responses to selective activation of motor cortex inputs from both ipsi- and contralateral hemispheres. Furthermore, single claustral neurons received functional synaptic input from both ipsilateral somatosensory cortex and contralateral motor cortex. These results indicate that individual claustral neurons perform multimodal integration of sensory inputs. We are currently planning experiments combining imaging and optogenetic stimulation *in vivo* (Packer et al. 2015) to elucidate the function of this elusive brain region.

Title: Neuronal responses in primary somatosensory cortex during a whisker discrimination task

Authors: T. VINHOLO, *A. C. KUNICKI, R. MOIOLI, M. I. SILVA, E. MORYA;
Edmond and Lily Safra Intl. Inst. of Neurosci., Inst. Santos Dumont, Macaiba, Brazil

Abstract: The rat primary somatosensory cortex (S1) has been known to be critically involved in a whisker-dependent tactile discrimination task. To determine how S1 neurons are collectively encoded by populations during the discrimination task we recorded the neural activity of 6 rats Long-Evans during their performance, where animals were trained to discriminate the width of two different apertures (wide versus narrow) using only their large mystacial vibrissae to receive a water reward. We defined a trial as the 2-second period centered around the discriminatory bars. The discrimination happened when there was a beam break upon contact between the bars and whiskers. When the animals achieved a performance of > 75% correct they were implanted bilaterally with an array of 32 electrode channels on each side of S1. The recordings were divided into 3 different time slots: anticipatory (from -0.5 to 0 s), discrimination (from 0 s to 0.3 s) and reward periods (from 0.3 s to 2.0 s). A total of 287 single and multi-units were recorded in 6 behavioral sessions. The firing rates observed in peristimulus time histograms shows that S1 neurons present complex excitatory and/or inhibitory patterns. The formation of specific firing rate patterns within neuronal clusters supported our hypothesis that there is a trend upon different stimuli throughout the task as well as stands to the S1 neurons multimodal property.

Title: Intra-claustral connectivity in the rat measured with voltage sensitive dye imaging

Authors: *A. A. ROBINSON, M. P. WITTER;
Kavli Inst. For Systems Neurosci, CNC, NTNU, Trondheim, Norway

Abstract: The claustrum is a small and highly conserved nucleus that extends rostrocaudally in the forebrain. In the rat, the claustrum is located lateral to the external capsule, bordering the insular and piriform cortices. The claustrum comprises two subregions, the (dorsal) claustrum and the endopiriform nucleus. Previous studies have shown that there are reciprocal connections with many areas of the cortex, however, little is known about the intrinsic connectivity and the function of the claustrum. One hypothesis is that the claustrum is able to synchronize and coordinate the activity of distant cortical areas based on this strong reciprocal connectivity. However, since there is a topographical arrangement of the reciprocal cortical connections of the claustrum, a strong intrinsic network within the claustrum must exist for it to be able to coordinate the activity of distant cortical regions. The current study aimed to investigate the potential intrinsic network within the claustrum and the dorsal endopiriform nucleus of the rat. Connectivity within the claustrum was analyzed with optical imaging, using the voltage sensitive dye (RH-795) in 400 μm thick brain slices from Long Evans rats of 23-30 days old. Sections through the claustrum in both the horizontal and the sagittal planes were used to investigate the connectivity along the anterior/posterior or dorsal/ventral directions respectively. Our results indicate that there is connectivity in all directions tested, with bidirectional activation observed throughout the claustrum and dorsal endopiriform nucleus. More experimental data are needed to confirm the connectivity within and between the claustrum and dorsal endopiriform nucleus and to establish the cells of origin and their postsynaptic targets that form this intrinsic network.

Title: Effects of enucleation on the direct reciprocal corticocortical connections between the primary visual and somatosensory cortices of the mouse

Authors: *I. O. MASSE, G. BRONCHTI, D. BOIRE;
Anatomie, UQTR, Trois-Rivieres, QC, Canada

Abstract: In the sensory deprived brain, the heteromodal cortical connections appear to play a more significant role in sensory processing (Merabet & Pascual-Leone, 2010). Although some studies report enhanced functional heteromodal cortical connectivity in the blind (Fuji et al., 2009; Klinge et al., 2010), others report a contradictory finding of decreased functional connectivity of the visual cortex in blind subjects (Liu et al., 2007; Yu et al., 2008). The purpose of this study is to compare the direct reciprocal corticocortical intermodal connections between the primary visual cortex (V1) and the primary somatosensory cortex (S1) in intact and C57BL/6 mice enucleated at birth, and to determine quantitative differences in the strength and laminar distribution of neurons and terminals in these projections. MATERIALS AND METHODS: In adult mice, iontophoretic injections of high molecular weight biotinylated dextrans (10kDa) and of the B fragment of cholera toxin (CTB) were performed in V1 and in S1 of intact and mice enucleated at birth. Axonal swellings were sampled using the software Stereo Investigator (MBF Bioscience). The size of swellings was measured and the frequency distribution was determined for each cortical layer. CTB retrogradely labeled neurons were used to estimate the relative weight of the projections between V1 and S1, and their laminar distribution was used to classify the projections as feedback, feedforward or lateral. RESULTS: Injections of CTB in V1 resulted in a greater proportion of labeled cells in the barrel field of intact mice than of enucleated mice. Following injections of BDA in V1, a greater range of axonal swelling size was observed in S1 of intact mice compared to enucleated mice. Large axonal swellings were observed in all cortical layers in S1 of intact mice whereas only small swellings were observed in enucleated mice. Injections of CTB and BDA in S1 of enucleated mice, however, resulted in no significant differences from intact mice. CONCLUSION: In the enucleated mice, the projection from V1 to S1 appears to play a different role in sensory processing. The absence of larger axonal swellings in the projection from V1 to S1 of enucleated mice strongly suggests that S1 no longer receives the Class 1 B driver inputs from V1 which were found in intact mice and that V1 inputs to S1 now have a predominant modulatory influence. This study provides evidence for alterations in heteromodal connections through anatomical changes following visual deprivation.

Title: Pruritic (itch) response in the nervous system of *Drosophila* melanogaster

Authors: *C. JOHN, R. K. MURPHEY, K. DAWSON-SCULLY, J. R. NAMBU;
Biol. Sci., Florida Atlantic Univ., Jupiter, FL

Abstract: Pruritus, or itch, is an unpleasant sensation that evokes an intense desire to scratch. Itch can be classified as an acute or chronic condition. Acute itch typically results from a bite or sting and can serve as a protective mechanism against tissue damage caused by parasites. However, chronic itch can occur when the immune and/or nervous systems dysfunction. It can also result from the dysregulation of itch and pain signaling. In mammals, pruritogens, or itch inducing agents, stimulate peripheral unmyelinated c-fiber pruriceptors, which are pruritogen detecting primary sensory neurons in the skin, causing transmission of sensory input to interneurons and projection neurons of the brainstem via the spinothalamic tract. This induces the itch sensation in the brain and the subsequent scratching behavior. Pruritic mediators include nerve growth factors, serotonin, endothelin-1 and TNFα, among numerous others. Commonly studied pruritogens include histamine, which is released during mast cell degranulation; compound 48/80, which induces histamine release; cowhage spicules, which signal a histamine-independent pathway and Chloroquine, an antimalarial drug for which itch is a side effect. Itch is a primary symptom in patients with skin diseases and systemic and metabolic disorders, including liver and kidney diseases, HIV and AIDS, brain cancer. It is also seen in psychiatric disorders like anxiety, depression, schizophrenia and delusions of parasitosis, which leads to self-injurious behavior. Since treatments currently available are ineffective in treating most cases of pruritus, elucidation of the mechanisms that underlie this condition using *Drosophila* will allow for identification of more specific anti-itch treatments. In current study, we are developing *Drosophila* as a model organism for investigating pruritus. To analyze the effects of pruritogens on *Drosophila* behavior, we administer aerosolized pruritogens, allowing the pruritogen to be taken up through their cuticle and spiracles. Our preliminary results indicate that both Histamine and Compound 48/80 evoke a significant behavioral response in flies resulting in longer grooming bout duration, compared to the control flies. However, Chloroquine and cowhage do not appear to significantly affect the flies' grooming behavior. Since some of the pruritogens tested evoked a response in the flies, while others did not, we believe the behavioral response we observed was a pruritic response. Therefore, based on these findings, we conclude that

Drosophila can indeed be used as a model organism for investigating pruritus and that both vertebrates and invertebrates experience itch.

Title: Transcriptional profiles of supragranular-enriched genes predict corticocortical network architecture in the human brain

Authors: *F. M. KRIENEN[1], B.-T. T. YEO[2], C. J. CHARVET[1], R. L. BUCKNER[3], C. C. SHERWOOD[1];

Abstract: The human brain is patterned with distributed networks that connect a disproportionately large cerebral cortex across multiple association zones in the frontal, temporal and parietal lobes. The expansion of the cortical surface, along with the emergence of new cortical areas and long-range connectivity networks, may be reflected in changes to the underlying molecular architecture. Using the Allen Institute's transcriptional atlas of the human brain, we demonstrate that genes that are particularly enriched in supragranular layers in the human cerebral cortex relative to mouse (Zeng et al. 2012) are correlated with large-scale network organization measured by functional connectivity MRI (Yeo et al. 2011). Candidate genes focused on those that are preferentially expressed in human upper layers (layers II/III), while in mouse are enriched in deep layers (layers V/VI). Microarray expression data for candidate genes from postmortem human brains (n=6) were cross-correlated to identify molecular profiles for each available cortical location. These were then clustered according to consensus maps of human functional connectivity networks (7 or 17 cortical networks, n=1000; Yeo et al. 2011). Results indicate that regions falling within sensory and motor zones have similar molecular profiles, despite being distributed across the cortical mantle. Sensory and motor region profiles were also anti-correlated with the profiles of limbic and association

regions. Alternate gene sets were tested, including, (1) using gene sets with annotated functional ontologies related to connectivity in mice (Wolf et al. 2011), (2) genes that are cortically enriched relative to subcortical structures (Konopka et al. 2012), and (3) genes with non-specific laminar distributions. Gene sets with conserved functional ontologies related to connectivity dissociated sensory and motor regions from limbic and association regions, but to a significantly lesser extent than the upper layer enriched set. Immunohistochemical and *in situ* hybridization expression data in nonhuman primates, including New World monkeys, Old World monkeys and apes, indicates that supragranular enrichment of these genes is not uniform across all primates. Molecular innovations of upper layer cortical architecture may be an important component in the evolution of increased long-range corticocortical projections across primates.

Ctr., Amsterdam, Netherlands; [4]Dept. of Hlth. Sci., Boston Univ., Boston, MA

Abstract: Structural connectivity among areas of the cerebral cortex provides the substrate for information exchange and is characterized by systematic patterns of presence or absence of connections between specific areas. Such pattern results in a topology that is essential for functional features characterizing healthy brain functioning. What principles govern this cortical wiring diagram? Building on prior work in the cat and macaque cortex (Beul et al., 2014a; 2014b) we investigated the relation of physical distance and cytoarchitecture with the connectional architecture of the mouse cortex and the organization of ipsilateral and contralateral connections. We use two independent datasets that constitute the current best estimate of mouse

cortico-cortical connectivity (Oh et al. 2014; Zingg et al. 2014). First, we reveal a mirrored and attenuated organization of ipsilateral and contralateral connections. Second, both physical distance and cytoarchitecture significantly relate with the presence and absence of connections. Notably, this analysis demonstrated that: i) Both factors conjointly relate better to the mouse cortico-cortical pattern than the contribution of each factor in isolation. ii) The two factors contribute differently to ipsilateral and contralateral connectivity. While physical distance, when compared to cytoarchitecture, is more tightly related to the presence or absence of ipsilateral connections, the opposite holds for the contralateral connections. The current results, conjointly with findings for the cat and macaque cortex, suggest that despite the striking differences of mouse, cat and macaque brains across space (brain size) and time (phylogenetic scale), common principles seem to pertain to the wiring of these systems. The identified wiring principles offer a guiding thread for unveiling neurobiological mechanisms that result in the close relation between the physical, cytoarchitectonic and connectional architecture of the brain. Title: Multisensory plasticity in the superior colliculus: different rules for time and space

Authors: ***C. DONG**, B. E. STEIN, B. A. ROWLAND;
Dept. of Neurobio. and Anat., Wake Forest Univ. Sch. of Med., Winston Salem, NC

Abstract: The physiological products of multisensory integration in the deep layers of the superior colliculus (SC) are dependent on the spatial and temporal configurations of cross-modal cues. Whereas spatially and temporally concordant cross-modal cues typically elicit responses that are more robust than the component cues (multisensory enhancement), spatially and/or temporally disparate cues elicit responses that are weaker (multisensory depression). These spatial and temporal principles of multisensory integration are popularly summarized as a singular "spatiotemporal principle", according to which concordance yields enhancement and discordance yields depression. The aim of the present study was to evaluate whether the similarity evident in the tuning of the multisensory process to spatial and temporal displacement was echoed in the sensitivity of this tuning to short-term sensory experience. In short, the question was whether the presumptive plasticity of the system was equivalent across space and time. Adult SC neurons were repeatedly presented with many (100) exposure trials of visual-auditory (VA) cues that were in one of 3 configurations: (a) spatiotemporally concordant (same location, V leading A by 50ms), (b) spatially disparate (V inside and A outside its receptive field), or (c) temporally disparate (V leading A by 100ms or 150ms). Responses were compared to baseline measures taken before exposure. The data revealed that this short-term experience could alter the temporal preferences of many neurons, but had little effect on their spatial preferences. In many cases neurons switched their temporal preferences toward the disparity presented in the exposure trials. In contrast, neither exposure to spatially concordant nor spatially disparate configurations induced reliable changes in the multisensory products of their synthesis. These results reveal an asymmetry in the short-term plasticity of the spatial and temporal principles of multisensory integration. Furthermore, they suggest that there are different rules for incorporating these principles during development, and for maintaining or adapting them to changes in environmental conditions.

Radiology and Nuclear Med., Univ. of Maryland, Sch. of Med., Baltimore, MD; [4]Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA; [5]Psychiatry, Univ. of North Carolina, Chappel Hill, NC

Abstract: Although the developmental trajectory of multisensory processing has long intrigued scientists, contrasting views have been proposed for its ontogeny. One view, posits that the different unimodal sensory modalities are segregated at birth and multisensory processing occurs only after appropriate postnatal experience. An alternate view argues that newborns are born with multisensory connectivity which becomes refined and segregated by sensory experience. To assess whether humans exhibit crossmodal connectivity at term (birth) or not, we used resting state fMRI to evaluate the corticocortical connectivity of two areas known to be multisensory in adults: the Intraparietal Sulcus (IPS; a region of largely visual-somatosensory convergence) and the Superior Temporal Sulcus (STS; a region of largely visual-auditory convergence). Data for term infants were obtained from University of North Carolina, Chapel Hill (UNC cohort, n=9) and from University of Maryland, Baltimore (UMD cohort, n=6), each of which revealed no structural anomalies on MRI and performed within the normal range on a comprehensive neurological examination. The rsfMRI results demonstrated, that there was significant functional connectivity at term of the IPS with visual association (MT, V3) and somatosensory association areas (S3), which is similar to the connectivity of the adult IPS. Similarly, the STS in newborn infants showed significant functional connectivity with the visual association areas (MT, V4), primary auditory cortex (A1) and, to a lesser degree, the somatosensory association areas (S2 and S3), which mirrors the pattern of adult connectivity. Thus, rsfMRI provides convincing evidence that both the IPS and STS areas already display functional communication with multiple sensory cortices at birth. These data are consistent with demonstrations of multisensory processing in human newborns that can visually recognize objects previously explored only by touch, or that have visual perceptions modified by the presence of an auditory stimulus. Collectively, these observations support the multisensory at birth view of sensory ontogeny.

Title: The functional development of macaque inferotemporal cortex

Authors: *J. L. VINCENT, K. SRIHASAM, M. LIVINGSTONE;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Primate inferotemporal cortex is subdivided into domains for biologically important categories, such as faces, bodies and scenes. How this organization comes about is unknown. To monitor the normal development of category selective domains we collected functional MRI on five normally developing infant macaques while they passively viewed movies and images of faces and objects in the scanner. We have developed techniques for safely and non-invasively doing functional MRI in alert infant macaques and have longitudinally scanned monkeys from as early as 7 days old. Our results indicate that the development of visual responsiveness in IT proceeds from early, posterior, visual areas towards anterior IT. The youngest monkeys (1-2 weeks old) showed visually evoked signal only in LGN and the superior colliculi. Early visual areas and inferotemporal cortex did not show significant signal change to visual stimulation until approximately 1.5 and 3 months of age, respectively. This slow maturation is surprising in light of reported early maturity of single unit responsiveness in both V1 (Wiesel & Hubel, 1974) and IT (Rodman et al. 1993); we do not know whether this delay represents immaturity of vascular responsiveness or the physiology of neuronal populations. Category-selective responses to faces or object stimuli were first observed in the superior temporal sulcus and middle temporal gyrus at approximately 6-7 months of age.

Title: The amygdala is causally connected to the superior temporal sulcus (STS) for dynamic face perception

Authors: *D. PITCHER, S. JAPEE, L. UNGERLEIDER;
NIH/NIMH, Bethesda, MD

Abstract: Non-human primate neuroanatomical studies demonstrate that a cortical pathway from the superior temporal sulcus (STS) projects into the dorsal regions of the amygdala but whether this same connection exists in human cortex remains unclear. In the present study we addressed this question by combining thetaburst transcranial magnetic stimulation (TBS) with functional magnetic resonance imaging (fMRI) to causally test the prediction that the STS and the amygdala are functionally connected for processing the dynamic aspects of faces. Participants (N=22) were scanned over two sessions while viewing 3-second video clips of faces, bodies and objects. During these sessions, TBS was delivered over the right posterior superior temporal sulcus (rpSTS) or the vertex, a point on the top of the head that acted as a TMS control site. A region of interest (ROI) analysis revealed results consistent with our hypothesis. Namely, TBS delivered over the rpSTS reduced the BOLD response to faces and bodies (but not objects) in the rpSTS itself and the BOLD response to faces in the amygdalae bilaterally when compared with TBS delivered over the vertex control site. These results causally demonstrate that the rpSTS is functionally connected to the amygdala for the perception of dynamic faces.

Title: Feature derivation and facial image reconstruction from patterns of neural activation

Authors: *A. NESTOR[1], D. NEMRODOV[1], D. PLAUT[2], M. BEHRMANN[2];
[1]Univ. of Toronto Scarborough, Scarborough, ON, Canada; [2]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Recent attempts at neural-based image reconstruction, including facial image reconstruction, have established the ability of BOLD patterns to support this enterprise. However, these attempts rely on prespecified image features motivated by their general biological plausibility. Here, we take on the twofold task of deriving features directly from patterns of neural activation and of using those features for the purpose of face reconstruction. To be clear, reconstruction serves here both as a goal in itself and as a means of validating the visual code underlying neural face representations in the context of an assumption-sparse methodological framework. More specifically, we use a version of reverse correlation to derive facial features from patterns of activation in high-level visual areas and, then, we combine those features linearly to reconstruct novel face images from the activation that they elicit. This approach allows us to estimate an entire gallery of visual features associated with different cortical areas as well as to achieve significant levels of reconstruction accuracy as confirmed both by objective image metrics and by psychophysical data. Furthermore, we show how this approach can be immediately extended to both behavioral data and to other neuroimaging modalities (e.g., EEG). From a theoretical perspective, the present findings provide key insights into the nature of high-level visual representations and into their reliance upon specific neural resources (e.g., cortical areas, frequency bandwidths). At the same time, they open up the possibility of a broad range of image-reconstruction applications via a straightforward methodological approach.

Title: Temporal integration windows of AF face patch neurons using naturalistic movies

Authors: *B. E. RUSS, J. DAY-COONEY, D. A. LEOPOLD;
Section on Cognitive Neurophysiol. and Imaging, Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Previous studies have shown that a region of the anterior superior temporal sulcus of the rhesus macaque, the anterior fundus face patch (AF), is selective for faces. These studies most often involve the presentation of static images flashed in a subject's center of gaze for a few hundred milliseconds. Recent studies have begun probing AF and related areas with more ethologically relevant paradigms, using dynamic presentations of real world stimuli. Work from our lab has shown that individual neurons in AF respond in a consistent manner to the content of dynamic movies during free viewing. Although we found selectivity for flashed faces in most neurons, responses were weakly tied to the appearance of faces in the video. Many adjacent neurons were uncorrelated in their responses to natural videos. These results raise a set of challenging questions about how neurons in face patches process visual information under natural conditions. For example, to what extent do AF neurons integrate temporal information in their responses? Here we addressed this question using chronically implanted 64-channel microwire bundles in two rhesus macaques in the AF face patch. We recorded neural activity longitudinally from single units, isolated over several weeks, while interleaving a number of different tasks each day. In a fixation task, we assessed selectivity to a set of six static image categories. In a natural viewing task, we measured responses to several social movies, depicting interacting conspecifics interacting, as well as "non-social control" movies with no animals present. Additionally, we presented short movie clips, sampled at one-second intervals from one of the social movies and shown in random order. We varied the duration of the clips to systematically investigate the temporal response integration of AF cells. By arranging the randomly presented clips in their original chronology and comparing the reordered neural responses to those obtained during continuous viewing, we assessed the temporal integration properties of single AF neurons. Using this method, we found that temporal features elapsing over approximately 500ms shaped the responses of most neurons in this area. Mixed in with this population were neurons whose responses did not obviously depend on temporal information, as the reordered responses to flashed static images and brief clips closely resembled responses from continuous viewing. The categorical selectivity of individual neurons to flashed stimuli was not a reliable predictor of the cells' dependence on temporal integration. These results demonstrate the inherent response heterogeneity of "face cells" in the context of natural vision.

Title: Dissociations and associations between shape and category representations in the two visual pathways

Authors: *S. BRACCI, H. OP DE BEECK;
Lab. voor Biologische Psychologie, KU Leuven, Leuven, Belgium

Abstract: Both visual pathways represent visual and conceptual object properties. Recent reports tried to explain conceptual representations by referring to visual properties, but without dissociating the two alternatives. We present an event-related fMRI study that explicitly dissociates shape from category in order to investigate their independent contribution as well as their interactions through representational similarity analyses. Results reveal an independent contribution from each dimension in both streams, with a transition from shape to category along the posterior-to-anterior anatomical axis. The nature of these shape-independent category representations differs in the two pathways: ventral areas represent object animacy and dorsal areas represent object action properties. Furthermore, information about shape evolved from low-level to high-level shape following a posterior-to-anterior gradient similar to the shape-to-category emergence. To conclude, representations of shape and category independently coexist and interact throughout the visual hierarchy, as such reconciling visual and semantic accounts of the visual system functional organization.

Title: Beyond the core face-processing network: intracerebral stimulation of a face-selective area in the right anterior fusiform gyrus elicits transient prosopagnosia

Authors: *J. JONAS[1], L. MAILLARD[2], H. BRISSART[2], B. ROSSION[1];
[1]Catholic Univ. of Louvain, Louvain-la-Neuve, Belgium; [2]Univ. Hosp. of Nancy, Nancy, France

Abstract: According to neuropsychological evidence, a distributed network of face-selective regions of the ventral visual pathway supports face recognition. However, fMRI studies have generally confined to the posterior face-selective areas, i.e., the occipital face area (OFA) and the fusiform face area (FFA). There is recent evidence that intracranial electrical stimulation of the OFA and FFA elicits face recognition impairments. Here we were able to test for face recognition in a patient implanted with depth electrodes in the anterior temporal cortex. Electrically stimulating the right anterior fusiform gyrus, in a region located anteriorly to the FFA, induced a transient inability to recognize familiar faces (Fig. 1, stimulation of electrodes F3, F4, F4 and F6; movies available). This region was shown face-selective as revealed by intracerebral face-selective event-related potentials and gamma band activity recorded at these critical electrodes. However, no fMRI face-selective responses were found in this region due to severe BOLD signal drop-out caused by the ear canal artifacts (see raw EPI slices, Fig. 2). These results point to a causal role in face recognition of the right anterior fusiform gyrus and more generally of face-selective areas located beyond the "core" face processing network in the ventral temporal cortex. It also illustrates the diagnostic value of intracerebral recordings and stimulation in understanding the neural basis of face recognition and visual recognition in general

Title: Two neural pathways of face processing: An updated model

Authors: M. BERNSTEIN[1], J. ORON[1], *G. YOVEL[2];
[1]Sagol Sch. of Neurosci., [2]Tel Aviv Univ., Tel Aviv, Israel

Abstract: Faces elicit selective neural responses in various brain areas. According to current neural face models (Haxby et al., 2000, 2007) brain areas responsive to faces are divided into core face areas and extended face areas. The core face areas extract visual information from faces and include the face-selective areas in the lateral occipital cortex (occipital face area - OFA), the fusiform gyrus (fusiform face area - FFA) and the posterior superior temporal sulcus (pSTS face area - pSTS-FA). Furthermore, there is a division of labor between the core areas such that the FFA extracts invariant aspects of faces (e.g. identity, gender) and the pSTS represents changeable facial aspects (e.g., expression, gaze). The extended face areas are not selective to faces but are responsive to face-related information such as speech, semantic & emotional information. This dominant model is primarily based on studies that presented static images of faces. Recently we have started examining the neural representation of dynamic faces and reveal several new findings that call for an updated neural model. First, dynamic faces generate face-selective activations in additional areas not included in the original model in the anterior STS (aSTS) and the inferior frontal gyrus (IFG). Second, the primary division of labor between the ventral and dorsal face areas is to form and motion, rather than to invariant and changeable aspects. Specifically, the OFA and FFA do not extract additional information from dynamic than static faces, whereas the STS is highly responsive to dynamic facial information regardless of whether subjects are performing an expression (changeable) or gender (invariant) task. Third, the dorsal face areas are not only selective to dynamic faces but are highly selective to human voices (e.g., cry, laugh, cough) relative to non-human sounds (e.g. ring, beep), whereas the ventral face areas are not responsive to human voices. Taken together our results as well as additional recent findings in the literature, we suggest an updated model according to which the neural face network is composed of two main pathways, a ventral pathway, which is unimodal

and extracts form information from both invariant and changeable aspects of faces and a dorsal pathway, which is multimodal and extracts dynamic visual and auditory information about people.

Title: Deep neural networks models predict spatio-temporal cortical dynamics of visual object recognition

Authors: ***A. OLIVA**[1], A. KHOSLA[1], D. PANTAZIS[2], A. TORRALBA[2], R. M. CICHY[2]; [1]CSAIL, [2]MIT, Cambridge, MA

Abstract: The cortical basis of visual object recognition in humans is a rapidly unfolding, complex multistage process in space and time whose understanding necessitates a model capturing its complexity. A major impediment in creating such a model is the highly nonlinear and sparse nature of neural tuning properties in mid- and high-level visual areas, precluding principled understanding. We propose a framework that obviates this impediment by comparing brains to deep convolutional neural networks (CNN), i.e. computer vision models whose model neural tuning properties are set during supervised learning without manual intervention (Fig. 1a). We recorded MEG and fMRI data in 15 participants while those viewed images of 118 images (Fig. 1b). Using representational similarity analysis, we compared brain responses to a state-of-the-art CNN trained on object categorization (object-CNN). By comparison of MEG data to the CNN, we showed that each layer of the object-CNN predicted brain representations (Fig. 1c), and the relationship was hierarchical: low layers of the CNN correlated with MEG early in time, and high layers later (Fig. 1d). By comparison of fMRI data to the CNN using a spatially unbiased searchlight approach, we showed that CNNs predict visual representations in the ventral, but also the dorsal stream, providing novel support for object representations in parietal cortex independent of motor movement or attentional confounds. Together, our results provide a novel, algorithmically explicit perspective on the nature of visual object recognition in the human brain in the first few hundred milliseconds of vision.

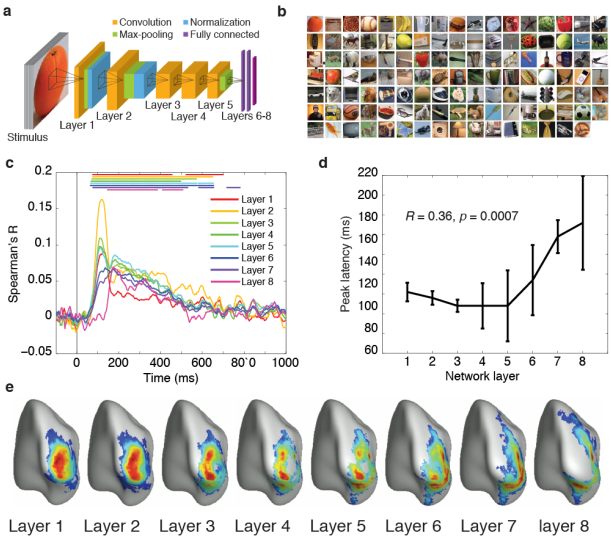

Figure 1. a) The Convolutional neural network (CNN) had an 8-layer architecture, implementing biologically plausible operations such as convolution, max pooling and normalization. **b)** The image set consisted of 118 images of real-world objects on natural backgrounds. **c)** All layers of the CNN predicted MEG responses with different time courses. **d)** There was a temporal hierarchical relationship between network layer position and peak latency of the layer-specific MEG time courses: the higher the CNN layer, the later the peak in predicting MEG responses (R=0.36, p= 0.0007). **e)** We found a spatial hierarchical relationship between network layer position and cortical regions, too: while low layers predicted fMRI activity in the occipital pole, higher layers predicted activity in more anterior regions along both the ventral and dorsal visual stream.

Title: Functional correspondence between human and monkey face-selective regions in processing face configuration

Authors: *Q. ZHU[1], M. SPRONK[1], W. VANDUFFEL[1,2,3];
[1]Lab. For Neuro- and Psychofysiology, K.U. Leuven, Leuven, Belgium; [2]Dept. of Radiology, Harvard Med. Sch., Boston, MA; [3]A.A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: The monkey plays a critical role in understanding the neural mechanisms of face perception. However, it is unclear whether monkeys process faces in a similar holistic manner as humans and how monkey and human face-selective regions correspond. To address this, we performed the same fMRI experiment in these two species. We presented human face parts in either their normal composition or deviant compositions in different blocks. Veridical and scrambled faces were created by disassembling the same composite images (four veridical faces positioned around a fixation point) in two different ways. We either presented each full set of face features from one of the four veridical faces separately, or spread them over the four faces (hence showing four different features from the four different faces). This resulted in scrambled faces that fully controls for local low-level stimulus differences compared to the veridical faces while destroying the veridical configurations. To further control for different degrees of stimulus spreading and asymmetry, we created two other conditions with face features arranged in a scrambled configuration at each of the four positions in the initial composite images. Finally, two additional control conditions were created with objects instead of face parts. Three monkeys and twenty humans were scanned while they performed a fixation task. An independent localizer experiment was performed in the same subjects to identify face-selective regions. We found a significant face configuration effect in monkey face-selective regions PL, ML, MF and lMFa, and in human OFA, FFA, rpSTS and rmSTS. In addition, compared to the spreaded version, the scrambled faces and objects elicited a significantly lower response in monkey PL and ML, and in human OFA and FFA, likely due to surround suppression in the latter stimuli, whereas the same contrast revealed a significant positive activation in monkey MF and lMFa, and in human rmSTS. In PL and OFA, the veridical faces elicited a similar response as their spreaded version, whereas the veridical faces elicited a significantly higher response in FFA and all the other regions, suggesting a correspondence between PL/OFA. Furthermore, through an inter-species multiple voxel representational similarity analysis, we found that the pattern dissimilarity between the four types of faces in human rmSTS is more similar to that in monkey MF and rAF, whereas the pattern dissimilarity in human OFA, FFA and rpSTS is more similar to that in monkey PL and ML. Taken together, these results suggest a similar face processing system between humans and monkeys, with possible functional correspondences between PL/OFA, ML/FFA and MF/rmSTS.

Title: Temporal processing capacity in high-level visual cortex is domain-specific

Authors: *A. STIGLIANI, K. S. WEINER, K. GRILL-SPECTOR;
Psychology, Stanford Univ., Stanford, CA

Abstract: Prevailing hierarchical models propose that temporal processing capacity - the amount of information that a brain region processes in a unit time - decreases at higher stages in the ventral stream. However, it is unknown if high-level visual regions have temporal processing capacities that are domain-general or domain-specific. Using a novel fMRI paradigm, we estimated the temporal capacity of functional regions across the human ventral stream. Contrary to hierarchical models predicting domain-general capacities, our data reveal domain-specific processing capacities: (1) regions processing information from different domains have differential temporal capacities within each stage of the visual hierarchy and (2) regions processing the same domain display the same temporal capacity irrespective of their position in the processing hierarchy. In general, character-selective regions have the lowest capacity, face- and place-selective regions have an intermediate capacity, and body-selective regions have the highest capacity. Notably, cortical temporal processing capacities are not inherited from V1 and have perceptual implications. Behavioral testing revealed that the encoding capacity of body images is higher than that of characters, faces, and places and there is a correspondence between peak encoding rates and cortical capacities for characters and bodies. The present evidence supports a model in which the natural statistics of temporal information in the visual world guides domain-specific temporal processing and encoding capacities. These findings suggest that the functional organization of high-level visual cortex may be constrained by temporal characteristics of stimuli in the natural world, and this temporal capacity is a characteristic of domain-specific networks in high-level visual cortex.

Title: The functional organization of early and higher-order visual cortex in patients with lobectomy/hemispherectomy

Authors: ***M. BEHRMANN**[1], T. LIU[2], A. NESTOR[3], K. KAY[4], M. VIDA[2], J. A. PYLES[2], X. ZHANG[5], C. PATTERSON[6];

Abstract: The recovery of perceptual functions that occurs following cortical damage can offer key insights into the nature and plasticity of brain organization. In this respect, studies of individuals' post-lobectomy/hemispherectomy offer a unique window into the nature and extent of cortical plasticity. First, in contrast with more common lesions, the extent of the damage in such patients can be extreme (i.e. an entire hemisphere in some cases) yet, at the same time, very well controlled - both cortical and subcortical structures of the remaining hemisphere are

typically intact. Second, the extent of the recovery is often disproportionate relative to the extent of the damage - many compromised functions are regained partly or even completely. Our present work uses fMRI to characterize the changes in topography and functional organization of extrastriate cortex and of visual field maps (VFMs) in children who have undergone surgical lobectomy or hemispherectomy of ventral cortex (compared with control participants who have undergone resections to other areas such as dorsal cortex). We uncover atypicalities in the selectivity of high-level visual cortex to common visual categories (face, object, and word) and show changes in this reorganization over the course of time post-surgery. Plasticity in earlier parts of visual cortex appears more limited and retinotopic organization in the affected hemisphere is either absent or largely abnormal. Overall, the current results suggest that extensive removal of visual cortex may lead to atypical selectivity for common visual categories but has limited effect on plasticity of early visual cortex.

Title: Exploring the representational structure in visual object-responsive cortex

Authors: ***T. A. KONKLE**[1], A. CARAMAZZA[2];
[1]Psychology Dept, [2]Psychology Dept., Harvard Univ., Cambridge, MA

Abstract: The human visual system is built to efficiently extract and encode the structure of the natural world, transforming information from early sensory formats into increasingly abstract representations of its content that support our behavioral capacities. What are the different levels of representation from “low” to “high” level properties? To explore a broad space of possibilities, we considered properties that reflect how we interact with objects (action), where they are found (context), what they are for (function), how big they are (real-world size), and what they look like (object gist). Estimates for these feature spaces were obtained for a set of 200 inanimate objects, using either behavioral rating experiments or image-based measures that capture global shape structure (Oliva & Torralba, 2001). Using fMRI, we obtained neural

response patterns for 72 of these items in 11 participants. To analyze the structure in the neural responses, we used a feature-modeling approach (Mitchell et al., 2008; Huth et al., 2012), which fits a tuning model for each voxel along a set of feature dimensions (e.g. object gist features, action features). In areas V1, V2, and V3, the responses were well-fit by the object gist model (mean r2=0.54) and performance in a leave-two-out classification procedure was near perfect (96% SEM=1%). In contrast, the higher level feature spaces were not significantly above chance prediction in this cortex. In object-responsive cortex beyond early visual areas, the object gist model also outperformed the more abstract feature spaces (83% SEM=3%). However, feature spaces of action, context, function, and real-world size all were also able to classify objects above chance (61%-68%). These models fit best along more anterior regions of object-responsive cortex, extending along PHC, TOS, and IPS. Thus, while these abstract properties of objects capture some of the structure in neural object responses, the results indicate that visually-responsive object cortex most strongly represents global form properties.

Title: Spatial and temporal dynamics of face processing in the human ventral temporal cortex

Authors: *V. RANGARAJAN[1], B. L. FOSTER[2], S. GATTAS[1], J. PARVIZI[1];
[1]Neurol. (SHICEP), [2]Psychology, Stanford Univ., Stanford, CA

Abstract: Functional neuroimaging studies have revealed regions within the lateral and ventral temporal cortex that exhibit category specific neuronal responses to visual stimuli such as faces, objects, and places. These category responses display a consistent spatial organization with respect to well-established anatomical landmarks such as the Superior Temporal Sulcus, Fusiform Gyrus and mid-Fusiform Sulcus. Though several studies have mapped the spatial organization of face responses, the slow temporal dynamics of fMRI have provided limited temporal details of such activations. Moreover, few studies have explored sub-category level

visual activations (e.g., human versus mammal faces) in these regions. In the current study, we utilized electrocorticography (ECoG) data from 6 subjects implanted with subdural electrodes during two tasks. Task 1 contained images of human faces, places, English words, Spanish words, numerals, foreign numerals, corporate logos, and false fonts; In Task 2, subjects saw faces or bodies without heads (human, mammal, bird, fish), objects, places, and limbs. In both tasks, subjects were instructed to press 1 when a red target appeared. Leveraging the high spatial and temporal resolution of ECoG, we analyzed High Frequency Broadband (HFB: 70-150 Hz) power changes across all channels. In concordance with our previous work (Rangarajan et al., 2014), several face-selective FG electrodes were identified bilaterally using the Task 1 data. Data from Task 2 were used to explore the temporal dynamics of activity in these (face-selective) electrodes of interest and their neighboring sites to determine if the onsets and peaks of their activations revealed novel information about the temporal evolution of face processing. Our analysis revealed that electrodes of interest (identified from task 1) showed both larger magnitude and earlier HFB response onsets (~110 ms +/- 0.19) to faces than their immediate neighbors, supporting their focal selectively. Additionally, when several face-selective segregated electrode clusters were identified, many showed near simultaneous face response onsets, rather than a hierarchical (posterior to anterior) temporal organization. Lastly, within face-selective areas, the onset of responses to sub-categories of faces was earliest for human faces compared to animal, bird, or fish faces by 15 +/- 0.22 ms. Altogether, our findings provide electrophysiological evidence for a temporal dissociation between face-selective and neighboring sites in processing face stimuli and in prioritizing human versus other sub-categories of faces in face-selective regions.

Title: Beyond Brodmann: Quantifying the functional and microstructural heterogeneity of human high-level visual cortex

Authors: *K. S. WEINER[1], M. BARNETT[1], S. LORENZ[2], J. CASPERS[2], A. STIGLIANI[1], K. AMUNTS[2], K. ZILLES[2], B. FISCHL[3], K. GRILL-SPECTOR[1];
[1]Stanford Univ., Stanford, CA; [2]Res. Ctr. Jülich, Jülich, Germany; [3]Massachusetts Gen. Hosp., Boston, MA

Abstract: Human high-level visual cortex consists of functionally and microstructurally heterogeneous areas. Here, we compared and quantified the heterogeneity of functional and cytoarchitectonic regions in human ventral temporal cortex (VTC) using cortex based alignment (CBA) techniques. Functional magnetic resonance imaging (N=12; 2.4mm isotropic voxels; TR=2s) and a standard localizer experiment (Stigliani et al., 2014) enabled the identification of face- (pFus-faces/FFA-1 and mFus-faces/FFA-2), place- (CoS-places/PPA), and limb-selective (OTS-limbs/FBA) functional regions of interest (fROIs). Using an observer-independent cytoarchitectonic method (N=10 postmortem brains, 20 micron resolution) to determine transitions in cortical microstructure, we identified four areas (FG1, FG2, FG3, and FG4; Caspers et al., 2013; Lorenz et al., 2014). fROIs and cytoarchitectonic (cROIs) regions were registered to the FreeSurfer average brain using CBA (Fischl et al., 1999). We then generated maximum probability cROIs and quantified the proportion of each individual subject's fROIs within each cROI. Our results reveal three main findings. First, face- and place-selective regions are cytoarchitectonically dissociable. Nearly all face-selective regions are localized in FG2 and FG4 (90±8%, mean±std), while CoS-places was localized in FG3 (77±7%). Second, fusiform face-selective regions are also cytoarchitectonically dissociable: pFus-faces is located in FG2 while mFus-faces is located in FG4. Third, multiple fROIs can be located within a single cROI as both OTS-limbs (81±20%) and mFus-faces (84±14%) are within FG4. Together, our findings indicate that cytoarchitectonic structure may constrain functional differentiation both within a domain (e.g. between mFus- and pFus-faces) and across domains (e.g. between mFus-faces and CoS-places), but that cytoarchitectonic regions may also contain heterogeneous functions (e.g. both face- and limb-selective regions). These findings link the functional heterogeneity to the microstructural heterogeneity of high-level visual cortex for the first time. Additionally, the finding that a single cytoarchitectonic region is functionally heterogenous challenges classic views of cytoarchitectonic areas.

Title: Motion-Induced color appearance shift

Authors: *S. HONG[1], M.-S. KANG[2];
[1]Psychology, Florida Atlantic Univ., Boca Raton, FL; [2]Psychology, Sungkyunkwan Univ., Seoul, Korea, Republic of

Abstract: Surrounding chromatic context modulates perception of color, which indicates that color appearance is not solely determined by spectral light reflected from a surface or an object. Here we present a novel and strong chromatic induction, in which color appearance of two identical objects, presented on a equiluminant equal-energy-spectrum (EES) 'white' background, shifted away from each other by setting one of the objects in motion. The direction of shift in color appearance of the stationary one is consistent with the one observed after prolonged adaptation to chromatic contrast, desaturation. On the other hand, color appearance of the moving one becomes more saturated. The shift in color appearance of the stationary dot is not due to local adaptation, because the appearance goes back to the baseline color after motion offset. Further, continuous flickering of multiple dots in the surrounding context is not potent enough to induce color shift of the stationary dot, indicating that motion-specific neural response rather than transient neural signal causes the appearance shift. We propose that the shift in color appearance of the stationary and the moving dots result from neural normalization of chromatic responses triggered by motion. This novel color induction by motion demonstrates a tight coupling between color and motion processing.

Title: Neural locus of simultaneous color contrast

Authors: *A. KHACHATRYAN[1], P. FUNG[1], C. LE'PRE[1], R. BACHY[2], Q. ZAIDI[2], Y. XIAO[1];

Abstract: Simultaneous color contrast is a classical contextual effect that has been extensively studied using psychophysics and modeling, but its neural locus remains uncertain. To address this question, we have recorded neuronal activity from macaque extra-striate cortex, using a psychophysical method that isolates lateral interactions from adaptation. Imaging of intrinsic optical signals was used to visualize color-preferring modules in areas V2 and V4, where hue maps were found in previous studies. Neuronal activities in and near these modules were then recorded with multi-channel electrode arrays. Two sets of visual stimuli were used. The first set comprised full-screen (40x30 degrees) modulations along cardinal axes in the DKL color space that correspond to color preferences of different subcortical channels. The second set was identical to the first one except that the central region remained static at the mid-gray. The static central region (2-8 degrees) fully covered the receptive fields of the recorded neurons. Perceptually, the physical modulation of color in the surround induced complementary colors in the central region, i.e. an opposite-phase modulation of reduced contrast was seen where no physical modulation was present. A critical signature for the neural locus of simultaneous color contrast is that cells should exhibit similar behavior, i.e. their maximal response to full-screen or surround modulation occur at opposite phases. Many cells in or near the color-preferring modules in V2 and V4 responded to full-screen modulation of color at the temporal frequency of the stimuli. This finding suggests an important role of color-preferring modules in encoding spatially uniform color, given that previous studies with random penetrations in V2 and V4 found fewer cells that responded to uniform color. While the vast majority of such cells in V2

responded maximally to similar temporal phases of the full-screen and surround modulations, a significant portion of them in V4 responded best to opposite phases of full-screen and surround modulations. These results suggest that simultaneous color contrast emerges in area V4 in functional compartments that are involved in color perception, which is consistent with previous findings that V4 plays an important role in various forms of contextual effect on color.

Title: The dynamics of color processing in humans measured with MEG

Authors: ***K. L. HERMANN**[1,2], D. PANTAZIS[2], B. R. CONWAY[1,2];
[1]Neurosci. Program, Wellesley Col., Wellesley, MA; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: At what point after a stimulus arrives at the eye is its color decoded by the brain? To address this question, we applied a decoding analysis to determine the time at which color information can be read out from a magnetoencephalography (MEG) signal. We presented two types of stimuli: color stimuli, and images of human faces and bodies. The color stimuli were square patches (6.2° across), of four hues at four luminances (i.e. 16 stimuli), presented at the fovea surrounded by a neutral gray. The colors were defined by a cone-opponent color space, had matched saturation, and were +/-30% or +/-60% luminance contrast. Each stimulus appeared 50 times in random order. Data were sampled at 1 kHz using a 306-channel Elekta Neuromag Triux, and pre-processed with Maxfilter software (Elekta) and band-pass filters (Brainstorm software; Tadel et al., 2011). Decoding analyses were done using the Neural Decoding Toolbox (Meyers, 2013) with a maximum correlation coefficient classifier. We did 50 decoding iterations, with 4 cross-validation splits, averaged trials in sets of 10, and used the 25 most selective channels at each time point. On average (in N=3), the onset latency for decoding faces versus

bodies was 91-96 ms. By comparison, we were able to determine which color (of 16 presented) a subject was shown as early as 78-83 ms after stimulus onset ($p < 0.005$, permutation test). To test whether luminance or hue information alone could drive decoding performance, we created two models. In Model 1, for each color, we assigned the correct luminance label with probability equal to the accuracy observed on a separate luminance decoding problem, and chose the hue label at chance. In Model 2, we assigned hue labels with probability equal to accuracy observed in a hue decoding problem, and luminance labels, at chance. We compared the relative magnitudes of the observed color decoding accuracy and the model predictions at the time of peak decoding; neither model accounted for the accuracy observed ($p < 0.001$ for both comparisons, by permutation test), suggesting that the observed color decoding depends upon neural sensitivity to both hue and luminance. But at what point in the visual system? Representational similarity analyses show that MEG onset latencies of 50-80 ms correspond to V1 activity (measured with fMRI), while those of 80-200 ms correspond to IT activity (Cichy et al., 2014). Isik et al. (2014) decoded the identity of object images at 60 ms, and identity invariant to changes in size and position at 125 and 150 ms. Taken together, our results on body/face decoding and color decoding suggest that the colors presented here are decoded relatively late in the visual-processing hierarchy, perhaps V4 or IT.

Title: Color perception can be multistable as revealed by #TheDress

Authors: ***B. R. CONWAY**[1,2], K. L. HERMANN[1,2], R. LAFER-SOUSA[2];
[1]Neurosci., Wellesley Col., Wellesley, MA; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: To guide behavior, the brain must resolve ambiguity of sense data. Ambiguous shape information is typically resolved into two or three stable states. At any instant, the Necker cube is seen as popping out, receding away, or rarely as a hatch-work on a plane. How does the visual

system resolve color ambiguity? Although people might disagree about the exact color of a test (teal, blue, or green?), it has been widely assumed that most subjects would match the test to essentially the same color target, suggesting the disagreement is more about variability in language than perceptual mechanisms. We revisited this question by quantifying the perception of 'the dress' photograph. The colors of individual pixels when viewed in isolation are blue or brown, colors associated with natural illuminants, but popular accounts suggest the dress appears white/gold or blue/black. The phenomenon was an internet sensation because it seems to contradict popular belief, suggesting that color is, in fact, subject to discrete stable percepts (multistability). But there is a less exciting alternative: that the observed categorical responses arose because the social-media question was framed as a two-alternative forced choice. We used two experiments to test these alternatives. We surveyed 1348 subjects using Mechanical Turk and 53 subjects in-lab. First, we asked subjects to complete the sentence: "this is a ___and___dress". Most subjects reported white/gold or blue/black, but some said blue/brown. Second, we performed a language-free color-matching experiment in which we asked subjects to identify from a complete color gamut the two components of the dress. Each color match was defined by three coordinates (L, u, v). We used principle component analysis to define a vector through the cloud of data points (separate analysis for the two dress' components), and plotted for each subject the weight of the first PC for the "blue" pixels against that for the "brown" pixels. The plot shows three peaks, which correspond to the color-matches of the three sub-populations (W/G, B/K, B/B) identified in experiment 1. These results document one of the most compelling examples of striking individual differences in color perception, and show that the brain resolves ambiguity in 'the dress' into one of three stable states, not unlike how the brain handles ambiguous shape. But the "stickiness" of these states seems to be different for 'the dress' compared to the Necker cube. Although we found that the colors of the dress switch for some people (~11%), it appears that many people are incapable of switching their perception of the dress (unlike the Necker cube), and for those who do switch, the dynamics are slower.

Title: Effect of the mode of color appearance upon amplitude of steady-state visual evoked potential

Authors: *H. HIROSE[1,2], Y. KOIKE[2];
[1]AISIN COSMOS R&D Co.,Ltd., Kariya, Aichi, Japan; [2]Dept. of Information Processing, Tokyo Inst. of Technol., Yokohama, Japan

Abstract: Several studies have been making clear that amplitude of steady-state visual evoked potential (SSVEP) varies in relation to physical aspects (e.g. brightness, hue and saturation) of flickering visual stimulus. However, there were little studies that revealed association between SSVEP amplitude and psychological aspects. This study aimed to elucidate the association between SSVEP amplitude and the mode of color appearance that is a psychological phenomenon. We investigated about SSVEP amplitude changes under two kinds of the mode of color appearance (aperture and surface color mode) condition. In experiment 1, we instructed subjects to gaze into 8 different flickering visual stimuli for 5 seconds under the conditions. Each stimulus was consisted of achromatic square and chromatic square that was colored with red, orange, yellow, yellow-green, green, blue-green, blue or purple. Their colors were selected from a Derrington-Krauskopf-Lennie (DKL) color space and were the same luminance (approximately 40 cd/m2). Flickering frequency of them was 12 Hz. Apparent size was 10 degrees. In the aperture and the surface color mode condition, background color was achromatic and has a luminance of approximately 0 cd/m2 and 40 cd/m2, respectively. These stimuli were presented one at a time on the center of a LCD screen. Electroencephalograms (EEGs) were measured at 8 loci (POZ, 3, 4, 7, 8 and OZ, 1 ,2) on the back of the head over the visual area of brain. Power spectral densities were calculated from the measured EEGs by using a frequency domain analysis. We focused on amplitude changes of fundamental component (F1) and second harmonic component (F2) of SSVEP. From the experiment 1, SSVEP amplitude changes related to the color of the flickering visual stimuli were observed in each condition. Furthermore, the SSVEP amplitude changes related to the mode of color appearance were also detected. These changes occurred in both the F1 and the F2. The SSVEP amplitudes obtained in the surface color mode condition had a tendency to be larger than those in the aperture. In experiment 2, we instructed the subjects to rank the flickering visual stimuli according to his/her flickering perception under the conditions. The subjects orally answered the rank in the descending order. These stimuli were simultaneously presented on the LCD screen. The other presentation methods were the same as the experiment 1. From the experiment 1 and 2, we found a positive correlation between the amplitude changes of the F2 and the rank of the stimuli in the aperture color mode condition. These results suggested that both physical and psychological aspects of flickering visual stimulus could influence SSVEP amplitude.

Title: Differential cerebral sources of human color responses

Authors: *C. W. TYLER[1], L. LIKOVA[2];
[1]Smith-Kettlewell Brain Imaging Ctr., [2]Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Introduction. Color responses have been extensively studied in terms of their temporal and spatial properties, but little work has been done to identify their sources within the brain and the time courses of the color responses for the respective sources. Methods. Electrical responses to uniform 180 deg color fields were recorded on a 128-electrode whole-head EEG recording system (EGI). Color fields of 465 nm, 540 nm and 605 nm were modulated sinusoidally at 5 Hz and the response waveforms recorded for 60 s. The waveforms were averaged to the 200 ms cycle timebase and filtered 60 Hz pick-up and blink artifacts. A spatiotemporal component analysis identified the scalp topography of the source activations for each stimulus color. Results. Temporal response components were identified with latencies from 40 ms to 170 ms after the positive-going zero-crossing of the sinusoidal waveform. These components had distinctive scalp topographies, including a ventral occipital band, a focal vertex peak, a lateralized occipital dipolar response, and double-peaked occipital response. Component analysis of the response time courses showed classic bimodal, rectifying unimodal and local spike-like waveforms. Conclusions. This first study of the differential scalp topography of full-field color responses across the spectrum indicates markedly different source distributions and response timings for the respective color channels. Part of the differences in topography can be attributed to the differential foveal-to-peripheral weighting of the S-cones relative to the L- and M-cones across the retina, and to the complementary distribution of the rods (which were shown contribute to the cortical responses even at relatively high luminance levels). The shortest-latency responses are shorter than the known latency of any cortical responses, and may represent the first report of EEG response from the lateral geniculate nucleus.

Title: Determinants of qualia of a profoundly ambiguous stimulus in the domain of color vision

Authors: *P. WALLISCH;
Ctr. Neural Sci., New York Univ., New York, NY

Abstract: Subjective perception of the environment is highly idiosyncratic. This is not surprising, as the interpretation of the physical world is fundamentally underdetermined by the information available to the brain. Although all stimulus displays are inherently ambiguous, "bistable stimuli" - stimuli with two stable (with varying time constants) and radically different interpretations are usually used to study the way in which the brain makes inferences about the outside world. Such stimuli have been known in the domains of object and motion vision for well over a century, but were thought not to exist in the domain of color vision until February 2015. Here, we report on the subjective color perception of the picture of a dress that is typically perceived either as white and gold or as black and blue. We recruited 7917 participants online, mostly via media and social media. Data was collected online, via a 20 question survey hosted on Surveymonkey.com. We asked questions about the subjective perception of the dress, such as whether the percept switched after the first exposure as well as questions about lifestyle and demographics, such as chronotype (i.e. whether participants are most active during daytime or whether their circadian rhythms are phase-shifted), age, time spent outside or time spent in front of screens. 61% of respondents saw the dress as white and gold during the first exposure and most participants (94%) report that they were unaware of the true color of the dress at that point. This percept was modulated by factors such as circadian type or whether participants believed the dress to be in a shadow when the picture was taken, with a modulation range between 5 and 15 percent. Effect sizes like those for gender, age or favorite color were small (modulation ranges on the order of 1-3%), but nevertheless significant as the large sample sizes conveyed strong power. We conclude that our results support the interpretation that different priors for luminance and fabric as well as differing beliefs about illumination can account for most of the reported differences in subjective experience of dress color while demographic factors do not.

Title: Color and luminance selectivity of neurons in the monkey inferior temporal cortex using high-dynamic-range display

Authors: *K. KOIDA;
EIIRIS, Toyohashi Univ. of Technol., Toyohashi Aichi, Japan

Abstract: Color is a manipulatable attribute independent to the shape and luminance. Some neurophysiological and psychological studies support the independence of color signals; however, those examinations were limited in stimulus range due to the display gamut. Here, I examined color selective response and luminance dependency of the neuron in the anterior inferior temporal cortex of the macaque monkey using a custom-made, high-dynamic-range display. Stimuli were an equiluminant uniform surface with its color systematically distributed from the RGB gamut of the display. Luminance varied from 1 to 500 cd/m2. Single unit recordings were made of the awake monkey and stimuli were presented on the center of the screen while the animal was fixating. Besides the known type of cells showing invariant color selectivity across the 1:500 luminance range, I found that color-selective cells showed novel luminance selectivity, which prefers specific luminance. Those cells showed similar color selectivity to the isochromatic colored object which has luminance shades. This color selectivity indicates that both color and luminance were jointly coded and might form the invariant color cognition of colored objects.

Title: Cortical representation for the categorical color perception in infants investigated by near-infrared spectroscopy

Authors: ***J. YANG**[1], S. KANAZAWA[2], M. K. YAMAGUCHI[1], I. KURIKI[3];
[1]Chuo Univ., Tokyo, Japan; [2]Japan Women's Univ., Kawasaki, Japan; [3]Res. Inst. of Electrical Communication, Tohoku Univ., Sendai, Japan

Abstract: Perceptual color is continuous, however we tend to classify colors into a handful number of categories. Color categories are closely related to language, and are known to be common among most developed languages. Several behavioral studies have reported that infants hold categorical color perception (e.g. Bornstein, Kessen, & Weiskopf, 1976; Franklin & Davies, 2004). However, it is controversial whether color categories are inherent to the structure of the visual system. In the present study, we measured brain activity changes in prelinguistic infants (5- to 7-months old) in relation to categorical color differences using near-infrared spectroscopy (NIRS). Two types of visual stimuli were used: color alternations (1Hz) between green and blue or between two shades of green for between- and within-category conditions, respectively. Color differences were equated in CIE Lab space for both stimuli. Channels around the T5 and T6 in the International 10-20 system showed selective increase in oxy-Hb for the between-category condition. However, such selectivity was not observed in occipital region. This implies that different color categories are represented differently in the bilateral temporal regions in infants of 5-7 months. The 12 channels in each hemisphere were further classified into anterior, posterior, dorsal, and ventral groups. The grouped-channel analysis showed a significant activity in the posterior part in both hemispheres. The T5/T6 channels correspond near the border of middle temporal gyrus and fusiform gyrus in each hemisphere, and, in adults, the Wernicke's area resides in the anterior part of this junction in the left hemisphere. However, the adults' NIRS data did not show significant laterality. Also, lingual process in the Wernicke's area is known to start after 13-14 months from birth. Our results suggest that categorical color perception could be based mainly on visual, non-lingual, processing.

Title: Receptive field properties of neurons in primary visual cortex (V1) of normal and red light reared tree shrews

Authors: W. DANG[1], P. S. MAIRE[1], *H. M. PETRY[2];
[1]Psychological and Brain Sci., Univ. of Louisville, Louisville, KY; [2]Univ. Louisville, Louisville, KY

Abstract: Tree shrews (Tupaia) possess dichromatic color vision based on short-wave-sensitive (SWS) and long-wave-sensitive (LWS) cones. Deep red-light-rearing (RLR) selectively deprives SWS cones, and produces a differential stimulation of color and luminance pathways. Our behavioral studies showed that even after many months of subsequent housing in normal white light, RLR shrews display poorer color discrimination (Petry & Kelly 1991) coupled with enhanced visual motion sensitivity at high temporal frequencies (Callahan & Petry 1995). Retinal ganglion cells (RGCs) of RLR shrews also are tuned to higher temporal frequencies (Lu & Petry, 2002) indicating an initial retinal locus of this effect. Two-photon imaging showed this enhancement to be present in neurons in layers II/III of V1 in RLR shrews (Van Hooser et al., 2014). The present study assessed receptive field (RF) properties of single neurons in layer IV, the primary target of geniculate projections to V1. RLR shrews were reared from birth to 8-wks of age in deep red light (Kodak 1A tungsten illumination), then housed in normal white light until recording. Extracellular responses (obtained with metal microelectrodes) from single V1 neurons in adult normal and RLR shrews were used to measure temporal tuning curves and spatiotemporal receptive fields (STRF). Stimuli were drifting achromatic sine-wave gratings and sparse noise, respectively. Band pass, but not low pass, cells in RLR V1 showed stronger responses to higher temporal frequency stimuli. This finding strengthens our evidence for an enhancement of temporal vision (paired with a deficit in color vision) in RLR shrews that can be perceived and used in their behavior. This result, taken with our imaging data (Van Hooser et al., 2014) indicates that striate cortex is capable of processing higher temporal frequencies than those commonly recorded in normally-reared animals and suggests that temporal filtering mechanisms in cortex can be mediated by other inputs (e.g., color pathways). A competitive interaction (likely at earlier levels of processing) during post-natal development is indicated. A variety of STRF structures were found in both groups. Most cells had a biphasic temporal response, with spatially overlapped ON- and OFF-centers. About 2/3 of those cells had single ON and OFF sub-fields, thus could be fitted with two Gaussians, while the other 1/3 had spatially discontinuous ON or OFF regions. While most cells revealed space-time separable RFs, a very small proportion were space-time inseparable. The preferred frequencies of cells were much lower than the linear prediction of their STRFs, suggesting a nonlinear mechanism in temporal processing.

Title: Linear and nonlinear cone signal combination in macaque V1

Authors: *J. P. WELLER, G. D. HORWITZ;
Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: In the Old World primate retina, signals from the L- and M-cones combine synergistically and antagonistically to form the basis of luminance and chromatic vision. How these cone signals are represented in the primary visual cortex (V1), however, remains poorly understood. Early investigations found that most V1 neurons represent cone signals as a weighted sum, but a more recent study found that approximately half of V1 neurons combine cone signals nonlinearly (Horwitz and Hass, 2012). This nonlinearity may derive in part or entirely from the stimulus they used - a drifting Gabor patch that encroached on the extraclassical surround - or even from interactions within the classical receptive field (RF), itself. If so, we expect small, brief stimuli to elicit responses with a greater degree of linearity than observed with larger, more complex stimuli. We tested this hypothesis by measuring the responses of V1 neurons to punctate flashes targeted to spatially distinct RF subunits. A rhesus macaque fixated a central spot on a CRT monitor. We probed each V1 neuron in a two-stage procedure. First, we used a spatiotemporal white noise stimulus to modulate L- and M-cones randomly. From the spike-triggered average stimulus, we identified individual subunits within the classical RF, then presented brief (200 ms) flashes to the selected subunits (n = 100). The flashes modulated L- and M-cones in varying ratios and degrees; the broad scope of tested modulations allows for an unbiased, model-free assessment of response tuning across the LM plane of color space. The results revealed that many V1 neurons (~60%) carry a weighted sum of L- and M-cone signals, and that, within this population, cone weights in are highly stereotyped, with luminance cells having equal L- and M-cone weights (i.e. 1:1), and chromatic cells having equal-and-opposite weights (i.e. 1:-1). Some of these neurons responded to a both polarities of modulation along the luminance or chromatic axes, but others to only a single polarity. Responses of neurons sensitive to both color and luminance (~40%) are poorly described as a

weighted sum of cone signals, but are still highly stereotyped, and can be described by a relatively simple nonlinear combination of signals from luminance and chromatic neurons. As shown previously, some neurons responded to all directions in the LM plane. Here, however, we report the novel result that some V1 neurons responded to all but a single direction in the LM plane (e.g., all but red), and still others to only two perpendicular directions (e.g. red and +luminance). These results reveal how V1 builds up a mutual chromatic and luminance sensitivity to form the foundation for downstream color invariance.

Title: Non-linear visual cortical activity linked to human color perception

Authors: *R. M. SHAPLEY[1], V. NUNEZ[2], P. SCHUETTE[2], A. HANINEVA[2], A. AMIR[2], C. VELOZ[2], S. WHITTICK[2], J. GORDON[2];
[1]Ctr. for Neural Sci., New York, NY; [2]Psychology, Hunter Col., New York, NY

Abstract: Neurons in primary visual cortex (V1) have characteristics that link them to the processing of fundamental aspects of color perception. We examined this linkage quantitatively in humans by using hue and saturation scaling as a measure of perceived color and the chromatic visual evoked potential (cVEP) as a measure of neural activity. Isoluminant appearance-disappearance checkerboards or isolated-check patterns were square-wave modulated (0.5s on, 1.5s off) from gray to color and back to gray. The patterns had chromatic excitation purities ranging from 0.03 to 0.53. The square stimulus field was 10° across and the checks were 18.75' or 37.5' of arc. Luminance was 31.5 cd/m2. Human observers rated the stimuli for apparent color saturation. Apparent saturation was proportional to excitation purity. In the same observers we recorded cVEPs with a 64-channel BioSemi system. Responses were signal-averaged (30 repeats) and Fourier-transformed. The largest cVEPs were concentrated at electrodes at or around Oz, pointing to V1 as the major source of these responses. Previously the work of others indicated that the cVEP is driven by neurons in V1. Unlike the perceptual scaling results, cVEP peak amplitude grew rapidly with purity and then hit a ceiling response at relatively low purities. cVEP waveform was non-linear; it became faster with increasing excitation purity. The non-linear characteristics of the EEG response are indicative of cortical processing since we know

that the Parvocellular LGN input to the cortex is highly linear. The non-linear change in cVEP waveform produced a phase-advance with increasing excitation purity in most Fourier components of the response. Harmonic analysis of the cVEP also revealed that Fourier components of the response in the 6-20 Hz range were proportional to excitation purity like the perception while lower frequency components hit an amplitude ceiling. Our results show that there is a very strong correlation between measures of color perception and higher frequency response components of the cVEP of early visual cortex.

Title: A case of enhanced color vision

Authors: *R. SORRELLS;
Pacific Northwest Univ. of Hlth. Sci., Yakima, WA

Abstract: Current medicinal philosophy emphasizes the whole person, yet our case reports are often about a collection of symptoms, or a disease. The current case study is about a whole person and the connection between his brain and mind. Born red-green color blind, this individual fell on his head in January of 2014 and woke up to a splendid world of color. Functional MRI indicates that his cortical visual and color areas are responding to color stimulation, most noticeably when he named the color he viewed silently to himself. In other words, the signal was strongest when he viewed and thought about the color name simultaneously. In behavioral testing using color strips and environmental stimuli, the individual has no problems picking out colors, making subtle distinctions between red and green, and more importantly, he has a strong emotional reaction to the colors, for example, when he found a yellow streak of hair in his wife's long platinum locks. However, he continues to fail the Snelling tests, due in part to a Horner's syndrome and severe stigmatism, suggesting that this standard test for color blindness is confounded with visual acuity. It is well known that context, for example form and shape, plays an important role in the perception of color, and there is a large interplay

between color knowledge (what the person perceives) and object color knowledge (what color the object is supposed to be). This suggests that perhaps the patient is using knowledge from what others have told him, along with the extra attention to the new colors, and this has enhanced his perception.

Title: Spatial clustering of color-selective neurons in the striate cortex of macaque monkeys

Authors: A. KHACHATRYAN[1], P. FUNG[1], M. CRUMILLER[2], *Y. XIAO[1]; [1]Ophthalmology, SUNY Downstate Med. Ctr., Brooklyn, NY; [2]Lab. of Biophysics, The Rockefeller Univ., New York, NY

Abstract: Previous imaging studies have found hue maps in some visual areas of primates, including the striate cortex (V1). These studies suggest that these visual areas contain functional compartments where neurons are spatially organized according to their color preferences. To test this hypothesis, we have recorded single-unit activity from V1 of macaque monkeys and characterized each unit's cone inputs. Neuronal activity was recorded from anesthetized and paralyzed monkeys using 64- or 54-channel electrodes that spanned different columns or layers. High-quality spike sorting was achieved by an advanced algorithm that utilizes signals recorded from all channels (Swindale&Spacek, 2014). To determine cone contributions to each unit's receptive field (RF), we used Hartley stimuli that comprised cone-isolating gratings of various orientations, spatial frequencies and phases. RFs were reconstructed by reverse correlation. In agreement with previous studies, we found two types of RFs that received opponent L- and M-cone inputs. A double opponent (DO) RF had two main sub-regions that had opposite cone opponency (L+M- vs. L-M+). A single opponent (SO) RF had the same cone opponency across its receptive field. The sub-regions of the DO RFs were more elongated than the SO RFs, suggesting that the former were more selective for orientation than the latter. The SO RFs of

nearby units tend to have the same cone opponency, suggesting spatial clustering of SO neurons according to their color preferences. In contrast, there was equal chance for the DO RFs of nearby units to have the same or opposite cone opponency in each sub-region, suggesting that the DO neurons were not clustered according to their color selectivity for surface borders. Instead, the DO neurons were clustered according to their orientation preferences. Hue maps in V1 respond well to spatially uniform colors (Xiao et al., 2007), suggesting a major contribution from the SO neurons to their activity. Our result therefore supports the existence of hue maps in V1 where neurons are spatially clustered according to their color preferences. The SO and DO neurons may encode color information located at the interior and border of a surface, respectively. Their difference in spatial clustering points to different strategies for downstream areas to decode color information from these two populations.

Title: Aging effects on the luminance contrast response in Humans

Authors: ***E. BELLOT**[1], E. MORO[2], K. KNOBLAUCH[3], V. COIZET[1], M. DOJAT[1];
[1]Grenoble Inst. Des Neurosciences, La Tronche, France; [2]CHU de Grenoble, Hôpital Michallon, La Tronche, France; [3]Stem-cell and Brain Res. Inst. Dept. of Integrative Neurosciences, Bron, France

Abstract: Luminance contrast is a fundamental visual cue. Testing contrast response is of interest with respect to alterations in aging or in the progression of diseases, such as glaucoma and Parkinson's disease. Luminance contrast response functions were assessed in two ways. First, using high-resolution 3T-fMRI we explored for subjects with normal or corrected to normal vision and varying age (Young: n=10, 26±3Yo; Middle age: n=10, 47±4Yo; Aging: n=10, 65±3Yo), the luminance contrast response of three regions of interest (ROIs), located along the visual pathway and anatomically defined in each individual: i) the Superior Colliculus (SC), ii) the Lateral Geniculate Nucleus (LGN) and iii) the primary visual area V1. We used achromatic checkerboards varying in luminance (1-9%), flashing at 4Hz and alternately

presented in each visual hemi-field. Second, we estimated the perceptual response to contrast by using Maximum Likelihood Difference Scaling (MLDS), a method based on paired-comparisons of stimulus intervals and a signal detection model allowing estimation of response scales by maximum likelihood. In this psychophysical study, each participant performed 3 sessions, each session consisting of a 5 min random presentation of 120 ordered triads of checkerboards, draw from a set of 10 luminance contrast levels logarithmically spaced. The observer had to choose whether the middle contrast was more similar to the lower or higher one. Our results firstly demonstrated that, in all explored ROIs, BOLD responses increased progressively with luminance contrast. This confirms and extends to the low contrast range of previously published data. Moreover, a progressive decrease of the BOLD amplitude with age was observed in V1 and the LGN (V1 and LGN: $p<.01$). These data are consistent with the results obtained with the psychophysical task, showing on the one hand a response that increases with luminance contrast, reaching an asymptote at 20% and, on the other hand, a difference related to age at low range contrasts and even in the higher range tested. In conclusion, our findings indicate that the luminance contrast response is affected during normal aging, as tested by our rapid psychophysical technique, and also reflected by a BOLD signal decreasing along the visual pathway. Understanding the mechanisms underlying these changes that occur in normal aging is essential both for understanding the normal aging process and for comparisons between healthy aging subjects and aging patients with age-related visual and/or cortical/subcortical disorders.

Title: Fully automated training system for head-fixed mice

Authors: R. AOKI, R. NISHIYAMA, Y. GOYA, *A. BENUCCI;
RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: Training rodents in behavioral tasks is becoming an increasingly critical technique in Systems Neuroscience. However, not all rodents are equally suitable for training. The taxon rodents belong to (Rodentia) comprises of >2000 species, with an astounding diversity not only in the general phenotype (e.g. 1000 fold in body size) but also in their propensity for behavioral training. A classic example is the one of rats and mice. While rats are fairly easy to handle and train and can even be taught to self-restrain (Scott et al., 2013), mice are much more difficult in these respects, especially with the head-fixed setups often required for imaging/optogenetic experiments. Here we present a fully automated, head-fixed system for the behavioral training of mice. Mice are implanted with a 6mm-diameter head chamber for head fixation and for optical access to the brain. They are housed in a modified cage. Custom-made software (the controller) gives access to an adjacent self-latching zone twice a day, 30 min each time. After a pre-training phase of ~1 week, water-restricted mice learn to voluntarily latch their head chamber in order to reach a water spout. The controller then presents visual stimuli on a monitor in front of the animal for training in standard visual-discrimination tasks. The animal's choice is read out via a choice ball (Sanders & Kepecs 2012). The controller records the animal's weight for automatic alerts in case of unhealthy weight drops. Webcams connected to call-in software (Skype®) allow for 24/7 remote video access. We used this setup to train mice (n=3) in two-alternative forced choice tasks in contrast and orientation discrimination, and used signal-detection theory to quantify the behavioral performance (Fründ et al., 2011). For contrast discrimination, we used three levels of contrast difficulties (33%, 66%, and 100%). Mice easily learned this task reaching 90% correct. For orientation discrimination, we progressively increased the difficulty up to five levels, with a minimum orientation difference of 18 deg. Also in this case, performance reached 80% correct. When discrimination difficulty was increased, the psychometric sensitivity and success rate did not change significantly, suggesting that the mouse learned to generalize the discrimination rule. We are currently scaling-up the setups to implement parallel training strategies within a wider range of sensory decision-making tasks. Overall, we believe this approach will be ideal for combining high-throughput behavioral training with optical imaging and optogenetic experiments.

Agency, Saitama, Japan

Abstract: Purpose: Critical fusion frequency(CFF), defined as the frequency at which a flickering light is indistinguishable from a steady one, is one of the useful measures to evaluate visual temporal resolution based on functional separation of ON and OFF pathways. Temporal resolution has been studied by electrophysiological approach such as flicker electroretinogram(ERG) and visual evoked potential(VEP). However, the CFF analysis based on behavioral performance has not been studied. Here we established a method to evaluate visual temporal resolution in the behaving mice. Methods: C57BL/6 mice were trained to performance a two-alternative forced choice task in which steady illumination(250Hz) and flickering illumination(4-20Hz) were presented on a green light emitting diode(green LED, 508nm) screen. Mice responded to steady illumination by making nose-poke toward the screen. Each mouse performed the 4-Hz condition first, and proceeded to the next temporal frequency condition by reaching a criterion of proportion correct responses(PCRs) higher than 80% over three consecutive sessions. In the analysis, we determined a frequency that mice could not discriminate steady stimulation from flickering stimulation(approximately 50-60 percentage of correct) as CFF Results: In the 4-Hz condition, PCRs increased with sessions, and all the mice could discriminate between steady illumination and flickering illumination. Dynamic image analysis revealed that mice responded with shorter walking distances over the trials in the later sessions. In the frequency conditions of 5-10 Hz, all the mice reached the criterion within fewer sessions than in the 4-Hz condition. Although there were relatively large individual differences in the PCR data, the results suggested that CFF in the behaving mice is approximately 15Hz. Conclusion: We established the method to evaluate temporal resolution of ON and OFF pathway-mediated vision in the behaving mice. This behavioral assay of mouse model could contribute to development of diagnosis of human retinal disease by applying genetically manipulated mice.

Ctr., Jackson, MS

Abstract: Behavioral, neurophysiological and computational studies have revealed a general scheme of visual shape recognition, which starts from extracting local features followed by a feature binding process (Treisman and Gelade, 1980; Hubel and Wiesel, 1982; Marr, 1982). However, there is accumulated evidence arguing that human vision starts from extracting topological features (e.g., number of holes), which then facilitate processing local features (Chen, 1982, 2005). While the topological perception challenges the generality of the prevailing model of visual shape recognition, little is known about the underlying neural mechanisms. The primary goal of this study is to establish a non-human primate model of detecting presence of a hole in a visual object, a typical topological property. Monkeys were presented with a set of white visual stimuli in a black background and were trained to make a saccade to the odd-ball target. While white disk was used as the distractor in all conditions, the odd-ball target was different from the distractor in color (RED DISK vs. WHITE DISK), shape (WHITE SQUARE vs WHITE DISK), or topological property (WHITE RING vs. WHITE DISK). In the first experiment, we found that saccade latencies to the WHITE RING target were similar to that to the RED DISK target, but were shorter than that to the WHITE SQUARE target. Further control experiments showed that the short-latency detection of the WHITE RING target was not due to differences in local features, such as spatial frequency and luminance. In the second experiment, we examined how combinations of local features, color and topological features affect saccade latencies to the odd-ball target. We found that combination of color with shape or the topological property reduced saccade latencies to the odd-ball target. For example, using white disk as the distractor, saccade latencies to the RED SQUARE target were shorter than that to the RED DISK target or the WHITE SQUARE target; saccade latencies to the RED RING target were shorter than that to the WHITE RING target or the RED DISK target. To our surprise, we found that combination of local shape features and the topological feature exhibited significant interactions.

For example, using white disk as the distractor, we found that saccade latencies to the WHITE SQURE-shaped RING target were similar to that to the WHITE SQUARE target, which were longer than that to the WHITE RING target. In summary, these preliminary results established a non-human primate model of early detection of the topological property. Ongoing studies will further characterize this model to investigate the underlying neural mechanisms.

Title: Low ability to discriminate faces in common marmosets

Authors: *K. NAKAMURA, M. MIWA, R. KOBA, C. YAMAGUCHI, A. TAKEMOTO; Primate Res. Institute, Kyoto Univ., Inuyama, Japan

Abstract: We investigated characteristics of visual discrimination in common marmosets (Callithrix jacchus). Five marmosets were trained in a visual delayed matching-to-sample task. In this task, they were required to touch a visual sample stimulus presented on a PC monitor. After a short delay period, two visual stimuli were presented. One was the sample stimulus and the other was a stimulus different from the sample. They were required to touch the sample stimulus to obtain a reward. We used four categories of visual stimulus; graphic patterns, photographs of food, photographs of a flower, and photographs of a marmoset face. We first trained the marmosets with graphic patterns. Thereafter, we introduced 3 categories of photograph. All of the five marmosets quickly reached a criterion under the food- and flower-conditions. However, they hardly reached the criterion under the marmoset face-condition. Apparently, they showed difficulty in discrimination of marmoset faces. Common marmosets live in families. Within a family group, the breeding male and female are dominant. For the other members, social rank is usually based on age. Low social demand for discrimination of conspecific's faces can account for this low discrimination ability of faces.

Title: Is our sensing compressed?

Authors: ***G. KOVACIC**[1], V. BARRANCA[2], D. CAI[2];
[1]Mathematical Sci., Rensselaer Polytechnic Inst., Troy, NY; [2]Courant Inst. of Mathematical Sci., New York Univ., New York, NY

Abstract: Along the early stages of several sensory pathways, significant downstream reductions occur in the numbers of neurons transmitting stimuli. For example, in the retina, photoreceptors outnumber retinal ganglion cells by a factor of 100, and in the olfactory pathway, the olfactory receptors outnumber the mitral and tufted cells by about the same factor. To understand how much information is retained in such a reduction, we model it using an idealized neuronal network. Our model has two layers, receptors and sensory neurons immediately downstream, connected randomly and sparsely, with the receptors considerably outnumbering the sensory neurons. Our work reveals a mechanism for preserving information through bottlenecks in sensory pathways, related to the preservation of image quality using compressed-sensing type data acquisition. Through numerical simulations, we show that most information is retained when the convergence from the receptors to sensory neurons equals the ratio between the numbers of those two neuron types, and that information flow depends little on the connectivity architecture among the model sensory neurons. We find an optimal strength of the connections between the receptors and sensory neurons in the model. We find that the spike trains in the model network that retains most information exhibit the most variability, as represented by the maximal entropy, closest distance to gaussianity of their interspike-interval distribution, and least correlation times. In addition, the average neuronal membrane potential in such a network (roughly mimicking the local field potential) has the broadest power spectrum. Finally, we show that the more realistic version of the model, which samples the stimulus through localized

receptive fields rather than randomly as is common in engineering applications, retains at least 50% more information.

Title: The detection of contrast polarity of visual images in behaving rats

Authors: *C.-I. YEH[1,2,3], S.-H. WU[3];
[2]Psychology, Neurobio. and Cognitive Sci. Ctr., [1]Natl. Taiwan Univ., Taipei, Taiwan; [3]Grad. Inst. of Brain and Mind Sci., Natl. Taiwan Univ. Col. of Med., Taipei, Taiwan

Abstract: In several diurnal species including cat, macaque monkey and human subjects, many neurons in the primary visual cortex V1 have stronger responses to stimuli with negative contrast (black on gray) than with positive contrast (white on gray). The asymmetry in responses to different contrast polarities may explain why human subjects can detect negative contrast better and more easily than positive contrast. The black-over-white bias found in diurnal animals is ecologically plausible because it may help them to escape from predators that appear in a relatively brighter background. On the contrary, nocturnal animals such as rodents may need to develop a bias in detecting positive contrast. In accordance with this hypothesis, strong white-dominant responses were recently reported in rodent V1 with the voltage-sensitive dye (VSD) imaging technique (Polack & Contreras, 2012). Here we used a two-alternative forced choice task to test the contrast preference in behaving rodents (Long Evans). The rat started each trial in the central port of a three-arm device with a monitor in front of the animal. A bright or dark square against a gray background was then shown briefly on the left or right portion of the monitor. The animal was rewarded if the choice was correct (moving to the left or the right port where the stimulus was shown). We manipulated both the contrast (0%, 4%, 8%, 16%, 32%, 48%, 64%, 100%, either positive or negative in Weber contrast) and the mean luminance of the

screen (high: 50 cd/m2, low: 20 cd/m2). Surprisingly, preliminary results showed that the detection threshold tended to be lower for negative contrast than for positive contrast. The black-over-white bias is the largest at 100% contrast under the low luminance condition. The discrepancy between behavioral and neuronal results in rodents may be due to 1) the duration of the visual stimuli and 2) the difference in the mean luminance of the monitor. Overall, these behavioral results suggest that rodents, like other diurnal species, might be more sensitive to negative contrast than positive contrast.

Title: Memory precision in a contrast estimation task

Authors: ***S. JACKSON**[1], W. J. MA[1,2];
[1]Ctr. for Neural Sci., [2]Dept. of Psychology, New York Univ., New York, NY

Abstract: By providing continuous, high-resolution measurements of memory contents, delayed-estimation tasks have elucidated the nature of visual short-term memory (VSTM), most notably for orientation and color [1]. Such features are relatively stable across time [2], presumably due to the topographic form of their neural representations. For intensity-coded features such as luminance contrast, however, VSTM might be less stable over time [2]. Unfortunately, VSTM for luminance contrast has been characterized predominantly using relatively coarse discrimination tasks. Here, we systematically examined VSTM for luminance contrast using delayed estimation. On each trial, a small circular disc (1° diameter) was briefly presented (200 ms) to observers either left or right of fixation (4° eccentricity). Luminance contrast of the disc was set to one of eight positive values, which were interleaved in randomly shuffled order across each block of trials. After a brief delay (1500 ms), a disc of random contrast was presented at the same location as the first. Observers adjusted the contrast of the second disc (through thirty-eight possible values) until it matched the memorized contrast of the first, by moving a computer mouse horizontally. Trials were separated by an ITI of 1500 ms. Data (n = 8) consisted of estimate probability distributions for each of the tested contrasts.

Distributions were clearly distinguishable from one another, on average showing only a small bias towards the mean presented contrast. As contrast increased, the distributions shifted accordingly, and inter-quartile range broadened in approximately Weber's law fashion. We fit the data using a probabilistic model of neural responses, assuming Poisson noise and maximum-likelihood readout. When realistic forms of the contrast response function were incorporated into the model (e.g., Naka-Rushton, power law), it provided good quantitative fits to the distributions, predicting neurally plausible gain parameter values (e.g., Naka-Rushton exponent of ~2). In summary, error distributions for luminance contrast have not previously been investigated using delayed estimation, and may provide rich information for testing theories of VSTM for contrast. We measured these distributions and successfully characterized their shapes using a probabilistic model of neural responses. Future work may investigate how the distributions change with delay time and set size manipulations. Refs: [1] Ma et al., Nat. Neurosci., 17: 347-356, 2014; [2] Magnussen & Greenlee, Psychol. Title: Dynamic allocation of visual resources under change of task

Authors: *P. LADDIS[1], S. GEPSHTEIN[2], T. ALBRIGHT[2];
[1]Salk Institute, VCL-A, La Jolla, CA; [2]Salk Inst., La Jolla, CA

Abstract: We investigated how visual systems allocate their limited resources according to the demands of visual tasks. From Gabor's uncertainty relation it is expected that large receptive fields are more suitable for measuring stimulus frequency content ('identification') and small receptive fields are more suitable for measuring stimulus location ('localization') (Gepshtein et al., 2007). Visual systems would benefit from relying on small receptive fields for localization and on large receptive fields for identification. We tested whether human vision follows this strategy, i.e., whether the extent of spatial integration depends on visual task. In Experiment 1, we measured the spatial contrast sensitivity function (CSF) in identification and localization tasks using the same stimuli, under conditions of equal task difficulty. Sensitivity increased at low spatial frequencies and decreased at high frequencies in identification relative to localization, as if the sensitivity function shifted towards low frequencies, supporting the

prediction. In Experiment 2, we found that amplitude modulation sensitivity (Jamar et al, 1982) changed similarly. In Experiment 3, we observed that changing the task from localization to identification increased the critical area of spatial summation (Inui, 1981). Together, these results suggest that receptive field sizes are dynamically adjusted to meet demands of visual tasks.

Title: Mice can use second-order stimulus cues to guide visual perception

Authors: Z. KHASTKHODAEI[1,2], O. JURJUT[1], S. KATZNER[1], *L. BUSSE[1];
[1]Univ. of Tuebingen, Tuebingen, Germany; [2]Neurosci. Res. Ctr., Baqiyatallah Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: In primates, visual processing along the ventral stream takes place in a hierarchy of areas, characterized by an increase in invariance to changes of low-level stimulus attributes. A simple form is “cue-invariance”, where neurons show similar preference when driven by first-order stimuli (defined by changes in luminance) or second-order stimuli (e.g., defined by changes in contrast). While mice have gained popularity a as model system for early visual processing, it is still unclear whether their vision relies on more than luminance cues. Here, we asked whether mice can generalize orientation discrimination in a cue-invariant way, potentially mediated by cue-invariant representations of orientation in visual cortex. To address this question, we used first-order, luminance-modulated gratings *(LGs)* and second-order, contrast-modulated gratings *(CGs)*. We created two types of *CGs*, which consisted of a sinusoidal envelope with a spatial frequency optimal for mouse visual cortex and a static 1/f noise carrier, that differed in the distribution of Fourier energy. The low-frequency type contained all noise energy < 0.12 cyc/deg, the high-frequency type > 0.12 cyc/deg. We first tested whether mice can generalize from a learned orientation-reward association with *LGs* to different types of untrained *CGs*. We used a classical conditioning task, in which mice learned to perform an orientation

discrimination task on *LGs*. After learning (AUROC = 0.77), we replaced the *LGs* by *CGs* (low-frequency type), and found that, despite overall lower performance (AUROC = 0.63), mice could readily generalize across the two types of stimuli. Performance better than chance could even be observed for high-frequency type *CGs*, which do not contain energy in the typical pass-band of mouse V1 neurons. We then performed extracellular recordings in areas V1 and LM, where we compared orientation tuning curves to *LGs* and *CGs*. We noticed that fewer neurons responded to *CGs* than to *LGs* (area V1, 86%; area LM, 63%; $p < 10^{-4}$). For those neurons with significant responses to both types of gratings, peak responses were weaker to *CGs* compared to *LGs* ($p = 0.005$). Furthermore, orientation selectivity was lower for *CGs* compared to LGs, and this reduction was particularly pronounced for area V1 ($p = 0.006$). Despite this generally reduced responsiveness and selectivity for *CGs*, preferred orientations in response to *CGs* and *LGs* were broadly similar ($p = 0.005$). We conclude that mice can, at least in a rudimentary form, use second-order stimulus cues to guide visual perception and that this ability might potentially be mediated by a cue-invariant representation in early visual areas.

Title: Grouped icEEG evaluation of the temporal pole during visual naming of common and proper nouns

Authors: *C. M. KADIPASAOGLU, N. TANDON;
Neurosurg., Univ. of Texas Med. Sch. At Houston, Houston, TX

Abstract: Selective conceptual deficits for unique entities (i.e. proper nouns) have been linked with damage to the most anterior portion of the temporal lobe, the temporal pole (TP). These deficits suggest the TP may mediate storage and retrieval of semantic knowledge specifically for proper nouns. However, neuropsychological evidence from degenerative diseases (e.g. semantic

dementia) suggests that the TP may instead function as a generalized hub for all conceptual knowledge (i.e. common and proper nouns), with response properties graded in relation to semantic demand (response to proper > common nouns). The TP's proximity to air-filled sinuses and superficial musculature has made noninvasive study of this region difficult, precluding consensus regarding even basic distinctions of TP function. We leveraged millisecond-resolution human, intracranial EEG (icEEG) data to critically evaluate these unique-entity (UEM) and general-hub (GHM) models of TP function. If the UEM is accurate, we hypothesize that the TP would respond preferentially to proper nouns. In contrast, the GHM predicts that the TP would respond to all salient stimuli, irrespective of noun class. Data were collected in a large cohort (21 subjects; 12 LH; 9RH; 15 female) performing a visual confrontation-naming task of common objects (common nouns), famous faces (proper nouns), and scrambled control images of the same stimuli (scramble). We observed a transient, early (~200 ms after stimulus onset) increase, bilaterally, in high-frequency broadband gamma activity (BGA; 60-120 Hz; percent change from pre-stimulus baseline of -700 to -200ms) for all three stimuli. However, in the left TP only, peak percent change in BGA was strongest for proper, followed by common, and then scrambled stimuli. In contrast, no significant conditional differences were observed in the right TP. Finally, in the left TP, a subsequent increase in BGA was observed for correctly named common and proper nouns, but not for incorrectly named nouns or scrambled stimuli. Together, these results provide empirical evidence in support of the GHM, with novel insights into the temporal profile of TP activity during visual naming. In sum, our findings reveal an early (~200ms), obligate, and bilateral response to all visual stimuli in the TP, and a continued role for the left TP during both common and proper name retrieval.

Title: Regional difference in characteristics for top-down modulation in the ventral visual stream

Authors: Y.-W. SUNG[1], H. YOON[2], U.-S. CHOI[3], *S. OGAWA[1];
[1]Touhoku Fukushi Univ., Sendai, Miyagi, Japan; [2]Daegu Cyber Univ., Daegu, Korea, Republic of; [3]Neurosci. Res. Inst., Gachon Univ. of Med. and Sci., Incheon, Korea, Republic of

Abstract: Top-down modulation to low level areas from high cognitive areas has been reported in number of electrophysiology studies. In particular, ventral visual stream has shown area-specific characteristics such as center-peripheral specialization and categorical specialization. In terms of center-peripheral specialization, lateral areas supposed to be more sensitive to center vision and facial like stimuli, whereas medial areas to peripheral vision than building stimulation. There is a possibility that ventral visual stream has similar regional differences in characteristics for top-down modulation. In this study we examined by fMRI a possible difference in top-down modulation depending on areas in the ventral visual region. Top-down modulation is generally known to be dependent on stimuli per se. Here, we intend to examine whether such modulation mechanism seems to exist after the stimuli response, namely the feedback. Participants performed a well-characterized visual and auditory categorization paradigm, in which they had to decide, in combination with line drawings of faces, whether the pitch of frequency-modulated (FM) tones was rising or falling. After the decision the feedback follows either with no interval or 1 second delay. Line drawings of faces with positive and negative emotional cues were used for the feedback provider. We found activations at some areas in early visual and in occipitotemporal regions. The fMRI response signals were different across areas and between non-delay and delay. Notably, the fMRI responses for the delayed feedback showed the shifted time course than for the non-delay at the medial areas of the occipitotemporal region as well as in the fovea and peripheral areas at V1 but not at the lateral areas of occipitotemporal region. This difference in occipitotemporal region might reflect the different feedback characters in the lateral and medial areas of early visual cortices, which seem to be influenced by top-down modulation. This result indicates the area-specific differences to the feedback in the ventral region.

Title: Activity change in the left fusiform cortex suggests learning in face detection

Authors: *J. E. GOOLD, M. MENG;
Psychology and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The ability to detect a face is the gateway to individual identification and social interaction. Previous research has suggested two possible mechanisms for how the human brain detects a face: 1) the right fusiform gyrus responds categorically to face/non-face images. It will selectively respond in an "all-or-nothing" burst as to whether an image is a face. 2) The left fusiform gyrus responds in a graded manner to how "face-like" an image is. It will estimate how much an image looks like a face, with genuine faces getting the highest response (Meng et al., 2012). To evaluate these possibilities, the present study examines whether training in face/non-face categorization vs. training in face-likeness analysis may improve face detection and change how the brain detects a face. Two types of stimuli were used for training and testing the effect of training respectively. The first set of stimuli consisted of gray-scale (easy to detect) images ranging from no resemblance to faces to genuine faces. The second set of stimuli consisted of two-toned, black and white (hard to detect) Mooney images generated from the gray-scale images (Mooney, 1957). The study contained three parts: First, brain activity was measured by using fMRI for all participants (N=24) when they were shown a randomly chosen half of the set of two-toned (hard) images and instructed to respond 'face' or 'not-face' to each image. Next, participants were randomly split into two groups for training. Both groups viewed the gray-scale (easy) stimuli three times a day for five days. However, the categorical group was instructed to make 'face' or 'not-face' judgments about whether the images were faces, while the graded group was instructed to rate the images on a Likert scale of 1-5 for how "face-like" they were. For the third part of the study, all participants repeated the fMRI scan with the other half of the two-toned (hard) stimuli. Our findings show that when participants were trained categorically, the response in the left fusiform gyrus to the two-toned (hard) images changed from graded to categorical. By contrast, we found no significant change in brain response in the graded group. These results suggest that learning of the face/non-face categorical boundary instead of evaluating face-likeness is critical for improving face detection. Moreover, whereas activity in the right fusiform cortex correlated with face/non-face categorization but remained unchanged, the activity change in the left fusiform cortex underlies the effect of learning in face detection. This suggests complementary functional roles of the two hemispheres in face perception and learning.

Title: Expectation about face identity biases emotion categorization: evidence from behavioral modeling and pupillometry

Authors: *M. EL ZEIN, V. WYART, J. GREZES;
LNC/INSERM U960/ENS/PSL, Paris, France

Abstract: Expectation in perceptual decision making influences neural and behavioral responses by facilitating the processing of expected stimuli (*Summerfield & DeLange, 2014*). During our social interactions, most of our interpretations and decisions are based on past experience and priors about people and events. Particularly, expectations about people's characters and moods build upon previous encounters with these people. Here we aim to identify the mechanisms of identity expectation influence on the categorization of facial expressions during an eye tracking behavioral study including 31 healthy human participants. We manipulated expectations about emotional expressions (Fear and Anger) of identities by presenting subjects with short periods at the beginning of each block where identities (32 in total) expressed either only anger (Anger group) or only fear (Fear group). During the rest of the block, all identities expressed anger and fear equally, while their emotional intensity varied parametrically. Importantly, during both periods, subjects performed an emotion categorization task (Fear or Anger?) and had no explicit warning of any change occurring between the periods. Finally, they reported during a post test whether the 32 encountered identities expressed more anger or fear during the experiment. Increased accuracy for expected stimuli (angry expressions of Anger group and fearful expressions of Fear group) during the unbiased blocks showed that participants integrated the information about stimulus identity although it was manipulated implicitly. Model comparisons characterized the effect by showing that subjects' decision bias rather than their choice sensitivity was influenced by identity expectation: response bias pulled toward anger for the Anger group and toward fear for the Fear group. Subjects were at chance level during the posttest, suggesting that the bias was implicitly induced. Interestingly, the identities they explicitly and incidentally assigned to Fear and Anger in the posttest also strongly biased their decisions throughout task. Pupil dilation tracked both the perceptual evidence to response by decreasing with stimulus intensity and response bias by increasing when subjects responded against their bias (*de Gee et al. 2014*). To conclude, these results imply that both experience (implicit learning of identity/

emotion associations) and incidental associations (spontaneous associations explicitly reported) shape expectations about people's mood (*Todorov et al. 2015*). Further, these expectations shift the decision bias about facial expressions in response-selective, not stimulus-selective structures.

Title: Inter-area signal targeting translaminar processing during successful memory retrieval in macaque temporal cortex

Authors: *M. TAKEDA[1,2], K. W. KOYANO[1], T. HIRABAYASHI[1], Y. ADACHI[1], T. ISHII[1], Y. MIYASHITA[1,2,3];
[1]Univ. of Tokyo Sch. of Med., Tokyo, Japan; [2]Juntendo Univ., Tokyo, Japan; [3]Core Res. for Evolutional Sci. and Technology, Japan Sci. and Technol. Agency, Saitama, Japan

Abstract: Memory retrieval in primates is orchestrated by a brain-wide neuronal circuit. To elucidate the operation of this circuit, it is imperative to comprehend neuronal mechanisms of coordination between area-to-area interaction and information processing within individual areas. Converging evidence from neuropsychological, anatomical and lesion studies has suggested that memory processes including consolidation and retrieval are implemented by the interaction between the medial temporal lobe and the domain-specific association cortices. Area

TE, which is part of the temporal association cortex, is adjacent to and interconnected with area 36 (A36) of the perirhinal cortex which is part of the medial temporal lobe. These brain areas are known to engage in the associative representations of long-term memory of visual objects and to play distinct roles in memory retrieval. While the perceptual activity of visual objects emerges earlier in TE than A36, memory retrieval activity for the sought target emerges earlier in A36 than TE, suggesting that a backward signal flows from A36 to TE during memory retrieval. The inter-area signal, if present, would modify local signal processing implemented by laminar neuronal circuits in the target area. To test this hypothesis, we simultaneously recorded from A36 and TE while monkeys performed a pair-association memory task (Takeda et al., 2015). We found two distinct inter-area signal flows during memory retrieval: A36 spiking activity exhibited coherence with low-frequency field activity in either the supragranular or infragranular layer of TE. Of these two flows, only signal flow targeting the infragranular layer of TE was further translaminarly coupled with gamma activity in the supragranular layer of TE. Moreover, this coupling was observed when monkeys succeeded in the retrieval of the sought object but not when they failed. The results suggest that local translaminar processing can be recruited via a layer-specific inter-area network for memory retrieval. Title: Neural correlates of statistical learning in the inferior-temporal cortex of rhesus monkeys

Authors: *S. KUMAR, P. KAPOSVARI, R. VOGELS;
K U Leuven, Leuven, Belgium

Abstract: We learn to implicitly extract the statistical regularities in the environment around us, e.g. sequences of stimuli that follow each other (e.g. letters in specific words). In the visual domain, human observers can extract regular sequences of visual stimuli from a continuous stream of visual shapes. The neural correlates of such visual sequence learning are still unclear. Previous electrophysiological studies on visual sequence learning in the macaque inferior temporal (IT) cortex, using pairs (Meyer and Olson, 2011, PNAS) and triplets (Meyer et al, 2014, J. Neurosci) of images, showed stronger neural responses to a stimulus that deviated from the one expected in the learned pair or triplet. In these studies the learned stimulus pairs or triplets were clearly temporally delineated by an inter-sequence interval unlike in behavioral statistical learning studies in which a continuous, uninterrupted stream of stimuli are presented. Furthermore, the separated stimulus sequences were each followed by a reward, which may have aided learning. Here we mimicked behavioral and imaging studies of statistical learning by exposing monkeys to a continuous stream of images. The stimulus stream consisted of 3 fixed sequences of 5 grayscale images each and these 3 short sequences were presented in a random order. We randomly rewarded the monkeys with a fluid reward for fixation and the reward timing was unrelated to the stimulus presentation or identity. After a passive exposure to the sequences for two months, we assessed whether the responses of IT neurons showed a correlate of the sequence learning by introducing deviant stimuli in the fixed standard sets. The deviant stimuli were either stimuli from one of the other 2 short sequences or a stimulus from the same sequence but at a wrong position within that sequence. We compared the multiunit neuronal responses for the deviant stimuli with identical stimuli when presented in the standard, learned sequence. We observed a significant enhancement of the responses to the deviant stimulus and the trailing standard stimuli, when the deviant was either from the same sequence ($p < 0.05$) or from the other two sequences ($p < 0.0005$). The neuronal responses to a second deviant stimulus (which followed the first deviant in the standard set) did not differ significantly from the standard. These results demonstrate that monkey IT cortex, under learning conditions that mimic those of statistical learning in human behavioral and imaging studies, encodes at least part of a learned temporal sequence in which a stimulus is presented.

Title: Electrophysiological predictors of an anticipated stimulus during visual sequence learning

Authors: M. SENOUSSI[1,2], *R. VANRULLEN[2,1], L. REDDY[1,2];
[1]Univ. de Toulouse; UPS; Ctr. de Recherche Cerveau et Cognition, Toulouse, France; [2]CNRS, Toulouse, France

Abstract: Learning sequences of events is a fundamental ability, allowing us to remember landmarks on the way to a new job, or to play a song without the sheet music. Anticipation of upcoming stimuli in a known sequence can improve their detection, but the way our brain builds up this directional association between stimuli is poorly understood. Here we investigated whether learning a visual sequence would elicit neural activity patterns selective for the next-to-come stimulus. Sixteen human subjects performed a visual sequence learning task while their neural activity was recorded using Electroencephalography (EEG). Six images from distinct categories (car, pinecone, face, camel, house and phone) were presented in a predictable sequence, as if rotating on a virtual "wheel" composed of 6 black square canvases. In each trial the wheel rotated to the next position for 0.5s, stopped and the central black canvas revealed either the corresponding image (stim trials, 45% of all trials) or a neutral gray square (catch trials, 45% of all trials) for 1s. Then the image turned black again, and the wheel started rotating for the next trial. In randomly interleaved test trials (10% of all trials) the sequence was stopped and subjects reported via button press which of two simultaneously displayed images was to appear next. All images were equalized in 2D Fourier power spectrum. We hypothesized that as a result of learning, brain activity in catch trials (with no image on the screen) should reflect the identity of the image that should have been presented at that point in the sequence; alternately, if no learning occurred all catch trials should be treated similarly by the brain. To uncover selective brain activity we used a Support Vector Machine classifier based on spatial patterns of spectral information (for each time point and oscillatory frequency, the amplitudes across 64 electrodes). To limit the influence of residual activity from preceding stim trials on the classifier performance, we only considered trials preceded by a catch trial. As a first validation of our analysis, we computed classification accuracy during stim trials (image on-screen). On average across subjects, the classifier reached 62% accuracy, with chance level at 16.6% (permutation

test, 10,000 surrogates, p < 10-4). Critically, on catch trials we could also decode above chance the category of the image that should have appeared (19.3 %, p < 10-4), even though only a neutral gray square was on the screen. This ability was mainly driven by high-alpha or low-beta frequencies (11-16Hz). These results show that learning a visual sequence induces selective oscillatory activity in the absence of an anticipated stimulus.

Title: Enhanced readout of early visual cortex after perceptual learning measured with fMRI

Authors: *B. JANS[1], V. VAN DE VEN[2], L. WALDORP[3], M. M. BEEN[2], I. BLOEM[4], K. ULUDAğ[2,5], R. GOEBEL[2,5], P. DE WEERD[2,6];
[1]Maastricht Univ., Maastricht, Netherlands; [2]Cognitive Neuroscience, Maastricht Univ., Maastricht, Netherlands; [3]Fac. of Social and Behavioral Science, Univ. of Amsterdam, Amsterdam, Netherlands; [4]Psychological and Brain Science, Boston Univ., Boston, MA; [5]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [6]Donders Inst. for Brain, Behavior, and Cognition, Radboud Univ., Nijmegen, Netherlands

Abstract: As an explanation of visual skill learning, one class of models emphasizes enhanced readout from low-level areas by high-level areas [1, 2]. To test this idea, 7 human participants performed an easy orientation discrimination task at a fixed orientation difference with gratings at a 1-32% contrast range in a ‘training’ quadrant. Simultaneously, ignored stimuli were shown in an ‘exposure’ quadrant. A third quadrant served as ‘unstimulated’ control. We performed 4-6 3T fMRI scans of V1, V2, and V3 in each participant while they performed the task in the

training quadrant and ignored gratings in the exposure quadrant, or performed an attention demanding task at fixation while ignoring the gratings in both quadrants. During training, the % correct performance increased strongly for lower but not higher contrasts. Before learning, a baseline scan during the fixation task in the training and exposure quadrants confirmed a parametric effect of contrast with the lowest contrast eliciting the lowest fMRI response, whereas in the unstimulated quadrant no fMRI response was observed for any contrast. Interestingly, during the first task performance, there was a parametric effect of contrast not only in the training quadrant, but also in the unstimulated quadrant. Furthermore, fMRI responses to lower contrasts in the training quadrant showed a gradual increase over the course of learning. Once participants reached asymptotic performance, fMRI response amplitudes to lower contrasts equaled those evoked by the highest contrasts. The same trend over sessions was also present in the simultaneously measured fMRI responses in the unstimulated quadrant, although in that quadrant, when attention was at fixation, there was never any response associated with the co-occurring stimuli in the trained quadrant. V1, V2 and V3 showed similar results; trends in exposed quadrant were not significant. Based on findings in training and unstimulated quadrants, our results show that bottom-up responses to ignored stimuli are limited to the site of stimulation. Moreover, we suggest that fMRI responses during task performance reveal a correlate of read-out, which appears to be spatially aspecific, and which show increased amplitude to low contrasts in a manner correlating with behavioral performance increments during training. The readout component revealed here may contribute to spatial generalization of early perceptual learning [3]. [1] Law & Gold, Nat. Neurosci., 2008; [2] Ahissar & Hochstein, Nature, 1997; [3] Xiao et al., Current Biology, 2008.

Title: Donepezil improves perceptual-cognitive performance of healthy young adults

Authors: ***M. CHAMOUN**[1], F. HUPPÉ-GOURGUES[1], I. LEGAULT[1], P. ROSA-NETO[2], J. FAUBERT[1], E. VAUCHER[1];

[1]Optometrie, Univ. De Montreal, Montreal, QC, Canada; [2]Douglas Res. Ctr., McGill Univ., Montreal, QC, Canada

Abstract: Donepezil, a cholinesterase inhibitor that acts by blocking the breakdown of acetylcholine (ACh) in the synapse, is used in the treatment of Alzheimer's disease. Donepezil has been demonstrated to increase perceptual learning by improving the performance in a specific repetitive training task. As ACh is involved in cortical plasticity and experience-dependent increase in cortical activity, this suggests that a cholinergic enhancement through donepezil could be used to improve visual performance in healthy and visually impaired persons. Our study examines whether repetitive acute administration of donepezil improves perceptual-cognitive performance in a highly demanding attentional task defined by visual tracking of moving spheres in a 3D space over five consecutive weeks. A double-blind, placebo controlled design was used to evaluate the effect of cholinergic enhancement - donepezil administration (5 mg, given per os) - on visual attention or visual detection. 10 young healthy adults were enrolled in each group. The task was performed 3 hours after the donepezil (or placebo) intake to synchronize with the peak plasma concentration of the drug. The multifocal attention of the participant was tested by the multiple object tracking task 3D-MOT (Legault and Faubert, 2012). During this perceptual-cognitive task, the observer is required to simultaneously track multiple moving items among distracters in a dynamic virtual reality environment. The task is repeated once a week during 5 weeks to test the effect of learning. It has been proven that performing 3D-MOT speed task over consecutive weeks results in an increase in performance of healthy young adults. For our experimental design this significant increase in performance from the first week baseline was revealed starting the 4th session for donepezil group, in comparison with control group who only showed significant improvement in the last session (5th). Motion and direction identification thresholds for the first order and second order visual detection before and after donepezil intake were however not altered. Our results show that an acute 5mg dose of donepezil improves perceptual-learning performance for healthy young participants in a highly demanding perceptual-cognitive task. Additional studies are needed to better define the involvement of acetylcholine enhancement on perceptual learning/attentional tasks. The long-term goal is to improve, for rehabilitation purposes, the visual performance of people having a visual or attention deficit.

Title: Learning for perception and action: motion prediction in humans and non-human primate pursuit

Authors: T. MUKHERJEE[1], G. ZAKHARY[1], W. BIALEK[2], *L. C. OSBORNE[1];
[1]Neurobio., Univ. of Chicago, Chicago, IL; [2]Physics, Princeton Univ., Princeton, NJ

Abstract: Prediction is one of the fundamental problems in neural computation. Much of what we admire in expert human performance is predictive in character: the point guard who passes the basketball to a place where his teammate will arrive in a split second, the chess master who knows how moves made now will influence the end game two hours hence, the investor who buys a stock in anticipation that it will grow in the year to come. More generally, we gather sensory information not for its own sake but in the hope that this information will guide our actions. But acting takes time, and sense data can guide us only to the extent that those data inform us about the state of the world at the time of our actions. In short we learn the likelihood of future events and use those predictions to guide behavior. There are limits on the accuracy of prediction, and here we ask how close organisms come to optimal performance. We use pursuit eye movements, along with perceptual reports, as a model system in which to explore the learning of probabilities from examples. We have created a simple task where we control the elements of randomness in prior experiences and observe its effect on learning rates for pursuit and perception. We find that subjects make anticipatory eye movements in proportion to confidence in future target movements. We use the anticipatory movements as a metric to quantify motor learning, and, in human subjects, compare to perceptual predictions. Generating target motion sequences from different probability "landscapes", we ask how much information about the underlying distribution is incorporated into predictive behavior compared to an ideal observer. We find that probability learning is adaptive, changing how past experiences are weighted to guide future action based on the correlations in motion probabilities over time.

Title: A mouse model for selective spatial attention

Authors: *E. MCBRIDE, E. CALLAWAY;
Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Attention focuses our limited perceptual resources toward the most relevant stimuli in a distracter-filled environment. Work in primate visual cortex has shown that attending to a location in the visual field enhances neural responses and perceptual sensitivity to stimuli presented there and suppresses responses and sensitivity to stimuli elsewhere. However, neural recording methods available for use in primates are limited in their ability to probe neural circuitry, thus the specific mechanisms and circuits that influence attention and behavior remain mostly unknown. A more detailed description of these circuits requires simultaneous recordings from large populations of neurons in different brain regions, direct manipulation of the activity of specific neuron types, and observation of associated behavioral changes. Genetic tools for selective targeting and manipulation of identified circuit components in the mouse make these experiments possible. When a mouse runs, neural responses are enhanced in response to a visual stimulus, similar to the effect of attention. The circuit mediating this effect has been shown to involve cholinergic projections from the basal forebrain. However, this is likely a global alertness state primarily due to locomotion-induced bottom-up processes. No study yet has examined selective spatial attention in mice, which is likely mediated by top-down projections encoding a decision to selectively attend. To investigate how neural circuitry mediates and is affected by attention, I have successfully trained mice to report the termination of an attended visual stimulus in a specific spatial location, and ignore distracter stimuli. Moving bars display on two screens, one in front of each eye, and the mouse's attention is cued to a particular side. Stimuli are presented simultaneously, but have different durations, and the mouse reports when the target stimulus ends by licking a sensor. In order to perform above chance, the mouse must attend to the target and ignore the distracter. This task will enable us to combine

electrophysiology with optogenetic methods to measure receptive field properties and visual responses under attended and unattended conditions and to probe the role of specific neuronal populations in the control of attention.

Title: The impact of visual salience on noise correlations in the barn owl optic tectum

Authors: *D. TOTTEN, W. M. DEBELLO;
UC Davis, Davis, CA

Abstract: The deep layers of the optic tectum integrate information across modalities to generate a topographic map of space. The spatial and salience tuning of single units in the barn owl optic tectum have been well characterized; however the simultaneous responses in populations of neurons have not been described. We have used multi-electrode recordings in awake barn owls to explore how simultaneously recorded neurons change their firing rates, spatial tuning, response variance and noise correlations in response to changes in stimulus salience. The results demonstrate that there are changes in inter-neuronal noise correlations that can not be accounted for by changes in firing rate or changes in spatial tuning. The impact of these correlations on the ability of theoretical linear decoders to estimate stimulus location given neural responses was investigated. These results suggest that while spike count correlations are prevalent and dynamically regulated in the optic tectum, they do not have a measurable impact on the capacity of the network to localize visual stimuli. Finally, these experiments establish a framework for investigating the potential role of noise correlations in stimulus competition, bimodal processing, plasticity and learning.

Title: Effects of superior colliculus inactivation on visual attention at the fovea

Authors: *R. J. KRAUZLIS, A. R. BOGADHI, A. BOLLIMUNTA;
Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: Clinical and experimental studies show that the superior colliculus (SC) plays a crucial role in visual spatial attention. Specifically, we have previously demonstrated that inactivation of the superior colliculus (SC) in monkeys causes large deficits in perceptual decisions based on visual signals located in the affected part of the visual field. Because these previous studies tested attention at peripheral locations, it is not known whether the role of the SC is limited to directing attention away from the fovea, or whether the SC is also important for visual attention at the fovea, where much of primate vision takes place. We have now investigated this issue by measuring performance on a foveal visual task, before and during SC inactivation. Two rhesus macaques were trained to perform a foveal change-detection task, which required them to continuously fixate a central visual stimulus for the duration of each trial. At a randomized time, the luminance of the fixated stimulus decreased, and the animal's task was to release the joystick immediately after this change in order to receive a juice reward. The size of the luminance decrement was adjusted to be at each animal's perceptual threshold. We measured performance before and during injection of muscimol, a GABA agonist, into the intermediate layers of the SC centered at different retinotopic locations. The extent of the inactivation caused by the muscimol injection was estimated from the decreases in the peak velocities of saccades to visual targets across the visual field. Performance on the foveal change-detection task was significantly impaired during SC inactivation, but only during inactivation experiments that substantially affected the foveal part of the SC retinotopic map. In three experiments in the two animals, the percentage of correctly detected luminance changes was ~40% during inactivations that included the central ~3 degrees of the SC map, compared to ~62% before the inactivation. These findings suggest that the role of the SC in the control of attention is not restricted to peripheral parts of the visual field or only to shifting attention to new stimuli, but also includes sustained visual attention at the fovea.

Title: Attention-related BOLD and single-unit modulation with and without superior colliculus inactivation

Authors: *A. BOLLIMUNTA[1], A. R. BOGADHI[1], D. A. LEOPOLD[2], R. J. KRAUZLIS[1]; [1]Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The superior colliculus (SC) contributes to visual spatial attention through mechanisms that can be dissociated from the classic attention-related modulation in visual cortex (Zenon & Krauzlis, 2012). It is not yet known whether SC influences attention-related activity in the lateral intraparietal area (LIP) or frontal eye fields (FEF). We have now tested this by doing fMRI and single-unit recordings in monkeys during a spatial attention task. We used the same behavioral tasks and inactivation methods for both the fMRI and single-unit experiments. The tasks required the monkey to respond to stimulus changes in one of three different conditions that were interleaved within each run. These conditions included Baseline (B), Foveal Attention (FA) and Peripheral Attention (PA). In B block trials, the monkey released a lever in response to the unpredictable dimming of a central fixation point. FA block trials were similar to B block trials but also included a peripheral motion-change stimulus as an irrelevant distracter. In PA block trials, the fixation point did not dim, and the peripheral motion-change was the relevant stimulus. The task of the monkey was to maintain central fixation and to report the peripheral motion-change by releasing a lever to get a juice reward. To reversibly inactivate the SC inactivation, we injected muscimol in the intermediate and deep layers. In the fMRI experiments, control and inactivation data were collected on interleaved days. Mean % change in BOLD during PA and FA blocks was used to calculate the Attention-related Modulation Index (AMI). In the single-unit experiments, recordings were made with tetrodes in FEF ipsilateral to the inactivated SC. Data were collected from units whose receptive fields overlapped with the inactivated region, before and during inactivation. During inactivation, performance was significantly impaired for stimuli in the contralateral region. Nonetheless, both fMRI and single-unit data revealed a normal attention modulation of cortical areas, consistent with previous results (Zenon and Krauzlis, 2012). The attention-related BOLD modulation was intact not only

in visual cortical areas MT/MST (AMI control: 0.4; inactivation: 0.38), but also in areas LIP and FEF (AMI control: 0.47, 0.57; inactivation: 0.39, 0.58). Consistent with this observation, preliminary single-unit recordings in FEF revealed that attention-related modulation of neural firing rate remained intact during inactivation (AMI control: 0.18, n = 6; inactivation: 0.21, n = 8). These findings suggest that the SC contributes to spatial attention through circuits outside visual cortex and the well-known fronto-parietal network.

Title: Searching for a frequency based signal for attention

Authors: *V. L. MOCK, J. R. HEMBROOK-SHORT, F. BRIGGS;
Physiol. and Neurobio., Geisel Sch. of Med. At Dartmouth, Lebanon, NH

Abstract: Local field potentials (LFPs) provide information about a local population of neurons and can be used to explore how the activity of these neurons encodes specific cognitive functions. We are interested in exploring these signals to determine how information carried in specific frequency bands is linked to visual attention. We examined how attention alters specific frequency modulations in LFPs across the layers of primary visual cortex (V1) and coherence between the visual thalamus (lateral geniculate nucleus or LGN) and V1. We recorded LFPs through electrodes placed within retinotopically-aligned regions of the LGN and V1 in awake-behaving monkeys performing a contrast change detection task that required covert shifts in visual spatial attention. We observed consistent peaks in the power spectra of V1 LFPs at alpha and beta frequencies with a modest peak in gamma. We observed some laminar differences in alpha and beta power between layers 4 and 6 that were most pronounced during visual stimulus presentation periods of the trials. Further, although all layers show an increase in LFP amplitude following stimulus onset, regression fits of LFPs showed a greater amplitude increase in layer 4 compared to layer 6. Modulations in gamma band activity were different from those of alpha and beta bands in a number of ways, suggesting that modulations at gamma frequencies carry more

attentional information compared to modulations in alpha and beta bands. In contrast to alpha and beta band power, which increased during the visual stimulus period, gamma power was higher during the cue period. Additionally, we observed an attentional modulation of the phase of V1 LFPs with the most pronounced phase advance with attention at gamma frequencies. When we examined coherence between V1 contacts and LGN contacts, alpha and beta coherence appeared to be related to the visual stimulus, whereas gamma coherence was strongest during the cue phase. Furthermore, gamma coherence peaked at deep contacts corresponding to layer 6, which contains corticogeniculate neurons. Together, these results support the idea that the gamma frequency band may specifically convey attention signals within V1 and between V1 and LGN.

Title: Attentional modulation of V1 neurons depends on physiological response properties in the primate

Authors: *J. R. HEMBROOK-SHORT, V. L. MOCK, F. BRIGGS;
Physiol. and Neurobio., Geisel Sch. of Med. at Dartmouth, Lebanon, NH

Abstract: Attentional modulation of firing rate varies across visual cortical neurons whereby attention can lead to increases or decreases in neuronal firing rate. However, whether the physiological response properties of individual neurons contribute to this variation is not known. In order to explore potential sources of variation in attentional modulation across neurons, we examined a variety of visual response properties for neurons spanning the cortical layers of primary visual cortex (V1) of awake-behaving monkeys. A 24-contact linear U-probe (Plexon Inc.) was used to record single-unit activity while animals performed a contrast-change discrimination task, which required covert shifts in visual spatial attention. The visual physiology of recorded single-units was determined based on their responses to drifting sinusoidal gratings

varying in contrast, orientation, size and spatial and temporal frequency. Attentional modulation was assessed by comparing neuronal firing rates across trials in which animals attended towards versus away from a visual stimulus that overlapped recorded receptive fields. Over our entire population of well-isolated units in V1, there was a small but significant positive shift in attentional modulation of firing rate and a significant increase in the signal-to-noise ratio of spike waveforms on attention trials compared to tuning trials in which animals were simply required to fixate and ignore grating stimuli. Additionally, we noted wide variation in attentional modulation of firing rates with many V1 neurons demonstrating reduced firing rates with attention. We discovered a number of visual physiological response properties that partially explain this observed variability. The strongest predictor of attentional modulation was the f1-to-f0 ratio with complex cells showing significantly greater attentional modulation of firing rate compared to simple cells, which were suppressed by attention on average. Sharpness of orientation tuning and strength of surround suppression also predicted attentional modulation of individual V1 neurons. Finally, neurons most selective for the stimulus feature modulated in the discrimination task were most strongly enhanced by attention. Thus, match between feature selectivity and task type may also be a predictor of attentional modulation.

Title: The effects of attentional field size on neuronal population responses in V1 of behaving monkeys

Authors: ***M. GADOT**, I. SHAMIR, H. SLOVIN;
Gonda Multidisciplinary Brain Res. Ctr., Bar-Ilan Univ., Ramat Gan, Israel

Abstract: Spatial selective attention allocates the brain's resources to process certain location (or locations) in the visual field, where stimuli can appear. Ample evidence demonstrated that visual attention facilitates perception and improves behavioral performance; however the neuronal mechanisms underlying spatial attention are not fully understood. To investigate the neural correlates of spatial attention we used voltage sensitive dye (VSD) imaging and measured neural population responses from the primary visual cortex (V1) of behaving monkeys. We trained two macaque monkeys to perform a covert spatial attention task, where a briefly presented spatial cue

(SC) indicated with high reliability to the location of a variable contrast target (focal attention). In addition, we manipulated the attentional field by presenting multiple SCs simultaneously (distributed attention). Our behavioral results show improved performance under focal attention in respect to catch trials (invalid trials) and in the distributed condition, performance was better than invalid trials, but lower than the focal attention condition. In addition RTs were shorter in focal attention then on invalid cueing. We investigated the effect of spatial attention on the signal to noise ratio (SNR) of the neuronal responses. The VSD signal revealed that attention increased the population activity of V1 neurons. Neuronal responses in the imaged area were enhanced for the attend-in condition, relative to the attend-away condition. This attentional modulation persisted long after the SC was turned off. Furthermore, in the distributed attention condition, the attentional modulation was smaller compared to the attend-in condition. We also found that relative to the distributed condition, the activity in the attend-in condition was enhanced in regions retinotopicaly corresponding to the SC and its surrounding region but this enhancement declined at regions located more remotely from the SC. Finally, we tested the effect of attention on the neuronal variability. We calculated the trial-to-trial variability and noise correlation in the attend-in, attend-away and distributed conditions, but could not find a significant attentional effect. To conclude, spatial attention induces increased responses of V1 neurons and modulates the attentional field size. Our results therefore, support the limited capacity hypothesis.

Title: Attentional modulation of V1 population responses to shapes and natural scenes

Authors: *P. JENDRITZA[1,2], A. E. LAZAR[3], L. KLEIN[3,2], W. SINGER[3,4,1];
[1]Ernst Strüngmann Inst. (ESI) For Neurosci., Frankfurt, Germany; [2]Intl. Max Planck Res. Sch. for Neural Circuits, Frankfurt, Germany; [3]Max Planck Inst. for Brain Res., Frankfurt, Germany; [4]Frankfurt Inst. for Advanced Studies, Frankfurt, Germany

Abstract: Most of our understanding about the function of the primary visual cortex (V1) relies on studies of individual neurons stimulated with response-tailored visual input. However, it is not yet clear how populations of cells act together to perform the computations necessary for processing complex visual scenes. Inspired by concepts from machine learning, we used a naive

Bayesian classifier to decode stimulus identity from both multi unit (MUA) population activity and band-limited gamma power in a top-down attention paradigm. Data were obtained through chronic recording techniques from two adult male rhesus macaques (Macaca mulatta) implanted with a microdrive containing 32 independently movable electrodes in V1. Naturalistic scenes, shapes and scrambled control stimuli were used to evoke stimulus-specific population responses. The temporally resolved classification of stimulus identity for each task condition (attention outside the receptive fields vs. attention inside the receptive fields) revealed that both MUA activity and gamma oscillations contained information about the visual stimuli and were modulated by attention. Firing rates were increased (Chalk et al. 2010) while the ramp-up in gamma band power during the task (following a 'hazard rate' function) was decreased with attention. Interestingly, oscillatory responses to the naturalistic scenes and shapes differed markedly from the responses to the control images. Visual stimulation with phase scrambled control images or noise images diminished the observed ramp-up in gamma band power. Moreover, the relationship between MUA response magnitude and decoding performance did not follow simple linear characteristics. The decoding performance reached a maximum at the moment of stimulus change (30° rotation of the image), despite a lower firing rate compared to stimulus onset. This suggests a complex relationship between firing rate and information content.

Title: Laminar organization of visually evoked gamma power in area V4

Authors: *M. P. JADI, A. S. NANDY, T. J. SEJNOWSKI, J. H. REYNOLDS;
Salk Inst., La Jolla, CA

Abstract: Precision of spike times is crucial for information coding in the cortex. Gamma bursts (30-100 Hz) in cortical activity are thought to co-ordinate spike times, thus regulating information transmission. In the visual cortex, visual stimulation has been shown to elevate gamma power in the local field potentials (LFP) and spatial attention has been shown to further enhance this. In visual area V1, elevated gamma power shows a layer specific signature along

the anatomically identified supra, input and deep layers that terminate and initiate distinct input and output pathways. However, the laminar distribution of enhanced gamma power is not well understood in area V4. Also unknown is the layer specificity of attentional modulation of gamma. Using laminar array electrodes, we recorded electrophysiological activity while a monkey performed an attention-demanding task. We identified the three layers using current source density estimates and characterized visually induced gamma power in each. Understanding the layer specificity of attentional modulation of gamma power will facilitate a more complete understanding of their role in cortical processing.

Title: Laminar organization of attentional modulation in area V4

Authors: A. S. NANDY, J. J. NASSI, *J. H. REYNOLDS;
Salk Inst. SNL-R, La Jolla, CA

Abstract: In order to flexibly adapt to behavioral demands, the brain needs to rapidly modulate the operating mode of the underlying cortical circuits and thereby control the way information is routed. For example, when an observer directs visual attention to a behaviorally relevant stimulus, this reconfigures cortical circuits to selectively process information about the attended stimulus. Tasks that control attention thus provide a powerful way to manipulate cortical information processing. Traditional single unit electrophysiology has provided key insights into the probable neural mechanisms underlying attention in macaque visual area V4, including modulation of mean firing rate and reduction in correlated variability among pairs of simultaneously recorded units. These changes in neuronal response are thought to result from feedback signals generated in attentional control centers, which impinge on the laminar circuits of the visual cortices. To gain insight into the role of laminar circuits in this transformation one must measure the laminar profile of attentional modulation. To do so, the laminar electrode must run down the cortical column and it must therefore be positioned perpendicular to the cortical

surface. In V4 this is a challenge because V4 straddles a narrow gyrus, with only a narrow strip of cortex that lays flat beneath the calvarium. Here, we replaced the native dura with a silicone based optically clear artificial dura. This allowed us to very precisely target laminar array electrodes to pass down the cortical column, normal to the cortical surface. We recorded activity while a monkey performed an attention-demanding task. We obtained receptive field maps down the laminar contacts that were well aligned, and clear current-source-density (CSD) maps, both indicating that the electrode was well aligned with the cortical column. We used CSD maps to distinguish the laminar position (granular, infra-granular, supra-granular) of each channel, and found differential modulation of sensory gain and correlated variability across layers, which will be useful in constraining laminar circuit models of selective attention.

Title: Graded population activity in area V4 during cued and uncued spatial attention

Authors: ***J. P. MAYO**[1], J. H. R. MAUNSELL[2];
[1]Dept. of Neurobio., Duke Univ., Durham, NC; [2]Dept. of Neurobiology; Grossman Inst., Univ. of Chicago, Chicago, IL

Abstract: Studies of the neuronal mechanisms of visual spatial attention have relied on the cueing paradigm for decades. Validly cued responses occur during trials where the event occurs at the cued location and invalidly cued responses occur when the event occurs at the unexpected location. Validly and invalidly cued trials are used to measure the effects of attending and not attending to a stimulus location. But human psychophysicists also frequently include an uncued, or neutral, condition where the task event is equally likely to occur at either stimulus location. The uncued condition may better capture the uncertainty inherent in our natural environment and therefore could be a useful tool for studying attention-related changes in neuronal activity. Human performance in the uncued condition is usually better than in the invalidly cued condition

and worse than in the validly cued condition. From this evidence, it is reasonable to expect that neuronal activity in the uncued condition to be similarly intermediate. However, prominent theories of visual attention propose a singular focus of attention such that neuronal responses in the uncued condition would function in a binary manner, exhibiting valid-like or invalid-like patterns of activity at any moment. To study uncued spatial attention, we recorded from populations of neurons in visual area V4 in ~30 recording sessions in two monkeys trained to detect a change in orientation at one of two possible stimulus locations. We interleaved blocks of validly cued, invalidly cued, and uncued trials in each recording session and measured changes in average firing rate and neuronal correlations. We found that firing rates in the uncued condition were lower than those of the validly cued condition but higher than the invalidly cued condition, consistent with the intermediate effects of uncued attention on the animal's behavior. Likewise, neuronal correlations were strongest when the stimulus was unattended, intermediate when uncued, and weakest when attended. Our work supports the hypothesis that neuronal populations in area V4 function in a graded, continuous manner to represent the validity of cued and uncued spatial attention.

Title: Implicit associations between achromatic cues and spatial attention

Authors: *A. T. MARIN[1], S. A. DREW[2];
[2]Psychology, [1]California State University, Northridge, Northridge, CA

Abstract: Random events seen within our external environment, when repeated, tend to exhibit statistical regularity. Past research has suggested both bottom-up and top-down mechanisms are involved in the documented relation between spatial attention and emotion. Research also suggests the same for achromatic perception and emotion. In this study, we investigated potential low-level behavioral mechanisms underling the relation between achromatic perception (e.g. black and white) and vertical spatial attention (e.g. bottom and top). Thirty participants were tested in a spatial configuration search task that was programmed using the computer software program MATLAB. The task was to locate a single target “T” amongst twelve distracter “Ls”. The background (e.g. black and white) and location of the target (e.g. top and bottom of the

display) varied trial to trial. Results show a significant interaction between the background color and target location in terms of reaction time, $F(1, 29) = 15.57$, $p = .001$, partial $^2 = .35$. Participants were significantly faster in identifying a bottom target when cued with a black screen compared to a white screen. Participants were also faster in identifying a top target when cued with a white screen compared to a black screen. There were also significant main effects of location, $F(1, 29) = 5.59$, $p = .025$, partial $^2 = .16$, but not of background, $F(1, 29) = 2.44$, $p = .129$, partial $^2 = .08$. In order to follow up on these significant findings, a second experiment was conducted in order to separate the co-occurrence of the black and white backgrounds from the visual search task, which returned no significant findings. Theoretical implications are discussed as well as future directions that are in line for the next phase of data collection. Taken together, these results suggest an implicit relationship between achromatic perception and vertical spatial attention. *Keywords:* Visual & Spatial Attention, Statistical Regularities, Achromatic Perception, Natural Scene Statistics

Title: Feature-based attention regulates long-range neural interactions in monkey area V4

Authors: *R. XIA, S. GUAN, D. SHEINBERG;
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Feature-based attention facilitates the representation of visual objects that share attended features regardless of their spatial location. While most studies have focused on the attentional effects at the single neuron level, the underlying network mechanisms remain poorly understood. Inter-neuronal synchrony, as a hypothetical indicator of neural interactions, provides a novel perspective for investigating the network dynamics of attention regulation. Recent studies have shown that attention not only regulates the firing of individual neurons, but also dynamically modulates the temporal coherence between neurons. For instance, in visual area V4,

selective attention enhances the pairwise synchrony when both neurons' receptive fields (RF) overlap with the attended location (Fries et al. 2001). However, these neurons can be physically close to each other due to the retinotopic structure of V4. It remains unclear whether and how feature-based attention regulates the long-range horizontal interactions between neurons with distinct RFs across visual field. To study the network dynamics of feature-based attention in a larger scale, we recorded the neural activity simultaneously from multiple sites in monkey area V4 using a 32-channel Gray Matter drive while the monkey performed a cued visual search task. In the task, a color cue (colored spot) or an orientation cue (black-white Gabor patch) was initially shown at the fixation location to indicate the feature of the target. Following cue offset, two Gabor stimuli with different orientations and colors appeared at opposite directions. A saccade to the target location after the stimulus disappearance was rewarded with juice. Our preliminary results showed that the cue-induced attention regulated both the firing rate and local field potential (LFP) of the recorded population. Neurons/channels selective to cued features were more likely to have higher firing rate and gamma-band LFP power in response to the onset of visual stimuli. More strikingly, some recorded channels showed enhanced LFP-LFP coherence during and after the cueing period, even between those preferring foveal and peripheral locations. Furthermore, using a classifier to decode the feature information from different types of neural signals, it appears that pairwise synchrony plays a role in coding the attended feature, but does not contribute to representing target location. Our ongoing project aims to explore how feature-based attention regulates the horizontal interaction pattern based on the feature tuning of neurons, and our network-level analysis will provide insights to understanding the general mechanism of top-down regulation.

Title: Maintenance of spatial information modulates the correlated variability of MT neurons based on their spatial selectivity

Authors: *Y. MERRIKHI[1], M. PARSA[2], B. NOUDOOST[2];
[1]school of cognitive sciences, Inst. For Res. In Fundamental Sci., Tehran, Iran, Islamic Republic of; [2]cell biology and neuroscience, montana state university (MSU), Bozeman, MT

Abstract: Previous studies have shown that maintaining spatial information improves the discrimination of visual targets at the remembered location.Changes in the correlations in trial-to-trial variability of pairs of extrastriate neurons (noise correlations) have been proposed as a means for improving visual discrimination. We studied how memory-related spatial signals modulate the correlated activity of pairs of neurons within extrastriate areas, and the degree to which these modulations depend on the similarity between the spatial and feature selectivity of the two neurons. In two macaque monkeys, multiple neurons in the middle temporal area (MT) were simultaneously recorded using 16-channel linear array electrodes. The spatial selectivity of the neurons was quantified by measuring their response to probes presented in a 7x7grid centered around their estimated receptive field (RF). Feature selectivity was measured in a separate task in which moving gratings with 8 different directions of motion were presented within the neuron's RF. To test whether the maintenance of spatial information alters the correlated variability of these neurons, we then recorded their activity during the memory guided saccade task. The animal had to remember the location of a target and maintain fixation throughout a 1s delay period, then saccade to that location at the end of the trial. The noise correlations between pairs of MT neurons were measured both prior to target presentation and during the memory period of the task. Pairs of neurons were categorized based on whether the remembered location fell within one, both, or neither of the neurons' RFs. Our results indicate that maintenance of spatial memory changes the correlations in activity between pairs of neurons, and that this change depends on the arrangement of the neurons' RFs relative to the remembered location. In contrast, the degree of feature similarity within a pair had negligible effect on the changes in their noise correlation during memory maintenance. These findings demonstrate how the top-down spatial signal interacts with the spatial and feature preferences of neurons within extrastriate areas, providing a more complete picture of how these changes in correlated activity can contribute to enhancing visual representations.

Title: Response modulations by spatial but not by feature-based attention are correlated with reduction in bursty firing in area MST

Authors: *C. XUE[1], B. S. KRISHNA[1], S. BALONI[1], D. KAPING[1,2], S. TREUE[1];

Abstract: Visual attention is known to modulate the firing rate of neurons in many areas of the primate visual cortex. In addition the temporal pattern of neuronal activity can also vary according to behavioral context. In particular, the burstiness of firing patterns of V4 neurons has been shown to decrease when spatial attention is directed into their receptive fields (Anderson, Mitchell and Reynolds, Nat. Neurosci., 2013). However, it remains unclear if this result extends to other brain regions and types of attention, and how the variation in burstiness relates to the well-known modulation of firing rate by attention. Here, we analyzed extracellular neuronal data recorded from area MST of two rhesus monkeys (Macaca mulatta) while they performed a task in which they had to respond to a brief motion direction change in one (the 'target') of two moving random dot patterns (RDPs), while ignoring similar changes in the other RDP (the 'distractor'). When the RDPs moved in the preferred direction of the recorded neuron, comparing the responses when the RDP in the receptive field (RF) was the target or the distractor enabled us to examine the effects of spatial attention. Similarly, when the distractor was in the RF and moved in the preferred direction, comparing the responses when the distractor RDP outside the RF moved either in the preferred or anti-preferred direction enabled us to examine the effects of feature-based attention. Both spatial attention into the RF (relative to spatial attention directed outside the RF) and feature-based attention to the preferred direction (relative to the non-preferred direction) enhanced the firing-rate of MST neurons, as expected. However, while spatial attention also led to a concurrent net reduction in burstiness (as reported earlier from V4), feature-based attention was not associated with a clear effect on burstiness. This lack of a net effect on burstiness could not be explained by the fact that feature-based attention's effect on firing-rate was smaller than that of spatial attention. Our results confirm the effects of spatial attention on burstiness in MST, and indicate that spatial and feature-based attention have different effects in MST neurons.

Title: "Everything you always wanted to know about fitting tuning curves* (*But were afraid to ask)": model-free characterization of tuned responses and of their attentional modulation

Authors: *M. HELMER[1,2], V. KOZYREV[3,4], V. STEPHAN[4,2], S. TREUE[4,2], T. GEISEL[5,2], D. BATTAGLIA[6,2];
[1]Max-Planck-Institut F Dynamik U Selbstorganisation, Goettingen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany; [3]Inst. of Neuroinformatics, Ruhr-University, Bochum, Germany; [4]Cognitive Neurosci. Lab., German Primate Ctr., Goettingen, Germany; [5]Dept. of Nonlinear Dynamics, Max Planck Inst. for Dynamics and Self-Organization, Goettingen, Germany; [6]Inst. de Neurosciences des Systemes, Aix-Marseille Univ., Marseille, France

Abstract: Tuning curves are the functions that relate the responses of sensory neurons to various values within one continuous stimulus dimension (such as the orientation of a bar in the visual domain or the frequency of a tone in the auditory domain). They are commonly determined by fitting a model e.g. a Gaussian or other bell-shaped curves to the measured responses to a small subset of discrete stimuli in the relevant dimension. However, as neuronal responses are irregular and experimental measurements noisy, it is often difficult to determine reliably the appropriate model from the data. We illustrate this general problem by fitting diverse models to representative recordings from area MT in rhesus monkey visual cortex during multiple attentional tasks involving complex composite stimuli. We find that all models can be well-fitted, that the best model generally varies between neurons and that statistical comparisons between neuronal responses across different experimental conditions are affected quantitatively and qualitatively by specific model choices. As a robust alternative to an often arbitrary model selection, we introduce a model-free approach, in which features of interest are extracted directly from the measured response data without the need of fitting any model. In our attentional datasets, we demonstrate that data-driven methods provide descriptions of tuning curve features such as preferred stimulus direction or attentional gain modulations which are in agreement with

fit-based approaches when a good fit exists. Furthermore, these methods naturally extend to the frequent cases of uncertain model selection. We show that model-free approaches can identify attentional modulation patterns, such as general alterations of the irregular shape of tuning curves, which cannot be captured by fitting stereotyped conventional models. Finally, by comparing datasets across different conditions, we demonstrate effects of attention that are cell- and even stimulus-specific. Based on these proofs-of-concept, we conclude that our data-driven methods can reliably extract relevant tuning information from neuronal recordings, including cells whose seemingly haphazard response curves defy conventional fitting approaches.

Title: Feature-based attention to visual motion directions increases response and contrast gain: evidence for tuned normalization

Authors: ***P. SCHWEDHELM**[1,2], B. S. KRISHNA[1], S. TREUE[1,2,3];
[1]German Primate Ctr., Goettingen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany; [3]Fac. of Biol. and Psychology, Univ. of Goettingen, Goettingen, Germany

Abstract: Paying attention to a sensory feature improves the perception of that feature and can impair processing of other features. Recent work has shown that a Normalization Model of Attention (NMoA: Reynolds & Heeger, 2009) can account for a wide range of physiological findings and is also consistent with the measured influence of different attentional manipulations on visual performance (Herrmann et al. 2010, 2012). A key prediction of the NMoA is that feature-based attention (e.g. attention to orientation or motion direction) will impact neuronal responses by multiplicative scaling of the responses of neurons tuned to the attended feature (response gain), rather than by increasing the effective sensory input strength of the attended feature (input gain). Under the assumption of an optimal perceptual read-out, an effect on

neuronal responses translates to similar patterns of improvement in behavioral performance; with psychometric functions showing response gain rather than input gain when attention is directed to the task-relevant feature. This prediction has been confirmed by one recent report using attention to orientation (Herrmann et al. 2012). However, using a similar experimental design to measure the effects of feature-based attention to visual motion directions, we observed a different pattern of results. We found that when human subjects are cued to attend to one of two motion directions in a transparent motion display, attentional effects on direction discrimination performance are a combination of input gain and response gain. This contradicts predictions made by the NMoA, especially since we found the effect size of input gain to increase when attention is focused on a narrow range of motion directions compared to when it is directed towards a broader range. In order to account for our observations, we suggest a revision of the assumptions made by the NMoA: Adding a direction-tuned, stimulus-independent, attentional contribution to the normalization pool fully accounts for our pattern of results. This proposed direction-tuned attentional normalization is consistent with the feature-similarity gain model of attention and the attentional modulation in extrastriate cortical area MT, where neuronal responses are enhanced or suppressed by attention to preferred and non-preferred motion directions respectively.

Title: Top-down attention de-correlates early visual cortex

Authors: *S. KWON[1,2], M. WATANABE[2], A. BARTELS[1,2];
[1]Vision and Cognition Lab., Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Max Planck Inst. Biol Cybernetics, Tuebingen, Germany

Abstract: Attention allows our brain to focus its limited resources on a selected task. It does so by the selective modulation of neuronal activity of task-relevant cortical areas, and by the

simultaneous change of communication between sets of regions. Previous fMRI evidence in the human brain showed selective increases in functional connectivity within visual cortex and between visual with fronto-parietal networks. However, these studies examined relatively brief attention periods that are affected by task-induced signal transients. We designed an experiment involving very long (2 min) trials of attention and rest that would allow us to discard initial transient periods (30 s), and to analyze slow (0.004-0.05Hz) and fast frequency (0.05-0.2Hz) bands of fMRI signals driving connectivity changes. We analyzed functional connectivity between visual regions, the dorsal attention network, and the resting state network. We found that attention increased long-distance connectivity between the dorsal attention network and visual regions and within the resting-state network. It decreased connectivity between resting-state and attention networks, but also between distinct visual regions and within distinct parts of the same visual region (left/right, dorsal/ventral parts). The change in connectivity strength was correlated with hierarchical distance, such that the increase between the dorsal attention network and visual cortex was more pronounced for higher than lower visual regions. Correspondingly, the decrease within visual cortex was the more pronounced the closer the hierarchical proximity was between neighboring regions, and was highest within regions. A frequency-segregated analysis showed that long-distance effects between dorsal attention network and visual regions were mediated by slow and fast fluctuations, whereas only fast fluctuations mediated de-correlation among visual regions. These results may pinpoint two fundamentally distinct effects of attention on connectivity. A long-range facilitation of information flow between distinct networks, and a short-range de-correlation within sensory cortex that may indicate and increase of information and decrease of redundancy.

Title: Attentional priority signals in human frontoparietal cortex correlate with performance in a feature-based attention task

Authors: ***M. JIGO**, T. LIU;
Dept. of Psychology, Michigan State Univ., East Lansing, MI

Abstract: It is generally accepted that top-down visual attention selects goal-relevant stimuli to facilitate task performance. Hence, fluctuations in endogenous attentional control should influence performance in tasks relying on visual selection. Previous research has implicated a dorsal frontoparietal network, including regions in intraparietal sulcus (IPS) and frontal eye field (FEF), in the maintenance of attentional priority for visual features. However, the relationship between the quality of these neural representations and task performance is not well understood. Using two speed detection tasks in an fMRI experiment, we tested whether the quality of an attentional template, i.e., the neural representation of an attended direction of motion, correlated with task performance. In the first task (attention), subjects were cued to attend to one of two overlapping dot fields, one that rotated in a clockwise (CW) direction and another that rotated in a counter-clockwise (CCW) direction. Subjects were instructed to report the presence or absence of a brief speedup in the cued direction. The magnitude of the speedup was controlled by a staircase that constrained performance at 75% correct. In the second task (baseline), subjects similarly reported the presence or absence of a speedup, but they only viewed a single dot field that rotated in either the CW or CCW direction. Speedup magnitudes were equated between tasks. The patterns of neural activity for correct and incorrect trials in each motion direction in the attention task were obtained as the measure of the attentional templates. To get a measure of their respective quality, these templates were compared to the neural patterns obtained from the baseline task, which served as the benchmark template. We found that the attentional templates in posterior IPS and FEF were more similar to the benchmark template for correct than incorrect trials. These effects were not found in visual areas and inferior prefrontal areas. Furthermore, for average fMRI response across voxels, we found a slightly smaller amplitude and temporally more extended profile for incorrect than correct trials in these areas, as well as anterior IPS and inferior prefrontal areas. These results revealed neural correlates of task performance for feature-based attention and suggest that posterior IPS and FEF maintain attentional templates that facilitate the successful selection of relevant visual features.

Title: Parietal theta burst TMS: functional fractionation observed during bistable perception not evident in attention tasks

Authors: *J. BRASCAMP[1,2], G. SCHAUER[3], R. KANAI[3];
[1]Utrecht Univ., Utrecht, Netherlands; [2]Michigan State Univ., East Lansing, MI; [3]Sackler Ctr. for Consciousness Sci., Univ. of Sussex, Brighton, United Kingdom

Abstract: When visual input is ambiguous or inconclusive, perception spontaneously alternates between interpretations: bistable perception. The idea that these perceptual alternations are related to attention function has a long history, but arguably the most compelling evidence comes from recent studies using transcranial magnetic stimulation (TMS). These studies have identified two distinct sites near the right intraparietal sulcus (IPS) where offline TMS affects the frequency of occurrence of these alternations, but strikingly with opposite directions of effect for the two sites. Although this clearly implicates right parietal cortex in bistable perception, the functional nature of this involvement remains unclear. It is natural to suppose a link to attention-related functions, as numerous lesions studies, as well as TMS work, have indicated the right parietal cortex in tasks involving functions like attention to spatial locations and sustained attention. Here we use this knowledge in an attempt to functionally interpret right-parietal involvement in bistable perception. Specifically, we used the exact theta burst TMS protocol that we previously used to affect perception of ambiguous stimuli, yet measured its effect on tasks involving attention to lateralized targets and sustained attention. Although there was a trend for TMS to affect these tasks, trends were consistently similar for both parietal sites, with no indication of opposite effects as had been found for perception. We interpret this as signifying that the previously observed parietal fractionation of function regarding the perception of ambiguous stimuli, is not due to TMS-induced modification of spatial or sustained attention.

Title: The impact of spatial focusing on global feature-based attention

Authors: *M. V. BARTSCH[1], H. STRUMPF[2], M. A. SCHOENFELD[1,2], J.-M. HOPF[1,2]; [1]Leibniz Inst. for Neurobio., Magdeburg, Germany; [2]Dept. of Neurol., Otto von Guericke Univ., Magdeburg, Germany

Abstract: Attention to features operates in a location-unbound manner, which is referred to as global feature-based attention (GFBA). GFBA is typically revealed by assessing the brain response to task-irrelevant feature probes outside the spatial focus of attention (FOA) as a function of probe-to-target feature similarity (unattended probe paradigm). While this experimental approach yields consistent effects of GFBA, it has some disadvantages. The most important one pertains to the fact that the allocation of spatial attention needs to be carefully controlled, which may be hard to accomplish in particular in experimental designs using onset stimulation. For example, with stimulus onset the spatial FOA may transiently widen and encompass both the target and the probe - a situation that would confound GFBA with transient effects of spatial selection. Here, we address this issue in a series of magnetoencephalographic (MEG) experiments in human observers performing a color attention task by manipulating the allocation of spatial attention to the color target in three different ways: (1) We motivate stronger spatial focusing by increasing the difficulty of discriminating the color target. (2) We facilitate more consistent focusing by demarcating the target location with placeholders prior to stimulus onset. (3) We aid optimal spatial focusing by presenting the target at fixation. We observe that all three manipulations leave the spatiotemporal pattern of modulations underlying global color-based attention largely unchanged. The pattern appears as a series of modulations of the neuromagnetic response in ventral extrastriate cortex contralateral to the probe, which was previously documented in Bartsch et al. (2014). These results together suggest that the GFBA response as revealed by the unattended probe paradigm indexes a true global selection effect that is not simply arising from inconsistent spatial focusing.

Title: Attention and normalization responses of area 8a of the primate dorsolateral prefrontal cortex are cell type dependent

Authors: *L. DUONG[1], F. PIEPER[2], J. MARTINEZ-TRUJILLO[3];
[1]Robarts Res. Inst., London Ontario, ON, Canada; [2]Inst. for neuro- & pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [3]Physiol. and Pharmacol., Robarts Res. Institute, Western Univ., London Ontario, ON, Canada

Abstract: It has been proposed that attention modulates the responses of neurons in early visual cortex of primates by regulating the strength of normalization mechanisms. However, whether a similar argument applies to executive areas such as the prefrontal cortex, where attentional modulation of neuronal responses is particularly strong, remains unclear. Here we recorded the responses of neurons in area 8A of the dorsolateral prefrontal cortex of two non-human primates during a task that required the animals to fixate on a central point on a computer screen while being presented with one stimulus presented in one of four quadrants of the visual field, or four stimuli presented simultaneously (one in each quadrant). When multiple stimuli were presented, the animals were cued to attend to one of the four quadrants while holding fixation on the center of the screen. We found that in general, the neuronal firing rates to the four stimuli presented together differed greatly from the sum of firing rates for when they were presented alone, consistent with previously described normalization processes in other areas of the brain. Further, the extent of a neuron's firing rate suppression during single stimulus presentation was related to its firing rate during multiple stimulus presentation. With four stimuli in the visual field, computations resembled an averaging response under conditions with no attention; interestingly however, when attention was directed to one of the stimuli, the response of a subset of contralateral selective cells more closely resembled a winner-take-all computation. Correlational analysis reveals that neurons selective for the ipsilateral or contralateral hemifield may indeed be governed by different underlying circuitry.

Title: Clues about the neuronal basis of UV avoidance in larval zebrafish

Authors: *D. A. GUGGIANA-NILO, F. ENGERT;
Harvard Univ., Cambridge, MA

Abstract: Light in the ultraviolet region is invisible to humans, but is ubiquitous in nature as it is one of the components of sunlight. This range of the electromagnetic spectrum is of particular importance to organisms in contact with it, given its higher energy per photon and concomitant potential to generate cellular damage and trigger mutations in DNA. The ability to detect these low wavelengths is present in a variety of organisms, ranging from mammals to insects. One of such organisms is the larval zebrafish (Danio rerio). This small teleost possesses 4 types of cone photoreceptors that can detect wavelengths from the red to the UV and are active as early as 4 days post fertilization (dpf). Additionally, this organism is a newly encumbered model for a variety of fields in biology such as development, pharmacology and neuroscience. This is due to a combination of well-described genetics, rich behavioral and physiological repertoire and optical transparency. In the past we have shown that larvae avoid UV light in an intensity dependent manner and that UV light is able to overcome phototactic behavior. For this we utilized a closed loop paradigm where the fish is tracked as it swims freely in an arena and a projection follows it in real time, forcing a choice of turning direction between 2 different visual stimuli, presented separately to each eye. Given the visual range of the animal, we modified an existing DLP projector to present stimuli fitting the absorption region of the zebrafish and we synthesized color-isolating stimuli to probe each channel separately. In this work we show how mutant larvae with genetically inactivated UV cones fail to avoid UV light, while their wild type siblings show the expected avoidance behavior.

Title: Relating individual variability of behavior and neural circuitry in the optomotor response of larval zebrafish

Authors: *E. A. NAUMANN[1,2], T. W. DUNN[1], J. E. FITZGERALD[1], J. RIHEL[2], F. ENGERT[1];
[1]Harvard, Cambridge, MA; [2]Univ. Col. London, London, United Kingdom

Abstract: How are individual behavioral differences manifested in underlying neural circuits? In order to study the heterogeneity of a basic vertebrate visuomotor neural circuit, we performed a detailed kinematic analysis of behavioral signatures across individual zebrafish swimming in response to monocular and binocular optic flow stimuli. Using a closed-loop assay to control the visual environment precisely while monitoring behavior, we quantified kinematic variability across individual fish. While each fish effectively matches its behavior to the speed and direction of visual motion, we find that the exact behavioral implementation varies substantially across individuals. To correlate fish-specific behavioral idiosyncrasies with neural circuit activity, we used whole-brain calcium imaging to examine functional differences across the same individuals subjected to behavioral assays. Our results show that individual differences in cumulative angle changes and binocular integration correlate the distribution of specific neural response classes in the pretectum, a brain region primarily involved in optic flow processing. These correlations parameterize model families that generate predictions for circuit composition and connectivity strength between functional cell types. Together with anatomical tracing of neural projection patterns and assessments of neurotransmitter identity, these experiments establish a theoretical minimal neural circuit and illustrate the degree to which circuit architecture is degenerate across individuals. This study of circuit heterogeneity across individuals is crucial for our understanding functional degeneracy within neural circuits and suggests limitations for standard models fit on average data.

Title: Experience shapes prey capture behavior and neural representations in larval zebrafish

Authors: *C. OLDFIELD[1], E. CARROLL[2], M. CHAVEZ[3], C. WYART[4], E. ISACOFF[2];
[1]Isacoff lab - MCB, UC Berkeley, Berkeley, ; [2]Isacoff lab - MCB, UC Berkeley, Berkeley, CA; [3]ICM - UPMC, Paris, France; [4]ICM, Paris, France

Abstract: When larval zebrafish first open their mouths and start hunting for prey during their fifth day post-fertilization (5 dpf), they may have seen edible organisms before, but without ever eating. Despite this lack of experience, they capture prey, such as paramecia, in a highly stereotyped manner. Prey is detected visually, the fish then reorients its body precisely towards the prey and darts forward to engulf the prey in a final capture swim. Recent work has dissected the visual circuits that lead to prey capture, but how information is transmitted to motor centers is unclear. Using a combination of behavioral assays and whole brain calcium imaging, we are working to understand the relationship between experience-based changes in brain activity and prey capture behavior.

Title: Light-evoked diving reflex in zebrafish larvae

Authors: B. H. BISHOP, B. C. FRESHNER, *E. B. GAHTAN;
Psychology, Humboldt State Univ., Arcata, CA

Abstract: Escape behaviors have been studied in many organisms by neuroscientists seeking detailed, cellular- and synaptic-level descriptions of functional circuits. Escapes are useful because they can be elicited repeatedly and have consistent kinematics. Analysis of escape circuits in fish have revealed mechanisms for movements away from a threatening stimulus (contraversive) in the lateral plane, such as commissural projections and population coding of escape turn angle. However, while most fish navigate in 3 spatial dimensions, few studies have examined neural mechanisms of vertical movements during escape. We characterized vertical escape swimming in zebrafish larvae using synchronized imaging from two cameras viewing a 10cm3 tank. Escapes elicited by dimming of ambient light consistently elicited downward spiral swimming (dives). At 20s post dimming, larvae showed more vertical (-18.8±2mm) than horizontal (3.2±0.6mm) displacement. The average slope of dives was -1.9±.35, meaning larvae move about twice as fast vertically than horizontally along their spiral paths. In a tubular tank with more vertical (400mm) than horizontal (100mm) range, vertical movement 120s after light dimming was -353±8.39mm (~70 body lengths downward). Dives typically began within 1s after

light dimming and continued until the tank bottom was reached. Maximum descent rate was 10.75mm/s (at 58s post dimming), and average descent rate was 5.41±0.24mm/s. Auditory taps also elicited rapid escape swimming with equivalent total distance traveled 20s post stimulus but with significantly less vertical and more horizontal displacement than on dimming-evoked escapes. These results suggest that light dimming-evoked spiral diving in larval zebrafish may be a protean escape reflex to specific types of predation threats, and that neural circuit models of escape control must look beyond mechanisms for lateral contraversive movements and also consider vertical movement control elements.

Title: A novel neuromodulatory circuit for short-term motor memory

Authors: *T. KAWASHIMA, C.-T. YANG, M. B. AHRENS;
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: Animals continually adapt to the dynamics of environmental feedback arising from behavior. Here we report on the discovery of a novel neural substrate of a short-term memory of adapted behavioral states mediated by the dorsal raphe nucleus, a neuromodulatory serotonergic nucleus in vertebrates. When larval zebrafish perform adaptive motor control within the optomotor response (OMR), extended exposure to a given feedback gain - the strength of visual feedback driven by fictive swimming - establishes a short-term memory of the matched locomotor drive, which is maintained for periods of up to 20 seconds of behavioral inactivity. We used light-sheet microscopy to perform whole-brain calcium imaging in larval zebrafish behaving in virtual reality to identify neural circuits underlying this short-term motor memory. Functional brain maps identified the dorsal raphe nucleus (DRN) as a key regulatory region for the memory of attenuated locomotor drive resulting from high feedback gain. Activity of DRN neurons built up during low locomotor drive, was maintained during periods of behavioral inactivity, and was predictive of the subsequent motor output, indicating that DRN activity can support a persistent memory trace of the adapted locomotor state. Spiking responses of DRN

neurons showed a combination of phasic sensorimotor responses and additional modulation of tonic activity. Chemical-genetic lesions of DRN serotonergic populations reduced the ability to form the short-term motor memory; and optogenetic activation of DRN neurons induced lasting depression of locomotor drive similar to the experience-induced attenuation of behavioral vigor. These results uncover a novel mechanism for a short-term motor memory.

Abstract: Innate defense behaviors (IDBs) evoked by threatening sensory stimuli are essential for animal survival. Although subcortical circuits are implicated in IDBs, it remains largely unclear whether sensory cortex modulates IDBs and what are the underlying neural pathways. Here, we show that optogenetic silencing of corticotectal projections from layer 5 (L5) of the mouse primary visual cortex (V1) to the superior colliculus (SC) significantly reduces a SC-dependent innate behavior, i.e. temporary suspension of locomotion upon a sudden flash of light as short as milliseconds. Surprisingly, optogenetic activation of SC-projecting neurons in V1 or their axon terminals in SC sufficiently elicits the behavior, in contrast to other major L5 corticofugal projections. Thus, via the same corticofugal projection, visual cortex not only modulates the light-induced arrest behavior, but also can directly drive the behavior. Our results suggest that sensory cortex may play a previously unrecognized role in the top-down initiation of sensory-motor behaviors.

Title: Visual context and neural control of headbobs in gerbils

Authors: ***H. R. RODMAN**[1], G. KUI[2], K. BANDA[3], M. KRYSIAK[1];
[1]Dept. of Psychology, [2]Dept. of Biol., Emory Univ., Atlanta, GA; [3]Dept. Primate Behavior and Ecology, Central Washington Univ., Ellensburg, WA

Abstract: Head bobs are up-down movements, associated with the use of motion parallax for depth perception, that are displayed by many animals, including rodents, birds, and humans. Mongolian gerbils *(Meriones unguiculatus)* show robust visually guided jumping behavior and often execute a series of head bobs prior to jumping. Here, we asked if head bobs are affected by ecologically significant aspects of the visual context, specifically ambient light level and distance to target. In addition, we explored the role of two brain regions - the temporal posterior cortical area (TP) and the superior colliculus (SC) - expected to have important roles in rodents' ability to process visual motion cues. Gerbils were tested on a jumping stand task and head bobs videotaped under three light levels: bright (akin to low daylight; ~1000 lux), dim (akin to dawn or dusk; ~100 lux), and low light (akin to moonlight; ~1 lux), across a range of gap distances (5-45 cm between jumping and target platforms). Infrared illumination was used with a sensitive security camera (Sony SSC-M183). Following euthanasia, cortical flatmounts were prepared, sectioned, and stained for myelin (Gallyas method) to reveal TP, and brainstems were sectioned coronally and stained with cresyl violet. Head bobs were defined as repeated vertical displacements of the head with forepaws resting on the edge of the start platform, facing the landing platform. Head bobs increased with gap distance until an intermediate point and then decreased, suggesting that they are maximally executed under conditions where they are most useful. Significant effects of light level ($p < 0.05$) were found for intermediate distance and intermediate illumination as well as for low illumination and short distances. Thus, the effect of

illuminance on head bobs appears to interact with distance. There was a positive correlation between head bob frequency and relative SC volume, but no overall relationship between head bobs and relative area of the TP region. The results suggest that gerbils use a specific visuomotor strategy for depth perception differentially under different conditions and that the SC is involved in headbob generation and/or use, although further work is needed to investigate potential cortical mechanisms and to pinpoint the role of the SC. The findings are consistent with our earlier work (Krysiak et al., 2011, *Behavioural Processes*) showing that both visuomotor behavior and visual discrimination are modulated by ambient illumination, underscoring the importance of employing ecologically relevant lighting conditions in comparing visual specializations and their neural control across taxa.

Title: Effects of transcranial direct-current stimulation on the primary visual cortex excitability in alert rabbits

Authors: *J. MARQUEZ-RUIZ[1], C. AMMANN[1], T. COSTA[2], G. LOURENCON[2], I. CORDONES[3], A. GRUART[1], J. DELGADO-GARCÍA[1], D. VENTURA[2];

Abstract: During the last decades, transcranial direct-current stimulation (tDCS) has demonstrated to be a valuable tool for non-invasive manipulation of cortical excitability. The aim of this study was to investigate the effects of tDCS over the primary visual cortex (V1) of alert rabbits, demonstrating the capability of tDCS to modulate the sensory perception involved in complex cortical processes, such as the acquisition of an associative learning task, as well as the way in which tDCS affects the oscillatory activity of cortical circuits. For this objective four male rabbits were prepared for chronic recording of visual evoked potentials (VEPs) and classical eyeblink conditioning during simultaneous tDCS. To describe excitability changes of V1 after anodal and cathodal tDCS presentation (2 mA, 20 min), VEPs were recorded before and after tDCS in response to visual stimulation induced by trains of flashes (20 flashes, 1 Hz). tDCS stimuli were applied through four silver ball electrodes placed above the skull (targeted active electrode) and a saline-soaked sponge attached to the contralateral ear serving as a counterelectrode. To show whether changes induced by tDCS in V1 excitability modify associative learning in rabbits, a classical eyeblink conditioning was carried out in the animals. Accordingly, we used a trace paradigm presenting a train (100 ms, 50 Hz) of flashes as conditioned stimulus (CS), followed 250 ms later by an air puff (100 ms) as unconditioned stimulus (US). Anodal and cathodal tDCS (2 mA, ~20 min) were applied during conditioning day 2 (C2) and day 8 (C8), respectively. The EMG activity of the orbicularis oculi was used to define the conditioning responses (CRs). The results show a significant long-lasting increase of the P1 amplitude after cathodal stimulation, while anodal stimulation did not induce any change in VEPs. The analysis of the event-related spectral power associated to the VEPs showed that cathodal tDCS on V1 reduces 70-100 Hz and increases 5-40 Hz bands spectral power whereas no changes were observed after anodal tDCS. In addition, the presence of anodal tDCS during C2 did not show any effect on the acquisition of the CRs, while during cathodal stimulation during C8 animals showed a statistically significant lower percentage of CRs with CRs showing lower orbicularis oculi EMG activity and slower latencies. The present work highlights new electrophysiological and behavioural data, obtained for the first time in awake animals, demonstrating the long-lasting modulation effects of cathodal tDCS on V1 excitability, and its consequent modulation of visual perception involved in the performance of an associative learning task.

Title: Pulvinar inactivation impairs the visually guided saccade in the blindsight monkeys

Authors: ***M. KINOSHITA**[1], R. KATO[2], K. ISA[2], K. KOBAYASHI[3], H. ONOE[4], T. ISA[2]; [1]Hirosaki Univ. Sch. of Med., Hirosaki, Japan; [2]Dept. of Developmental Physiol., [3]Section of Viral Vector Develop., Natl. Inst. for Physiological Sci., Okazaki, Japan; [4]Ctr. for Life Sci. Technologies, RIKEN, Kobe, Japan

Abstract: Damage to the primary visual cortex (V1) causes a loss of visual awareness in the corresponding visual field. Some patients with such cortical scotoma in V1, however, can localize a visual target presented in such blind visual field. This phenomenon is called 'blindsight' and thought to be derived from the function of residual visual pathways bypassing the V1. The critical role of superior colliculus (SC) was indicated by the inactivation of SC in unilateral V1-lesioned monkeys (Mohler and Wurtz 1977; Kato et al., 2011). It has been proposed that the pulvinar nucleus, which receives input from SC and sends information to higher visual cortical areas, relay the visual signal for the blindsight. However, a recent study proposed that the lateral geniculate nucleus, instead of the pulvinar, is essential for the blindsight (Schmid et al., 2010). In this study, we have tested the role of the ventrolateral part of pulvinar nucleus (vlPul) for the visually guided saccade (VGS) task in the unilateral V1-lesioned monkeys. We trained two unilateral V1-lesioned macaque monkeys to perform a VGS to the target presented in the blind visual field corresponding to the lesioned V1. To identify the location of vlPul, we made electrophysiological recordings in the pulvinar and sought for the sites which contained neurons with mono- or oligo-synaptic responses to the electrical stimulation of the SC. Subsequently, we made micro-injections of muscimol (0.2-0.5 µl, 0.5 µg/µl) into the vlPul. The correct ratio of the VGS task in the blind field was significantly decreased and saccadic reaction times were prolonged after the injection. This result suggests that the vlPul plays a critical role for the blindsight. The pulvinar receives input not only from SC but also from other areas. Therefore, the next question was whether the SC-vlPul pathway was important for the blindsight. To answer this question, we tested the VGS performances after the selective blockade (Kinoshita et al., 2012) of the SC-vlPul pathway. We injected the retrograde viral vector carrying tetanus neurotoxin gene (FuGB2-TRE-eTeNT.GFP) into the vlPul and injected the anterograde vector (AAV1-CMV-rtTAV16) into the SC. Several weeks after these injections, only neurons with cell bodies at SC and projection to the vlPul expressed the tetanus neurotoxin, which blocks their synaptic transmission, under the administration of doxycycline. Several days after start of the doxycycline administration, we found the impairment of VGS performance in the blind field. These results suggest that the vlPul plays a critical role for the blindsight and that the SC-vlPul pathway mediates the visual signal.

Title: Bayesian priors created by single trials in smooth pursuit eye movements

Authors: ***T. DARLINGTON**[1], S. LISBERGER[2];
[1]Dept. of Neurobio., Duke Univ., Durham, NC; [2]HHMI and Duke Univ. Dept. of Neurobio., Durham, NC

Abstract: Many behaviors operate in a Bayesian framework, where actions are guided by a complex interaction between current sensory information and past experience, or "priors". When current sensory information is weak, it is advantageous to allow the prior to guide behavior. However, the value of prior experience lessens as sensory information strengthens. A previous publication from our lab has shown that several days of experience can create a prior for estimates of target direction to drive pursuit eye movements. We now show that priors can be modified on a trial-by-trial basis. Two male rhesus macaque monkeys were trained to track a 100% contrast patch of dots (strong sensory stimulus) and a 12% contrast sine wave grating (weak sensory stimulus) with smooth pursuit eye movements. In one set of experiments, we found that pursuit direction on a "test" trial was biased toward the target direction of the "prior" trial. The effect of the prior appeared when the direction difference between two trials was 15, 45, or 90 degrees and was largest when the difference was 45 degrees. The prior was expressed more strongly on test trials that used the weak motion provided by low-contrast gratings. The directional bias continued to grow during the steady-state phase of pursuit for grating targets, but was suppressed after the initiation of pursuit for patch targets. In a second set of experiments, we found that the magnitude of expression of the prior on a "test" trial increased as the number of identical "prior" trials increased from 1 to 10. We conclude that smooth pursuit is able to operate under a Bayesian-like framework on the scale of single trials.

Title: Neck muscle sensory noise alters visual-proprioceptive integration weights due to stochastic reference frame transformations

Authors: *P. ABEDI KHOOZANI[1], G. BLOHM[2,3,4];
[2]Ctr. for Neurosci., [1]Queen's Univ., Kingston, ON, Canada; [3]Canadian Action and Perception Network (CAPnet), Kingston, ON, Canada; [4]Assn. for Canadian Neuroinformatics and Computat. Neurosci. (CNCN), Kingston, ON, Canada

Abstract: During reaching, humans combine visual and proprioceptive information in a statistically optimal manner (Multi-Sensory Integration, MSI). To do so, the weak fusion model stipulates that these signals should undergo a reference frame transformations (RFT) into a common frame before integration. A previous study (Burns & Blohm, 2010) observed that introducing Head Roll (HR) increased the variability in Reach Errors (REs) and speculated that signal-dependent noise (SDN) in HR estimation adds variability to the transformed signals and thus affects their MSI weights. An alternative interpretation is that MSI weights change due to uncommon head roll postures instead of added noise in RFTs. To distinguish between these alternatives, we set out to modulate neck muscle sensory noise by loading the head. Participants stood in front of a virtual reality robotic setup (KINARM, BKIN Technologies) and performed center-out reaches toward one of eight visual targets uniformly distributed on a 10cm radius circle, while keeping their gaze at the center. A conflict between visual and proprioceptive information occurred by shifting the hand 2.5cm either vertically or laterally while providing visual feedback showing initial hand position at the center. The task was with 3 HR rotations; 0 and ±30 degrees and 3 Neck Load (NL) conditions (1.8kg simulating neck muscle tension at 30deg HR; leftward/rightward and no load) for each HR. We hypothesized that altering neck muscle force will create different levels of SDN in HR estimation, which should result in more variability in RFTs ultimately affecting the weights of MSI and reaching pattern. For 0 deg HR, we found that REs in the control condition (no NL and no HR) fell between REs observed when applying NL, with significant shifts in RE curves (ANOVA: $F(44,2) = 8.29$, $p=0.0004$). In addition, the variability in RE in trials with NL was higher than during controls. We also found increase in variability by changing HR at no NL conditions, consistent with Burns & Blohm (2010). However, we found higher variability in REs for changing HR (@ NL = 0) compared to changing NL (@ HR = 0). This increase in variability by increasing the HR estimation suggests that SDN in the internal estimate of HR induces variability into the RFT. As a result, MSI weights decreased for transformed signals when applying either HR (NL=0) or NL (HR = 0) with a higher decrease for changing HR. Together, these results confirm that RFTs should indeed be regarded as stochastic in nature and that previous results cannot be explained by unfamiliar postures. It also shows that noise in muscle spindles has an observable effect on reference frame transformations underlying reach planning.

Title: Learning time-to-contact in ball catching without haptic information

Authors: ***H. KAMBARA**, N. HAMA, T. KAWASE, N. YOSHIMURA, Y. KOIKE;
Tokyo Inst. Technol., Yokohama, Japan

Abstract: A successful catch of a falling ball requires an accurate estimation of Time-to-Contact (TTC), that is, the time remains before the ball hits the hand. In a series of past experiments, human subjects exhibited the ability to catch a ball in a virtual reality environment where the virtual ball fell with several different accelerations. Since our visual system is poor in detecting exact acceleration of moving objects, some kind of information about its acceleration must be learned and used as the prior knowledge in TTC prediction. In this study, we hypothesize that human can modify internal model of the acceleration of the freely falling ball according to the error between expected and actual hand motion before and after catching the ball. To verify this hypothesis, we conducted ball-catching experiments in a virtual reality environment, which allowed participants to recognize the ball contact to the hand by visual information only. Our results indicated that three out of four participants could learn another acceleration other than the gravitational acceleration by visual information.

Title: The significance of measurement location in human stick balancing

Authors: Y. LEONG[1], B. CHRISTALIN[1], *J. W. BURDICK[2], J. C. DOYLE[1];
[1]Control & Dynamical Systems, [2]Caltech, Pasadena, CA

Abstract: Human stick balancing has been extensively studied as a simple case study of human sensorimotor control. Multiple control frameworks were proposed to explain experimentally observed dependencies in delay, noise, and stick center of mass (COM). The goal of this research is to merge these seemingly independent observations into a single consistent framework - robust control theory. It provides a fundamental limit on the robustness (ability to balance) of a feedback control system (stick balancing) independent of the controller details (nervous system). Analytical analysis shows that: a) feedback delay reduces robustness, b) lower COM is harder to balance, c) measurement location (the point where the eyes focus on a stick) below the COM is extremely hard to balance, and d) stick mass has minimal effects on robustness. Inspired by the analytical results, the effects of COM location (L), measurement location (L_0), and stick mass (M_s) in balance performance are studied experimentally. Twelve healthy adult subjects (23 - 29 y/o) engaged in 2 sets of experiments. The first set (5 subjects) studies the influence of M_s and L, and the second set (7 subjects) studies the influence of L and L_0. In each trial, a subject balances a stick while looking at a specific location on the stick until the stick falls or the balancing time reaches 1 min. Subjects wear a cap to limit peripheral vision above L_0. The stick and subject's head motion are tracked using OptiTrack. The ability to balance is quantified using standard deviation of stick tilt angle, mean speed of the COM, and length of balancing time. Below, the term "hard to balance" implies these quantities are large. The major finding of these experiments (see figure) is that small L_0 = L is hard (consistent with previous work), but L_0 < L is dramatically harder, an effect never considered in previous studies. Apart from this main result, consistent with analytical predictions, we find that changing M_s has minimal effect. Lastly, the stick most frequently falls in the sagittal plane, implying that the stick motion in sagittal plane is hard.

Title: Auditory and proprioceptive reaching in a patient with optic ataxia

Authors: *S. CORNELSEN[1], M. HIMMELBACH[2];
[1]Ctr. For Neurology, Hertie-Institute for Clinica, Tuebingen, Germany; [2]Ctr. for Neurology, Hertie-Institute for Clin. Brain Res., University of Tübingen, Germany

Abstract: Patients with optic ataxia show deficits in reaching movements to visual targets in the peripheral visual field. Even though the very name optic ataxia suggests an isolated deficit in visuomotor coordination, there is some evidence that the disorder is not restricted to visual targets, but also affects reaching to proprioceptive and auditory targets. These findings suggest that optic ataxia is a multimodal deficit. However, similar proprioceptive misreaching can also be observed in the absence of optic ataxia. In their seminal group study Perenin and Vighetto (1988) excluded any auditory misreaching but reported only qualitative observations without any quantitative data. Taken together, there is conflicting evidence for a new interpretation of optic ataxia as a multimodal ataxia. We investigated a chronic patient (IT) with optic ataxia and visual hemiagnosia in reaching tasks with visual, auditory and proprioceptive targets, for the first time directly comparing all three modalities. Our results replicated the characteristic pattern of visual misreaching in optic ataxia patients: IT was comparable with age-matched healthy controls when reaching to foveated visual targets, but her end-point accuracy decreased for peripheral targets in the contralesional hemifield with larger errors for her contralesional hand than for her ipsilesional hand. This visual misreaching was dissociated from auditory-guided reaching since IT's movements to auditory targets revealed no deficits in comparison to healthy controls. Her movements to proprioceptive targets and movement errors were influenced by the amount and kind of visual feedback with different error patterns with closed eyes in comparison to open eyes with and without fixation during movement execution. We conclude that spatial errors consistent with optic ataxia can co-occur in other modalities, but the disorder is not necessarily multimodal in nature.

Title: Selective attenuation of visual reafferent signals in parietal cortex during movement

Authors: *P.-M. BERNIER[1], M. BÉNAZET[1], F. THÉNAULT[1], K. WHITTINGSTALL[2]; [1]Dept. de Kinanthropologie, [2]Radiologie diagnostique, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Cortical processing of sensory information is modulated by descending motor commands. For instance, proprioceptive signals from one's moving limb are attenuated in secondary somatosensory areas during voluntary movement (Blakemore, Wolpert, & Frith, 1998). Similarly, auditory signals are attenuated in primary auditory cortex when self-initiated (Baess et al., 2009; Horvàth, 2015). Strikingly, this phenomenon has not been investigated in the visual domain. In particular, it is unknown whether reafferent visual signals from one's moving limb are also attenuated at the cortical level during voluntary movement. Here we address this issue by recording electroencephalography and measuring the visual evoked potentials (VEPs) elicited by visual feedback of the hand in motion. Nineteen subjects had to move their right hand to a target located 20 cm straight ahead in ~800ms. We manipulated the temporal relationship between hand visual feedback (represented via a cursor) and actual hand motion. In the real-time condition, subjects were shown their hand visual feedback with 0ms lag. In the delayed condition, they were shown their hand visual feedback with a 150ms lag. Critically, the spatial properties of the visual feedback being provided was identical in both conditions. We hypothesized that VEPs would be attenuated in the real-time condition as compared to the delayed condition. We focussed on the VEPs in parietal and premotor regions, which are known to receive and process visual information (Tanne-Gariepy et al. 2002; Grefkes & Fink, 2005; Theys et al., 2013). We report two main findings. First, in line with our hypothesis, we found a significant attenuation of the N1 component at bilateral parietal electrodes (P1, CP1, P2, CP2) in the real-time condition as compared to the delayed condition, peaking 160 ms after presentation of visual feedback ($p < 0.05$). Second, we observed the reverse modulation in the left premotor electrodes (C3, FC3). Specifically, VEP amplitude was significantly facilitated in the real-time

condition as compared to the delayed condition, peaking 140 ms after presentation of visual feedback ($p < 0.01$). These results demonstrate that reafferent visual signals from one's moving limb are attenuated during voluntary movement. However this effect is selective to parietal areas at a relatively late stage of visual processing (~160ms). The modulation in parietal responsiveness to visual stimuli may be linked the implication of parietal regions in integrating sensory modalities such as vision and proprioception during reaching (Andersen et al., 1997; Baumann et al., 2009).

Title: Video games and visuomotor-related brain activity in women

Authors: *D. J. GORBET[1], L. E. SERGIO[2];
[1]Ctr. for Vision Res., York Univ., North York, ON, Canada; [2]Sch. of Kinesiology and Hlth. Sci., York Univ., Toronto, ON, Canada

Abstract: Action video games are fast-paced games requiring quick reactions and focused attention. The scientific literature is beginning to accumulate a lot of convincing evidence that a history of playing action video games is associated with enhancements to some forms of visual perception and attention relative to individuals who do not play these types of games. These findings make action video games an increasingly attractive possibility for creating visuomotor neurorehabilitation approaches that are both effective and enjoyable. Indeed the use of video games for neural rehabilitation has become increasingly common in clinical settings. However, in the current literature, studies of the effects of long-term action video game play focus almost exclusively on male participants. Given that there are known sex-related differences in the functional brain networks involved in visuomotor control, it is important to gain an understanding of the potential effects of video game play in women in addition to men in order to design games that can be used as effective rehabilitative tools. In the study presented here, we used fMRI to examine visuomotor-related brain activity in women who have played action video

games for a minimum of 10 hours a week for at least the last 3 years. Preliminary results suggest that relative to women who play little or no video games, action video game play is associated with decreased activity in the left medial parietal-occipital cortex and bilaterally in the superior posterior cerebellum. These results shed light on the neural correlates of action video game play in women. Importantly, these results differ somewhat from what we have previously observed in men (Granek et al., 2010), suggesting that it will be necessary to examine potential sex-related differences in the effects of video game-induced neural plasticity. Title: Virtual breakfast: reference frames for goal-directed reaching in a 3D virtual reality environment

Authors: ***I. SCHUETZ**, M. KLINGHAMMER, K. FIEHLER;
Justus-Liebig-University Giessen, Giessen, Germany

Abstract: When reaching for an object such as a coffee mug on a desk, humans are able to integrate egocentric (i.e., relative to themselves) and allocentric spatial information (i.e., relative to other objects in the visual scene). So far, these processes have mostly been studied using abstract stimuli such as LEDs or simple shapes, limiting the possibility to generalize these findings to more natural situations. Using naturalistic photographs of a breakfast table, a previous report from our lab has shown that a change in surrounding objects (i.e., landmarks) influences reaches towards a target object in the scene (Fiehler et. al, 2014). The present experiment aims to further increase the ecological validity of this paradigm by presenting a visual scene in a 3D virtual reality (VR) environment instead on a 2D monitor. Second, we aimed to extend our previous findings to the integration of egocentric and allocentric information in depth. We presented a breakfast scene with six possible goal objects stereoscopically using an Oculus Rift DK2 head mounted display (HMD). To control for correct fixation, eye movements were recorded in VR using an eye tracker installed in the HMD. Participants freely explored the

scene visually, which then disappeared following a button press. After a mask image and subsequent delay, the scene reappeared with one object missing (= reach target) and the others shifted on the table surface either horizontally (left- or rightwards) or shifted in depth (forward or backward). Participants indicated the remembered target location by reaching to the corresponding position on the table in front of them with their right index finger. Finger position was measured using Optotrak and a cursor indicating the current finger position was always visible in the VR environment. We then compared actual reach endpoints in the object shift conditions to the baseline condition in which no object shifts occurred. We found that horizontal reach endpoints were systematically shifted in the predicted direction, i.e. right when the landmarks were moved rightwards and vice versa. In the horizontal direction, the size of the effect was comparable to our previous studies using 2D images. Moving the landmarks in depth also produced systematic reach errors, but effects were more variable across participants. Our results confirm that humans combine egocentric target information with allocentric information from surrounding objects when performing memory-guided reaching movements in a naturalistic 3D scene. This study also highlights the use of VR in action research.

Title: Prevalence of hybrid body-hand reference frames for reaching in area PEc

Authors: V. PISERCHIA[1], R. BREVEGLIERI[1], K. HADJIDIMITRAKIS[2,1], F. BERTOZZI[1], C. GALLETTI[1], *P. FATTORI[1];
[1]Univ. of Bologna, Bologna, Italy; [2]Monash Univ., Melbourne, Australia

Abstract: A debated topic of research in neuroscience is that of reference frame transformations. The neural processes that underlie these transformations occur mainly in the posterior parietal cortex (PPC). In the medial part of PPC, targets are represented in body- centered and mixed body/hand-centered frame of reference caudally (area V6A), and in hand-centered frame of

reference rostrally (area PE). Here, we assessed the reference frames of neurons in area PEc, located between V6A and PE, during the planning (PLAN) and execution (REACH) of arm reaching movements. We examined the activity of 104 single cells recorded in three Macaca fascicularis. The animals performed in darkness a foveal reaching towards targets located at different depths and in different directions. The reaches could start from two different hand positions, one close to the body and the other far from it, at a different depth. We show that most neurons (80% during PLAN and 65% during REACH) encode targets in a mixed body/hand-centered reference frame. Some (15% during PLAN and 28% during REACH) body-centered cells were present, while a marked absence (5% during PLAN and 7% during REACH) of hand-centered coding was found in both epochs. Present results demonstrate that in PEc there is an intermediate coding between body and hand coordinates in the large majority of the cells. Compared with our recent findings in V6A, under identical task conditions, the effect of initial hand position was stronger in PEc. In summary, the functional properties of PEc suggest that it represents an intermediate node -between V6A and PE- in the gradual transformation of reference frames in the medial PPC.

Title: Effect of visuo-proprioceptive realignment on motor cortex excitability

Authors: *F. MUNOZ[1,2,3], A. K. LYNCH[4], H. J. BLOCK[4,2];
[1]Program in Cognitive Sci., [2]Program in Neurosci., [3]Dept. of Statistics, [4]Dept. of Kinesiology, Indiana Univ., Bloomington, IN

Abstract: There is a strong relationship between sensory and motor functions: sensory information guides our actions, while our actions typically have sensory consequences. Previous research has shown that active motor learning generates somatosensory changes as measured by sensed limb position. In contrast, passive movements do not show a comparable effect (Ostry et al., 2010). Here we focus on the reverse question: do changes in sensed limb position affect

motor areas of the brain? Transcranial magnetic stimulation (TMS) was used to assess motor cortex physiology before and after participants performed a reaching task. Each participant took part in two sessions: one where visuo-proprioceptive spatial realignment was expected to happen during the reaching task, and another that served as a sham reaching task. Specifically, a recruitment (I/O) curve for the motor cortex representation of first dorsal interosseous (FDI) in the left hand was computed. Motor evoked potentials (MEPs) were recorded for TMS intensities ranging from 90%-130% of the intensity necessary to produce a 1 mV response (SI1mV). For the reaching task, subjects pointed with their right finger to visual (white square), proprioceptive (left index finger), and combined targets with no vision of either hand. In the "real" session, the visual target gradually shifted away from the proprioceptive target so that without subjects noticing, the white square was eventually displayed 70 mm ahead of the left index finger. We have shown previously that this misalignment causes subjects to realign vision, proprioception, or both (Block & Bastian, 2011). In the "sham" session, the white square remained directly over the left index finger. Currently, 2 participants have completed both sessions and 3 participants have completed one session. Thus, the results reported here consider 3 participants in the "real" condition and 4 in the "sham" condition. Data analysis focused on changes in the I/O curve slopes from pre- to post-reaching task. Preliminary results show that the percent change of I/O curve slope is +51.2% (SE 32.5) for the "real" session, and -11.9% (SE 10.4) for the "sham" session. From this preliminary data, it appears that visuo-proprioceptive realignment may lead to a steeper I/O curve for a finger muscle that experiences sensory realignment. It is known that somatosensory and motor cortices have reciprocal anatomical connections. Taken together with what is described by Ostry et al. (2010), this novel result could indicate the existence of reciprocal functional interactions between motor and somatosensory systems.

Title: Effects of gravitational signals on visuo-kinesthetic sensory transformations during hand movements

Authors: *M. TAGLIABUE[1,2], D. DAL CANTO[1,3], M. CASADIO[3], J. MCINTYRE[4,2,1];

Abstract: Recent studies based on a virtual reality experimental paradigm suggest that head orientation affects not only the capacity of the brain to encode sensory information with respect to gravity, but also the effectiveness of transformations across sensory modalities that are needed to control goal oriented hand movements. For instance, when reaching for an object, the brain can be required to transform visual information about the object, intrinsically encoded in a retinal reference frame, to express it in a body-centered reference frame, so that it can be used to control the arm movement, whose position is inherently encoded in this reference frame. More precisely, we have shown that sensory transformations performed with the head tilted are noisier than those carried out with the head upright. Our hypothesis is that the gravity vector, which may be sensed through utricular signals, represents a stable reference frame through which the transformations between other sensory modalities are performed. It follows that the alignment of gravity and the references frames in which are encoded the available sensory signals (e.g. retina orientation, head/body axis) facilitates cross-modal transformations. To test whether the vestibular organs play a predominant role in the transformation of information between sensory modalities, we tested how a supine posture affects the execution of a task requiring visuo-kinesthetic transformations, such as reaching-to-grasp a visual target without visual feedback of the hand. To do so we applied the same virtual reality experimental protocol that we have used previously with seated subjects to subjects lying in a supine position and we compared performance between the two postures. The results show that movement variability is significantly greater in the supine than in the seated position. Moreover, the use of a special sensory conflict technique allowed us to estimate in which reference frame the sensory information is encoded. Subjects that performed the task in the sitting position first (Chair-First), showed a clear change of sensory encoding strategy when lying supine, which consisted of a shift from a kinesthetic body-centered toward an external visual encoding of the task. On the other hand, subjects that performed the task in the lying posture first (Bed-First) did not show consistent modifications of their sensory encoding strategy. This could be due to the fact than, whilst the Chair-First subjects had to face a ‘deprivation’ of a sensory input, which results in a necessity to change strategy, the Bed-First group faced the possibility, but not the necessity, to start using gravitational signals.

Title: Compensating for a visuomotor rotation in the absence of sensory prediction errors

Authors: *D. E. PARVIN[1], R. J. MOREHEAD[2], R. IVRY[2];
[1]UC Berkeley, Berkeley, CA; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Human motor adaptation is thought to occur via error based learning. Differences between predicted and actual sensory feedback are used to update an internal mapping to reduce errors on subsequent movements. One of the hallmarks of adaptation is an aftereffect, the persistence of the learned behavior after visual perturbation is removed. The magnitude of this aftereffect provides a measure of the extent of adaptation. Recent work has highlighted how multiple mechanisms, other than error-based learning, play a role in sensorimotor learning. It remains unclear how these mechanisms influence the aftereffect. In order to study non-adaptive contributions to the aftereffect, we trained participants on a variant of a visuomotor rotation task in which error-based learning was minimized. Participants were trained to reach to visual targets while receiving visual feedback of the hand via three cursors. One corresponded to the veridical position of the hand. The other two were displaced 15° clockwise and anti-clockwise of the hand position. During the perturbation phase the Adaptation group was instructed to hit the target with the middle cursor while all cursors were rotated by 15° in the clockwise direction. Here, the net rotation of all three cursors results in a 15° visuomotor discrepancy, which should engage an error-based learning mechanism. Participants in the non-adaptation group were instructed to hit the target with one of the side cursors. With this type of display, there is no visuomotor discrepancy and performance changes should occur in the absence of sensory prediction errors. Taken together, participants in the two groups should arrive at the same ideal behavior, allowing a comparison of the time course and form of behavioral change with and without error-based adaptation. We did not find a significant difference between the groups during learning of the rotation task. However, there was a significant aftereffect only for the Adaptation group. We conclude that the aftereffect was attributable to error based learning adapting to the net rotation of the three cursors. This three cursor paradigm can serve as a useful method to eliminate error-based learning from visuomotor rotation tasks, to better characterize non-adaptive learning mechanisms.

Title: Proceduralization of declarative knowledge in a motor adaptation task following prolonged training

Authors: *D. M. HUBERDEAU, J. W. KRAKAUER, A. M. HAITH;
Dept. of Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: When adapting to a perturbation of ones movements, human subjects typically exhibit savings, or faster re-adaptation when the same perturbation is seen more than once. This property of adaptation reflects a form of long-term memory, and understanding what underlies this change may help clarify how behaviors are learned in general. For instance, a recent study has shown that savings is attributable to a single component of learning (Haith, et. al., J. Neurosci, 2015). Specifically, adaptation exhibited during movements with sufficiently long reaction (RT) is more complete than when the RT is limited, and savings is only seen for trials with sufficient RT. Other recent studies have also shown a similar dissociation based on implicit and explicit learning processes (Huberdeau et al. *Curr Op Neurobiol*, 2015). Following only a single exposure to a perturbation, therefore, it seems that savings does not occur in the implicit component of adaptation. This raises the question, however, of whether savings could ever be obtained in this component. We first demonstrate that following repeated exposure to alternating perturbations, savings can in fact be realized when the RT is limited. What enables this change in the nature of savings under low-RT conditions? Is it due to a change in the learning rate of the implicit component, or does the explicit component consolidate such that it can be expressed at low-RT? We hypothesized that the expression of savings under limited RT following repeated exposures reflects the ability to more rapidly express an explicit strategy. To test this hypothesis, we sought to further differentiate between RT-sensitivity and the implicit process by also periodically instruct subjects to “reach directly for the target” within blocks of adaptation to a rotation (Benson, et. al. J Neurophysiol, 2011). Using this method, we found no evidence of savings in the implicit component, suggesting that savings in the low-RT condition reflects proceduralization of the explicit component (i.e. formation of a rapidly expressible stimulus-response association) rather than modulation of the learning rate of the implicit component. This

mechanism of proceduralizing declarative knowledge may be an important aspect of skill learning more generally.

Title: Hand and Tool positions differentially affect saccadic reaction times

Authors: *L. CARDINALI[1], T. R. MAKIN[3], J. C. CULHAM[2];
[2]Dept. of Psychology, [1]The Brain and Mind Institute, Western Univ., London, ON, Canada;

Abstract: Eye-hand coordination is a fundamental part of efficient interaction with the environment. Previous studies showed a mutual influence of the eye and hand motor systems. Specifically, Thura et al. (2008) showed that saccadic reaction times (SRT) are modulated by whether the target appears close to or far from the participants' static hand position and whether participants perform the saccade immediately upon the target onset or following a 1-s delay. In our daily life, we perform many actions not just with the hand along but with a tool in hand. Here we wondered whether saccades would also be modulated by the position of a tool. We measured SRT to targets appearing in the right or left visual hemifield, close to or far from (1) a grabber tool (held with the right hand), (2) the participants' right hand, during a resting posture (palms down), or (3) the participants' right hand in an action posture (thumb-index finger pinch). In half of the trials participants were instructed to saccade toward the target at its appearance while in the other half we introduced a 1-s delay. We found that SRTs were modulated by the side in which the stimulus appeared, the presence of a delay, and the congruency between the target and the effector side. The tool condition and the pinch condition (where the motoric aspect of the posture was strengthened) showed similar patterns of SRTs compared to the static hand condition. These results suggest that the eye-effector link remains strong even during tool use

and they contribute to our understanding of how tool use is based on visuo-motor mechanisms for hand control.

Title: Proprioceptive weights are independent of left and right hand sensory reliabilities

Authors: ***L. MIKULA**[1,2], L. PISELLA[2], G. BLOHM[3], A. Z. KHAN[1];
[1]École d'Optométrie, Univ. De Montréal, Montréal, QC, Canada; [2]Impact, Ctr. de Recherche en Neurosciences de Lyon, INSERM U1028, CNRS UMR 5292, Bron, France; [3]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: When planning to reach, information about both the target location as well as the initial hand position yield the movement vector. The initial hand position can be determined by proprioceptive information as well as visual information, if available. Bayesian integration posits that we utilize all information available, with greater weighting on the sense that is more reliable; thus generally weighting visual information more than the usually less reliable proprioceptive information. The neural mechanism by which information is weighted still remains unclear. It has been assumed that the weights are based on task- and effector-dependent sensory reliability requiring an explicit neuronal representation of variability. However, the weights could also be determined implicitly through learned modality-specific integration weights. While the former hypothesis predicts different proprioceptive weights for left and right hand, the latter predicts the same integration weights across the two arms. In order to discriminate between these two hypotheses, we designed two separate complementary tasks to measure the sensory variability for both vision and proprioception. Each task allowed us to assess the visual and proprioceptive variability either in a perceptual context (without reaching movements) or in a motor context. In addition, we applied prisms inducing a horizontal visual shift while participants were asked to point toward visual targets with both the left and right hands in separate trials. This third task was used to quantify the relative weighting given to each sensory modality when planning reaching movements. We found that the sensory weights for the left and right hands were extremely consistent regardless of large differences in sensory variability for the two hands, as measured in each of the two different contexts. Thus, we propose that weights for sensory

information during reaching are learned across both hands, rather than specific to each effector based on its variability.

Title: Limb position drift indicates independent modules for planning movement vectors, and for representing limb configuration

Authors: ***J. R. PATTERSON**[1], R. SAINBURG[2,3], L. BROWN[4];
[2]Kinesiology, [1]Penn State Univ., State College, PA; [3]Neurol., Penn State Col. of Med., Hershey, PA; [4]Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: We previously showed that when performing repetitive point-to point movements without visual feedback about hand position, the position of the arm drifts in space due to an accumulation of movement dependent errors (Brown et al, 2003). Regardless of participants' apparent lack of knowledge about their drift, joint torque patterns are progressively modified to maintain movement direction and extent over substantial changes in limb configuration. We now attempt to resolve this apparent paradox between knowledge of limb position for maintenance of posture and knowledge of limb configuration for control of movement. We hypothesize that planning of movement direction and distance depends on declarative knowledge of hand position, which depends on the last-seen position. In contrast, planning of movement dynamics depends upon updated and accurate proprioceptive information about actual hand position. In a VR environment, the arms were supported on an air sled apparatus to remove the effects of gravity and friction. Healthy young volunteers made continuous movements between two targets positioned 20 cm apart, paced by a 2 Hz metronome. After 20 cycles, cursor feedback of hand was removed for the next 160 cycles, which induced drift in the average hand position of roughly 6 cm. We then presented two new targets, and asked the participants to verbally identify which target is closest to their hand position, and then to move to that target. We hypothesized that if participants have declarative knowledge of their actual hand position, they will identify targets that are closest to their actual hand position, and if not, they will identify the target that is closest

to the original ‘start’ target. By assessing their movement, we will determine whether movements are planned and controlled based on the actual, or previously displayed hand position. Our preliminary results indicate that participants identify target positions that are closest to the previously displayed, not the actual, hand position and that movement direction and distance reflect planning from this same position. We conclude that participants do not have declarative knowledge about their drifted hand position, nor do they use the actual hand position in planning the direction and distance of their motion. Nevertheless, the ability to make accurate direction and distance movements suggest accurate proprioceptive information. Overall, these results support the premise that information about hand position is derived from different sources for different planning and control modules.

Title: Idiosyncratic matching errors cannot solely be explained by sensory biases

Authors: *I. A. KULING, M. C. W. VAN DER GRAAFF, E. BRENNER, J. B. J. SMEETS; VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Moving one’s hand to a visually presented target on a surface under conditions that prevent one from seeing the hand generally results in idiosyncratic endpoint errors (e.g. Rincon-Gonzalez et al., 2011; Kuling et al., 2013). Do such matching errors reflect a mismatch between the senses due to stable sensory biases? If so, moving your unseen index finger to a visual dot or moving a visual dot to your unseen index finger should give rise to an equivalent matching error. Similarly, the error found when moving with the right and the left unseen index finger to a visual dot should be equivalent to the error when directly matching the position of the two unseen index fingers. To test these hypotheses, we designed a positioning task in which subjects had to indicate the location of a target on a surface with different indicators. The target was a visual dot or the left or right index finger and the indicator was the left or right index finger or a dot-shaped mouse cursor. We found that the matching errors for moving the unseen hand towards a visual dot differed considerably from those for moving a visual dot towards the hand. Also, the errors

found when moving with the right and the left unseen index finger to a visual dot do not lead to a similar error as matching the position of the two unseen index fingers directly. These results suggest that systematic matching errors are not exclusively the result of sensory biases.

Title: Cognitive-motor integration performance and cerebellum volume in females with post-concussion syndrome

Authors: *J. HURTUBISE, D. GORBET, L. SERGIO;
Kinesiology & Hlth. Sci., York Univ., North York, ON, Canada

Abstract: Cognitive-motor integration is often required when performing movements where a rule is used to align the required motor output and the guiding visual information. We propose that measuring this integration under conditions which place demands on visual-spatial and cognitive-motor processing may provide an effective behavioural means for detection of brain alterations associated with concussion. Our previous research has shown cognitive-motor integration declines in both university-aged and child athletes who had a history of concussion but were deemed recovered at the time of evaluation. The role of the cerebellum in sensorimotor integration has been well defined within the literature, however the effects of concussion on cerebellum functioning has not been thoroughly investigated. Cerebellar volume atrophy has been noted in both grey and white matter in moderate-to-severe traumatic brain injury patients, even when it was not the location of the focal injury. While recent murine models have suggested long-term cerebellar degradation following concussion (Kan et al. 2013), to our knowledge there has been no investigation of cerebellum volume in post-concussion syndrome (PCS) in humans. Here we examined cognitive-motor integration in females with PCS lasting more than 6 months at time of examination. Participants were administered the current international sport concussion assessment tool (SCAT3), along with four visuomotor transformation tasks (3 of which require cognitive-motor integration). In addition, anatomical

brain images were acquired using MRI. The behavioural tasks were completed on a tablet linked to a desktop computer monitor. The participants displaced a cursor from a central target to one of four peripheral targets by sliding their finger on the tablet either directly to the viewed target or with decoupled eye-hand coordination (targets viewed on vertical monitor, 180° cursor feedback rotation, or both). We observed that those with PCS had significantly worse symptom scores (both in number and severity) than controls, while no differences were found in any other aspect of the SCAT3. Those with PCS performed worse on the visuomotor tasks, with symptoms being correlated to this performance decline. Notably, cerebellar volume was decreased in those with PCS compared to controls. Cognitive-motor integration decline may be related to decreased cerebellum volume in these adults with PCS. Future work will investigate whether decreased connectivity involving the cerebellum is responsible for the volume differences seen in those with PCS. Ref: Kan, E. et al. (2013) SFN Abst#11.04.

Title: Comparing three tablet-based visuomotor tasks to standard laboratory versions

Authors: *C. BEDORE, J. LIVERMORE, H. LEHMANN, L. E. BROWN;
Trent Univ., Peterborough, ON, Canada

Abstract: The visuomotor system is important to everyday activity and assessment of its function can provide important information about neurological status. Although various visuomotor tasks are available for testing in the laboratory or clinic, attempts to make these tests portable so that quick and reliable psychometric assessments of performance can be conducted have been limited. We developed an assessment tool using three common laboratory visuomotor tests as a tablet (iPad) application: the double-step task, an interception task, and the stop-signal task. The double-step task measures participants' ability to redirect their reach to an unpredictable target displacement (Pelisson et al., 1986). The interception task measures

participants' ability to intercept accelerating targets (Brown et al., 2007). Finally, the stop-signal task measures participants' ability to interrupt movement preparation and initiation in response to an unpredictable stop signal (Logan, 1981). We compared performance of each task on the tablet to the standard laboratory setting. On the double-step task, participants adjusted to the displaced target adequately in both the lab and tablet versions. On the interception task, participants adequately intercepted non-accelerating targets, and performed worse on accelerating targets in both versions of the task. On the stop-signal task, participants' ability to interrupt movement initiation varied with the timing of the stop signal in a similar way in both versions of the task. These findings suggest that the tablet version of these tasks assesses similar visuomotor processing as the respective laboratory version. We now aim to assess the clinical usefulness and validity of the tablet tasks on patients with visuomotor deficits.

Title: tDCS over somatosensory cortex alters the balance of visuo-proprioceptive weighting and realignment

Authors: Y. LIU[1], B. SEXTON[1], P. CELNIK[3], *H. J. BLOCK[1,2];
[1]Kinesiology, [2]Program in Neurosci., Indiana Univ., Bloomington, IN; [3]Neuroscience, Neurology, Physical Med. & Rehabil., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The human brain processes multisensory information to control voluntary movement. Visual and proprioceptive estimates of hand position are weighted and combined to compute a motor command to move the hand. Changes in vision or proprioception will thus affect multisensory processes, and ultimately motor behavior. E.g., if slicing an onion in a sink full of water, the brain's visual estimate of hand position is shifted away from proprioception by water refraction. A healthy person will compensate by adjusting the weighting of vision versus proprioception, by spatially realigning visual or proprioceptive estimates of hand position, or both. The minimum variance model suggests that realignment will be related to weighting: a person who relies heavily on vision will realign proprioception more and vision less, and vice

versa. This relationship is not obligatory, but exists in many cases, suggesting a role in multisensory precision and thus accurate motor control. Here we investigated visuo-proprioceptive weighting and realignment in healthy adults when proprioception related to the left hand was manipulated by applying excitatory or inhibitory transcranial direct current stimulation (tDCS) over right somatosensory cortex (S1), where proprioception for the left hand is processed centrally. Each subject completed 3 sessions with anodal (excitatory), cathodal (inhibitory), or sham tDCS over S1. Two blocks of reaches were completed with three target types: a white box (visual target), left index fingertip (proprioceptive target), or combined. During the adaptation block, a 70mm visuo-proprioceptive misalignment was imposed by gradually moving the visual target forward. No subject noticed this perturbation. Preliminary results (N=8) suggest that both anodal and cathodal tDCS increase the slope of the relationship between weighting and realignment relative to sham, meaning that for a given weight of vision versus proprioception, there is more visual and less proprioceptive realignment. Slope was 49.7, 99.5, and 94.0 for proprioceptive realignment versus weight; and -73.6, -93.6, and -109.9 for visual realignment versus weight (sham, cathodal, and anodal respectively; correlation R values for the tDCS sessions were > 0.8 or <-0.8; p-values < 0.01). This may be a function of changes in the proportion of visual versus proprioceptive realignment with different stimulation conditions. Interestingly, the slopes changed in the same direction for anodal and cathodal tDCS; it is possible that any external alteration of S1 physiology biases visuo-proprioceptive processing, or that tDCS has a non-specific effect.

Title: Reaching target representation in the three-dimensional peripersonal space in the medial posterior parietal cortex

Authors: P. FATTORI[1], A. BOSCO[1], R. BREVEGLIERI[1], K. HADJIDIMITRAKIS[2], *C. GALLETTI[1];
[1]Univ. Bologna, Bologna, Italy; [2]Monash Univ., Clayton, Melbourne, Australia

Abstract: The neural encoding of coordinate systems based on eye and target position in posterior parietal cortex has been traditionally studied in 2-dimensional plane, where the direction of movement was the only variable to consider in the computation of reaching metric. Only few studies focused on the combined influence of depth and direction on the definition of reference frame used by single neurons. Here we present single-unit data recorded from area V6A, a visuomotor area located in the caudal aspect of the superior parietal lobule, during a delayed and dissociated reaching task where eye and target positions varied both in direction and depth. We analysed the neural activity during pre-movement- and movement-related phases to establish whether cells encoded the target relative to the eye, encoded the target in spatiotopic coordinates, or on a mixed reference frame. We also analysed the interaction between depth and direction on the computation and the temporal evolution of reference frames. In all epochs studied, 12% of cells contained a pure reference frame centered on target position (spatiotopic or target-related coordinates), 24% was related on eye/target relative position (retinocentric or eye/target-related coordinates), and 63% to various types of mixed reference frame. Among the cells that used pure reference frames (target- and eye/target-related), some showed a competitive model where both representations were present but one prevailed on the other. In all categories, the modulation was found in depth, in direction or in both, covering the whole tested reaching space. The contribution of the two signals, depth and direction, to the definition of reference frame was characterized by a complex interaction in 85% of cells and by a gain relationship in 15% of cells. In the pre-movement epochs the resolution quality of reference frame was smaller compared with the movement-related phases, demonstrating a strong decrease of noise and variability during the movement execution with respect to planning phases. These data suggest that V6A contains different target representations that allow an accurate estimate of reaching positions in the 3D peripersonal space. This supports a dynamic and flexible encoding of reaching goals that allows the recruitment of neural patterns using different level of generalization depending on the sensory contingencies of external environment.

Title: The effect of tool-vibration on unimanual reaching

Authors: *L. B. BAGESTEIRO[1], L. E. BROWN[2];
[1]Dept. Engenharia Eletrica, Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil; [2]Dept. of Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Many workers are exposed to hand-arm vibrations while handling power tools. Previous research on exposure to hand grip mechanical vibrations have shown that frequencies up to 400 Hz affects sensory systems and can result in physiological and pathological disorders. The purpose of this study was to investigate how short-term exposure (< 10 minutes) to different frequencies of tool vibration influence arm reaching coordination. Four subject groups, each comprising ten right-handed healthy subjects, made 20 cm center-out planar arm reaching movements to two randomly-presented visual targets (target 1 oriented 60° relative to the horizontal axis and target 2 oriented at 120°). Each participant group experienced one of four vibration frequencies (40, 70, 100 or 115 Hz) while holding onto a custom-made pointing tool that was fitted with a vibration device. Each subject was given a practice session (10 trials) to familiarize with the task, followed by three blocks of 30 trials during which they experienced no-vibration (pre-exposure session), vibration (exposure session) and no-vibration (post-exposure session). Four measures were computed to examine group differences: movement distance error at final position, hand-path trajectory direction deviation, movement duration, and total distance traveled. We examined the effect of vibration on initial exposure and final adaptation assessing early and late trials on the vibration session. Preliminary data analysis showed that there was a main effect of target ($p < .001$) and epoch ($p = .013$) on movement distance, as well as an interaction between target and epoch ($p = .036$). Movement distance was shortened when vibration was first applied (mainly for 70 and 100 Hz frequencies), but subjects seemed to adapt and increase the distance traveled towards the end of the vibration experience. This effect was more evident for the 120° target and was confirmed by the increased variability on movement distance during baseline conditions and first exposure. Vibration influenced movement direction in a similar way, with main effects for target ($p < .001$), epoch ($p = .040$) and target-epoch interaction ($p = .002$). Following vibration, movements were faster and longer, and were accompanied by an increase in movement variability (distance and direction). These results suggest that tool vibration does influence arm reaching and should be studied further to fully determine its effects on upper limb coordination.

Title: Movement planning in freely moving monkeys - the reach cage

Authors: *M. BERGER[1], A. GAIL[1,2,3];
[1]Cognitive Neurosci. Laboratory, Sensorimotor Group, German Primate Ctr., Göttingen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Göttingen, Germany; [3]Fac. of Biol. and Psychology, Göttingen Univ., Göttingen, Germany

Abstract: Sensorimotor neuroscience investigates spatial parameters which influence neuronal sensorimotor processing, such as head position, gaze direction, and body posture. Especially in neuroscience with non-human primates, these requirements lead to highly specialized and controlled experimental setups with strongly constrained motor behavior. Typically, monkeys are seated in a primate chair and respond to sensory cues by operating a manipulandum or touchscreen, thereby limiting the type of behavior accessible to investigation to movements in the peripersonal space. Motor behavior to the extrapersonal space, i.e., beyond the immediate reach of the monkey requiring relocation towards the target, was prevented. Yet, studies on movement observation revealed mirror neurons [1] responsive for peripersonal or extrapersonal space in area F5 of rhesus monkeys, and human spatial neglect patients partly show deficits specific to either space [2,3], suggesting dedicated processing of extrapersonal space in brain areas related to motor control. Here, we introduce a neuroscientific experimental setting which allows comparing motor planning to targets in peripersonal and extrapersonal space. We developed a 1.4 cubic meter cage environment for conducting controlled sensorimotor tasks in physically unrestrained rhesus monkeys ("reach cage"). The reach cage is equipped with computer-controlled, capacitive touch sensors including multi-color LEDs serving as visually cued reach targets. As a first proof of concept, we trained the monkey on a memory-guided reach task to targets in peripersonal space inside the reach cage. We tracked the monkey's right hand movements with a video-based 3D-motion tracking system. As a result, hand trajectories could be tracked with 20 mm precision and 33 ms temporal resolution over the relevant workspace. Despite the animal not being physically constrained, movement trajectories and speed profiles were stereotyped and revealed typical properties of ballistic movements, similar to conventional chair-based task performance. Our results demonstrate that the reach cage is a valuable tool for

verifying conventional models of movement planning and control in a more complex environment and for expanding these models to movement planning in extrapersonal space. 1.Caggiano, V., et. al. Title: Changes in motor cortical inhibition following a bimanual movement task

Authors: *A. T. BRUNFELDT[1], F. A. KAGERER[2,3];
[2]Kinesiology, [3]Neurosci. Program, [1]Michigan State Univ., East Lansing, MI

Abstract: Recent studies suggest hemispheric differences in the effectiveness of inhibitory processes in unimanual tasks. The goal of our study was to compare inhibition in both hemispheres before and after a bimanual movement task, using transcranial magnetic stimulation (TMS), and measuring short-interval intracortical inhibition (SICI). Six right-handed participants (mean age: 22.3) performed a bimanual center-out task, moving two KINARM end-point robots from two home positions (one per hand) to peripheral targets at 90º or 270º (distance: 10cm); vision of the hands was occluded. Participants performed a visual baseline condition, with both cursors visible, and a kinesthetic baseline (pre-exposure) where visual feedback was only present for the right hand, but not the left. They were then exposed to a 40o rotation of visual feedback in the right hand (exposure), and were instructed to continue moving straight with the 'invisible' left hand. Finally, the kinesthetic baseline condition was reintroduced to assess aftereffects of the adaptation. Initial directional error (IDE) was used to determine the feedforward directional control component of the movements. For TMS, resting and active (10% MVC) motor thresholds for the extensor digitorum were determined over each hemisphere, and recorded with surface electromyography (EMG). Cortical excitability and inhibition were determined prior to the adaptation task, using a single pulse paradigm set to elicit a 1mV peak-to-peak amplitude motor

evoked potential (MEP), and a paired-pulse paradigm for SICI at 2.5ms interstimulus interval. Inhibition was calculated as a percentage of the single pulse MEP (1mV) amplitude. MEP amplitude, obtained at the same stimulator output immediately after exposure was compared to pre-exposure. Preliminary results show a reduction of IDE over the exposure trials, indicating that the visible hand adapted to the kinematic perturbation, whereas the invisible hand showed small, yet consistent directional interference effects. No differences in cortical excitability before and after the adaptation task were found for either hemisphere. SICI, however, was modulated differentially for each hand, in that inhibition decreased (indicating disinhibition) more in the left hemisphere than in the right. This decreased disinhibition of the right motor cortex may reflect ongoing inhibitory mechanisms involved in control of the 'invisible' hand, in order to maintain a straight-line path, and resist the directional interference exerted by the concurrently moving perturbed contralateral hand.

Title: Adaptation of ultra-rapid visual response on human upper limb muscle during visuomotor rotation

Authors: *C. GU[1,4,2], J. A. PRUSZYNSKI[3,4,5], P. L. GRIBBLE[3,4,2], B. D. CORNEIL[3,2,4,5]; [2]Psychology, [3]Physiol. and Pharmacol., [1]Univ. of Western Ontario, London, ON, Canada; [4]Brain and Mind Inst., London, ON, Canada; [5]Robarts Res. Inst., London, ON, Canada

Abstract: We have the ability to rapidly adapt our motor commands in novel environments. For example during the visuomotor rotation task, the sensory-mapping of the visual representation of the target is altered, so that a new motor command is required to accurately reach the target. Previous work has demonstrated an ultra-rapid (70-110 ms) stimulus-locked response (SLR) on human upper limb muscles to visual stimuli; furthermore this response also integrates proprioceptive limb position to generate the correct movement in limb-centric space towards the

visual target. Here we investigated the change in the tuning of the SLR pre- (no rotation), peri- (60° counter-clockwise [CCW] rotation) and post- (no rotation) visuomotor rotation in 8 subjects while they performed center-out reaches to 8 equidistance targets. While they performed the task we recorded intramuscular EMG activity from the clavicular head of the pectoralis muscle. 7 out of the 8 subjects had a SLR pre-visuomotor rotation, and the preferred direction (PD) of the SLR (176°± 4°) was similar to the PD of the movement-related activity (183° ± 6°) in the pre-condition. During the 60° CCW rotation, the movement-related activity rotated on average 56° ± 8° CW relative to the visual target to counteract the visuomotor rotation, however the SLR response rotated on average 17° ± 8° CW in the new adapted state. Post-visuomotor rotation, both the movement-related activity (0° ± 4° CCW compared to per-trials) and the SLR (3° ± 5° CCW) returned to the pre-visuomotor rotation PD. This result suggests that the neural circuits needed to perform the visuomotor rotation task influence the SLR.

Title: Varied tuning properties of single-units in human posterior parietal cortex during reach and saccade planning

Authors: *J. M. WEISS[1,2], W. M. MAGUIRE[1], A. P. BATISTA[2,3], J. L. COLLINGER[1,2,3,4], R. A. GAUNT[1,2];
[1]Physical Med. and Rehabil., [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [3]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [4]DVA, Pittsburgh, PA

Abstract: The posterior parietal cortex (PPC) is generally understood to be involved in multisensory integration and movement planning. In monkeys, the parietal reach region (PRR) is more active when planning reach than saccades [Snyder 1996], and encodes reach-plans in predominantly eye-centered coordinates [Batista 1999]. fMRI studies have suggested the existence of multiple analogous parietal reach regions in human PPC [Filimon et al., 2009]. Here we characterize the activity of individual neurons in human PPC. Under an FDA Investigational Device Exemption, a human subject with a C5 spinal cord injury was implanted with four Utah

Arrays (Blackrock Microsystems, Utah), including two 32-channel electrode arrays implanted in posterior parietal cortex. The subject performed (1) a delayed center-out reaching task, while maintaining fixation at either a central or peripheral point, (2) a delayed saccade task and (3) a coordinated saccade and anti-reach task. We characterized the tuning properties of units recorded during these tasks. By comparing the data from these three tasks we evaluated whether units were tuned for reaches or saccades, whether they exhibited target tuning that depended on gaze, and whether tuning favored the target location or the intended reach direction. We found that human PPC units have varied tuning characteristics, consistent with the notion that this cortical region is responsible for complex sensory integration. Units recorded from the more medial of the two arrays, located within Brodmann area 5, responded to the tasks in several ways. Most units responsive to reach direction also exhibited a weaker response to saccade direction. During both the delay and reach phases of the delayed-reaching tasks, some units had preferred directions that varied with gaze, while others maintained stable preferred directions regardless of changes in the direction of gaze. Preferred direction often varied throughout the delay period. This is especially true during the coordinated saccade and anti-reach task, in which many units exhibit a change in preferred direction approaching 180 degrees halfway through the delay period, from initially aligned with the target's visual location to aligned with the direction of the intended reach. Other units do not exhibit this shift in preferred direction, and are always tuned to the direction of the illuminated target. We also found units that encoded reach velocity, but did not respond to target presentations during the delay period. These varied results suggest that human posterior parietal cortex contains a diverse population of neurons encoding multiple aspects of visuomotor integration.

Title: Environmental constraints delay eye-hand coordination during a reaching task

Authors: *J. J. MARIMAN[1,2,3], B. CATALAN[2], P. DEL CAMPO[2], D. SALVATIERRA[2], M. REYES[2], P. E. MALDONADO[1,3];
[1]Univ. De Chile, Santiago, Chile; [2]Kinesiology, Univ. Metropolitana de Ciencias de la Educación, Santiago, Chile; [3]Biomed. Neurosci. Inst., Santiago, Chile

Abstract: Environment determines several aspects of the motor control. This is evident, for instance, during the realization of reaching movements, when visual feedback due in needed to guide hand displacements. Even though this sensorimotor coupling is well known, is still unclear how environmental characteristics may constraint sensory detection, planning and execution stages. Using a behavioral paradigm, we analyzed eye-hand coordination of twelve subjects during a classical reaching task to eight concentric locations. The contrast of targets relative to the background was managed to impose a visual constraint. Subjects must control a cursor on a screen while their eye movements were recorded with an eye-tracking system. Our results show that the reaction time of reaching movement, reflected by the cursor displacement, was greater at low-contrast in comparison with high-contrast targets (0.52 ± 0.09 s vs 0.46 ± 0.09 s, $p < 0.001$). As expected, saccades movements anticipated the reaching movements; however, the time difference between eye and hand movement was greater at the low-contrast than high-contrast targets (0.17 ± 0.1 s vs 0.13 ± 0.1 s, $p = 0.002$). This time-delay in planning did not impact the execution of movement, reflected in both reaching duration and angular displacement. Surprisingly, the time delay decreased with the practice of the task for both conditions, showing a narrow execution of eye and hand movement in the last stage. In case, the delay was significantly greater at the low-contrast target (0.09 ± 0.1 s vs 0.05 ± 0.09 s, $p = 0.03$), when we compare with the initial stage (0.23 ± 0.1 s vs 0.17 ± 0.1 s, $p = 0.19$). Overall, our experiments suggest that visual constraints delay the planning of reaching movements but not the sensory detection of its target or the execution of the reaching movement. These results indicate the necessity of more information to reduce the uncertainty of the target location. This necessity could be reduced with experience, reflecting an adaptation of the sensory processes to the environmental constraint in combination with the use of predictive mechanisms for movement planning.

Title: Movement kinematics and brain lateralization predict intermanual transfer of visuomotor, prismatic adaptation for each individual

Authors: ***F. R. SARLEGNA**, A. G. RENAULT, H. LEFUMAT, C. BOURDIN, L. BRINGOUX, J.-L. VERCHER;
CNRS and Aix-Marseille Univ., Marseille, France

Abstract: Humans can adapt their motor behavior to various environmental conditions, yet it remains unclear which factors enable us to transfer what we have learned with one limb to the other. Previous work has shown the importance of factors such as the trained limb (Sainburg and Wang 2002; Criscimagna-Hemminger et al. 2003) or the nature of the perturbation (Malfait & Ostry 2004; Berniker & Kording 2008). Recently, we examined the intermanual transfer of Coriolis force adaptation: as in DiZio & Lackner (1995), subjects were asked to perform forward reaching movements with the upper limb toward flashed visual targets in pre-adaptation, adaptation and post-adaptation tests. Only the dominant arm was used during force-field adaptation and interlimb transfer was assessed by comparing performance of the non-dominant arm before and after exposure to the novel force field. On average, significant but limited transfer was observed, and we also uncovered a substantial heterogeneity of interlimb transfer across subjects. Critically, we showed that interlimb transfer can be qualitatively and quantitatively predicted for each healthy young individual based on his/her task performance, most notably motor variability and peak velocity during learning, and laterality quotient, a classic measure of brain lateralization (Oldfield 1971). Our study thus highlighted how individual characteristics shape the way the nervous system can generalize adaptation to a novel force field. However the differences between adaptation to a novel force field and adaptation to a visuo-motor transformation are well documented (Krakauer et al. 1999; Pipereit et al. 2006; Rabe et al. 2009). More recently, we thus hypothesized that intermanual transfer of prism adaptation (Harris 1963; Martin et al. 1996) is also determined by individual characteristics. We used the same paradigm as described previously except subjects had to adapt to prisms rather than to a novel force field. Preliminary results (N=20) indicate a large heterogeneity in interlimb transfer but still point toward the critical role of laterality quotient and peak velocity during the adaptation phase to predict generalization of sensorimotor adaptation across upper limbs.

Title: Long-term motor adaptation: Time is not what matters

Authors: *K. VAN DER KOOIJ[1], K. E. OVERVLIET[2], J. B. J. SMEETS[3];
[1]VU Univ. Amsterdam, The Netherlands, Amsterdam, Netherlands; [2]Univ. Hamburg, Hamburg, Germany; [3]VU Univ., Amsterdam, Netherlands

Abstract: In this study we investigated how motor adaptation progresses over six sessions, performed over a two-week period. Motor adaptation is generally studied within sessions of about half an hour and its sub-processes have been found to occur on different time-scales. A fast process learns and forgets rapidly whereas another process learns slowly but has good retention (Smith et al., 2006). When repeating the experiment, some retention manifests itself as a changed initial baseline performance whereas other learning manifests itself as faster relearning, or savings (Krakauer & Shadmehr, 2006). However, it is not very well known how learning at different timescales compares to adaptation over the time course of days rather than minutes. We tested adaptation in a 3D pointing task in which subjects aligned their (unseen) hand with virtual red target cubes that were projected one by one at pseudo-random locations in 3D space. Terminal feedback was given by projecting a virtual feedback cube once a movement had ended. To introduce a bias that subjects had to adapt to, the tracked position of the hand was rotated by ten degrees around the cyclopean eye before rendering the feedback cube based on this position (equivalent to wearing wedge-prisms). A session consisted of five alternating blocks without and with feedback that allowed us to assess both learning from the feedback and forgetting of what had been learned. We analyzed the rate of learning and retention by fitting a two state - gain independent - multi rate model (Smith et al., 2006) to the data in the individual sessions. Our paradigm produced similar learning and retention as observed in earlier studies. Foremost, we found that forgetting (return to baseline) between sessions was much smaller than that predicted by a time-dependent retention rate, albeit somewhat larger than the forgetting that would be predicted by a trial-dependent retention rate. Second, we found that subjects improved their asymptotic level of adaptation by a small amount within each additional session of adaptation. We found no evidence of savings. Long-term adaptation could not be predicted by the retention

and learning rates of the first session, because retention appeared to be affect both by trial-dependent and time-dependent forgetting (which had a different time-constant).

Title: Reference frames for goal-directed reaching in natural scenes: The role of task relevance and scene coherence

Authors: ***M. KLINGHAMMER**[1], G. BLOHM[2], K. FIEHLER[1];
[1]Justus-Liebig Univ. Giessen, Giessen, Germany; [2]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: When interacting with objects in daily life situations, our brain relies on information represented in two main classes of reference frames: an egocentric (relative to the observer) and an allocentric (relative to objects or the environment) reference frame. In a recent study (Fiehler, Wolf, Klinghammer, & Blohm, 2014) we demonstrated that allocentric information is integrated into the movement plan when participants performed memory-guided reaching movements to targets surrounded by allocentric cues in a complex environment (i.e. images of a breakfast scene). In our current study, we aimed to investigate how task relevance and/or the coherence of the scene influence the integration of allocentric information into the movement plan. To this end, we presented participants 3D-rendered images of a breakfast scene on a computer screen with some objects on and some objects behind a table. Six of these objects served as possible reach targets and had to be learned before the experiment. Thus, the scene contained task-relevant and task-irrelevant objects. After free exploration of the encoding scene and a 1s delay, the test scene reappeared for 1.3s with one of the six possible targets missing. Moreover, task-relevant and task-irrelevant objects were shifted either to the left or to the right resulting in six different conditions: a) only relevant or b) only irrelevant objects were shifted in the same direction, c) relevant and irrelevant objects were shifted together in the same or d) opposite direction, e) only relevant or f) only irrelevant objects were shifted into opposite directions. After the test scene vanished, participants had to reach towards the memorized location of the missing

target on a grey screen. We predicted higher systematic deviations of reaching endpoints into the direction of the object shifts if task-relevant objects were shifted and the scene remained coherent (i.e. objects were shifted into the same direction) compared to conditions with shifts of task-irrelevant objects or with incoherent object shifts. We found stronger weighting of allocentric cues and higher precision of reaching endpoints in conditions with coherent shifts of only task-relevant objects but did not find an effect of coherence in conditions with shifts of only task-irrelevant objects. If task-relevant and task-irrelevant objects were shifted together, an object shift into the same direction led to higher weighting of allocentric cues compared to conditions with shifts in different directions. Our results demonstrate that task-relevance and image coherence are important, interacting factors for the integration of allocentric information for goal-directed reaching.

Abstract: Both our sensorimotor system and the environment are full of uncertainty and nonlinearities. Our nervous system must account for these factors in order to produce accurate goal-directed movements. Research has shown that humans use: 1) Bayesian-like inference to minimize reach errors when perturbed by symmetrically uncertain, visual feedback, and 2) a sensorimotor loss-function that is robust to outliers. Unlike a symmetrical probability distribution (PD), a skewed PD can be used to find the underlying loss-function because it separates several

statistics. For example, the mean and median correspond to minimizing the squared or absolute error, while the mode maximizes the likelihood of a hitting a target. Currently, it is unknown if the nervous system can also integrate skewed uncertainty in a Bayesian way; and if so, what is the sensorimotor loss-function? To investigate, participants held a robot manipulandum as they performed reaching movements to a target. Participants had no vision of their arm. We informed participants that the visual feedback flashed halfway through a reach represented their hand position. Visual feedback was presented as either a single dot, a cloud of dots or withheld. For three different groups, visual feedback was laterally shifted according to a right-skewed, symmetric, or left-skewed PD. The mode of each PD was 0, 1 and 2 cm, respectively. The mean of each PD was shifted 1 cm rightward from the true hand position. As previously shown with symmetrical PDs, participants compensated for the 1 cm rightward shift by reaching 1.03 (+/- 0.07) cm leftward of the final target when visual feedback was withheld. Participants in the right- and left-skewed groups reached leftwards 0.92 (+/-0.07) and 1.12 (+/- 0.05) cm when no feedback was given. Both of these values are between the mean and median, and are inline with a loss-function robust to outliers. Interestingly, however, this strategy caused participants in the skewed PD groups to miss the final target when visual feedback was withheld. Our data show that the nervous system can integrate skewed uncertainty in a Bayesian-like way, and uses a loss-function robust to outliers at the expense of maximizing the likelihood of success.

Title: A coordinated saccade with a reach increases reach accuracy in the absence of target foveation

Authors: *Y. VÁZQUEZ ZÚNIGA, D. J. HAWELLEK, B. PESARAN;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: In primates looking and reaching to the same target is a common behavior leading to precise reaching. Several factors contribute to precise reaching. When targets are constantly visible, the saccade foveates the target before the hand arrives. Furthermore, evidence from neural recordings suggests that when coordinated eye and reach movements (i.e. saccade and reach to the same spatial location) occur, both the saccade and reach systems interact. If so, coordinated saccadic eye movement planning may influence the plan and execution of the reach movement and improve reach accuracy. Importantly, this improvement due to a coordinated saccade should occur in the absence of target foveation. In order to assess the contribution of a coordinated saccade to reach accuracy we tested reach accuracy under four different conditions: 1) when a reach is coordinated with a saccade to a visual target (delayed-reach-and-saccade: DRS); 2) when a reach to a visual target is performed while keeping central fixation (delayed-reach-and-fixation: DRF); 3) when a reach is coordinated with a saccade to a remembered target (memory-reach-and-saccade: MRS); and 4) when a reach to a remembered target is performed while keeping central fixation (memory-reach-and-fixation: MRF). We found that reach accuracy is improved by adding a saccade without any visual information about the target (MRS trials). Accuracy is improved to a level similar as having peripheral vision of the target without the saccade (MRF trials).The hand mean error for MRS (*1.76° ± 0.03°)* trials was significant smaller in comparison to the DRF (*2.31° ± 0.04°*) and MRF (*2.95° ± 0.04°)*, but significantly larger than the DRS (*1.5° ± 0.02°;* one-way ANOVA, p=2e-176, F=302.44, df=3, Bonferroni corrected, n=967 trials). This finding could be explained by: 1) interaction between the saccade and the reach system, leading to a common motor plan, 2) interaction between the reach system and the saccade efferent copy, proprioceptive signals or a combination of both, 3) hand foveation leading to online reach corrections, and 4) a mixture of the above.

Title: Eye-hand coordination in visual search

Authors: *S. JANA[1], A. GOPAL[3], A. MURTHY[2];
[1]Ctr. for Neurosci., Indian Inst. of Sci., Kolkata, India; [2]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India; [3]Natl. Brain Res. Ctr., Gurgaon, India

Abstract: In the context of coordinated eye-hand movements, previous work from the lab, using a combination of eye and hand reaction time (RT) measures, electromyography (EMG) and drift diffusion model in pointing and redirect task has suggested that brain employs a common network for coordinated eye-hand movements (Gopal et al., 2015). One of the striking observations was that mean hand RT was greater than eye RT but their standard deviations (SD) were similar. This cannot be explained by considering two separate drift diffusion processes for eye and hand each with different drift rates, as the drift diffusion model suggests that the SD of the accumulation process scales along with the mean. Further, the correlation between eye and hand RT was high. These suggested that both eye and hand movements were generated by a common motor command (CC model) with the delay in hand muscle activation (motor delay) resulting in increased mean hand RT compared to mean eye RT. Here we investigated the ability of CC model to explain coordinated eye-hand movements, when the task involved a more complicated decision i.e. a visual search task where the target would be hidden among distractors. 10 naive subjects were instructed to make eye-hand movement to the target located among 3 distractors. There were alternating simple and difficult search blocks, each having 12-20 trials, with the simple block having red and green colours and the difficult block having green and blue-green colours. Further the colour of the target and distractor was randomly swapped. Correct trials were trials in which the direction of the first saccade and the direction of first hand movement, was in the direction of the target, while error trials were those in which either of the two movements was towards a distractor. Subjects fared better in simple search than difficult search with mean eye and hand RT and error % increasing in the difficult trials. Further mean hand RT was greater than mean eye RT in both conditions; however their SDs were similar ($p>0.05$ for both conditions), as predicted by the CC model. The Pearson's correlation between eye and hand RT was moderate to high for all subjects as predicted by the CC model (Easy: mean = 0.51; Difficult: mean = 0.71). We also found that the %dissociated trials (the direction of the first saccade and first hand movement was different) was strongly correlated with the difference in SD of eye and hand RT ($r = 0.59$, $p = 0.006$), suggesting that when the CC model was not applicable the chance of independent eye and hand movements increased. These results suggest that the CC model can be extended from coordinated eye-hand movements during pointing to movements which involve a more complicated decision.

Title: Mirror-reversed visual feedback reduces quick somatomotor response evoked by mechanical perturbation

Authors: *S. ITO, H. GOMI;
NTT Communication Sci. Labs., Atusgi-City, Kanagawa-Pref., Japan

Abstract: Quick somatomotor response evoked by mechanical perturbation (stretch reflexes) is flexibly modulated depending on environmental dynamics. For instance, long-latency stretch response is adjusted to a novel dynamics after an adaptation to a force field (Cluff & Scott 2013). It is, however, still unknown whether or not somatomotor response is modulated by an exposure of a novel visuomotor environment. Previous research showed that somatosensory evoked potentials are cortically suppressed by giving a mirror-reversed vision (Bernier et al. 2009). From this observation, it could be inferred that somatomotor responses decrease by giving a novel visuomotor relationship, in addition to the reduction of visuomotor response (Gritsenko & Kalaska 2010). To examine this prediction, we asked participants to make a one-dimensional reaching movement (45 deg, wrist flexion) with normal (NVF) or mirrored (MVF) visual feedback of fingertip position. To examine the quick visuomotor and somatomotor responses, we applied target jumps (positive and negative) and mechanical perturbation, respectively, during the movements (random trial order). Participants were required to correct their reaching movement toward the new target location as quickly as possible (Pro-task). The visuomotor response was evaluated by the acceleration deviation to the new target, and somatomotor response was evaluated by the muscle activities of wrist flexor and extensor. In addition, we also acquired these responses in the anti-correction task for target jumps (Anti-task) with NVF, by which the quick visuomotor response would decrease (Day & Lyon 2000). As a result, we observed longer latencies of visuomotor responses both for Pro-task with MVF and for Anti-task with NVF, as in the previous studies. In contrast, we found a significant reduction of the long-latency somatomotor response (50-100[ms] after perturbation) during the Pro-task with MVF, while no significant reduction was found during Anti-task with NVF. These results suggest that visuomotor and somatomotor responses are not always synchronously modulated. Considering the comparable delay in visuomotor responses in Anti-task with NVF and in Pro-task with MVF, the decrease in somatomotor responses in the MVF condition was not accounted for by an

increased task difficulty (cognitive load). We conclude that the observed decrease in somatomotor response is attributed to the strong visuomotor discordance due to the mirrored visual feedback.

Title: Acid induced itch and the roles of proton-sensing ion channels in pruritoception

Authors: *S.-H. LIN[1,2], C.-C. CHEN[2,3];
[1]Inst. of Biomed. Sciences, Academia Sinica, Taipei, Taiwan; [2]Inst. of Biomed. Science, Academia Sinica, Taipei, Taiwan; [3]Taiwan Mouse Clinic-National Comprehensive Mouse Phenotyping and Drug Testing Ctr., Taipei, Taiwan

Abstract: Itch and pain are closely related but distinct sensations. Intradermal injection of acid generates pain in both rodents and human; however, few studies address the intriguing issue whether protons can be regarded as a pruritogen as well. We reported here that acid (in 0.2M citric acid) pH-dependently induced scratching response in mice when applied intradermally to the neck skin. In the cheek assay, citric acid (pH=3.0) induced both scratching and wiping/digging behavior when compared with the well-known pruritogen “chloroquine” and algogen “capsaicin”, respectively. Like the action of many other pruritogens, acid at pH3.0 elevated intracellular calcium in a small population of TRPV1-positive DRG neurons. These results implicated that proton could be a potent pruritogen apart from its well known role as an algogen. To identify the target acid-sensing receptor that is involved in the proton-evoked itch, we screened phenotypes in the citric acid-induced itch model with several mutant mice lines lacking a proton-sensing ion channel, such as ASIC1a, ASIC2, ASIC3, ASIC4, TRPV1, or TRPA1. Results indicated that acid-induced itch could be separated into two phases: (1) the first acute phase (~5 minutes) was mediated by TRPV1 in a pH-independent manner; (2) the later prolonged phase (5-30 minutes) was TRPV1-independent and the scratching response was

increased in a pH-dependent manner. Compared with WT mice, acid-induced scratching response was specifically decreased in the first acute phase in TrpV1-/-. Normal acid-induced itch response was observed in TrpA1-/-, Asic3-/- and Asic4-/- mice. Our results provide the first evidence that proton is a potent pruritogen and intradermal administration of proton can evoke itch response. TRPV1, but neither TRPA1 nor ASICs, initially mediates the scratching response induced by acid.

Title: Exploring the mechanisms of itch and skin inflammation of poison ivy contact dermatitis

Authors: ***B. LIU**, Y. TAI, S. ACHANTA, A. CACERES, M. KAELBERER, P. BONNER, S. JORDT;
Anesthesiol., Duke Univ., Durham, NC

Abstract: Background: Allergic contact dermatitis (ACD) is a common skin condition triggered by environmental or occupational allergens. In the US, the most common ACD is caused by contact with poison ivy, with more than 10 million cases each year. The major clinical manifestations of poison ivy-induced ACD are characterized by skin rashes, swelling, severe itch (pruritus). However, still little is known about the detailed immune and pruritus mechanisms involved in poison ivy-induced ACD. Objective: We aim to explore the mechanisms underlying poison ivy-induced skin inflammation and severe pruritus. Methods: We established a mouse model of poison ivy-induced ACD using the major allergen in poison ivy−urushiol. We compared the macroscopic features of dermatitis induced by urushiol with the widely used experimental allergen oxazolone by means of pathology scoring and transepidermal water loss (TEWL). The cellular immune responses and endogenous pruritogens were examined by transcriptome microarray, qPCR, ELISA and immunohistochemistry. Behavioral assays were

also performed to judge the pruritus responses of the mice. Results: The mice treated with urushiol developed skin inflammation and intense scratching behaviors. Compared with oxazolone, urushiol induced stronger skin swelling, erythema and TEWL changes. In terms of cellular immune responses, oxazolone showed potent inductions of Th1/Th2 components, while urushiol demonstrated a strong TH2 bias and some TH17 contributions. We also identified specific endogenous pruritogens as possible mediators of pruritus responses in the urushiol model. Conclusion: This mouse model we established recapitulates many key features of human poison ivy ACD. We believe our study will unravel the mechanisms of skin inflammation and pruritus in poison ivy-induced ACD and provide a wider range of therapeutic options.

Abstract: The respiratory system is densely innervated by vagal sensory neurons. However, to what extent the vagal sensory neurons contribute to the development of respiratory diseases is largely unknown. Mrgprs (Mas-related G protein-coupled receptors) are a family of GPCRs consisting of more than 50 members in the mouse genome. Based on sequence homology, Mrgprs can be grouped into several subfamilies: MrgprAs, MrgprBs, MrgprCs, and MrgprD-G. Our previous studies have demonstrated that Mrgprs are expressed in subsets of DRG sensory neurons mediating itch sensation in the skin. Recently we found that itch receptors Mrgprs are

also expressed in subpopulations of vagal sensory neurons. Neuronal retrograde tracing showed that MrgprC11+ vagal sensory neurons innervate the airway. Application of MrgprC11 agonist, Bam 8-22 peptide, induced a significant increase in airway resistance (Rrs) which could be blocked by vagotomy and cholinergic blocker (ipratropium bromide). These results demonstrated that activation of MrgprC11+ vagal sensory nerves in the airway evoked cholinergic reflex bronchoconstriction. Moreover, HDM-induced allergic inflammation in the airway enhanced the expression of itch receptors in vagal sensory neurons. Interestingly, pretreatment of the animal with Bam8-22 significantly increased the airway sensitivity to MCh. Our results thus indicate the role of itch receptor Mrgprs in the pathogenesis of airway hyperresponsiveness.

Abstract: Itch is described as an unpleasant or irritating skin sensation that elicits the desire or reflex to scratch. MrgprA3, a member in Mrgprs family, specifically expresses in a subpopulation of dorsal root ganglion (DRG) in peripheral nervous system (PNS). These DRG neurons, which express MrgprA3, were identified as itch-specific neurons. They could be induced by a compound named as chloroquine which was used as a drug to treat malaria. In the present study, we labeled these itch-specific neurons through using the method of molecular

genetic marker, and studied their electrophysiological properties. We firstly found that MrgprA3 could negatively regulate the excitability of DRG neurons. The number of action potential (AP) was obviously reduced in MrgprA3 positive (MrgprA3+) neurons than in MrgprA3 negative (MrgprA3-) neurons when a train of depolarizing steps current (Δ=20 pA) with 200ms duration were applied to induce AP generation. In most cases, MrgprA3+ neurons only generated single AP, however, in MrgprA3- neurons, the same stimulation could induce multiple AP firing. The reason was the greater voltage-gated potassium (Kv) current existed in MrgpA3+ than in MrgprA3- neurons. Thus, the Kv current plays an important role in regulation of excitability itch-specific neurons.

Title: Neurotrophic factors selectively modulate scratching behavior and sensory neuron responses to pruritogens

Authors: ***M. V. VALTCHEVA**[1], A. M. KEANE[2], J. P. GOLDEN[1], R. W. GEREAU, IV[1], S. DAVIDSON[1];
[1]Pain Ctr. and Dept. of Anesthesiol., Washington Univ. in St. Louis, Saint Louis, MO;
[2]Washington Univ. in St. Louis, St. Louis, MO

Abstract: Neurotrophic factors such as nerve growth factor (NGF) and the glial cell line-derived neurotrophic factor (GDNF) family of ligands can modulate nociceptor structure and function, but little is known about how they may affect itch. Skin samples from patients with chronic itch conditions such as atopic dermatitis or psoriasis exhibit increased intraepidermal nerve fiber density, increased GDNF and artemin, and increased NGF and its receptor TrkA. Additionally,

we have recently demonstrated a selective increase in fibers expressing Ret, the receptor for GDNF family ligands (GFLs), in a mouse model of dry skin itch. Based on these findings we hypothesized that neurotrophic factors (NTFs) contribute to the development and maintenance of chronic itch. In our current studies we investigated whether NGF and the GFLs GDNF, neurturin, and artemin can directly induce or modulate histaminergic and non-histaminergic itch. First, scratching and wiping behavior after intradermal injection of NTFs into the cheek skin of mice was quantified to determine whether NTFs alone can induce pain or itch. The effects of acute and chronic NTF pretreatment on histamine- and chloroquine-induced scratching were also determined. We found that acutely injected NTFs did not induce scratching or wiping behavior by themselves. Chronic NTF treatment also did not alter spontaneous scratching or wiping behavior. On the other hand, acute 1 hour pretreatment with NGF selectively potentiated histamine-induced scratching, while artemin potentiated chloroquine-induced scratching. To elucidate the mechanisms by which specific NTFs potentiate histaminergic and histamine-independent itch, dissociated trigeminal ganglion neurons from Ret-eGFP reporter mice were pre-incubated with NTFs and examined for calcium responses to pruritogens and transient receptor potential (TRP) channel agonists. Our ongoing studies suggest that NTFs modulate the peak calcium responses and overall proportion of sensory neurons that respond to pruritogens.

Title: Human sensory neuron: a novel strategy for translational approaches to pain and itch

Authors: *B. A. COPITS[1], M. VALTCHEVA[1], S. DAVIDSON[1,2], R. W. GEREAU, IV[1];
[1]Pain Center, Dept of Anesthesiol., Washington Univ. Sch. of Med., Saint Louis, MO;
[2]Anesthesiol., Univ. of Cincinnati Med. Ctr., Cincinnati, OH

Abstract: Biological differences in sensory processing between human and model organisms may present significant obstacles to translational approaches in treating chronic pain and itch. Such obstacles may include functional differences in target receptor pharmacology and signaling or fundamental differences in neuronal physiology. Although cultures of rodent dorsal root ganglion (rDRG) neurons have proven useful for identifying new analgesic targets and elucidating signaling pathways, notable translational failures have recently raised questions about the wisdom of developing drugs for pain relief in rodents for eventual use in humans. While limited evidence suggests that questions regarding human sensory neuron physiology may be addressed in recordings from cultured human DRG, tissue is often obtained from patients with chronic pain or before the nervous system has fully developed. We recently reported the first study of the electrophysiological properties of cultured human sensory neurons from young-adult donors without chronic pain, indicating that these types of studies are feasible and could be a powerful approach to understanding the biology of human neurons and development of novel therapeutic strategies. We have now developed an approach to culture human sensory neurons in our lab and perform a variety of molecular biology, imaging, and electrophysiological experiments to develop a comprehensive picture of their neurobiology. We have begun to use single-cell RT-PCR to assess the transcriptional profile of ion channels, receptors, and other signaling molecules in individual neurons to correlate their expression with the electrophysiological properties and channel conductances from individual neurons. Using both whole-cell recordings and calcium imaging, we are now characterizing excitability signatures and population responses to algogens, pruritogens, and other neuro-active molecules to understand the chemosensitivity of these sensory neurons, with the long-term goal of correlating these signatures to patients' medical history of chronic pain or itch. We have also been successful in co-culturing human DRG with non-neuronal human keratinocytes, to investigate whether signaling cross-talk and sensitization may occur, especially in cases of chronic itch. We anticipate that these approaches will be very informative of the underlying neurobiology of human DRG and allow for the improved translational outcomes.

Ctr. at Houston, Houston, TX

Abstract: Chronic itch is a major clinical issue involving both allergic and non-allergic mechanisms. Although cutaneous cells play critical roles in skin barrier function and immune surveillance, their role in the pathogenesis of chronic itch is not fully understood. Here we show that activation of transient receptor potential vanilloid 4 (TRPV4) channels expressed by skin keratinocytes and innate immune cells is sufficient to generate a scratching response. More importantly, spontaneous scratching in mouse models of both chronic dry skin itch and allergic contact dermatitis, which recapitulates symptoms of skin disorders in humans, is also severely reduced by genetic ablation of the TRPV4 function. Most importantly, platelet- but not mast cell-derived serotonin is required for generating TRPV4-mediated scratching. Our study reveals a unique function of the TRPV4-expressing cutaneous cells in the genesis of both acute and chronic itch and might provide new insights into the development of effective therapies for chronic itch.

Title: Activation of T-type Ca^{2+} channel regulates PAR2 dependent allergic contact dermatitis

Authors: *Y. KIM, S. CHUNG;
Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Activation of T-type Ca^{2+} channel regulates PAR2 dependent allergic contact dermatitis The protease-activated receptor (PAR)2, a family of G-protein coupled receptors, is expressed on peripheral sensory neurons and its activation evokes itching, but its cellular mechanism is still unknown. Recently, it has been reported that T-type Ca^{2+} channel contribute to nociception and augmentation of T-type calcium current (I_{ca-T}) may evoke itching by sensitizing peripheral nociceptors. So we hypothesized that a PAR2-induced itching may be due to sensitization of primary sensory DRG neurons evoked by augmentation of I_{ca-T}. Either trypsin (300 nM) or PAR2-activaing peptide H-Ser-Leu-Ile-Gly-Arg-Leu-NH2 (SL-NH2) (100 μM), augmented Ica-T in phospholipase C (PLC)- dependent but, Ca^{2+} and protein kinase C (PKC)-independent manners. In current-clamp experiments, PAR2 agonists increased after depolarizing potential (ADPs) and this effect was completely inhibited by application of mibefradil, a potent T-type channel blocker. In addition, trypsin increased excitability by lowering the threshold for AP firing even at the physiological resting membrane potential (RMP). Mibefradil reversed the effects of trypsin (300 nM). Finally, intraplantar (i.pl.) injection of PAR2 agonists lowered paw withdrawal threshold (PWT) compared to that of vehicle-treated rats. This reduced PWT was completely reversed by co-treatment of mebefradil. These observations suggest that PAR2 activation readily augment I_{ca-T} in peripheral nociceptive neurons and this augmentation of I_{ca-T} may be involved at least, in part, in PAR2-evoked itching.

Title: A chemogenetic model for studying itch in awake mice

Authors: *B. SHARIF[1], X. DONG[3], P. A. SEGUELA[2];
[1]Physiol., [2]Neurol. and Neurosurg., McGill, Montreal, QC, Canada; [3]Johns Hopkins, Baltimore, MD

Abstract: Itch, or pruritus, can be described as an unpleasant sensation that leads to scratching behavior or the desire to scratch. Due to high prevalence in numerous diseases and widespread occurrence as a side effect of many medications, itch has become a research topic of choice in recent years. Despite significant structural and behavioral overlap of pruriception and nociception, the underlying neurophysiological basis of itch sensation and its relation to pain remain unclear. Taking advantage of chemogenetic tools with Cre recombination-based transgene expression and viral gene delivery methods, we targeted the Gq-coupled DREADD, HM3D, selectively to the MrgprA3-expressing peripheral afferent subpopulation. HM3D is an engineered muscarinic receptor activated solely by the inert ligand clozapine N-oxide (CNO). The target primary nociceptors, expressing the chloroquine receptor MrgprA3, constitute a subpopulation of afferents specifically linked to itch (Han et al., 2013). Selective expression and trafficking of HM3D-mCherry to the surface and terminals of MrgprA3 neurons were validated in fluorescence microscopy. Functionality of HM3D was also validated using electrophysiology and calcium imaging on dissociated DRG neurons *in vitro*. Injection of CNO in the skin of transgenic mice expressing HM3D in MrgprA3 neurons induces robust itch responses. Using the cheek model of itch (Shimada and LaMotte, 2008), we observed that CNO injection evokes stereotypical itch behavior (scratching with the hind paw) rather than pain response (wiping with the forepaw). These results confirm the unique properties of this small population of C-fibers and validate a novel model to investigate the cellular and molecular basis for itch sensation. Combined with optogenetic techniques to gain high spatiotemporal precision, the chemogenetic control of MrgprA3 neurons provides a powerful *in vivo* tool for studying the mechanisms of discrimination between itch and pain in the somatosensory system.

Title: Chemogenetic sensitization of pain pathways in freely moving animals

Authors: *H. ALKHANI, P. SEGUELA;
Montreal Neurolog. Institute, Dept of Neurol. and Neurosurgery, McGill Univ., Montreal, QC, Canada

Abstract: Pain is an unpleasant acute or chronic sensation experienced following peripheral injury, inflammation or ischemia. Current models used to investigate pain behaviors in rodents are plagued with pitfalls ranging from lack of spatiotemporal specificity to mandatory invasiveness. Here, we report a novel transgenic mouse model based on hM3D (Gq-coupled DREADD)-mediated sensitization of peripheral nociceptive pathways in virally-transduced Nav1.8(+) nociceptors, without administration of any external noxious stimuli or injury. Systemic activation of hM3D induced by intraperitoneal clozapine N-oxide (CNO) injections evoked strong nocifensive behavior with reduced locomotion, squinting of the eyes and ruffled fur. Intradermal paw injections of CNO resulted in robust acute thermal and mechanical sensitization as measured in Hargreaves and Von Frey tests. Moreover, CNO induced edema and redness in the injected paws, indicating the activation of neurogenic inflammatory mechanisms similarly observed in sensitization protocols with capsaicin. The observed nocifensive behaviors appear to be specifically due to the contribution of small and medium diameter Nav1.8(+) DRG neurons, as indicated by our histology data, with fiber projections limited to the lamina I and II layers of the dorsal horn of spinal cord. These findings demonstrate for the first time the chemogenetic control of peripheral sensitization in behaving mammals and enables selective activation of the same class of afferents *in vivo*. Our results provide a proof-of-concept demonstration that chemogenetic interrogation of the contribution of specific classes of genetically-identified primary afferents to peripheral sensitization is possible. Non-invasive chemogenetic rodent pain models combining effective spatial penetrance with neuronal specificity have the potential to facilitate drug development and target validation for migraine or chronic pain relief.

Title: Eact, a small molecule activator of ANO1, activates TRPV1 and elicits pain- and itch-related behaviors

Authors: J. FENG[1], S. LIU[1], J. LUO[1], P. YANG[1], *H. HU[2];
[1]Anesthesiol., [2]Washington Univ. in St. Louis, St. Louis, MO

Abstract: TMEM16A, also known as anoctamin 1 (ANO1) channel, is a member of the Ca2+-activated chloride channels (CaCCs) family, and serves as a heat sensor in the primary nociceptors by detecting noxious thermal stimuli. Eact is a recently discovered small molecule activator of ANO1. We thus asked if Eact produces sensory hypersensitivity *in vivo* and investigated the cellular and molecular basis of Eact-mediated responses in primary sensory neurons. We performed behavioral testing combined with pharmacological inhibition and genetic ablation studies to identify molecules responsible for Eact-evoked itch- or pain-related responses. We performed Ca2+ imaging and patch-clamp recordings to investigate the effects of Eact on ion channels heterologously expressed in HEK293T cells and endogenously expressed in dorsal root ganglia (DRG) neurons isolated from wild-type (wt) and TRPV1 (transient receptor potential vanilloid 1)-deficient mice. We also used site-directed mutagenesis of TRPV1 channel to determine the structural basis of Eact-mediated responses. Administration of Eact elicited both itch- and pain-related behaviors. Unexpectedly, the Eact-elicited sensory hypersensitivity was dependent on the function of TRPV1 as shown by pharmacological inhibition and genetic ablation studies. Eact activated membrane currents and evoked intracellular free Ca2+ increase in both TRPV1-expressing HEK293T cells and isolated DRG neurons in a TRPV1-dependent manner. Mutations disrupting the capsaicin-binding sites severely attenuated Eact activation of the TRPV1 channel. Our results suggest that Eact activates primary sensory nociceptors and produces pain and itch sensations mainly through direct activation of TRPV1.

Title: Identification of ion channels involved in compound 48/80 mediated degranulation of mast cells

Authors: *B. LEE[1], H. CHUN[2], H. KIM[2], J. WEE[2], I. CHOI[2], U. OH[2,3];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Sensory Res. Center, Creative Res. Initiatives, Col. of Pharmacy, Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Dept. of Mol. Med. and Biopharmaceutical Sciences, Grad. Sch. of Convergence Sci. and Technology, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Compound 48/80 is a mixed polymer of p-methoxy-N-methyl phenylethylamine crosslinked by formaldehyde. Compound 48/80 is known to cause severe itch because it specifically activates and degranulates mast cells and thus release histamine. Thus, compound 48/80 is often used as a pruritogenic substance. However, the mechanism underlying its mast cell degranulation is not well understood. Thus, we aimed to determine ion channels that are activated specifically by compound 48/80. To do that, a rat basophilic leukemia cell line (RBL-2H3) was used as a mast cell model. As a result, application of compound 48/80 to RBL-2H3 cells evoked robust Ca2+ increase. The EC50 of compound 48/80 was about 100 ug/ml. This Ca2+ response is induced by the influx of Ca2+ from the outside cell because Ca2+-free bath solution failed to show the increase in intracellular Ca2+. The compound 48/80-induced Ca2+ was not blocked by ruthenium red, a TRP channel blocker. Surprisingly, The compound 48/80-induced Ca2+ was completely blocked by the application of 4,4'-diisothiocyano-2,2'-stilbenedisulfonic acid (DIDS), a Cl- channel blocker, suggesting the involvement of chloride channels. Thus, future study is directed to determine which Cl- channels are involved in the compound 48/80-induced Ca2+ signal in RBL-2H3 cells. The understanding of channels activated by compound 48/80 will lead to the detailed mechanisms underlying pathologic pruritus and may be useful for developing new anti-pruritic drugs.

Title: Rolipram ameliorates chemotherapy-induced neuropathic pain in rats by decreasing inflammatory cytokines in the dorsal root ganglia

Authors: S. KIM, H. KIM, H. LEE, S. ABDI;
Pain Med., Univ. of Texas, MD Anderson Cancer Ctr., Houston, TX

Abstract: Chemotherapy agents including taxanes, vinca alkaloids, and platinum complexes produce peripheral neuropathic pain which is a dose-limiting side effect. We previously reported that rolipram (ROL) ameliorates paclitaxel (PAC)-induced neuropathic pain in rats. The purpose of this study was to investigate the effect of ROL on PAC-induced inflammatory cytokines in dorsal root ganglia (DRGs). PAC (2 mg/kg on days 0, 2, 4, 6) or vehicle (4% dimethyl sulfoxide and 4% Tween 80 in saline) was intraperitoneally injected in adult male Sprague-Dawley rats. ROL treated rats received intraperitoneal injection of 3 mg/kg of ROL on PAC-injected rats and then the DRGs were dissected at 1 hour after ROL injection. The L1-6 DRGs were dissected, homogenized in RIPA lysis buffer, separated in SDS polyacrylamide gens and then transferred to polyvinylidene fluoride membrane. For detections, blots were incubated with the primary antibody to phosphorylated NFκB (p- NFκB), IL-1β, TNF-α, and GAPDH, respectively and then incubated with the horseradish peroxidase-conjugated secondary antibody. The immunoblots were detected by a chemiluminescence detection system and normalized to GAPDH. Equal protein loading was performed using GAPDH expression as a control. PAC significantly increased the levels of p-NFκB, TNF-α and IL-1β in the DRGs at 14 days after the first PAC injection. Further, PAC-induced increase in p-NFκB, TNF-α, and IL-1β protein levels in the DRGs were decreased by ROL treatment. This result indicates that PAC increases the production of phosphorylated NFκB, TNF-α, and IL-1β in the DRGs and inhibition of PAC-induced inflammatory cytokines level in the DRGs may be the mechanisms underlying the analgesic effect of ROL for chemotherapy-induced neuropathic pain in rats.

Title: Cortical reorganization in at-level central neuropathic pain

Authors: *G. H. BLUMENTHAL[1], M. R. DETLOFF[2], B. NANDAKUMAR[1], K. A. MOXON[1];
[1]Sch. of Biomed. Engineering, Sci. & Hlth. Systems,, Drexel Univ., Philadelphia, PA; [2]Dept. of Neurobio. & Anatomy, Spinal Cord Res. Ctr., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: While the intensity of chronic neuropathic pain (CNP) has been directly associated with the degree of reorganization in the somatosensory cortex (S1), many of these studies have focused on peripheral nerve injury and deafferentation in which the cortical representations surrounding the painful, deafferented regions expand. After spinal cord injury (SCI), similar reorganizational patterns have been seen in patients experiencing below-level pain, where representations neighboring the deafferented region display significant reorganization. It is unlikely that the patterns of S1 reorganization in SCI patients experiencing at-level pain are similar due to the extent of intact afferent input originating from the painful area. We hypothesize that after SCI, development of at-level tactile allodynia will be associated with an expanded somatosensory representation of the painful area. To test this, a spinal cord contusion injury at vertebral level T10 in the female Sprague Dawley rat was used. Increased incidence of supra spinal behaviors such as vocalization and avoidance in response to tactile stimulation of the injured area was used to indicate at-level CNP. Animals were tested for 5 weeks following injury using a 26 gram Von Frey filament applied to 24 locations on the trunk area spanning two dermatome levels above and below T10. Animals were then separated into at-level allodynic and non-allodynic group based on their responses at week 5. Sensory mapping experiments were performed on both groups of animals as well as normal controls. A high impedance tungsten microelectrode was lowered through cortical layers I-IV in 10 locations spanning the hind limb, forelimb, and trunk cortices. For each neuron recorded, receptive fields to tactile stimulation of the entire body surface were recorded. For each cortical location, the proportion of cells responsive to trunk stimulation was calculated and comparisons were made between groups. Our results show that for at-level allodynic animals, cortical locations extending into the forelimb representation had a higher proportion of cells responsive to trunk stimuli when compared to both non-allodynic and normal animals. Expanding on these result, we would like to explore therapies which address this maladaptive plasticity in order to attenuate or prevent the development of CNP.

Title: Molecular mechanisms of satellite glia-dependent spinal cord microglia activation in nerve injury-induced neuropathic pain

Authors: ***S. LEE**[1], H. LIM[2], H. LEE[1], K. NOH[1], B. YOU[1], J. OH[3], H. MOK[4], B. KIM[5], J.-S. PARK[3], K. KIM[4];

Abstract: Increasing evidence supports the notion that both microglia activation in spinal cord and satellite glial cell (SGC) activation in dorsal root ganglion (DRG) play important roles in the development of neuropathic pain after peripheral nerve injury, yet their relative contributions to neuropathic pain induction remain elusive. To address this issue, we generated SGC-specific ikkβ conditional knockout mice in which IKK/NF-κB-dependent proinflammatory SGC activation is abrogated. In these mice, nerve injury-induced proinflammatory gene expression and macrophage infiltration into the DRG were severely compromised. Likewise, nerve injury-induced spinal cord microglia activation and pain hypersensitivity were significantly attenuated in these mice compared to control mice. However, macrophages recruited into the DRG per se have minimal effects on spinal cord microglia activation suggesting a direct causal effect of SGC activation on spinal cord microglia activation. In an effort to elucidate the molecular mechanisms, we found that IKK/NF-κB-dependent SGC activation induced St3gal2 gene expression and subsequent ganglioside (GT1b) production in DRG neurons as well as in the spinal cord dorsal horn. Studies using St3gal2 knock-out mice indicated that the GT1b increase is required for the nerve injury-induced spinal cord microglia activation and pain hypersensitivity. Finally, GT1b induced pain-mediating gene expression in primary microglia via

directly activating toll-like receptor 2 (TLR2) *in vitro* and also activated spinal cord microglia *in vivo*. Taken together, our data uncovered a novel mechanism for spinal cord microglia activation after nerve injury; nerve injury-induced SGC activation leads to GT1b up-regulation at the central axon terminal of the sensory neurons, which in turn activates spinal cord microglia via TLR2.

Title: Coupled activation of primary sensory neurons contributes to chronic pain

Authors: *Y. KIM, K. PARK, S. JILAFU, Q. ZHENG, L. HAN, Z. LI, C. GONG, L. YOUNG, S. HE, F. ZHOU, Y. GUAN, M. CATERINA, X. DONG;
Dept Neurosci, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Primary sensory neurons in the dorsal root ganglia (DRG) play an essential role in initiating pain by detecting painful stimuli in the periphery and sending signals to the spinal cord via their axons. Pathological conditions such as inflammation and nerve injury can sensitize DRG neurons, causing heightened pain sensitivity and often leading to chronic pain. Although the mechanisms of hypersensitivity of individual neuron have been extensively studied, how DRG neurons function at a populational level under physiological and pathological conditions is unclear due to the lack of proper tools. By specifically expressing a genetically-encoded Ca2+ indicator in almost all dorsal root ganglion (DRG) and trigeminal ganglion (TG) neurons in Pirt-GCaMP mice. Using this technique, we developed an *in vivo* live imaging technique which allowed us to simultaneously monitor the activation of >1,700 neurons/DRG in response to mechanical stimulation applied to the receptive field in live mice. Using this powerful technique, we revealed a striking neuronal coupling phenomenon that is adjacent neurons tend to activate together in mice with inflammation or nerve injury, which rarely happens in naïve animals. The coupled activation occurs among various sizes of neurons including small-diameter nociceptors and large-diameter low-threshold mechanoreceptors. The transferring of non-membrane permeable dye between coupled-activating neurons suggests that the coupled activation is likely due to non-diffusible cell-to-cell communication. Combining pharmacological and genetic

approaches with the imaging technique, we found the coupling phenomenon is mediated by the upregulation of gap junction in satellite glial cells surrounding DRG neurons after injury. Blocking gap junction significantly attenuates neuronal coupling in the DRG and mechanical hypersensitivity. Therefore, neuronal coupling represents a new form of neuronal plasticity in the DRG and by "hijacking" neighboring neurons through gap junction it contributes to pain hypersensitivity. Finally, this study creates a new way of characterizing the physiological properties and functions for developing new pain- or other modality-specific drug target for a treatment with few side effects.

Title: Preemptive analgesia attenuates mechanical allodynia in rats with chronic constriction injury of infraorbital nerve

Authors: H. KIM[1], M. KIM[1], J. SON[1], J. JU[1], K. YANG[1], M. LEE[2], M. PARK[3], *D. K. AHN[1]; [1]Dentistry, Kyungpook Univ., Daegu, Korea, Republic of; [2]Dong-Eui Univ., Busan, Korea, Republic of; [3]Kyung-Woon Univ., Gumi, Korea, Republic of

Abstract: The purpose of present study is to examine effects of preemptive analgesia on the development of neuropathic pain. For this purpose, the mechanical allodynia has been evaluated in rats with chronic constriction injury of infraorbital nerve (ION-CCI) after perineural application of 2% QX-314 in the infraorbital nerve. The effects of MIP-1α antibody on anti-allodynic actions by QX-314-induced preemptive analgesia are also investigated. Experiments were carried out using male Sprague-Dawley rats weighing between 230 and 280 g. Under anesthesia, ION-CCI was performed. ION-CCI produced severe ipsilateral and contralateral mechanical allodynia. Perineural application of 2 % of QX-314 on time after ION-CCI reduced

neuropathic mechanical allodynia. Double application of QX-314 significantly attenuated development of mechanical allodynia compared to the single treatment with QX-314. Application of 2% QX-314, when pain is already established, did not affect neuropathic mechanical allodynia. Co-administration of MIP-1α antibody and QX-314 potentiated anti-allodynic effects of QX-314 as a dose-dependent manner. Application of QX-314 did not affect extravasated Evans' blue dye concentration and the number of ATF3-positive cells produced by ION-CCI. The up-regulated p-p38 expression is co-localized with NeuN, a neuronal cell marker. The application of QX-314 reduced the up-regulated GFAP and p-p38 expression produced by ION-CCI in the trigeminal ganglion. These results suggest that QX314-induced long lasting preemptive analgesia produces inhibition of development of neuropathic pain through a regulation of the satellite glial cells and neuronal p-p38 expression in the trigeminal ganglion. Importantly, these results provide a potential preemptive therapeutic strategy for the treatment of neuropathic pain following nerve injury.

Title: Dynamic changes of CCR2+ monocyte and Cx3CR1+ microglia in a mouse model of neuropathic pain

Authors: ***L. LIU**, Z. HUA, H. WU, J. CHENG;
LRI, Cleveland Clin., Cleveland, OH

Abstract: Backgrounds: Neuropathic pain affects millions of Americans and can be severely debilitating. It has been recognized that the development of neuropathic pain in response to peripheral nerve injury in a large part depends on activation of microglia located in the dorsal horn of the spinal cord. Two chemokines (CCL2 and CCL21), which are expressed in injured neurons, have been indicated in the signaling pathways between injured neurons and microglia.

However, it remains to be elucidated that how a peripheral nerve injury initiates microglia responses in the dorsal horn of the spinal cord as there is no evidence that microglia express CCR2. We are particularly interested in the role of CCR2 expressing monocytes in this process and specifically investigated the dynamic distribution of monocytes from the circulation in the sciatic nerve, the dorsal root ganglia (DRG), and the spinal cord in response to chronic constriction injury (CCI) of the sciatic nerve in mice. We hypothesized that CCR2 expressing monocytes are attracted by CCL2 released from the injured DRG neurons to the spinal cord and DRG in response to CCI of the sciatic nerve in mice. We further hypothesized that CX3CR1 expressing microglia are activated in response to the nerve injury. **Methods:** With IACUC approval, CCI of the right sciatic nerve was induced by loose ligation on Cx3CR1GFP/+; CCR2RFP/+ transgenic mice. Sham-operated animals (sciatic nerve exposure without ligation) were used as controls. Mechanical allodynia was evaluated on day 0, day 7, day 14, day 21 and day 28. Mice were sacrificed and perfused at these time intervals. Samples of the sciatic nerve, DRG, and spinal cord of both sides were collected for immunohistochemistry examination to identify CCR2+ expressing monocytes and CX3CR1 expressing microglia. **Results**: CCI of the sciatic nerve induced a significant reduction of withdrawal thresholds to mechanical stimulation on post-injury day 7 through day 28. CCR2+ monocytes were identified in the sciatic nerve and DRG, but not in the spinal cord. An increase of CX3CR1 expression (activation of microglia) was found in the spinal cord dorsal horn ipsilateral to the CCI. The increase was noticeable in post-injury Day 3, peaked at Day 14, and waned at Day 28. **Conclusions**: We have demonstrated an infiltration of monocytes in the sciatic nerve and DRG, but not in the spinal cord, in response to the sciatic nerve injury. Further, we have shown a dynamic expression of CX3CR1 in the spinal cord, which is likely to be related to the mechanical allodynia. The link between monocyte infiltration and microglia activation remains to be established and is being actively investigated.

Title: Changes in DNA methylation in the rodent prefrontal cortex in chronic neuropathic pain: effect of S-Adenosylmethionine (SAM) on pain behaviors and epigenetic process

Authors: *S. GREGOIRE[1,2], R. MASSART[3,1], M. MILLECAMPS[2,1], S. DYMOV[3,1], S. DO CARMO[3,1], A. CUELLO[3,1], M. SZYF[3,1], L. STONE[2,1];
[2]Dent., [3]Pharmacol. and Therapeut., [1]McGill Univ., Montreal, QC, Canada

Abstract: Despite considerable advances in understanding mechanisms involved in chronic pain, it remains difficult to treat effectively. Co-morbid conditions including anxiety, depression and cognitive impairment further impact quality of life. Chronic pain is associated with reversible changes in brain anatomy and function and with long-term alterations in gene expression. One mechanism underlying stable, long-term programming of gene expression is DNA methylation, a dynamic process that responds to environment and experiences throughout the life cycle. We previously reported a decrease in global DNA methylation in the prefrontal cortex (PFC) in a rodent model of chronic neuropathic pain (Spared Nerve Injury, SNI). However, neither the identity of individual differentially regulated genes nor the effect of increasing global methylation on pain, mood and cognitive have been examined. In the current study, DNA methylation was first explored in SNI and control animals in rat PFC nine months following nerve injury. Genome-wide DNA methylation analysis revealed difference in the DNA methylation landscape in the brain at over 12,000 individual genes. DNA methylation of numerous individual genes the PFC showed robust correlation with pain sensitivity (von Frey test), including genes involved in pain modulation (e.g. opioidergic, dopaminergic or glutamatergic signaling) as well as in epigenetic processes (e.g. DNA methyltransferases). This first study supports the plausibility of DNA methylation involvement in chronic pain. In the second study, the effect of modulating DNA methylation on pain-related behaviors was assessed. Animals with nerve injury and sham surgery controls were treated with the methyl donor S-adenosylmethionine (SAM). SAM serves an important biological function as a methyl donor for DNA methyltransferases (DNMTs) in a multitude of cellular methylation reactions in all organisms. Three months following nerve injury, SAM or saline solution was given orally for four months and the effect of SAM on sensitivity to mechanical and cold stimuli, anxiety/depressive-like behaviors, pain avoidance and cognitive ability were measured. SAM attenuated SNI-induced mechanical hypersensitivity and pain avoidance in SNI mice. SAM had no effect on cold sensitivity and on anxiety/depressive-like behaviors but reversed the SNI-induced cognitive impairment in the novel object recognition test. In summary, chronic neuropathic pain results in changes in the DNA methylation of thousands of individual genes in the rodent PFC and the repeated administration of a methyl donor attenuated sensory and cognitive symptoms associated with nerve injury.

Abstract: Sensory experience induces reorganization of synaptic structure and functions in the brain. Many studies have demonstrated dynamic changes such as spine formation, elimination, and maturation of spine morphology in visual cortex, somatosensory cortex, and motor cortex following sensory experience or motor learning. However, mechanisms underlying synaptic remodeling induced and maintained by sensory inputs are poorly understood. Here we have found that constant sensory inputs through nerve injury induces increased synthesis of synaptic proteins in the anterior cingulate cortex, which in turn supports experience-dependent remodeling of synaptic structure, function and following behavioral changes. (J.-H. CHOI and J.-I. KIM both contributed equally to this work)

Title: Suppression of GSKIP expression in mice enhance CCI-dependent neuropathic pain through GSK3β-mediated Drp1-associated mitochondrial dysfunction

Authors: *A.-K. CHOU[1], M.-C. HONG[1], Y.-R. HONG[2];
[1]Chang Gung Mem. Hosp., Kaohsiung, Taiwan; [2]Dept. of Biochemistry, Fac. of Medicine, Col. of Medicine, Kaohsiung Med. University, Kaohsiung, Taiwan, Kaohsiung, Taiwan

Abstract: Neuropathic pain is one of prevalent chronic pain, estimating to affect one-fifth of people in the world. Previous studies revealed peripheral neuropathy often induces ROS production and mitochondrial dysfunction. However, the antioxidants are often tended to have only a modest therapeutic effect in neuropathic pain due to the precisely pathogenesis mechanisms remain unclear. Recently, Drp1 and GSK3 inhibitors have been shown the therapeutic effects to alleviate symptoms of neuropathic pain by reducing ROS production and mitochondrial fragmentation. Accumulation of cytoplasmic β-catenin and cyclin D1 expression which somehow contributes to the persistence of neuropathic pain can be suppressed by blockage of WNT pathway. We previously identified a small AKAP, GSKIP (GSK3β interaction protein), which not only negatively regulates GSK3 to mediate Drp1 GTPase activity but also associates with β-catenin accumulation to promote cyclin D1 expression under RA stimulation, implicating that GSKIP is an inhibitor of GSK3. Furthermore, our results in SH-SY5Y cells showed that GSKIP tethering GSK3β to induce the phosphorylation of Drp1 Ser637 by cAMP-driven PKA across PKA/GSKIP/GSK3/Drp1 axis, indicating GSKIP may play a role to ameliorate mitochondria fragmentation and mitochondria-derived ROS production. Indeed, the level of pGSK3β S9 phosphorylation is reduced in heterozygous GSKIP KO embryo and almost disappeared in homozygous GSKIP KO embryo. After CCI nerve injury, the development of thermal hyperalgesia after 14 days was enhanced in the heterozygous GSKIP KO mice. Overall, all of the results suggested that depletion or decreasing of GSKIP expression in mice can lead to an intensely neuropathic pain at the late stage. Administration of GSKIP-specific peptides may provide a better therapeutic effect to reduce peripheral neuropathic pain.

Title: BDNF-mediated projection-specific modulation of depression and pain: Focus on dopaminergic neurons in VTA

Authors: *D. LIU, Q.-Q. TANG, C. YIN, H. LIU, S.-P. SONG, Y.-Q. LI, Z.-Q. PAN, H.-R. WANG, X.-Y. HONG, Y. LIU, X.-Y. GUO, X.-N. YANG, H.-L. DING, H. ZHANG, J.-L. CAO;
Xuzhou Med. Col., Jiangsu, China

Abstract: Preclinical and clinicalbrain functional imaging studies have indicated that mesolimbic reward circuitry might play the critical roles in regulation of both depression and pain. The great functional heterogeneity of dopaminergic (DA) neurons in ventral tegmental area (VTA), a critical brain structure of mesolimbic reward circuitry, is the base of its extensive effect on regulating different behavioral responses in depression and pain. However, how VTA DA neuronal heterogeneity regulating depression and pain behaviors remains unknown. Mice treated with 5 consecutive weeks of CUMS showed depressive behavioral phenotypes, but no significant thermal pain behavior was found. Compared to control group, the firing rates in prefrontal cortex (PFC) projecting VTA (VTA-PFC) DA neurons were decreased in CUMS-treated mice. In nucleus accumbens (NAc) projecting VTA (VTA-NAc) DA neurons, however, no significant alterations of the firing rates were observed subsequent to CUMS. Both VTA-PFC and VTA-NAc DA neurons showed the elevated response to morphine in CUMS mice. The dosage of morphine used in present study doesn't change VTA DA excitability in control mice. Behavioral tests showed that microinjection of morphine in VTA relieved the depressive symptoms, which was accompanied with thermal pain hyperalgesia. Depression relief effect in CUMS mice by micro-injection of morphine in VTA could be mimicked by micro-injection of exogenous BDNF and be blunted by micro-injection of TrkB-Fc in mPFC, but not in NAc. Thermal hyperalgesia induced by micro-injection of morphine in VTA in CUMS mice by could be mimicked by micro-injection of exogenous BDNF and be blunted by micro-injection of TrkB-Fc in NAc, but not in

mPFC. CUMS decreased BNDF expression in mPFC, not in NAc, but increased BDNF expression was observed in both after micro-injection of morphine in VTA. Our results demonstrated a novel mechanism of BDNF-mediated projection-specific modulation of depression and pain by mesolimbic reward system.

Title: Study of the expression of neuropeptide pituitary adenylate-cyclase activating polypeptide (PACAP) in neuropathic pain mice by psychological stress

Authors: ***Y. SHUDO**, M. SHIMOJO, M. FUKUNAGA;
Kansai Med. Univ., Hirakata/Osaka, Japan

Abstract: It has been widely recognized that physical stress can cause the physiological, biochemical, and behavioral changes, leading to depressive illness. Stress has recently been reported to be involved in the pathogenesis of neuropathic pain and psychiatric disorders. Neuropathic pain is one of the most common type of intractable pain which control is difficult and has an impact on psychological and social factors. It was reported that neuropeptide pituitary adenylate-cyclase activating polypeptide (PACAP) is required for the development of spinal sensitization and induction of neuropathic pain. PACAP is distributed widely in dorsal root ganglia (DRG) and increases after nerve injury in neuropathic pain model. We previously reported that expression of PACAP in DRG is regulated by RE1-silencing transcription factor (REST) through alternative splicing of REST in neuropathic pain model mice. (Shudo et al., under review 2015). In this study, the mice (6 weeks) were used for neuropathic pain model and after 1 week of surgery then mice were restrained for 2 hours daily for 6 days to stimulate the psychological stress. Degree of stress was assessed by measuring cortisol in blood by specific

ELISA. The effect of the restraint stress on mechanical allodynia was assessed in chronic constriction nerve injury (CCI) neuropathic pain model mice. The nerve injury-induced mechanical allodynia was evaluated by using von Frey test. DRGs were obtained in model mice and the expression of genes were analyzed with specific primers by quantitative RT-PCR. As a result, psychological stress induced nerve injury-induced mechanical allodynia and the expression of PACAP in DRG in CCI model mice. It was suggested that stress exacerbates neuropathic pain and induced the expression of PACAP. To address the mechanism of stress-induced pain and the expression of PACAP, we have been currently analyzing the expression of other neuropathic pain-related genes.

Title: Cancer chemotherapy-induced peripheral neuropathy phenotypic screen

Authors: ***B. SINGH**, E. BUTTERMORE, L. BARRETT, C. WOOLF;
FM Kirby Neurobio. center, Boston Children's Hosp. Harvard Med. Sch., Boston, MA

Abstract: Patients undergoing chemotherapy for cancer often suffer from dose-limiting side effects, including painful peripheral neuropathy, which occurs in 30-60% of patients. Multiple different classes of chemotherapeutic agents, such as vinca alkaloids, platinum based, taxanes and a newer class, proteasome inhibitors can cause chemotherapy-induced peripheral neuropathy (CIPN). CIPN can result in loss of sensation, reduced epidermal innervation, and neuropathic pain, which can be transient or persist long after treatment has ceased. Unfortunately, there are no treatments available to prevent or improve neuropathy, and the associated neuropathic pain is poorly controlled with currently available analgesics. Furthermore, there is no consensus on the mechanism(s) responsible for the induction of neuropathy in CIPN-treated patients, nor a robust *in vitro* assay to detect the risk of development of neuropathy. We have developed two high throughput phenotypic screens specifically designed to examine CIPN induced neural toxicity. The primary screen will utilize mouse primary sensory neurons and a secondary screen will utilize human fibroblast-derived nociceptor neurons, which are derived using a

transdifferentiation approach (Wainger et al., Nature Neuroscience, 2015). The purpose of utilizing mouse and human neurons is two-fold; first, to detect species-specific differences and second, to allow us to translate the findings into *in vivo* work in mice, as well as potential clinical trials. We use neurite outgrowth as a measure of neurotoxicity, and find that both mouse primary dorsal root ganglia (DRG) sensory neurons and human fibroblast-derived sensory neurons respond to Paclitaxel and Bortezomib with dose-dependent decreases in neurite outgrowth. We are evaluating full dose responses for different classes of chemotherapeutic agents using a Cellomics Arrayscan XTI system to image and analyze neurite outgrowth. Once we have these mouse and human toxicity profiles, we will begin to explore the mechanisms responsible for the neurotoxicity and assess if we can identify which patients are at risk of developing CIPN by making iPSC lines and assessing if *in vitro* toxicity of derived patient sensory neurons correlates with clinical neuropathy and pain response.

Title: Characterizing the effects of prenatal alcohol exposure on glial-immune responses during chronic neuropathic pain

Authors: *J. SANCHEZ[1,2], A. G. VANDERWALL[2,3], M. S. SUN[2], S. DAVIES[2], T. ANDERSON[3], J. P. NORENBERG[3], D. D. SAVAGE[2,4,5], E. D. MILLIGAN[2,3]; [2]Neurosci., [3]Anesthesiol. and Critical Care, [4]Psychology, [5]Pediatrics, [1]Univ. of New Mexico, Albuquerque, NM

Abstract: Introduction: Neuropathic pain occurs as a consequence of abnormal neuronal signaling. Immune signaling molecules such as cytokines and chemokines derived from activated non-neuronal spinal glial cells (astrocytes and microglia) are critical in mediating the development and maintenance of peripheral neuropathic pain. The pro-inflammatory cytokine, interleukin-1 (IL-1β), and the chemokine, CCL2, mediate neuropathic pain such as mechanical allodynia, which is painful sensitization to light touch. Clinically, individuals with altered immune function leading to peripheral nerve damage experience chronic pathological pain. Additionally, reports indicate that people with fetal alcohol spectrum disorder (FASD) may have aberrant immune responses. Studies in animal models of prenatal alcohol exposure (PAE)

demonstrate that PAE rats stimulated with antigen-specific adjuvants trigger greater disease severity with a protracted time course compared to controls. Therefore, we examined whether PAE resulted in heightened spinal glial activation, cytokine/chemokine levels, peripheral immune cell trafficking into lumbar spinal regions, and greater allodynia compared to non-PAE controls following sciatic nerve damage in adult rats. Methods: Either saccharin controls (Sac) or PAE rats underwent unilateral sciatic nerve chronic constriction injury (CCI) or sham surgery following baseline (BL) behavioral assessment for light mechanical touch (von Frey test), with behavioral re-assessment at 3 and 10 days later. On Day 10 post-CCI, all rats were anesthetized and whole animal nanoSPECT/CT™ imaging was performed. Intravenous indium-111-labeled peritoneal leukocytes (^{111}In-Leuk), collected from same-stock donor rats, were monitored for trafficking into spinal column regions. Following imaging, anesthetized rats underwent transcardial saline and paraformaldehyde perfusion, with subsequent dorsal lumbar (L4-L5) spinal tissue collection and processing for immunohistochemical (IHC) detection of astrocyte & microglial activation. Results: Adult rats with PAE and CCI revealed heightened allodynia, greater spinal lumbar joint (intervertebral discs) leukocyte accumulation, and heightened astrocyte activation compared to sham and/or Sac controls. Ongoing IHC studies are characterizing dorsal lumbar spinal microglial activation, IL-1β, CCL2, CCR2, β_2-Integrins (LFA-1 & MAC-1) and interleukin-10. These results indicate that PAE causes long-lasting alterations in neuroimmune responsiveness that heightens chronic pathological pain.

Title: Alterations in layer 5 pyramidal neurons of prelimbic medial prefrontal cortex in a rat model of neuropathic pain

Authors: *C. J. KELLY, M. MARTINA;
Physiol., Northwestern Univ., Chicago, IL

Abstract: Chronic neuropathic pain is a complex and debilitating condition for which effective treatments are often unavailable. In addition to the sensory component, neuropathic pain is often accompanied by cognitive symptoms such as depression, anxiety, and deficits in decision making and working memory. To understand how pain and cognition interact, the medial prefrontal cortex (mPFC) is a particularly interesting region to explore due to its role in integrating sensory and emotional information and its important role in working memory. Here, we examine pyramidal neurons in layer 5 of prelimbic mPFC in the spared nerve injury (SNI) rat model of neuropathic pain. We find that dendritic length and branching are decreased in SNI, specifically in the proximal apical dendritic region (the apical dendrite excluding the tuft). There is a corresponding slight reduction of frequency of mEPSC events. This reduction appears selective for smaller events, consistent with the idea that more distal synapses are particularly affected while basal dendrites near the soma are unaffected. The evoked synaptic current at a holding potential of -70 mV is also reduced in SNI animals. Somewhat unexpectedly, however, we did not detect any impairment in LTP in these neurons. Due to the localized morphological changes and the large variability in evoked responses, we hypothesize that changes in this region are input-specific.

Title: Antisense oligodeoxynucleotides CPEB suppresses neuropathic pain induced by HIV gp120 combined with ddC through ROS and CBP in Rats

Authors: *T. IIDA, S. LIU, H. YI, W. HUANG, D. LUBARSKY, S. HAO;
Univ. of Miami Dept. of Anesthesiol., Miami, FL

Abstract: Patients with HIV infection have numerous complications including neurological disorders. HIV-associated sensory neuropathy is one of the most common form of neuropathies. Both HIV infection-related distal sensory polyneuropathy and antiretroviral toxic neuropathy contribute HIV-related painful sensory neuropathy. The exact molecular mechanisms of HIV-associated neuropathic pain are still elusive. Cytoplasmic-element-binding (CPEB) protein is a sequence-specific RNA-binding protein that regulates protein translation involved in inflammation. Our previous studies showed that ROS was involved in the HIV-related pain. The role of cyclic-AMP response element-binding protein (CREB)-CREB binding protein (CBP) transcription factor in HIV neuropathic pain is not clear. In this study, we tested whether CPEB, ROS or CBP played a role in a rat pain model of HIV gp120 combined with anti-retroviral therapy. Neuropathic pain was induced by HIV coat protein gp120 application combined ddC (an anti-HIV drug). Mechanical threshold was measured using Von Frey fibers. Intrathecal antisense oligodeoxynucleotides (AS ODN) against CPEB, and mitochondrial superoxide scavenger Mito-Tempol reduced neuropathic pain. CPEB-AS treatment suppressed mitochondrial oxidative stress. Mito-Tempol reduced the expression of CBP in the spinal dorsal horn in the HIV pain model. Our results suggest spinal CPEB play a role in a rat pain model of HIV gp120 combined with anti-retroviral therapy through ROS and CBP.

Title: A role for noradrenergic modulation in neuropathy-induced hyperexcitability of pyramidal neurons in the medial prefrontal cortex

Authors: *S. CORDEIRO MATOS[1,2], Z. ZHANG[1,2], G. LONGO[3,2], A. RIBEIRO-DA-SILVA[3,2], P. SEGUELA[1,2];
[1]Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [2]Alan Edwards Ctr. for Res. on Pain, Montreal, QC, Canada; [3]Pharmacol. and Therapeut., McGill Univ., Montreal, QC, Canada

Abstract: It is well established that hyperpolarization-activated cyclic nucleotide-gated (HCN) channels regulate a variety of critical neuronal properties. Moreover, cationic currents mediated by HCN channels (Ih) play a role in peripheral pain pathways by facilitating ectopic firing and hyperexcitability. Consistently, mice in which HCN2 channels were selectively deleted in

Nav1.8-positive DRG nociceptors showed no neuropathic pain in response to mechanical and thermal stimuli. However, little is known regarding the role of Ih in supraspinal pain pathways. The medial prefrontal cortex (mPFC) is involved in affective aspects of pain and exhibits high HCN channel expression. Using the rat spared nerve injury (SNI) model of chronic neuropathic pain and whole-cell patch-clamp recordings in layer II/III pyramidal neurons of the mPFC, we observed a hyperpolarizing shift in the voltage-dependent activation of HCN channels in contralateral SNI neurons. Consistently, SNI neurons exhibited increased input resistance and excitability compared to sham neurons. However, the amplitude and density of maximal Ih were not significantly different between both groups. We previously observed that HCN channels modulate mGluR5-mediated persistent firing (PF), a cellular substrate for working memory, in layer II/III pyramidal neurons of the mPFC and that norepinephrine enhances PF via postsynaptic alpha-2 adrenoceptor-mediated HCN channel inhibition. Interestingly, subthreshold doses of the group 1 mGluR agonist DHPG evoked PF in SNI but not sham prefrontal neurons. Hence, this phenomenon may contribute to enhanced attention to pain and/or pain-related mnemonic processing. Furthermore, application of bromo-cAMP shifts the activation curve of HCN channels to more depolarized potentials in SNI neurons whereas application of the alpha-2 agonist clonidine induces a similar hyperpolarizing shift in the voltage-dependent activation of HCN channels as seen in SNI conditions. Interestingly, we further observed an increased density of noradrenergic fibers in the mPFC of SNI rats. These data suggest that noradrenergic modulation plays an important role in the HCN channel dysfunction observed in SNI neurons. Acute mPFC infusion experiments to investigate the behavioral consequences of altering cAMP levels or blocking HCN channels directly in sham and SNI rats are currently on-going.

Title: The first translatable prediction biomarker of painful peripheral neuropathy

Authors: *M. I. NEMENOV[1,2], M. BACKONJA[3,1];
[1]Lasmed LLC, Mountain View, CA; [2]Anesthesia, Stanford Univ., Stanford, CA; [3]Neurol., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Mechanisms of painful peripheral neuropathies (PPN) are still not well known and biomarkers are not available. Currently, there are no effective treatments or predictive biomarkers that would aid in preventing development of PPN. Recently, it was demonstrated that spontaneously active (SA) small diameter nociceptive C and Aδ fibers are a likely source of chemotherapy induced painful neuropathy (CIPN) in rodents and humans. Paradoxically, spontaneous activity of these C fibers is correlated with skin denervation and deficits in sensation in patients with chronic pain. In humans, the majority of SA fibers are subepidermal C mechano-insensitive fibers. Surface (contact, radiant or CO2 laser) heat stimulation as a method of testing small diameter fibers allows only for simultaneous activation of both superficially located Aδ and C fibers and does not allow for independent activation of fibers located deeper in the skin. Thus, there is an unmet medical need for a mechanism-based, reliable clinical biomarker for the risk for painful CIPN that would be translatable to, preclinical biomarkers for analgesic development. To address all of these deficiencies we developed a technique to selectively access Aδ and C fibers using diode laser fiber type selective stimulation (DLss). DLss radiation penetrates deep the in skin, homogeneously heats superficial and subepidermal skin layers, and allows access to deeply located SA C fibers in humans and rodents (Moeller-Betram et al., Pain Medicine 2013, Greffrath et al., Pain 2002). We tested patients with peripheral painful diabetic neuropathy and CIPN and found that, in spite of skin denervation, the intensity of response thresholds of C fibers was not increased compared to healthy subjects, as it would have when non-selective radiant, contact, or CO2 laser heat stimulation are applied. However, the intensity of thresholds for Aδ was increased compared to healthy subjects. Such results can be explained only because DLss activates sensitized SA C fibers located deep in the skin. We hypothesize that ratios between DLss intensity required for threshold stimulation of Aδ and C fibers could be a sensitive biomarker for early stage development of PPN and Aδ/C ratios change before pain symptoms begin. We find a significant difference when ratios between healthy subjects and patients with painful diabetic neuropathy and painful CIPN are compared. DLss is a noninvasive device that is appropriate for mechanisms based translational therapeutic development and for fast transition to the market. that would follow 510K guidelines.

Title: Neuropathic pain behavior is reversed with epoetin alpha: a pilot study in the NeuroDigm GEL(TM) model of neuropathic pain

Authors: ***M. R. HANNAMAN**[1], D. A. FITTS[2], J. L. BRYANT[3];
[1]NeuroDigm Corp, Colorado Springs, CO; [2]Univ. of Washington (ret.), Arlington, WA; [3]Univ. Of Maryland, Baltimore, MD

Abstract: INTRODUCTION: The biological physiology creating persistent neural pain after a soft tissue injury in man has not been studied. In order to create a physiological model of persistent neural pain without acute nerve injury the last stage of tissue healing, called tissue remodeling, was reproduced in this model creating a neural lesion. This neural site was then treated with a biologic. METHODS: 14 male rats from a prior study had a percutaneous perineural depot of GEL by the posterior tibial nerve. The GEL was created of tissue components and peptides and induced mechanical hyperalgesia (pinprick) for 4 months until end of study. After this experiment was over, the 14 GEL rats continued in a pilot study and received injections of epoetin alfa (EPO) 200 units in normal saline at the site of the original GEL procedure (n = 5), a subcutaneous EPO injection of 200 units in NS (n = 4), or EPO control (no injection, n = 5). Days 140 and 149 after the GEL injection were taken as baseline days and then EPO was injected in the EPO groups on day 152. Pinprick data were collected on days 152, 153, 154, 156, 159, and 160 (end of study). The resulting data were analyzed using a mixed model ANOVA with EPO injection group as the between subjects factor (3 groups) and days as one repeated measures factor (7 days) and side as a second repeated measures factor (left and right paws). RESULTS: The groups-by-days interaction was significant ($F(14, 77) = 8.208$, $p < .001$) indicating that the 3 groups in this pilot study (EPO at site, EPO Subcutaneous and Control) were the same on days before the treatment and different on days after the treatment. EPO subcutaneous had no effect. EPO at the site in 5 rats significantly reduced paw withdrawals in response to pinprick on 5 test days over 7 days to the same extent on the right and left sides ($p < .001$). CONCLUSION: The targeted application of epoetin alfa decreased for 7 days the pain behaviors that had persisted for 4 months. The targeted delivery of a biologic, such as epoetin alpha, near a neural lesion long after a soft tissue injury may be able to reverse neuropathic pain behaviors.

Title: Impact of genetic reduction of NMNAT2 on chemotherapy-induced losses in cell viability *in vitro* and peripheral neuropathy *in vivo*

Authors: *R. SLIVICKI[1], Y. O. ALI[3], H.-C. LU[3], A. G. HOHMANN[2];
[1]Psychological and Brain Sci., [2]Indiana Univ., Bloomington, IN; [3]Dept. of Pediatrics, Baylor Col. of Med., Houston, TX

Abstract: Nicotinamide mononucleotide adenylyl transferases (NMNATs) are essential neuronal maintenance factors postulated to preserve neuronal function and protect neurons from axonal degeneration. NMNAT1 and the NMNAT associated Wallerian degeneration slow (Wlds) protein have been shown to protectt against chemotherapy insult *in vitro*. We hypothesized that NMNAT2 plays a protective role against neurotoxic effects of chemotherapeutic agents. We used *in vitro* and *in vivo* approaches to assess the impact of NMNAT2 reduction on cellular and physiological functions induced by treatment with a vinca alkaloid (vincristine) and a taxane-based (paclitaxel) chemotherapeutic agent. Primary cortical neurons prepared from NMNAT2 null embryos were rendered sensitive to degeneration triggered by either vincristine or paclitaxel treatment. NMNAT2 null mutant (NMNAT2-/-) mice die at birth whereas NMNAT2 heterozygous (NMNAT2+/-) mice exhibit a 50% reduction of normal NMNAT2 levels and survive to adulthood (Hicks et. al (2012) PLoS One. 7(10): p. e47869). Therefore, we examined the impact of NMNAT2 knockdown on the development and maintenance of chemotherapy-induced peripheral neuropathy induced by vincristine and paclitaxel in NMNAT2+/- and wild type (WT) mice. NMNAT2 (+/-) did not show altered responses during the development or the maintenance of either mechanical or cold allodynia induced by either vincristine or paclitaxel treatment compared to WT mice. Intradermal injection of capsaicin, the pungent ingredient in hot chili peppers, failed to unmask differences in nociceptive responses in NMNAT2+/- and WT mice rendered neuropathic by previous toxic challenges with paclitaxel. Moreover, no differences in motor behavior were detected between genotypes in the rotarod test. Our studies demonstrate that a 50% reduction of NMNAT2 is not sufficient to alter the development or maintenance of mechanical or cold allodynia induced by vincristine or paclitaxel treatment. Our studies do not preclude the possibility that complete knockout of NMNAT2 in a conditional

knockout animal would unmask a role for NMNAT2 in protection against detrimental effects of chemotherapeutic treatment.

Title: Role of microRNAs in oxaliplatin-induced neuropathy

Authors: *M. LÓPEZ GONZÁLEZ[1], S. BENQUET[1], F. VIANA[2], M. LANDRY[1], A. FAVEREAUX[1];
[1]Central mechanisms of pain sensitization, Interdisciplinary Inst. For Neurosci., Bordeaux Cedex, France; [2]Inst. de Neurociencias de Alicante, Univ. Miguel Hernández-CSIC, San Juan de Alicante, Spain

Abstract: Oxaliplatin is a reference chemotherapeutic drug for the treatment of gastrointestinal tract tumors that induces sensorial neuropathy in 70% of patients. Oxaliplatin induces acute side effects, such as cold hypersensitivity, dysesthesia and paraesthesia, and can evolve to a long-term neuropathy in a fraction of the affected patients (around 15-20%). The chronic side effects may be severe enough to prevent patients from performing daily life activities and include impaired sensation, sensory ataxia, and/or deficit in fine sensory-motor coordination. This can oblige physicians to limit the treatment with potentially useful anticancer drugs. We have developed a mouse model that mimics patients' symptoms with a single intraperitoneal injection of oxaliplatin. By behavioral studies such as dynamic weight bearing, we saw that impaired sensation and motor coordination appear three days after injection and last for several weeks. We also saw that oxaliplatin treatment reduces arborization of sensory neurons in culture in a dose-dependent manner. In order to characterize how the regulation of gene expression may play a role in oxaliplatin neuropathy, we have screened all miRNAs in mouse genome. We focused our attention to miRNAs having a role in axon guidance and neurite outgrowth. As a result, we highlighted miR-204, a miRNA that controls expression of two axon guidance molecules; PlexinA2, a receptor of Semaphorin6A, and DCC, a receptor of Netrin-1. Interaction of miR-204 and its targets was confirmed at molecular level. Furthermore, overexpression of miR-204 in dorsal root ganglia (DRG) neuron cultures reduces expression of PlexinA2 and DCC at RNA level, but also reduces length and extension of DRG neuron processes. Our hypothesis is that

oxaliplatin impairs sensitivity and motor coordination by a reduction in axon arborization of DRG neurons through an overexpression of miR-204 that reduces PlexinA2 and DCC expression.

Title: Pentoxifylline ameliorates chemotherapy-induced neuropathic pain in rats by decreasing inflammatory cytokines in the dorsal root ganglia

Authors: *H. KIM, S.-H. HWANG, H. LEE, S. ABDI;
Dept. of Pain Med., MD Anderson Cancer Ctr., Houston, TX

Abstract: Chemotherapy agents including taxanes, vinca alkaloids, and platinum complexes produce peripheral neuropathic pain which is a dose-limiting side effect. We previously reported that pentoxifylline (PTX) ameliorates paclitaxel (PAC)-induced neuropathic pain in rats. The purpose of this study was to investigate the effects of PTX on the PAC-induced inflammatory cytokines production in dorsal root ganglia (DRG). Adult male Sprague-Dawley rats received i.p. injection of Paclitaxel (2 mg/kg on days 0, 2, 4, 6) or vehicle (4% dimethyl sulfoxide and 4% Tween 80 in saline). PTX treated rats were administered with PTX, 100 mg/kg i.p. and then the L1-6 DRGs were obtained at 1 hour post injection. The DRGs were dissected, homogenized in RIPA lysis buffer, separated in SDS polyacrylamide gens and then transferred to polyvinylidene fluoride membrane. For detections, blots were incubated with the primary antibody to phosphorylated NFκB (p- NFκB), IL-1β, TNF-α, and GAPDH, respectively and then incubated with the horseradish peroxidase-conjugated secondary antibody. The immunoblots were detected by a chemiluminescence detection system and normalized to GAPDH. Equal protein loading was performed using GAPDH expression as a control. PAC significantly increased the levels of p-NFκB, TNF-α and IL-1β in the DRGs at 14 days after the first PAC injection. Further, PAC-induced increase in p-NFκB, TNF-α, and IL-1β protein levels in the DRGs was decreased by PTX treatment. This result indicates that PAC increases the production of phosphorylated NFκB,

TNF-α, and IL-1β in the DRGs and inhibition of PAC-induced inflammatory cytokines levels in the DRGs may be one of the mechanisms underlying the analgesic effect of PTX for chemotherapy-induced neuropathic pain in rats.

Abstract: Neuropathic pain occurs by peripheral nerve injury and hyperalgesia or allodynia persists for a long time, which was attenuated in knock-in mouse with mutation of Tyr1472 to Phe of GluN2B (Y1472F KI). To clarify the mechanisms of neuropathic pain, we have analyzed the postynaptic density (PSD) fraction of spinal dorsal horn using Y1472F KI mouse after spared nerve injury (SNI) by proteomic approach and identified brain enriched guanyulate kinase associated protein (BEGAIN) as a novel neuropathic pain-related molecule in the neuropathic pain. A previous SfN meeting, we showed that mechanical allodynia by SNI, but not basal transmission, was significantly attenuated in BEGAIN knockout (KO) mice as compared to wild-type mice. Recently, we made BEGAIN specific antibody, and analyzed the localization of BEGAIN in the brain and spinal dorsal horn. BEGAIN was enriched in cerebellum, hippocampus and the dorsal horn, but not ventral horn, of the spinal cord. Moreover, BEGAIN was enriched in crude postsynaptic density (cPSD) in the hippocampus and spinal dorsal horn. The specific signal of BEGAIN was detected in layer II of spinal dorsal horn with IB4, a marker of layer IIi, and it was colocalized with PSD-95 and synaptophysin in the spinal dorsal horn, but

not GFAP-positive cell. Previous reports using BEGAIN KO mice and these results suggest that BEGAIN is involved in neuropathic pain in the spinal dorsal horn.

Title: Dendritic spine remodeling in lamina II dorsal horn sensory neurons after SCI

Authors: *L. W. PAPPALARDO, X. C. CAO, S. G. WAXMAN, A. M. TAN;
Yale Univ., New Haven, CT

Abstract: Neuropathic pain is a major complication of spinal cord injury (SCI) and despite aggressive efforts this type of pain is often refractory to available clinical treatment. Our previous work revealed a structure-function relationship between abnormal dendritic spine profiles on nociceptive sensory neurons in the deeper intermediate zone of the dorsal horn (laminae IV/V), and neuropathic pain following spinal cord injury (SCI). To extend these findings, we investigated whether abnormal dendritic spine remodeling occurs on superficial dorsal horn neurons located in the substantia gelatinosa, lamina II, after SCI. This region of the gray matter in the spinal cord is primarily involved in the integration of sensory stimuli that manifest as sensations of heat and pain. Although the literature has documented the presence of dendritic spines on lamina II neurons, their profiles have not been characterized following disease or injury. In this study, we analyzed dendritic spine morphometry and localization in adult rats one month after thoracic contusion SCI. In contrast to our previous published findings, the overall density of dendritic spines on sampled lamina II neurons did not increase. Instead, we observed a morphometric “switch”_ the density of thin-shaped dendritic spines decreased, whereas the density of mushroom-shaped spines concomitantly increased. Computer simulation data suggests that this switch from thin to mushroom spines (i.e., structures associated with

enhanced synaptic efficacy) in the superficial dorsal horn can contribute to nociceptive hyperexcitability. Intrathecal delivery of the Rac1-inhibitor, NSC23766, in animals with SCI significantly blocked the injury-induced switch from thin- to mushroom-shaped dendritic spines in lamina II. Taken together, these observations further support the link between abnormal dendritic spine remodeling and neuropathic pain after SCI, and the notion that dendritic spine dysgenesis can contribute to abnormal nociception.

Title: Characterization of the neuronal circuits in the spinal superficial dorsal horn: the application of multi-electrode array and cross-correlation analysis

Authors: Y. TAKEMURA, T. ASAKAWA, T. TERASHIMA, T. TAKASUSUKI, S. YAMAGUCHI, *Y. HORI;
Dokkyo Univ. Sch. Med., Tochigi, Japan

Abstract: Simultaneous recording of multi-neuronal activities using a multi-electrode array (MEA) system seems to be a powerful technique for characterizing neuronal interactions in local neural circuits. In the present experiment, we recorded spike activities simultaneously from multiple neurons in the spinal superficial dorsal horn (SDH) using the MEA system, and performed cross-correlation analysis of the spike trains in an attempt to characterize further the synaptic circuits underlying nociceptive processing in the spinal cord. Experiments were performed on 6- to 8-week-old male ICR mice. Under halothane anesthesia, the lumbar spinal cord was removed and transverse slices (400 μm in thickness) were made. The slices were placed into a recording chamber with the MEA (Multi Channel Systems, Germany). Electrodes were arranged 200 μm apart in an 8x8 pattern. The signals from the MEA electrodes were notch-filtered at 50 Hz to reduce power-line interference and sampled at 25 kHz. Only signals recorded from MEA electrodes located in the SDH were analyzed in the present experiments. In some

experiments, the sciatic nerve was partially ligated under halothane anesthesia according to Seltzer et al. (1990), and the development of mechanical allodynia was assessed by von Frey filaments. Off-line analysis of spike trains was conducted using DataView (Heitler, 2009). Single-unit spike trains were sorted from the recordings. Cross-correlograms between spontaneous spike trains of simultaneously recorded neurons in the SDH were constructed. The most frequent pattern observed in cross-correlograms was a flat histogram, indicating that there is no synaptic interaction between two neurons. However, a considerable number of neuron pairs exhibited significantly correlated activities. Among them were 1) common synaptic input to neuron pairs, which is evident from the presence of a central peak in the cross-correlogram; and 2) short-latency, monosynaptic excitatory and/or inhibitory interaction between neuron pairs, which is evident from the presence of a lagged peak and/or trough. Additionally, the incidence of significant cross-correlation between neural activities was increased in mice subjected to partial sciatic nerve ligation. The present observations seem to indicate that neurons in the SDH make excitatory and/or inhibitory synapses on the nearby neurons, and that synaptic connections among neurons in the SDH might change significantly after the development of neuropathic pain.

Title: Mitochondrial fission is involved in the HIV gp120-related neuropathic pain in rats---a preliminary study

Authors: S. LIU, H. KANDA, C.-H. LIU, W. HUANG, D. A. LUBARSKY, *S. HAO;
Dept Anesthesiol., Univ. Miami, Miami, FL

Abstract: Human immunodeficiency virus (HIV) infection induces painful sensory neuropathy in HIV/IDS patients, but the exact molecular mechanisms of HIV neuropathic pain are elusive. Mitochondrial fusion and fission regulate cellular signaling, development, and mitochondrial homeostasis. In the present studies, we investigated the role of mitochondrial dynamin-related protein 1 (Drp1, a GTPase that mediates mitochondrial fission) in the HIV coat glycoprotein gp120-induced neuropathic pain state, and in gp120 with chronic morphine state. Neuropathic pain was induced by the application of recombinant HIV-1 envelope protein gp120 into the sciatic nerve. In the gp120 with chronic morphine pain state, rats received repeatedly intrathecal gp120 and chronic morphine. Mechanical threshold was tested using von Frey filaments. Mitochondrial superoxide in the spinal dorsal horn was measured using mitoSox (a mitochondrial superoxide indicator) profile cells. Intrathecal administration of either antisense oligodeoxynucleotide (ODN) against Drp1 or mitochondrial division inhibitor-1 (mdivi-1) decreased mechanical allodynia in the peripheral gp120 model. Moreover, both intrathecal Drp1 antisense ODN and mdivi-1 reversed the upregulation of mitochondrial superoxide in the spinal dorsal horn in the peripheral gp120 neuropathic pain state. In the neuropathic pain model of gp120 plus morphine, intrathecal mdivi-1 reversed mechanical allodynia either. We will discuss the different effects and the possible pathway. These data suggested mitochondrial division is involved in the HIV gp120-related neuropathic pain state.

Title: Prolonged paclitaxel exposure modulates CGRP release induced by the activation of PKC in cultures derived from rat dorsal root ganglion

Authors: *L. DARBY, J. C. FEHRENBACHER;
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Paclitaxel is a microtubule stabilizing agent that is used in the treatment of solid tumor cancers such as breast, ovarian and lung cancer. Despite the efficacy of paclitaxel in cancer therapy regimens, patients are frequently forced to discontinue treatment due to the onset of peripheral neuropathy. Currently, no prophylactic or therapeutic treatments exist for peripheral neuropathy. This is, in large part, due to the lack of understanding regarding the basic mechanisms of action by which paclitaxel alters neuronal activity. A recent report demonstrates the activation of protein kinase C (PKC) following a 1-hr treatment of dorsal root ganglion (DRG) cultures with paclitaxel. Given that downregulation of PKC isozymes is pervasive upon persistent stimulation, we hypothesized that a prolonged exposure of sensory neurons to paclitaxel (48-72hr) would result in the downregulation of PKC and that this downregulation could underlie a loss of function observed in the sensory neurons, as we demonstrated previously. To address our hypothesis, we used an *in vitro* model of paclitaxel-induced neurotoxicity in primary cultures derived from rat DRG. The stimulated release of calcitonin gene-related peptide (CGRP) from these cultures was used to indicate activity of the peptidergic population of sensory neurons. In the absence of paclitaxel, activation of classic and novel PKC's with phorbol 12, 13 dibutyrate (PDBu; 10nM) enhanced CGRP release and this release was inhibited by **bisindolylmaleimide I** (1μM). After paclitaxel treatment, however, PDBu-stimulated release was attenuated in a concentration- and time- dependent manner, suggesting that paclitaxel decreases the function of one or more classic and/or novel PKC isozymes. Because PKCε has been proposed to play a major role in nociceptive signaling, we first examined expression of this isozyme. Paclitaxel decreased PKCε in a concentration- and time-dependent manner. Thus, the downregulation of PKCε is a possible mechanism by which paclitaxel attenuates neuronal activity of peptidergic sensory neurons. Further work is necessary to demonstrate a functional effect of PKCε activation and downregulation and to determine the role of other PKC isozymes in mediating the effects of paclitaxel on neuronal sensitivity.

Title: Different types of reactive oxygen species are involved in cell type specific synaptic plasticity

Authors: *A. BITTAR, J. JUN, J. WANG, K. CHUNG, J. CHUNG;
Dept Neurosci & Cell Biol, Univ. Texas Med. Br., Galveston, TX

Abstract: It has been demonstrated that spinothalamic tract neurons (STTn) develop long term potentiation (LTP) while GABAergic interneurons (GABAn) develop long term depression (LTD) in response to the same intense afferent stimulation. Both LTP in STTn and LTD in GABAn seem to contribute to neuropathic pain. Recent study further showed that the induction of these two opposite synaptic plasticity is related to the different types of reactive oxygen species (ROS) that are generated within these two types of neurons. Our current hypothesis is that not only the induction but also the maintenance of the LTP in STTn and LTD in GABAn depend on superoxide and hydroxyl radicals, respectively. To test this hypothesis, the effects of specific ROS scavengers on the maintenance of STT/LTP and GABA/LTD and pain behavior are examined in the mouse model of spinal nerve ligation (SNL) neuropathic pain. Whole cell patch clamp recordings were used to test the effect of specific ROS scavengers on evoked excitatory postsynaptic currents (eEPSCs) in STTn and GABAn with afferent conditioning stimulations (ACS) to the dorsal root entry zone (DREZ) of the spinal cord. The effects of a general ROS scavenger PBN, superoxide scavenger TEMPOL (1 mM) and hydroxyl radical scavengers DMSO (100 mM) and DMTU (20 mM) were examined. The specific scavengers were applied to the recording chamber for 10 min either before (for induction) or 20 min after (for maintenance) the ACS. The effects of same scavengers on mechanical hypersensitivity of the foot were tested in SNL mice. TEMPOL blocked induction and reversed both STT/LTP and GABA/LTD maintenance as well as hypersensitivity in neuropathic mice. DMSO/DMTU reversed only GABA/LTD maintenance and partially inhibited hypersensitivity. Results indicate that superoxide radicals are involved in both STT/LTP and GABA/LTD induction and maintenance, whereas hydroxyl radicals contribute only to GABA/LTD. Furthermore, mechanical hypersensitivity in SNL mice is the result of the combination of STT/LTP and GABA/LTD in the dorsal horn.

Title: The effect of partial sciatic nerve ligation on gabaergic function in the superficial dorsal horn: application of voltage-sensitive dye imaging system

Authors: *K. KANEKO[1], T. FUKUSHIMA[1], Y. NUMATA[2], T. TAKASUSUKI[2], S. YAMAGUCHI[2], Y. HORI[1];
[1]Dept. of Physiol. and Biol. Information, [2]Dept. of Anesthesiol., Dokkyo Med. Univ., Tochigi, Japan

Abstract: The dysfunction of GABAergic inhibition in the superficial dorsal horn (SDH) causes the neuropathic pain, but the precise mechanisms are not fully elucidated. To better understand the pathological process of neuropathic pain, we investigated the effects of the partial sciatic nerve ligation (PSNL) on GABAA receptor function in the SDH by means of voltage-sensitive dye imaging. Under halothane anesthesia, 3-week-old male ICR mice were subjected to PSNL according to Seltzer et al. (1990). The mechanical allodynia was assessed with a von Frey filament. Control mice were sham-operated. The optical imaging experiments were performed one week after surgery. The spinal cord was removed under ketamine and xylazine anesthesia. The transverse spinal cord slices (400 μm in thickness) were prepared. The slices were stained with a voltage-sensitive dye Di-4-ANEPPS (Wako, Japan), then rinsed with Krebs solution. After staining, the slices were placed into the recording chamber on the microscope stage. The slices were routinely perfused with oxygenated Krebs solution containing tetrodotoxin. The Di-4-ANEPPS fluorescence was measured using the MiCAM2 optical imaging system (Brain Vision Inc., Japan). We analyzed fluorescence change in the SDH in response to bath-application of GABA. The bath-applied GABA increased Di-4-ANEPPS fluorescence in the SDH. This fluorescence increase was abolished by a GABAA receptor antagonist bicuculline. Thus, the fluorescence increase corresponds to membrane hyperpolarization by GABAA receptor activation. The amplitude of GABA-induced fluorescence increase was significantly smaller in PSNL mice than in control mice. The time course of the GABA response was significantly longer in PSNL mice than in control mice. The presently observed decreased amplitude of GABA-induced fluorescence change might be explained by down-regulation of GABAA receptors in the SDH or by a depolarizing shift in the chloride equilibrium potential of the SDH. The attenuated inhibitory response would lead to the initiation of neuropathic pain. It has been reported that the GABAA receptor subunit composition influences channel kinetics. The long time course of GABA response observed in PSNL mice seems to suggest that changes in the subunit composition are associated with PSNL-induced allodynia. Thus, we are currently performing real-time RT-PCR analysis for GABAA receptor subunits in PSNL mice. Such a experiments might provide a clue to the pathogenesis of neuropathic pain.

Title: Minocycline prevents establishment of sensory hypersensitivity after a median nerve crush in rats

Authors: *S. SHAIKH, P. SHORTLAND, D. A. MAHNS;
Univ. of Western Sydney, Campbelltown, Australia

Abstract: Median nerve injury in the area of the axilla produces a bilateral hypersensitivity to mechanical and thermal (noxious heat and innocuous cold) stimuli that appears in the glabrous fore-paw within a week of the injury and persists for several weeks. The mechanisms underlying these phenomena remain to be elucidated. Nerve injury evokes a central glial reaction that is known to contribute to pain hypersensitivity. Drugs such as minocycline are known to affect microglial function and ameliorate pain sensitivity. This study has tested the hypothesis that minocycline can prevent the establishment of hypersensitivity after median nerve crush. Rats underwent unilateral median nerve injury or sham operation with naïve rats as controls. All animals were then randomized to receive either minocycline (40mg/kg i.p.) or a normal saline injection daily for 2 up to weeks. Researcher conducting the behavioural assessment randomized the mechanical and thermal tests and was blinded to the drug administration. Following behavioural assessment, animals were sacrificed and the C6-7 spinal cord and its corresponding ganglia were removed for immune-histochemical staining (microglia and astrocytes) or proteomic profiling of the dorsal horn of the spinal cord (2D gel electrophoresis using Coomassie brilliant blue). Consistent with our observation following median nerve transection a unilateral crush injury resulted in a 25-50% reduction in the withdrawal thresholds for tactile and noxious heating and the emergence of a marked intolerance to previously innocuous cooling. Minocycline successfully prevented the initiation and maintenance of behavioural hypersensitivity. Furthermore, comparison between vehicle treated (0.9% saline) and minocycline treated animals revealed a marked hypoalgesia in minocycline treated animals. Immuno- histochemical analysis of glial markers in the dorsal horn of the spinal cord (IBA-1 and GFAP) will define the relative contributions of neural versus non-neural contributions to hypersensitivity in this model. Furthermore, a non-selective proteomic profiling of the dorsal horn will reveal the up-regulated or down-regulated proteins centrally due to a peripheral nerve injury.

Title: Recruitment of unimodal and multimodal neurons during sensory-induced motor pattern selection

Authors: *C. J. GOLDSMITH, W. STEIN;
Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Most motor systems can generate a variety of behaviors, including categorically different behaviors and variants of a single motor act within the same behavioral category. In many cases this multifunctionality results from dynamic adaptations of existing, highly interconnected neural circuits. This temporary restructuring of the motor circuits is controlled by descending extrinsic projections that alter motor activity in response to different sensory stimuli. The mechanisms by which motor pattern selection is controlled in different sensory conditions are largely unknown. We examined motor pattern control in the crustacean stomatogastric nervous system where several projection neurons in the paired commissural ganglia (CoGs; Stein, *J Comp Physiol A* 2009) are activated by sensory pathways and modulate downstream motor circuits. While selective stimulation of individual CoG projection neurons can elicit distinct versions of the gastric mill motor pattern (Nusbaum & Beenhakker, *Nature* 2002), typically several projection neurons are activated by sensory stimulation. Since it has been shown that some CoG neurons receive inputs from multiple sensory modalities, we hypothesize that distinct but overlapping sets of CoG neurons are activated by sensory pathways to determine the output activity of the motor circuits. Using voltage-sensitive dye imaging, we found that the population activity of CoG neurons differs during stimulation of 3 different sensory modalities that elicit distinct gastric mill rhythms. CoG neurons displayed a variety of rhythmic and non-rhythmic activity patterns. Sensory stimulation altered the activity of many CoG neurons and recruited some into the various motor patterns. Specifically, 39.6 % of visible cells in N= 6 CoGs began to exhibit rhythmic membrane potential oscillations that were timed with the gastric mill

rhythm. CoG activity patterns continued after stimulation and were recognizable for the duration of the motor pattern. Changes in CoG neuron activity were correlated with those in the gastric mill rhythm such that weaker CoG neuron activity corresponded to weaker motor patterns. CoG neuron activity returned to baseline when the gastric mill rhythm stopped. This was consistent across modalities. Our data also indicate a differential activation of CoG neurons across modalities: distinct, but overlapping pools of CoG neurons were recruited. In total, 25.1 ± 8.3 % of all gastric mill-timed neurons (N=6 CoGs) were multimodal and responded to at least two sensory modalities. Currently, we are analyzing the individual combinations of CoG neurons activated to better understand their contribution to motor pattern control.

Title: Topological identification of projection neurons controlling motor circuits

Authors: *R. FOLLMANN, C. J. GOLDSMITH, W. STEIN;
Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Modulatory projection neurons play a key role in the control of multifunctional central pattern generator circuits by selecting distinct output patterns in different sensory conditions (Hedrich et al. 2009, J Neurophys). Projection neurons are influenced by many extrinsic inputs (Rossignol et al. 2006, Physiol Review), but the responses of discrete classes of projection neurons vary: some are very similar to others while some show substantially different responses. Little is known about whether the anatomical organization of projection neurons contributes to these response profiles. We are using the crustacean stomatogastric nervous system to examine this issue, aiming to better understand the roles of projection neurons in motor pattern selection. Here, we are particularly interested in the topological and structural identification of projection neurons in the commissural ganglia (CoGs) of C. Borealis. Each CoG contains around 20 neurons projecting to downstream motor circuits (Coleman et al. 1992, J Comp Neurol). An

unknown number of projection neurons that innervate other targets plus local interneurons involved in sensory processing are also present. Relative somata location was determined using a combination of retrograde backfills of projection neuron axons and CoG cell membranes stainings with lipophilic fluorescent dyes (Goldsmith et al. 2014, PLoS ONE). A topological reconstruction of the commissural ganglia was achieved by analyzing stacks of 100 individual photos in different focal planes (2 μm steps) for each CoG. A non-rigid registration was applied to stacks from several CoGs to put them into a common coordinate system. We used landmarks like the particularly large L-cell (Cooke & Goldstone, 1970, J Exp Biol) to help align the photos. Overall CoG topology was fairly stable across ganglia. CoGs had an approximate oval shape with average major and minor axis of 537.65±59 and 400.72±44 μm, respectively, and average dorsal to ventral size of 171±12 μm (N=4). We observed an average of 139.25±30 (N=20) CoG somata with diameters ranging from 5 μm to 75 μm, of which 74±5.2% were smaller than 20 μm. Our initial analysis shows that at least for larger cells somata location was rather conserved across ganglia. Projection neurons innervating the same target circuits were distributed across several layers of CoG cells, with some clustered together dorsally near the entrance of their axons to the CoG. We are currently testing whether there is segregation of projection neuron somata to discrete CoG regions and whether this may contribute to their distinct responses to sensory activity.

Title: Compartmental Hodgkin-Huxley model equations applied to the study of axonal modulation

Authors: *E. ROSA[1], R. FOLLMANN[2], W. STEIN[2];
[1]Physics, [2]Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Axons, although often thought of as mere conductors of action potentials, may have an important role in neuronal information and encoding. Ionotropic and metabotropic receptors for transmitters and neuromodulators found along the axon trunk can alter conduction velocity,

induce spike failures and initiate ectopic spiking, all of which in turn are capable of influencing information generation and processing. While these facts have long been ignored, recent advances in electrophysiological, imaging and molecular techniques show that the properties of the axon trunk potentially increase the computational capability of the neuron (Bucher et al, Prog Neurobiol 2011). Yet, these effects are difficult to study and an in-depth understanding of the influence of axon trunk modulation on the dynamics of spike propagation and initiation is still amiss. To provide insights into these dynamics, we are studying axon modulation in a Hodgkin-Huxley model of an axon trunk, consisting of a series of compartments with active properties. The model produces measurable action potential propagation delays, displaying a clear history-dependence and a concomitant change in firing rate at the distal end. Axon modulation causing ectopic spiking was implemented by altering the excitability of a few axonal compartments in the middle of the trunk. In specific, we added an h-current I_h to these compartments, since this current has been shown to be present and modulated in motor axons (Ballo et al, J Neurosci 2010) and we have experimental evidence that it underlies ectopic spiking in sensory axons (Daur et al, Frontier Comp Neurosci 2012). We found conceptually different effects on spike initiation and propagation: action potential velocity decreased with I_h and the relative timing of some action potentials at the distal end changed, indicating that changing axonal excitability is a mechanism for modulating *en passant* action potential propagation. Second, we found that ectopically generated action potentials in the middle of the axon affected action potential initiation at the proximal axonal segment with potential important consequences for neural coding. To initiate action potentials in the proximal segment, a ramp-shaped current injection was injected in compartment 1 to elicit bursts, mimicking slow synaptic input or peripheral sensory responses. Our preliminary data show that the structure of the elicited bursts depended on the ectopic spike frequency at the central spike initiation zone. Thus, not only action potential propagation but also encoding of sensory or synaptic information may be influenced by ectopic spiking.

Title: Differential modulation of circuit feedback determines activity rate of a circuit input

Authors: *D. M. BLITZ;
Biol., Miami Univ., Oxford, OH

Abstract: Similar to many neural circuits, those underlying rhythmic behaviors (central pattern generators: CPGs) provide feedback to their projection neuron inputs. However, little is known regarding the function of such feedback. We are investigating roles of CPG feedback in the crab, *Cancer borealis,* stomatogastric nervous system. Extrinsic inputs (sensory, modulatory) activate projection neurons with different activity patterns and rates, which in turn enable projection neurons to elicit distinct chewing rhythm versions. During chewing, feedback neurons regulate projection neuron activity patterns, as occurs across rhythmic motor systems. Here I determine whether CPG feedback also regulates projection neuron activity rate. Brief stimulation of mechanosensory or peptidergic modulatory neurons each triggers long-lasting excitation of an identified projection neuron, CPN2, but each triggers different chewing rhythm versions (Blitz & Nusbaum, J Neurosci, 2008). I find that CPN2 firing rate was higher with CPG feedback intact than with feedback blocked, when CPN2 activity was triggered by the mechanosensory neurons ($p<0.001$, $n=10$) but not when triggered by the peptidergic neurons ($p>0.05$, $n=5$). Specifically, CPN2 activity rate was higher with CPG feedback only during the phase of the rhythm when the feedback neuron Int1 is silent. I thus determined CPN2 responses to pauses in Int1 activity. Brief pauses in Int1 activity triggered CPN2 rebound bursts after mechanosensory stimulation, but not under control conditions ($n=3$). To determine why the impact of this feedback synapse changed, I measured Int1 inhibitory synaptic currents (IPSCs) in CPN2. I found that mechanosensory stimulation triggered an increased Int1 IPSC amplitude ($p<0.01$, $n=4$). Increased Int1 activity alone was not sufficient to alter IPSC amplitude ($p=0.5$; $n=2$), suggesting modulation of the Int1 to CPN2 synapse. Thus, I propose that increased Int1 feedback strength elicits a higher activity rate because it triggers a rebound burst, which increases CPN2 rate above that due solely to direct mechanosensory effects. Conversely, I find that peptidergic neuron stimulation, after which feedback does not impact CPN2 activity rate, decreased Int1 IPSC amplitude ($p=0.02$, $n=2$). Thus, the modulatory status of CPG feedback determines not only the activity pattern (Blitz & Nusbaum, J Neurosci, 2012) but also the activity rate of a projection neuron input, thereby shaping motor circuit output. These results highlight the flexibility of circuit feedback and the importance of incorporating plasticity at this stage of a motor pathway into our understanding of how particular motor outputs are selected.

Title: A circular model for song motor control in Serinus canaria

Authors: *G. B. MINDLIN[1], A. AMADOR[2], R. ALONSO[2], M. TREVISAN[2], F. GOLLER[3]; [1]universidad buenos aires, buenos aires, Argentina; [2]UBA, Buenos Aires, Argentina; [3]U. Utah, Salt Lake city, UT

Abstract: We built a model for birdsong production, whose variables are the average activities of different areas of the song system. One of the areas will be in control of the expiratory activity during song production, which is highly associated with different song features and can be compared to the actual behavior. We test the hypothesis that it is possible to construct a model in which 1. The activity of this area fits the observed expiratory patterns used by canaries, and 2. Another of the areas is sparsely active, simultaneously with significant motor instances of these patterns. We show that in order to achieve these two requirements, the area involved in the control of expiratory pulses needs to receive two inputs: a direct one, and its copy after processing by other areas of the song system. The model makes specific predictions on the timing of HVC activity for different classes of pressure patterns.

Title: Common mechanisms and specializations in force detection and control in cockroaches, stick insects and *Drosophila*

Authors: *S. N. ZILL[1], A. BüSCHGES[2], J. SCHMITZ[3], D. NEFF[4], S. CHAUDHRY[1]; [1]Anat. and Pathology, J.C. Edwards Sch. Med., Huntington, WV; [2]Dept. of Animal Physiology, Zoological Inst., Univ. of Cologne, Cologne, Germany; [3]Dept. of Biol. Cybernetics, Univ. of Bielefeld, Bielfeld, Germany; [4]Dept. of Chem., Marshall Unversity, Huntington, WV

Abstract: Detection of forces is an integral component of leg use in posture and locomotion. Information from receptors that monitor forces in multi-jointed legs may be particularly important in neural control of muscles as modular groups (synergists). We have performed comparative studies to characterize force detection and control in insects, using physiological studies in stick insects and cockroaches to gain insight into comparable mechanisms in fruit flies (*Drosophila*). Campaniform sensilla are mechanoreceptors that encode forces as cuticular strains through caps in the exoskeleton. The caps are organized in groups and the receptor responses are determined by the cap position and orientation. Previous studies have shown that the trochanteral and femoral groups are important in reinforcing muscle synergies. Current studies using confocal and light microscopy have identified many groups of sensilla that are homologous but the structure and responses of the femoral group (fCS) and mobility of the trochanter-femur joint (TrF) are species specific. Experiments to date indicate that in cockroaches, the TrF joint is mobile and movements are produced by a single muscle opposed by an elastic (resilin) band; the fCS are highly sensitive to posterior forces when the joint is engaged but relatively insensitive to forces in the almost perpendicular plane of movement of the coxo-trochanteral joint. In stick insects, the TrF joint is fused and fCS receptors discharge to both posterior forces and forces in the joint plane. The sensitivity to forces in the joint plane may be correlated with effects on muscle synergies: in stick insects, the fCS have strong effects on muscle synergies; in cockroaches, the dorsal campaniform sensilla (Gp3), that encode forces in the joint plane, have similar effects on use of leg muscles as synergists. Finally, in *Drosophila*, the fCS are the largest group of CS and are located on the ventral side of the femur in a position relative to the joint plane corresponding to the cockroach dorsal trochanteral sensilla. The position and orientation of the fCS in *Drosophila*, therefore, suggest that they should be sensitive to forces in the joint plane. Current experiments are characterizing the receptors in all serially homologous legs. Our working hypothesis is that receptors fulfill similar principal functions in different species but the effects of individual groups are determined by the specific forces they encode. These findings on force detection and muscle synergies may be paralleled in other animals, including vertebrates.

Title: Central coupling between locomotion and respiration in the metamorphosing frog

Authors: *D. COMBES, L. MERLET, M. THOBY-BRISSON, D. MORIN, J. SIMMERS; Univ. of Bordeaux, CNRS UMR 5287, BORDEAUX, France

Abstract: Xenopus metamorphosis involves a complete change of locomotor mode from tail-based undulatory swimming in tadpoles to adult quadrupedal locomotion. In parallel, the respiratory system switches from aquatic to aerial breathing. At critical stages, functional larval and adult locomotor and respiratory systems must co-exist in the same animal, implying a progressive reconfiguration of underlying neural circuitries and their functional interactions. The isolated brainstem produces, under high K+ saline, spontaneous respiratory output consisting of stage-specific patterns of bilaterally-synchronous impulse bursts in cranial motor nerves. In early premetamorphic tadpoles, high frequency, low intensity bursts corresponding to fictive gill ventilation are continuously generated by the caudal brainstem. Episodic waves during which the intensity of those bursts increases are observed in later premetamorphic stages. In postmetamorphic froglets, short and high intensity bursts are produced at lower frequency, corresponding to fictive lung breathing. Both rostral and caudal brainstem regions contribute to this adult motor pattern as evidenced by their persistent rhythmogenic capability after separation by a transverse section at the level of the VIIth nerve. Pulmonary bursting appears at prometamorphic stages and becomes increasingly present through the course of metamorphosis. The use of isolated brainstem-spinal cords with combined recordings of respiratory cranial nerves and spinal (in tadpoles) or limb (in froglets) motor roots also allowed us to explore the interaction between the two motor systems. In tadpoles where axial locomotion and gill breathing are used, each spontaneous locomotor episode is followed by a series of rhythmic respiratory bursts. Specific brainstem hemisections indicated that this coupling is mediated by ipsilateral ascending excitation of the brainstem respiratory networks from each side of the spinal cord. In postmetamorphic froglets that express appendicular locomotion and lung respiration, each spontaneous locomotor episode occurs conjointly with an episode of respiratory bursts triggered by an excitatory influence in time with limb extensor burst activity. Thus, in both pre- and post- metamorphic Xenopus, an efference copy of locomotor network activity provides a central coordinating drive to brainstem respiratory circuitry. We are now addressing how the underlying coupling pathways are adapted to changing locomotor strategy during

metamorphosis, especially at climax where the two modes of locomotion and respiration require complex dynamic interactions between all four co-existing networks.

Title: Effects of mechanical perturbations on fictive locomotion in the lamprey

Authors: D. R. BERNALES[1], *E. D. TYTELL[2];
[1]Biol., Boston Univ., Boston, MA; [2]Dept. of Biol., Tufts Univ., Medford, MA

Abstract: The neuronal circuit that generates locomotion in vertebrates, called a central pattern generator (CPG), is found in the spinal cord. This circuit produces rhythmic signals to contract the muscles and bend the body for locomotion. It also receives and processes proprioceptive sensory inputs. During locomotion, however, all animals must cope with unexpected stimuli that may affect or disrupt the normal locomotor pattern. In this project, we aim to understand the effect of such perturbations on the lamprey CPG, and how the CPG corrects itself to compensate after being disrupted. We isolated the spinal cord of the silver lamprey Ichthyomyzon unicuspis and evoked fictive locomomotion using D-glutamate in the bath. To mimic the normal swimming motion, we bent the spinal cord from one side to another using a motorized arm. As previously observed, the bending motion could entrain the CPG's rhythm over a range of frequencies. Once the CPG was entrained, we added brief triangle-wave perturbations at a range of different phases to the baseline bending pattern. We varied both the amplitude and the frequency of the baseline bending frequency and examined how the response to perturbations varied. We then measured the timing of the first burst that came after the perturbation, and compared it to when it would have occurred if the perturbation had not happened, constructing a phase response curve. Across five individuals, the change in the burst phase after the

perturbation is linearly related to the phase of the perturbation itself, but the perturbation does not simply reset the burst phase. Instead, perturbations that occur before a burst tend to delay the next burst and those that occur after a burst tend to advance the next one. We also compared the effect of the perturbations on their own, with no baseline bending, to their effect when superimposed on a sinusoidal bending motion. By themselves, the perturbations produce a much smaller effect than when they are superimposed on the bending motion, and the shape of the phase response curve is quite different. These results will help us to characterize how the lamprey and other vertebrates respond adaptively to perturbations during normal locomotor behavior.

Title: Reticulospinal neurons transmitting commands for modification of spinal reflex responses to body bending during escape behaviors in lampreys

Authors: L.-J. HSU, P. V. ZELENIN, *G. N. ORLOVSKY, T. G. DELIAGINA;
Karolinska Inst., Stockholm, Sweden

Abstract: In the lamprey, the proprioceptive information is provided by stretch receptor neurons (also known as edge cells, EC). They are located at the margins of the spinal cord and activated by longitudinal stretch of this area during body bending. ECs, when activated by lateral bending, cause activation of motoneurons on the convex side during fast forward swimming, and on the concave side during escape behaviors (slow forward swimming, SFS; backward swimming, BS; lateral turns, LT). These spinal reflexes, mediated by ECs, can be reversed by supraspinal signals. In the lamprey, supraspinal commands are transmitted mainly by reticulospinal pathway. The aims of the present study were: (i) to reveal reticulospinal neurons (RSNs) transmitting supraspinal commands for modification of EC-mediated reflexes in context of escape behaviors,

and (ii) to clarify if RSNs receive sensory feedback from ECs. For this purpose, the *in vitro* preparation consisting of the brainstem and spinal cord was used. To monitor EC-mediated reflexes evoked by lateral bending of the spinal cord, activity in ventral roots was recorded. Stimulation of specific sites of n. trigeminus was used to cause reversal of EC-mediated reflexes, as well as to evoke different types of escape behaviors. To reveal RSNs causing reflex reversal, RSNs were recorded intracellularly during EC-mediated reflexes, before and during stimulation that caused the reversal. Two groups of RSNs, differently activated by stimulation of the ipsi- and contralateral n. trigeminus, were found, suggesting that they transmit commands for the reflex reversal. Group 1 neurons were activated by stimulation of any n. trigeminus, and Group 2 neurons - by stimulation of the contralateral nerve only. Group 1 neurons and the majority of Group 2 neurons were located in the middle rhombencephalic reticular nucleus. We found that Group 1 neurons were activated during SFS and BS, suggesting that they caused reversal of EC-mediated reflexes during these behaviors. In contrast, during LT the reversal of reflexes was caused by neurons of both groups. To reveal sensory inputs from ECs to RSNs, responses of individual RSNs to bending of the spinal cord were recorded. We found that 76% of RSNs (located in different reticular nuclei) responded to bending, suggesting that they receive sensory feedback from ECs. Thus, in the present study two groups of RSNs transmitting commands causing reversal of EC-mediated reflexes during escape behaviors have been found, and existence of the sensory feedback from ECs to RSNs has been demonstrated.

Title: The neural basis for regional body bending in zebrafish startle behavior

Authors: *H. R. KATZ[1], Y.-C. LIU[3], M. E. HALE[2];
[1]Integrative Biol., [2]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [3]Vollum Inst., Portland, OR

Abstract: A major question on the organization of the vertebrate nervous system is how regionalization evolved in the spinal cord. In larval zebrafish, axial bending has generally been categorized as either anterior to posterior travelling waves that occur during rhythmic swimming or large unilateral bends of startles and maneuvers. We have recently described a third pattern of bending that occurs during a subtype of startle behavior, the formation of an axial standing wave with a rostral bend to one side of the body and caudal bend to the other. This movement pattern is more similar to tetrapod locomotion than other axial bending patterns previously described in larval zebrafish. By examining the mechanistic basis of this movement pattern, we aim to gain insights into potential mechanisms for regionalized bending in the zebrafish spinal cord. First, we performed behavioral kinematic studies in larval zebrafish to better characterize the two bends observed in the standing wave. This behavior can only be elicited by a caudal stimulus, so we used a tactile stimulus at different locations along the caudal region of the body. We found that the two bends are always produced in the same position along the body axis and do not vary with stimulus location, supporting the idea that there is a discrete demarcation between rostral and caudal regions. Second, we investigated the mechanism for the localization of these bends. Previous work has found no evidence of discrete organization of motor neurons or interneurons in these regions of the body axis. Our data on reticulospinal neurons indicate that they also do not play a role in this localized activity. We have identified Rohon Beard (RB) cells, a type of somatosensory cell, as a major sensory input that produces this regional, localized bending. Paired recordings have shown that caudal RBs synapse directly onto commissural local cells which inhibit contralateral caudal motor neurons and ultimately signal an S-start. This finding led us to investigate sensory input as a potential mechanism for regionalized motor activity. Because we only observe this inhibition in the caudal region, it suggests that there is regionalization in RB subtype distribution. Using both *in vivo* confocal imaging of GFP-labeled somatosensory neurons and antibody staining, we explore rostro-caudal differences in RB arborization and dendritic projections in zebrafish larvae to better understand how these subtypes may be distributed. This work may shed light on an early form of discrete regionalization within the vertebrate spinal cord and inform our understanding of how more pronounced regionalization may have evolved.

Title: Activity of individual spinal neurons during locomotion initiated from brainstem and from spinal cord

Authors: *P. V. ZELENIN[1], P. E. MUSIENKO[2], O. V. GORSKII[2], V. F. LYALKA[1], Y. P. GERASIMENKO[2], G. N. ORLOVSKY[1], T. G. DELIAGINA[1];
[1]Karolinska Inst., Stockholm, Sweden; [2]Pavlov Inst. of Physiol., St. Petersburg, Russian Federation

Abstract: In quadrupeds, the basic neural mechanisms controlling locomotor limb movements are located in the spinal cord. At present, operation of these mechanisms is poorly understood. Spinal locomotor networks can be activated by signals from the brainstem, as well as by direct stimulation of the spinal cord. The aim of the present study was to characterize the activity of the same individual spinal neurons under these two conditions, i.e., when locomotion is evoked by stimulation of the mesencephalic locomotor region (MLR), and when it is evoked by stimulation of the spinal cord (SC). For this purpose, these two modes of stimulation were used in the decerebrate cat to induce the hindlimbs walking on the treadmill. Spinal neurons were recorded in L4-L6 by a multi-electrode array (32 recording sites). Activity of individual neurons was extracted from the mass activity by spike-sorting procedure. We found that activity of most neurons was modulated in the locomotor rhythm, with a burst of activity in a definite part of the step cycle, and much lower activity between the bursts. Though SC-evoked locomotion is more dependent on peripheral feedback than MLR-evoked locomotion, we found that the phases of modulation of individual neurons were similar during locomotion initiated from these two sites, suggesting that the same spinal locomotor networks were activated in both cases. We divided all step-related neurons into five groups (S1-S5) according to the burst position in the step cycle, variability of this position, and burst shape. We suggested that the neurons responsible for generation of a step cycle have less variable activity than their targets outside the generator, and selected neurons with a smaller dispersion of their activity phase. Two distinct groups of such neurons were found. The S1 neurons generated a short-lasting burst in the swing phase of the step cycle or close to this phase. The S2 neurons generated a long-lasting burst in the stance phase, with a gradually increasing (ramp-shaped) firing rate. We suggest that these two groups

(each containing about 10% of all neurons) determine the swing and stance phases of the step cycle, respectively. To explain sequential generation of these phases, we propose an asymmetrical model of the step generator, in which SR2 neurons cause excitation of S1 neurons, whereas the latter cause inhibition of S2 neurons. Neurons of other groups (S3-S5) have a larger variability of the burst position in the cycle and of the burst pattern. We suggest that these neurons integrate inputs from S1 and S2 neurons and are responsible for activation of motoneurons of different limb muscles during step.

Title: Pre- and post-synaptic inhibitory mechanisms acting on lumber spinal cord neurons during generalized motor inhibition induced by stimulating the medullary reticular formation in the decerebrate cat

Authors: *K. TAKAKUSAKI;
Asahikawa Med. Univ., Asahikawa/Hokkaido, Japan

Abstract: An activation of the reticulospinal tract arising from the medullary nucleus reticularis gigantocellularis (NRGc) induced muscular atonia (generalized motor inhibition) in acutely decerebrated cat. We have demonstrated that this tract induced postsynaptic inhibition upon forelimb and hindlimb motoneurons and lumbar interneurons in reflex pathways. The inhibitory effects were possibly mediated by lamina VII interneurons that received inhibition from volleys in flexion reflex afferents (FRA) (Takakusaki et al. 2001, 2003; Habaguchi et al., 2002). The present study was designed to elucidate whether the reticulospinal tract also mediated presynaptic inhibition in primary afferents. For this purpose, we employed 14 decerebrate cat preparations. After identification of the medullary inhibitory region by stimulating the medial part of the NRGc (50Hz and 30-40 μA), the cats paralyzed and artificially respired. Then

potentials in dorsal root filaments of L6 segment and those in the ventral root filaments of L7-S1 segments were monitored. Short train pulses of stimuli (3 pulses, 5 ms interval and 30-40 μA) applied to the inhibitory region in the NRGc evoked negative potentials in the ventral roots and positive potentials in the dorsal root. The former had onset latency of 20-30 ms and peak latency of 50-60 ms, and the latter had onset latency of 10-20 ms and peak latency of 50-60 ms. Intracellular recordings of lumbar motoneurons (n=67) showed that the NRGc stimulation invariably evoked inhibitory postsynaptic potentials (IPSPs) whose time course was mostly the same as those in the negative ventral root potentials. Moreover, intra-axonal recordings revealed that the identical stimuli induced primary afferent depolarization (PAD), an indicator of presynaptic inhibition, in 50 % of intra-axonal sensory afferents (Ia fibers; n= 6/12, Ib fibers; n= 5/11 and cutaneous afferents; n= 7/13). The time course of the PAD was nearly the same as that of positive potentials in dorsal roots. These potentials were reduced in size when stimulating electrode was moved from the optimal site to dorsal, ventral and lateral sites. Moreover these potentials were reduced in size when conditioning volleys in FRA was preceded to the NRGc stimulation. These findings suggest that the reticulospinal tract from the medullary NRGc contribute to muscular atonia by both presynaptic and postsynaptic inhibitory mechanisms, which may be mediated by inhibitory interneurons in lamina VII of Rexed.

Title: Phase resetting of the respiratory rhythm elicited by the activation of a distinct central pattern generator

Authors: *R. MEZA-ANDRADE[1], B. DE LA TORRE-VALDOVINOS[1], N. HUIDOBRO[1], P. LINARES[1], R. TECUANHUEY[2], E. MANJARREZ[1];

[1]Inst. de Fisiología, [2]Facultad de Medicina, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: Phase resetting is a behavior in which the cycle period of a rhythm changes by a particular perturbation. Several studies have demonstrated a respiratory phase resetting which can be produced by stimulation of various nerves and structures related to the upper airways, as well as cortical and midbrain structures. However, to our knowledge there are no studies about a respiratory phase resetting produced during the activation of another rhythm generator unrelated to the respiratory centers. The aim of the present study was to show experimental evidence of a respiratory phase resetting elicited by the activation of the spinal central pattern generator (CPG) of scratching. This is relevant because the phase resetting elicited by physiological stimuli may shed light on the organization of a CPG and its interaction with other structures. Experiments were performed in five acute precollicular-postmammillary decerebrate cats. Extracellular unitary recordings of ipsilateral respiratory neurons from the ventrolateral and dorsal medulla were obtained by means of quartz-platinum/tungsten microelectrodes from Thomas Recording (1 to 3 MΩ). Additionally, electroneurograms of the ipislateral phrenic nerve (C5) as well as of the tibialis anterior and medial gastrocnemius nerves were simultaneously recorded. In all the experiments we found a significant respiratory phase resetting during episodes of fictive scratching in neurons of the hypoglossal nerve nucleus (n=2), the phrenic nerve (n=5), as well as inspiratory (n=9) and expiratory (n=3) neurons of the ventral respiratory column. We observed that the inspiratory neurons were activated during fictive scratching, whereas the expiratory neurons were silenced. The motor outputs were differentially affected: the phrenic nerve exhibited altered firing activity, while the hypoglossal nucleus was silenced. These results show the first evidence of a phase resetting produced by neuronal elements related to one CPG on another CPG. Specifically, we demonstrated the phase resetting of the respiratory rhythm elicited by the activation of a non-overlapping and functionally distinct central pattern generator.

Title: Bistability facilitates multifunctionality and improves performance in a neuromechanical model of motor pattern generation

Authors: *D. LYTTLE[1], J. GILL[2], K. SHAW[2], P. THOMAS[3], H. CHIEL[2];
[1]Biology, Mathematics, [2]Biol., [3]Mathematics, Case Western Reserve Univ., Cleveland, OH

Abstract: Motor systems in many animals are multifunctional, meaning that a single neuromechanical system is able to produce multiple, qualitatively different rhythmic motor behaviors (e.g. walking vs. running). We explore the consequences of the coexistence of multiple stable dynamical regimes in a biomechanically coupled model central pattern generator circuit, with sensory feedback governing the transitions between regimes. As a concrete example, we focus on a nominal neuromechanical model of the feeding apparatus of the marine mollusk *Aplysia californica*. In this model, three mutually inhibitory neural pools drive a biomechanical model of the *Aplysia* buccal mass, while proprioceptive feedback from the feeding apparatus is in turn sent back to the nervous system. At each cycle, the feeding apparatus attempts to grasp seaweed (represented as a fixed resisting force), but only succeeds in doing so with some probability. Once a piece of seaweed has been successfully grasped, the system must consume the entire seaweed strip before attempting to grasp another one. We find that the model can operate within two distinct regimes, and that the system exhibits bistability between the two. In the "heteroclinic regime", the system is sensitive to proprioceptive feedback from the muscles, which selectively prolongs specific motor phases. In the "limit cycle regime", the timing of the pattern is insensitive to proprioceptive feedback, and the oscillations are faster. These two regimes also differ in their responses to brief neural and mechanical perturbations. We find that the limit cycle dynamics are superior for grasping seaweed, whereas the heteroclinic dynamics are superior for consuming seaweed once it has been grasped. Moreover, we find that overall feeding performance is improved when the system can flexibly transition between regimes. Thus, neuromechanical bistability may allow motor systems to produce robust and flexible behaviors in a variable environment.

Title: Preparing the periphery for a subsequent behavior: Motor neuronal activity during biting generates little force but prepares a retractor muscle to generate larger forces during swallowing in *Aplysia*

Authors: *H. LU, J. M. MCMANUS, M. J. CULLINS, H. J. CHIEL;
Biol., Case Western Res. Univ., Cleveland, OH

Abstract: Some behaviors occur in obligatory sequence, such as reaching prior to grasping an object. Can the earlier behavior serve to prepare the musculature for the later behavior? If it does, what is the underlying neural mechanism of the preparation? To address this question, we examined two feeding behaviors in the marine mollusk *Aplysia* californica, one of which must precede the second: biting and swallowing. Biting is an attempt to grasp food that does not succeed; once an animal does grasp food, it immediately switches to swallowing to ingest food. The main muscle responsible for pulling food into the buccal cavity during swallowing is the I3 muscle, whose motor neurons, B6, B9 and B3 have been previously identified. By performing recordings from these neurons *in vivo* in intact, behaving animals or *in vitro* in a suspended buccal mass preparation, we demonstrated that the frequencies and durations of these motor neurons increased from biting to swallowing. Using the physiological patterns of activation to drive these neurons intracellularly, we further demonstrated that activating them using biting-like frequencies and durations, either alone or in combination, generated little or no force in the I3 muscle (illustrated by part A in the figure). When biting-like patterns preceded swallowing-like patterns, however, the forces during the subsequent swallowing-like patterns were significantly enhanced (illustrated by part B in the figure). Sequences of swallowing-like patterns, either with these neurons alone or in combination, further enhanced forces in the I3 muscle (illustrated by part C in the figure). These results suggest a novel mechanism for enhancing force production in a muscle, and may be relevant to understanding motor control in vertebrates.

Title: A kinematic model of surface conformational changes in the *Aplysia* feeding grasper

Authors: *C. E. KEHL[1], D. NEUSTADTER[2], S. LU[1], H. CHIEL[1];
[1]Biol., Case Western Reserve Univ., Cleveland, OH; [2]Calore Med. LTD, Or Akiva, Israel

Abstract: Biomechanics, the study of how the mechanics of the body affects both its capabilities and constraints, is the complementary partner to neural control for creating behaviors. The biomechanical properties of soft bodied organisms are a particularly challenging area for study, and have clinical implications for understanding such structures as tongues and the digestive system. These organisms can also serve as the basis for soft bodied robots, which can manipulate and maneuver through environments to which rigid systems might not have access. We have previously presented a kinematic model of the feeding grasper of the sea slug, *Aplysia californica*, derived from the segmentation of high resolution static magnetic resonance images (MRI). We have extended this model to incorporate segmentation of structures within the grasper from lower resolution MRI movies. The surface of the grasper overlies a complex musculature that allows it to open and close and to move towards the jaws (protraction) or towards the esophagus (retraction). Within the complex musculature are muscles known as the I4 and I6 muscles which form a horseshoe shaped structure through which an extension of the surface, known as the radular stalk, can move up and down. At the anterior of the I4/I6 muscles is a structure known as the prow, which may aid the grasper to protract through the jaws. The revised model suggests that rotation of the stalk and its movement towards and away from the prow plays a role in changes to the shape of the grasping surface. In addition, *in vivo* lesion studies and work with reduced preparations has led us to focus on the role of fine muscle fibers that attach underneath the grasping surface (sub-radular fibers). These fibers seem to be responsible for some of the changes in shape that the surface undergoes during opening and closing. Iteratively incorporating these features into our model allows it to conform more closely to the actual biological system, and provides insight into the detailed neural control of this flexible grasper.

Title: Getting to the right solution: Sensory feedback reduces motor neuronal individuality to satisfy behavior-specific biomechanical constraints

Authors: *J. P. GILL[1], M. J. CULLINS[1], J. M. MCMANUS[1], H. LU[1], K. M. SHAW[1], H. J. CHIEL[2];
[1]Dept. of Biol., [2]Depts. of Biol., Neurosci., and Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: Animals must continuously solve motor control problems posed by a variable environment. However, nervous systems are often intrinsically variable, and individuals also vary. How is this variability regulated so highly individual animals achieve comparable behavioral success? We hypothesized that intrinsic variability among individuals is constrained in motor neurons whose activities are essential for behavioral success, and sensory feedback is the mechanism that regulates this variability (see figure). To investigate this hypothesis, we studied rhythmic pattern generation in an animal model in which the majority of motor neurons controlling multiple behaviors are identified and can be simultaneously recorded during normal behavior. We quantified identified motor neuron activity mediating biting and swallowing in intact, behaving *Aplysia* californica. We measured multiple motor components: duration of activity of identified motor neurons and their relative timing during ingestive motor patterns. At the same time, we measured behavioral success: amplitude of grasping movement during biting, and amplitude of food movement during swallowing. By correlating motor neuronal activity with behavioral success, we obtained measures of motor neuronal efficacy. Biting and swallowing are distinct behaviors in which motor neurons may play different roles, so we expected to find differences in motor neuronal efficacy between biting and swallowing. Motor neuronal activity that was essential for the expression of biting or of swallowing was similar among animals, whereas motor neuronal activity that was not essential for that behavior varied more from individual to individual. What is the role of sensory feedback? We found that the removal of sensory feedback in the isolated ganglia increased individuality in the activity of motor

components most correlated with behavioral success. These results demonstrate that at the level of identified motor neurons, sensory feedback reduces motor neuronal variability when that activity matters for behavior.

Title: Modeling the Caenorhabditis elegans locomotion network: an opportunity in connectivity

Authors: ***G. HASPEL**[1], C. O. DIEKMAN[2];
[1]Biol. Sci., [2]Mathematical Sci., New Jersey Inst. of Technol., Newark, NJ

Abstract: The neuronal connectivity dataset of the nematode Caenorhabditis elegans has attracted wide attention from computational neuroscientists and experimentalists because it is currently the only organism-level connectome. However, the original electron micrographic dataset is incomplete, leaving 21 of 75 motoneurons of the locomotor network with partial or no connectivity data. Modeling efforts to date have either ignored the gap in data or used a simplified network that includes about half of the neuronal classes and omits most synaptic connections. We recently described how the existing connectivity dataset can be extrapolated into a complete neuromuscular network by identifying rules of connectivity (Haspel and O'Donovan 2011, J Neurosci 31(41):14611-14623). Here we use an extrapolated network that spans the full length of an animal and includes all the motoneurons of different classes, all muscle cells, and all synaptic connections, both chemical and electrical. The output of the network is the activity pattern of the muscle cells that can be directly interpreted as body

curvature. This level of comprehensiveness provides a unique opportunity to investigate network function within the constraints of its structure. We used an evolutionary algorithm to estimate cellular and synaptic parameters by optimizing over parameter sets to produce a propagating, dorsoventral alternating muscular activity that resembles the natural output of the locomotion network. We then assessed the importance of specific neuronal connections and [combinations of connections] by iteratively omitting random sets of connections from a pattern-producing network. We suggest that this novel virtual ablation approach to evaluating the importance of neuronal connections is useful when complete anatomical connectivity datasets (connectomes) of other animals become available. Together, these studies point out possible modes for the network to produce its output, within the constraints of known neurons, muscle cells, and their connectivity. All components of the model are identifiable in the real network and the results lead to experimentally testable predictions.

Title: Mechanisms of sensory feedback governing motor network dynamics in a locomotor circuit

Authors: *B. CHUNG[1], R. CLEWLEY[2], D. EDWARDS[2];
[2]Neurosci. Inst., [1]Georgia State Univ., Atlanta, GA

Abstract: Here, we use a perspective from dynamical systems to ask how the output of a locomotor network is organized across postural and actively rhythmic states. We show that while sensory feedback to the network based on its motor output changes the burst period, it does not qualitatively reorganize the dynamic structure of the network. Also, a subset of interneurons is necessary to organize three qualitatively different activity regimes. A computational model of the locomotor network controlling the first joint of each walking leg in crayfish was developed based on known elements of the circuitry [1]. Simulation results showed that the network model

accounted for reflexes and patterns of bursting activity observed from *in vitro* experiments [1, 2]. By varying the amount of tonic excitation driving the circuit model, we found that there are three distinct regimes of network activity: quiescence, bursting, and tonic spiking. In closed loop simulations, when sensory feedback to the network was based on its motor output, as well as in open loop simulations, when there was no sensory feedback, there were no differences in the boundaries of the activity regimes. In the quiescent regime, only resistance reflexes that act against imposed perturbations were present. In the bursting regime, the period of closed loop bursts was shorter than that of bursts in open loop simulations and both resistance reflexes and assistance reflexes that act to amplify imposed perturbations were present. Finally, when tonic excitation was increased further, the network entered a tonically active state in which one pool of motor neurons fired continuously interrupted only by short bursts of the antagonist motor pool. In order to identify the mechanisms that organize network activity in this way, we tested the effect of changing specific elements. Hyperpolarization of assistance reflex interneurons eliminated the tonic spiking regime and resulted in only quiescence and an extended bursting regime. These results suggest that sensory feedback in closed loop simulations reduces the network bursting period without affecting the organization of network dynamics. In addition, we showed that assistance reflex interneurons are necessary for the tonic firing regime of the network. By utilizing a network model of the locomotor circuit controlling the first joint of a walking leg in crayfish, we were able to identify and understand the organizing principles of the network's motor output. Title: A CPG driven dynamic model for the study of active tactile sensing in an insect

Authors: ***N. HARISCHANDRA**[1,2], T. HOINVILLE[1,2], A. F. KRAUSE[2], V. DÜRR[1,2];
[1]Dept. of Biol. Cybernetics, Univ. of Bielefeld, Fac. of Biol., Bielefeld, Germany; [2]Cognitive Interaction Technol. Ctr. of Excellence, Univ. of Bielefeld, Bielefeld, Germany

Abstract: A prime aspect of autonomous behaviors in animals is the active exploration of their environment using different sensing systems, allowing them to achieve context-dependent control of actions. Active touch is one such sensory system. Here, we are introducing a general framework of coupled Central Pattern Generators (CPGs) to be used in the context of movement generation for active tactile exploration. CPGs are biological neural networks that produce rhythmic outputs without rhythmical inputs. Stick insects (Carausius morosus) show rhythmic tactile exploration behavior during walking with coordinated movement of two joints per antenna. The phase difference of the distal scape-pedicel (SP) joint and the proximal head-scape (HS) joint is ~20º with the SP joint leading. Moreover, ablating proprioceptive hair fields on the antenna has no effect on the overall pattern of inter-joint coordination but affects the working-ranges of both antennal joints. The neuronal network that generates rhythmic antennal movement is unknown, but it has been localized in the brain and shown to be sensitive to the muscarinic acetylcholine agonist pilocarpine. Here, we develop a 3D dynamic, skeletal model of the stick insect head and antennae with physically realistic parameters. It is driven by a CPG consisting of two layers: phase-coupled Hopf oscillators for rhythm generation and, pattern formation networks for capturing frequency characteristics of individual joint oscillations. The model captures the joint kinematics essential for generating quasi-rhythmic and coordinated antennal movements and successfully produces biologically realistic movements on the skeletal model. We found that the phase lead of the SP joint could vary from ~10º to ~30º without disrupting the characteristic, elliptical trajectory of the antennal tip. We suggest that the constant phase shift seen in the antennal joint movements is coded into the CPG. The model is able to simulate the effect of hair-field ablations on the joint kinematics by changing the amplitude and offset of the corresponding oscillator in the CPG network. We propose that these hair fields control the local effective stiffness of each joint by acting through a negative feedback loop. In summary, we propose that the rhythmic searching movement of the stick insect antennal system is more centrally controlled and the proprioceptors are acting locally to regulate the joint movements. Our 3D dynamic model is capable of mimicking neurophysiological phenomena and will be useful in experiments on adaptive tactile exploration systems both in computer simulations and on biomimetic robots.

Title: Computer simulations of slope walking in the cat: Role of supraspinal input to extensor interneurons

Authors: *A. N. KLISHKO[1], S. N. MARKIN[2], N. A. SHEVTSOVA[2], M. A. LEMAY[3], I. A. RYBAK[2], B. I. PRILUTSKY[1];
[1]Sch. of Applied Physiology, Ctr. for Human Movement Studies, Georgia Inst. of Technol., Atlanta, GA; [2]Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [3]Dept. of Bioengineering, Temple Univ., Philadelphia, PA

Abstract: During cat walking on horizontal level, hindlimb flexors and extensors are normally active in the opposite phases of the locomotor cycle, swing and stance, respectively (Smith et al., 1998; Markin et al., 2012). This suggests that these muscles are activated primarily by corresponding inputs from the CPG flexor and extensor half-centers (McCrea, Rybak 2008). Generally similar activity patterns occur during upslope walking, although the magnitude and duration of extensor bursts increase (Carlson-Kuhta et al. 1998; Gregor et al. 2006). However during downslope walking, the flexor-extensor alternation breaks down at the hip joint: all hip extensors become silent during the entire walking cycle, while hip flexor iliopsoas (IP) generates activity bursts in both swing and stance phases (Smith et al. 1998; Akyildiz et al. 2015). This activity pattern appears to contradict the bipartite organization of locomotor CPG and has been previously explained within the framework of the unit burst generators (Smith et al. 1998; Grillner, 1981). The goal of this study was to investigate whether patterns of muscle activity during slope walking could be reproduced using a neuromechanical model of cat hindlimbs controlled by a two-level bipartite CPG (Markin et al. 2015). Parameters of the CPG model were tuned to fit multiple data obtained during fictive locomotion in the cat, whereas parameters of the hindlimb musculoskeletal model were optimized to reproduce mechanics of level walking. We took into account that (1) the transitions between extensor and flexor phases usually occurred at peaks of IP fascicle and muscle-tendon unit length during level and slope walking, and (2) the activity of ankle and knee extensors before ground contact was not substantially different in downslope conditions vs. level walking, whereas the activity of hip extensors was considerably reduced (Akyildiz et al. 2015). Therefore we hypothesized that major change in the muscle activities during downslope walking is provided by additional supraspinal drive to spinal circuits at the CPG pattern formation level that control hip extensor motoneurons. This change in muscle activation could occur without significant changes in sensory feedback synaptic weights from muscle and cutaneous afferents. To test this hypothesis, the supraspinal drive to extensor interneurons at the CPG pattern formation level was optimized to obtain the best match between

simulated and recorded patterns of muscle activity at different slope conditions. We suggest that the major features of hindlimb activity during slope walking could be reproduced by a two-level bipartite CPG with changing supraspinal drive to the CPG circuits.

Abstract: Stable heteroclinic channels (SHCs) are a dynamical architecture that, like biological pattern generators, can respond immediately to multi-sensory perturbations by modulating the dwell time at a particular phase of oscillation to vary force output, range of motion, or other characteristics of a physical system. SHCs are composed of sequences of saddle equilibrium points, which yields exquisite sensitivity. The strength of the vector fields in the neighborhood of these equilibria determines the responsiveness to perturbations and how long trajectories dwell in the vicinity of a saddle. For SHC cycles, the addition of stochastic noise results in oscillation with a regular mean period. We find SHCs are well-suited for modeling behaviors with smooth state transitions, e.g., using a set of muscles for a sequence of actions. SHCs can be responsive to noisy feedback, e.g., coordinating soft-body locomotion with many possible ground contacts. Further, for robotics applications, they are simple enough to run in real time on a microcontroller. To facilitate the use of SHC cycles as oscillators, we have derived analytic approximations for the mean and variance of the passage time through the neighborhood of a linear saddle equilibrium point. Combining these approximations with a convenient parameterization, we show how the desired mean sub-periods of individual saddles of noise-driven Lotka-Volterra SHC cycles can be directly (and independently) specified within 2% for a

typical parameter set. Further, after measuring the resultant simulated sub-periods over sufficient numbers of cycles, the noise magnitude can be adjusted to control the mean period with accuracy close to that of the integration step size. SHCTools, a Matlab toolbox, has been developed that implements the relevant equations and algorithms to aid in analyzing and visualizing SHC dynamics. With these relationships and design tools, SHCs can be more easily employed in engineering and modeling applications. We demonstrate the use of SHCs to control independently-actuated segments of a soft worm-like robot. This task is challenging because many compliant degrees-of-freedom must be coordinated while simultaneously maintaining physical constraints for effective locomotion. Load feedback from the robot's motors and the noisy Lotka-Volterra dynamics of the SHC controller are used to trigger transitions between expansion and contraction of each segment. The performance of our SHC controller is compared with that of an augmented finite state machine controller.

Title: Coordination and control of hind limb stepping in a rat model

Authors: A. HUNT[1], N. SZCZECINSKI[1], E. ANDRADA[2], M. FISCHER[2], *R. D. QUINN[1]; [1]Mechanical and Aerospace Engin., Case Western Reserve Univ., Cleveland, OH; [2]Inst. of Systematic Zoology and Evolutionary Biology, Friedrich Schiller Univ. of Jena, Jena, Germany

Abstract: We have developed a controller for hind limb stepping in a rat model based on research in biology and neuroethology. This research utilizes computational neuroscience models of neurons and synapses arranged in pathways discovered and theorized in the spinal cords of walking animals. These pathways are used to coordinate different joints together and control force output of the muscles. Desired muscle force activation patterns are calculated through inverse dynamics of high speed x-ray videos of walking rats. A four neuron central pattern

generator (CPG) model is analyzed and the results are used to develop a CPG which oscillates robustly while still responding to sensory feedback from the system. Critical network parameters are then trained to produce the desired motor neuron patterns through a combination of genetic and simplex search methods. This results in robust stepping patterns which reject perturbations and produces motions which are remarkably similar to that of a walking rat.

Title: Minimalistic central pattern generator for quadrupedal locomotion

Authors: *K. TUNTEVSKI[1], S. YAKOVENKO[2];
[1]Neurosci., West Virginia Univ. - Ctr. For Neurosci., Morgantown, WV; [2]Neurosci., WVU, Morgantown, WV

Abstract: Robust and computationally light models of the dynamic interactions that drive the spinal central pattern generator (CPG) of locomotion in mammals have been in demand for some time as they have a translational potential between quadrupedal animal models and human bipedal locomotion (McDermott, et al., 2011; Hoellinger et al., 2013). For this purpose, we have previously developed a leaky integrator model using ordinary differential equations (ODE) to describe the output of the spinal CPG for regular overground locomotion. The model consists of four leaky oscillators representing the temporal activity of motoneuron populations innervating flexor or extensor muscle groups on each side of the spinal cord, where contralateral flexor-extensor connections are mutually excitatory, while contralateral flexor-flexor and extensor-extensor interactions are inhibitory. The system is velocity driven and responds linearly to increasing input gain (Yakovenko, 2011), modeled as external parameters set from higher points on the motor control hierarchy (Prochazka & Yakovenko, 2007). The model parameters are iteratively optimized using error functions between recorded experimental and simulated outputs

accounting for the range of simulated velocities, the modulation of the stance phase duration as a function of step cycle duration (Halbertsma, 1983), and mismatch in coordination between bilateral phases and optimized using a Nelder-Mead heuristic downhill simplex method. Presently, we have expanded the model to accommodate asymmetric bipedal output, as well as quadrupedal forelimb-hindlimb synergistic interactions that are observed in healthy animal locomotion. The dynamic locomotor network was assayed with a precise foot placement locomotor task, which is known to require cortical activation for effective execution (Yakovenko et al., 2011). The task imposes spatial asymmetry to challenge either side of the motor cortex, and the temporal asymmetry between the left and right limb step cycles, termed the asymmetry index, and further shows promise for evaluation of both unimpaired and deficient locomotor networks.

[1]Neurosci., West Virginia Univ., Morgantown, WV; [2]Human Performance, WVU Sch. of Med., Morgantown, WV

Abstract: Periodic movement is controlled by oscillatory activity produced by neural elements termed the Central Pattern Generators (CPGs). CPGs can be expressed using systems of simple coupled leaky integrators, which is a system of ordinary differential equations (ODEs). The input-output relationship of these models is usually obtained using numerical methods associated with computational errors and additional parametric analyses. In particular, the velocity hypothesis, stating that the desired forward velocity drives the CPG, was supported by inverse numerical calculations only (Yakovenko, 2011). However, for some models analytical solutions may exist. Here, we present piece-wise analytical solution to the system of ODEs that provide

the dynamics of state evolution between phase transitions. It has the form: $x = A^{-1}(exp\{At\} - I)B + exp\{At\}x_0$, where x & x_0 denote a state vector and its value at the starting time, respectively; t is time; A is a matrix of leak values for integrators and the weights for connections between them; B is the input to the system, and I is the identity matrix. The combination of this solution with the relationship between speed of movement and the cycle duration (Goslow et. al., 1973) shows the result that is consistent with the hypothesis that the speed is linearly dependent on the input to this system. Our finding supports the hierarchical organization of neural processing for the execution of locomotion. References: 1. Yakovenko S. Title: Sparsity and inhibition in the pre-Bötzinger complex can explain levels of synchrony and the presence of expiratory neurons

Authors: ***K. D. HARRIS**[1], T. DASHEVSKIY[3], E. T. SHEA-BROWN[2], J.-M. RAMIREZ[3]; [1]Univ. of Washington, Seattle, ; [2]Applied Mathematics, Univ. of Washington, Seattle, WA; [3]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA

Abstract: The pre-Bötzinger complex (preBot) is now recognized as the essential core of respiratory rhythm generation and the inspiratory phase in particular. It is well known that the mechanism of rhythmogenesis is inherently excitatory, in contrast to canonical models of pattern generation such as the half-center, via an emergent network synchronization phenomenon. Using a biophysical model of the entire preBot, we examine how rhythmic activity of the population changes due to (1) the sparsity of connections between cells, (2) the fraction of cells which are inhibitory, and (3) the strength of excitatory and inhibitory synapses. We find that too much sparsity or inhibition disrupts rhythm generation, yet highly connected networks without inhibition also produce non-biological rhythms. As inhibitory neurons are added to the network,

some cells fire out-of-phase with the main population (inspiratory) rhythm, which offers an explanation for the expiratory cells observed in preBot. However, it is not possible to produce a two-phase (inspiratory-expiratory) population rhythm in our model without adding further structure to the network. These modeling results are compared to *in vitro* slice experiments in which we progressively block inhibitory and excitatory synaptic transmission. Slices exhibit rhythms that appear poised in the intermediate range of synchrony, and the fraction of expiratory cells *in vitro* is consistent with our model in this region. Being near the synchrony boundary may facilitate control of this rhythm. This offers a new paradigm for pattern generation where sparsely-coupled groups of cells act collectively as a single oscillator.

Title: Homeostatic plasticity maintains stable respiratory rhythmic activity within the pre-Bötzinger Complex

Authors: *N. A. BAERTSCH[1], J. M. RAMIREZ[2];
[1]Seattle Children's, Seattle, WA; [2]CIBR, Seattle Children's Res. Inst., Seattle, WA

Abstract: Stable breathing is critical for survival. The network responsible for the generation of the respiratory rhythm is located within the medulla, and one particular area that is essential for breathing and specifically involved in the neuronal control of inspiration is the pre-Bötzinger Complex (PreBötC). Following isolation in transverse slices, the preBötC continues to generate stable inspiratory activity. The synchronized inspiratory population activity is transmitted to respiratory motor pools including the hypoglossal (XII) nucleus. Modeling and experimental studies suggest that synchronization and regularity of rhythmic activity is determined by the strength of excitatory conductances and the number of excitatory connections within this network. However, the mechanisms that establish the strength and number of excitatory interactions within this network are unknown. We hypothesized that mechanisms of activity-dependent homeostatic plasticity operate within the preBötC to regulate the stability of the

inspiratory rhythm. To test this hypothesis we isolated transverse brainstem slices containing the PreBötC from p5-10 CD1 mice. AMPA and kainite receptor-dependent synaptic activity was blocked overnight (16 hrs) in slices incubated with 10 μM DNQX in artificial cerebrospinal fluid (ACSF) containing 8 mM K^+ and continuously bubbled with carbogen; and compared to controls incubated for an equivalent duration in ACSF. Following $\geq$ 2 hrs of drug washout, rhythmic population activity was recorded from the PreBötC and XII motor nucleus. PreBötC burst amplitude irregularity score was reduced in slices exposed to DNQX (0.13±0.02), compared to controls (0.28±0.04). Also, transmission of PBC activity to the XII nucleus was improved following incubation in DNQX (100%) vs. controls (84%). Our data suggest that reduced excitatory synaptic activity revealed mechanisms of homeostatic plasticity that may operate within the PreBötC to maintain stable respiratory rhythm generation and reliable transmission to respiratory motor pools. Ongoing studies are using these manipulations to further explore the characteristics and molecular determinants that govern the stability of respiratory rhythmic activity.

Title: Age-dependent effects of EEDQ on the affinity and efficacy of dopamine receptors in the caudate-putamen

Authors: A. MOHD-YUSOF, S. E. EATON, J. M. VALENTINE, D. E. HUMPHREY, A. E. GONZALEZ, C. A. CRAWFORD, *S. A. MCDOUGALL;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Dopamine (DA) receptor inactivation differentially affects the expression of behavior across ontogeny. When administered systemically, *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) blocks the DA agonist-induced behaviors of adult rats, while leaving

the NPA- and quinpirole-induced locomotor activity of preweanling rats unaffected. This paradoxical behavioral effect is even more pronounced when drugs are microinjected into the caudate-putamen (CPu), because EEDQ-treated preweanling rats exhibit a potentiated locomotor response after NPA or quinpirole infusions. The neural basis for EEDQ's age-dependent behavioral effects is uncertain, but we propose that in younger animals a disproportionate number of surviving or newly repopulated D2 receptors exist in a high affinity state. Stimulation of these $D2^{High}$ receptors is hypothesized to cause the potentiated locomotor response exhibited by young rats. The purpose of the present study was to determine whether EEDQ treatment results in a relatively greater proportion of $D2^{High}$ receptors in preweanling rats when compared to adolescents and adults. We also examined the efficacy of D2 receptors by measuring agonist-stimulated [^{35}S]GTPγS binding in vehicle- and EEDQ-treated preweanling, adolescent, and adult rats. In both experiments, male rats were given an IP injection of vehicle or EEDQ (2.5 or 7.5 mg/kg) on PD 17, PD 39, or PD 84. After 24 h, CPu sections were bilaterally dissected and stored at -70 °C. For the $D2^{High}$ assays, duplicate incubation tubes contained 0.15 ml of homogenate, 1.2 nM [^{3}H]-domperidone, and various concentrations of DA. Nonspecific binding was determined in the presence of 10 μM (-)-sulpiride. Agonist-effect curves of [^{35}S]GTPγS binding were performed in assay buffer containing 10 μM GDP, 50–75 μg protein, and various concentrations of NPA. Nonspecific binding was determined in the presence of 10 μM cold GTPγS. Results showed that pretreating rats with EEDQ significantly increased the percentage of $D2^{High}$ receptors in the CPu. Importantly, the proportion of $D2^{High}$ receptors was elevated in preweanling rats relative to the other age groups. EEDQ also increased the efficacy (E_{max}), but not the potency (pEC_{50}), of NPA-stimulated [^{35}S]GTPγS specific binding. This increase in efficacy was significantly greater in preweanling rats than adults. Our findings are consistent with the hypothesis that a relative excess of high affinity, high efficacy D2 receptors produces a state in which DA agonists cause an exaggerated locomotor response in preweanling rats.

Title: Environmental enrichment enhances synaptic plasticity by internalization of striatal dopamine transporters

Authors: ***J. YU**[1,2], M.-S. KIM[1], J. SEO[1,2], M.-Y. LEE[1], S. WI[1,2], S.-R. CHO[1,2];
[1]Rehabil. Med. Yonsei Univ. Col., Seoul, Korea, Republic of; [2]Brain Korea 21 PLUS Project for Med. Sci., Yonsei Univ., Seoul, Korea, Republic of

Abstract: Environmental enrichment (EE) with a complex combination of physical, cognitive, and social stimulations enhances synaptic plasticity and behavioral function. However, the underlying mechanism remains to be elucidated in detail. In this study, we aimed to investigate dopamine-related synaptic plasticity underlying functional improvement after EE. For this, 6-week-old CD-1 (ICR) mice were randomly allocated to EE conditions or standard conditions for 2 months. EE significantly enhanced behavioral functions such as the rotarod test and the ladder walking test. We then investigated the expression pattern of dopamine transporter (DAT) using positron emission tomography (PET), and expression of DAT in the striatum significantly decreased by approximately 18% in the EE mice relative to the control mice. DAT inhibitor administrated to establish the relationship of the DAT down-regulation to the treatment effect also improved rotarod performance, suggesting that DAT inhibition recapitulated EE-mediated treatment benefits. Next, EE-induced internalization of DAT was confirmed using a surface biotinylation assay. *In situ* proximity ligation assay and immunoprecipitation demonstrated that EE significantly increased the phosphorylation of DAT in the striatum as well as the levels of DAT bound with protein kinase C (PKC). In conclusion, we suggest that EE enables phosphorylation of striatal DAT via a PKC-mediated pathway and causes DAT internalization. As a result of DAT internalization and dopamine reuptake inhibition in the presynaptic region, increased levels of dopamine in the neural synapse might lead to functional improvement. This is the first report to suggest an EE-mediated mechanism of synaptic plasticity by internalization of striatal DAT.This study was supported by the Ministry of Science, ICT & Future Planning (NRF-2010-0020408 and NRF-2014R1A2A1A11052042).

Title: Striatal dopamine transmission is weighted differently within the striosome-matrix axis by Substance P

Authors: K. R. BRIMBLECOMBE, *S. J. CRAGG;
Univ. of Oxford, Oxford, United Kingdom

Abstract: The mammalian striatum has a topographical organization of input-output connectivity, but a complex intrinsic non-laminar neuronal architecture comprising projection neurons of two types interspersed among multiple interneuron types and potential local neuromodulators. From this cellular melange arises a compartmentalisation of areas termed striosomes and extra-striosomal matrix. The functions of these compartments are poorly understood but might confer distinct features to striatal signal processing and be discretely governed. Dopamine transmission occurs throughout striosomes and matrix, and is reported to be modulated by the striosomally enriched neuromodulator substance P. However, reported effects are conflicting, ranging from facilitation to inhibition. We addressed whether dopamine transmission is modulated differently in striosome-matrix compartments by substance P. We paired detection of evoked dopamine release at carbon-fiber microelectrodes in mouse striatal slices with subsequent identification of the location of recording sites with respect to μ-opioid receptor-rich striosomes. Substance P had bidirectional effects on dopamine release that varied between recording sites and were prevented by inhibition of neurokinin-1 receptors (NK1R). The direction of modulation was determined by location within the striosomal-matrix axis: Dopamine release was boosted in striosome centres, diminished in striosomal-matrix border regions and unaffected in the matrix. In turn, this different weighting of dopamine transmission by substance P modified the apparent centre-surround contrast of striosomal dopamine signals. These data reveal that dopamine transmission can be differentially modulated within the striosomal-matrix axis, and furthermore, indicate a functionally distinct zone at the striosome-matrix interface which may have key impact on striatal integration.

Title: Dopamine receptor inactivation in the caudate-putamen and nucleus accumbens differentially affects the locomotor activity of young rats

Authors: *K. RUDBERG, A. MORAN, J. RAZO, E. MACEDO, S. E. EATON, A. MOHD-YUSOF, C. A. CRAWFORD, S. A. MCDOUGALL;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Microinjecting the alkylating agent EEDQ into the caudate-putamen (CPu) of adult rats both inactivates DA receptors and blocks DA mediated behaviors. In contrast, DA receptor inactivation in the CPu of preweanling rats causes a paradoxical increase in DA agonist-induced locomotor activity. We have hypothesized that the heightened behavioral responsiveness exhibited by EEDQ-treated preweanling rats is due to elevated levels of high affinity D2 receptors. In other words, an EEDQ-induced increase in the percentage of $D2^{High}$ receptors is proposed to more than compensate for the overall loss of DA receptors, thus resulting in enhanced behavioral responsiveness when challenged with a DA agonist drug (cocaine or NPA). The purpose of the present study was threefold: (1) to replicate the finding that EEDQ potentiates the behavioral effects of NPA when microinjected into the CPu; (2) to determine whether administering EEDQ into the nucleus accumbens (NAcc) also potentiates the effects of NPA; and (3) to examine whether the ability to potentiate or attenuate DA agonist-induced locomotion is influenced by the amount of striatal and accumbal tissue affected by EEDQ. On PD 17, different volumes (0.25, 0.5, or 0.75 µl) of EEDQ (100 µg) or DMSO were bilaterally infused into the NAcc or CPu. On PD 18, basal locomotor activity was assessed for 40 min, after which rats received bilateral infusions of vehicle or NPA (10 µg). Locomotor activity was measured for an additional 40 min. Autoradiographic analysis showed that EEDQ caused a volume-dependent reduction in D2 receptor binding in the CPu and NAcc (i.e., increased dispersion of EEDQ resulted in greater receptor loss) with, presumably, a concomitant increase in the percentage of $D2^{High}$ receptors. Consistent with this finding, microinjecting 0.75 µl EEDQ into the CPu potentiated the NPA-induced locomotor activity of preweanling rats, while lesser volumes of EEDQ left the behavior of rats unaffected. We believe that an EEDQ-induced increase in the percentage of CPu $D2^{High}$ receptors is responsible for the potentiated locomotor response. A similar potentiated behavioral effect was not observed when 0.75 µl EEDQ was microinjected into the NAcc. The most parsimonious explanation is that EEDQ-induced alterations in the percentage of NAcc $D2^{High}$ receptors was insufficient to support a potentiated

locomotor response in preweanling rats. Even so, administering EEDQ into the NAcc of preweanling rats did not block NPA-induced behavior, as normally occurs in adult rats. Thus, inactivating DA receptors in either the CPu or NAcc does not cause adult-like behavior patterns in preweanling rats.

Title: Dorsal striatal mu opioid receptors inhibit cholinergic interneuron-driven dopamine release

Authors: *B. K. ATWOOD[1], Y. MATEO[2], D. M. LOVINGER[2];
[1]LIN, [2]NIAAA, Rockville, MD

Abstract: Dopaminergic input to the dorsal striatum from the substantia nigra is important for many forms of striatal plasticity and striatum-mediated behaviors. The regulation of dopamine release in this brain region is complex and involves multiple neurotransmitters. The role of the mu opioid receptor (MOR) in regulating dopamine release from these inputs is unclear. Some studies show that MOR activation within the dorsal striatum decreases dopamine release, which is curious considering the absence of MOR on dopaminergic inputs. However, MORs found on cholinergic interneurons (CINs) may allow for regulation of dopamine release independent of direct effects on dopaminergic terminals. CINs make up less than 5% of striatal neurons, yet have extensively arborized axons that broadly influence neurotransmission. Acetylcholine released by these interneurons drives local striatal dopamine release by activating nAChRs on dopaminergic terminals. Recent evidence demonstrates that activation of MORs on CINs inhibits the activity of these neurons. We tested the hypothesis that MOR-mediated reduction of CIN activity is responsible for the effect of MOR agonists on dopaminergic transmission. We utilized fast-scan cyclic voltammetry to determine the effects of opioid ligands on dopamine release in

striatal brain slices. The MOR agonist DAMGO inhibited dopamine release elicited by both electrical stimulation and optogenetic activation of CINs. These data demonstrate that MORs are important regulators of CIN-driven dopamine release. We are currently exploring the effects of genetic manipulations of MOR expression on CIN-driven dopamine release.

Title: Conditional knockout of tyrosine hydroxylase in midbrain dopamine neurons

Authors: *J.-F. POULIN, R. AWATRAMANI;
Neurosciences, Northwestern Univ., Chicago, IL

Abstract: Dopamine (DA) is principally produced by neurons located in the midbrain and influences a spectrum of behaviors including motor, learning, reward, motivation, and cognition. In accordance with its diverse functions, DA dysfunction is implicated in a range of disorders affecting millions of people, including Parkinson's disease (PD), schizophrenia, addiction, and depression. To investigate DA function, we generated a mouse with a tyrosine hydroxylase (Th) conditional allele and used a Dat::iCre driver to embryonically delete Th, thus depriving midbrain neurons of their ability to synthesize dopamine. In contrast to previously published studies where a similar Cre line was used to deplete dopamine or ablate dopamine neurons in the midbrain, our cKO mice had a severe hypokinesia, weight loss, and did not survive past three weeks of age. These results suggest that embryonic DA depletion does not inevitably lead to compensatory mechanisms preserving motor function. This mouse model will be very helpful to study the role of DA in the developmental organization of striatal connectivity. In addition, the Th cKO mice will facilitate the investigation of the midbrain DA system by allowing to inhibit

the synthesis of DA in the newly identified DA neuron subtypes using specific genetic entry points.

Title: DHHC15-mediated palmitoylation modulates striatal dopamine levels and spontaneous locomotion

Authors: *R. M. MEJIAS-ESTEVEZ[1], A. ADAMCZYK[2], M. NIWA[1], I. N. KRASNOVA[3], G. M. THOMAS[4], M. HAN[1], J. WANG[5], Z.-X. XI[3], R. L. HUGANIR[1], M. PLETNIKOV[1], J. L. CADET[3], A. SAWA[1], T. WANG[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Drexel Univ., Philadelphia, PA; [3]NIDA, Baltimore, MD; [4]Temple Univ., Philadelphia, PA; [5]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Dopamine (DA) is a major neurotransmitter in striatum and plays an important role in the modulation of activity, movement, rewards, motivation, and executive function. Regulation of striatal DA metabolism and signaling are extremely complex. Palmitoylation, a reversible lipid post-translational modification, is a newly recognized mechanism in the regulation of DA function. Several DA signaling proteins including dopamine transporter (DAT) and DA receptors (D1/D2L) are palmitoylated but their specific palmitoyl-acyl-transferases (PATs) have not been full characterized. Dat-knockout mice show extreme hyperactivity, reduced tissue DA levels and increased extracellular DA levels in striatum. We investigated a line of knockout mice of dhhc15, a neural-enriched PAT. Mutant mice exhibit an increase in the novelty-induced ambulatory activity in open field. Neurochemistry studies of monoamine levels in olfactory bulb, brain cortex, striatum, ventral mesencephalon, and hippocampal tissues in dhhc15-KO mice identified a significant and specific reduction of tissue dopamine and its metabolite, DOPAC in striatum. Interestingly, basal extracellular DA levels in ventral striatum of dhhc15-KO mice are

increased during the habituation time to a new environment using *in vivo* microdialysis methods. This profile suggests a partial DA reuptake or dopamine release defect in striatal dopaminergic neurons. Using an acyl-biotin exchange (ABE) assay, we found no significant difference in the steady-state palmitoylation levels of known DHHC15 substrates including postsynaptic density protein 95 (PSD95), growth associated protein 43 (GAP43), cysteine string protein (CSP), sortilin, and stathmin 2/3, in striatal tissues of dhhc15-KO mice. Characterization of palmitoylation levels of proteins involved in DA metabolism and signaling, including DAT and DA receptors, in the striatum of dhhc15-KO mice are in progress. Data from our studies implicate an important role of dhhc15-mediated pamitoylation in the regulation and release of striatal DA in mice.

Title: Motor skill learning in rats is accompanied by phase-dependent modifications in the cAMP/PKA/DARPP-32 signaling pathway

Authors: *Y. QIAN[1], H. FORSSBERG[2], R. DIAZ HEIJTZ[1];
[1]Dept. of Neurosci., [2]Dept. of Women's and Children's Hlth., Karolinska Institutet, Stockholm, Sweden

Abstract: Abundant evidence points to a key role of dopamine (DA) in motor skill learning. However, the cellular and molecular pathways mediating its effects are still poorly understood. In this study, we used a skilled-reaching paradigm to identify brain activity patterns associated with different phases of motor skill learning. We studied the induction of the plasticity-related gene Arc (also known as Arg3.1), and investigated learning-induced changes in the DA system (from gene expression to biochemical modifications of intracellular pathways). In the early phase of motor skill learning, Arc mRNA was significantly induced in the cortico-striatal circuit, including the medial prefrontal cortex (mPFC), cingulate cortex, primary motor cortex, and striatum. In the late phase, however, a shift in the expression pattern of Arc was evident. Expression of Arc decreased significantly in most brain regions examined, except in the mPFC and dorsal striatum. There were also significant changes in the expression of DA D1 receptors and their intracellular target DARPP-32 in the striatum (but not cortical regions) during the early, but not late, phase of motor skill learning. Western blot analysis of the phosphorylation state of DARPP-32 and its downstream target CREB in the striatum indicated increased levels of phospho-Thr34-DARPP-32 (but not at the Thr75 or Ser97 sites) and phospho-Ser133-CREB during the early, but not late, phase of motor skill learning. These findings implicate the cAMP/PKA/DARPP-32 signaling pathway in the acquisition of novel motor skills, and also demonstrate a dynamic shift in the contribution of cortico-striatal circuitry during different phases of motor skill learning.

Title: Cortical and striatal induced motor tics in rats, behavioral and electrochemical studies

Authors: *J. CHANG, D. J. WOODWARD;
Neurophysiol., Neurosci Res. Inst. North Carolina, Winston Salem, NC

Abstract: Tourette's syndrome (TS) is considered to be a neuropsychological disorder caused by basal ganglia thalamocortical system malfunction. Local injection of GABA antagonist in the striatum of different species yields an animal model of motor tics similar to that exhibited in patients with TS. Cortical regions, however, have been overlooked as a source of tic generation except few early studies in rats. It has been suggested that dopamine (DA) plays an important role in the pathophysiology of TS. However, detailed information about DA action during tics is elusive. Here we test the effect of microinjection of picrotoxin into the primary and secondary (M2) motor cortices to induce motor tics and compare with striatal injection. We also applied newly developed 8 channel fast scan cyclic voltammetry (FSCV) in conjunction with local microinjection technique to investigate the DA release in the striatum during motor tic. Microinjection of picrotoxin at a conventional dose of 1μg/1μl readily induced motor tics, but in some cases, especially in the M2 area, short lasting clonic seizures occurred. A low dose of picrotoxin (0.25-0.5μl/μl) injected into the motor cortices induced a motor tic similar to those initiated by striatal injection without behavioral and electrophysiological signs of seizures. No significant different in tic latency (measured between injection and first tic) was found between cortical and striatal groups while intervals between tics were significantly shorter in the cortical groups than the striatal group. FSCV detected periodic release at 40 s intervals of putative DA signals in regions surrounding the picrotoxin injection site in dorsal striatum. The phasic tics (at 3 s interval) thus were found superimposed on slow DA oscillations .The DA oscillations, not synchronized with individual tic, may be related to previously reported slow oscillation of firing rate in animal model and reaction time task in human patients as possible substrate of neuropsychological disorders. Single unit recording at the striatum injection site preceded activity in the substantial nigra reticulata as indicated by cross correlation analysis. This well controlled study demonstrated that an impaired GABA system both in the motor cortex or striatum mediates a local circuit pathology to generate motor tics. Our concept is that precision observation of modulation of tic generation will provide tools to assess ameliorative intervention.

Abstract: Ketamine is a common anesthetic that, when administered at sub-anesthetic doses, may be effective for the treatment of chronic pain, treatment-resistant depression, and L-DOPA-induced dyskinesia. Although ketamine is an NMDA antagonist and influences opioid and cholinergic receptors, few studies have investigated ketamine's impact on the release of dopamine in the nucleus accumbens. Understanding the impact of ketamine on nucleus accumbens dopamine concentration is important given dopamine's potential involvement in the anti-depressive and analgesic effects of ketamine administration. We investigated this issue by administering sub-anesthetic doses of ketamine (20 mg/kg) to an awake and freely behaving rat. Following a one-hour baseline collection period, a total of five i.p. injections of ketamine, each separated by two hrs, were administered over a 10 hr period. Basal dopamine concentrations were measured every 30 s using the recent-developed technology of fast-scan controlled-adsorption voltammetry (FSCAV). This technique permits measurement of basal dopamine concentration at temporal and spatial resolutions superior to techniques such as microdialysis. Using this approach, we observed 1) that following each ketamine injection there was an initial decrease in basal dopamine concentration (-17 ± 3% from time of injection within 13.9 ± 0.9 min, n = 5 injections/experiment, 3 experiments, ± SEM) that recovered after ~20 min and 2) stable basal dopamine levels increased following the five injections (23 ± 9 % above baseline during the final 30 min of measurement, n = 3 experiments, ± SEM), suggesting that repeated ketamine injection produces a persistent elevation of basal dopamine. Increases in basal dopamine levels may contribute to the effectiveness of ketamine for the treatment of depression, pain states, and the anti-dyskinetic effects reported by our group.

Abstract: Dopaminergic neurons projecting from the ventral tegmental area (VTA) to the nucleus accumbens (NAc) are crucial components of the brain-reward circuitry that drives approach behaviors necessary to acquire reinforcers such as foods.1 In the NAc, dopaminergic projections synapse on medium spiny neurons (MSNs), GABAergic cells that also receive glutamatergic input from the cortex, thalamus, hippocampus, and basal lateral amygdala.2,3 Understanding neurotransmitter actions at these synapses is necessary to elucidate mechanisms that can become high-jacked by drugs of abuse.4 Here we monitor brain activity with a carbon-fiber based probe5 that measures three independent components. Through cyclic voltammograms it quantifies synaptic dopamine overflow,6 through recordings of single-unit activity it simultaneously reveals neuronal firing rates,7 and through coupled micropipettes that form a microdelivery system for controlled iontophoresis, it allows identification of adjacent receptor subtypes in behaving animals.8 Its high spatial resolution for adjacent neurons and synapses, coupled to its high temporal resolution (subsecond) reveals local sites and time-points where specific neurotransmitter-receptor interactions occur. Here we show that a single dopamine concentration transient, triggered by a learned cue during intracranial self-stimulation (ICSS), a goal directed behavior, exerts modulatory responses on MSNs. Critically the data provide a causal link between dopamine release and the modulation of MSNs involved in cue responses by dopaminergic D2 receptors during a learned behavior.

Topic: B.07. Synaptic Transmission

Title: Methylphenidate modulates dopaminergic and glutamatergic transmission from ventral tegmental area to nucleus accumbens Shell

Authors: *C. REYES-VAZQUEZ, A. M. VAZQUEZ-ALVAREZ, B. PRIETO-GOMEZ; Depto. De Fisiología, Mexico DF, Mexico

Abstract: Dopaminergic (DA) neurons in ventral tegmental area (VTA) project to the core and shell subregions of the Nucleus Accumbens (NAc) in which DA release is induced by natural stimuli as well as by drugs of abuse. Synaptic transmission between VTA and NAc is critically involved in reward-motivated behaviors and thought to be altered in addiction. Also, glutamate (GLUT) is packaged and released by a subset of mesolimbic DA neurons, eliciting Excitatiory Postsinaptic Currents (EPSCs) onto medium spiny neurons in NAc. There is no information about the modulation of GLUT release from DA midbrain terminals by Methylphenidate (MTP). Using electrical stimuilation to selectively activate midbrain DA fibers, we compared the properties and modulation of EPSCs measured using whole-cell recordings in mouse brain slices. Mice (8-10 weeks old) were anesthetized with isoflurane and killed by decapitation. Brains were quickly removed, mounted, and sliced. Slice preparation and whole cell patch clamp recordings were performed using standart techniques. For electrical stimulation, a glass pipette filled with ACSF was placed in the NAc Shell and a rectangular pulse (0.2 ms) was applied every 2 min. The amplitude of the current pulse (100-250 μA) was adjusted to use the minimal current needed to generate a maximal and stable responses. Electrically induced EPSCs were inhibited by DA receptor D2R agonist and showed a marked paired-pulse depression that required 2 min for full recovery. MTP depressed EPSCs amplitude by 50% but enhanced the overall DA transmission from midbrain DA neurons. AMPA and NMDA receptor-mediated EPSCs were equally inhibited by MTP, suggesting a presynaptic mechanism of action. These findings demonstrate that acute MTP inhibits DA and glutamate release from midbrain DA neurons via presynaptic D2R but has differential overall effects on their transmissions in the NAc. Suggesting that MTP, by blocking DA reuptake, facilitates the feedback inhibition of DA and glutamate release from these terminals.

Title: Cell-type selective encoding of spontaneous movement by dopaminergic neurons

Authors: *P. D. DODSON[1,2], J. K. DREYER[4], K. A. JENNINGS[3], R. WADE-MARTINS[3,2], S. J. CRAGG[3,2], J. P. BOLAM[1,2], P. J. MAGILL[1,2];

Abstract: Loss of dopaminergic neurons in Parkinson's disease results in a compromised ability to initiate movement. However, while it is clear from the symptoms of Parkinson's that dopamine is critical for appropriate motor function, it is generally thought that the firing of dopaminergic neurons does not change during movement. Using *in vivo* recording and juxtacellular labelling of individual, identified midbrain dopaminergic neurons in head-fixed mice, we show that neurons encode the onset of spontaneous movement with a pause in their firing. Moreover, we found that this movement-related firing was cell-type specific, with dopaminergic neurons in the substantia nigra pars compacta (SNc) but not ventral tegmental area (VTA) significantly decreasing their firing rate at movement onset. To determine whether brief, movement-related firing of dopaminergic neurons could be 'read out' in target structures, we used fast-scan cyclic voltammetry and computational modelling. We show that movement-related firing results in significant changes in extracellular striatal dopamine concentration and receptor signaling in striatal spiny projection neurons (SPNs). To investigate whether movement-related firing patterns are altered in Parkinson's disease, we recorded from SNc neurons in a Parkinson's mouse model (SNCA-OVX mice); these mice express moderately elevated levels of human alpha-synuclein and develop age-dependent motor impairment and neurodegeneration. Consistent with our previous findings in anesthetized SNCA-OVX mice, we found that in awake mice at rest, the firing rates of surviving SNc neurons were significantly lower compared to those in littermate controls. Moreover, encoding of movement by SNc neurons and the resultant movement-related striatal dopamine signaling was lost in Parkinsonian mice. These findings demonstrate a role of substantia nigra dopaminergic neurons in encoding movement-onset and suggest that loss of appropriate signaling may contribute to motor impairment in Parkinson's.

Title: AMP kinase activation augments K-ATP current in rat midbrain dopamine neurons

Authors: *S. W. JOHNSON[1,2], Y. WU[2], A. C. MUNHALL[1], K.-Z. SHEN[2];
[1]Dept Neurol, Portland VA Med. Ctr., Portland, OR; [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: AMP-activated protein kinase (AMPK) is a master enzyme that regulates expression of ATP-sensitive K+ (K-ATP) channels in pancreatic beta-cells and cardiac myocytes. Midbrain dopamine neurons also express K-ATP channels, and they can exert strong influences on neuronal excitability. The present study used whole-cell patch-clamp recordings to investigate effects of AMPK on K-ATP channel function in substantia nigra compacta dopamine neurons in slices of rat midbrain. We first examined the actions of the AMPK activator A769662 on K-ATP currents evoked by 200 μM diazoxide. When added to the pipette solution, the AMPK activator A769662 (5 μM) was associated with a significant increase in currents evoked by bath application of diazoxide, that being 472% of control when measured 60 min after starting whole-cell recording. Current evoked by the K-ATP channel opener NN414 (10 μM) also increased significantly to 338 ± 21% of control 60 min after starting superfusion. Activation of AMPK by A769662 was confirmed by Western blot analysis, which showed that A769662 induced a concentration-dependent increase in Thr-172 phosphorylation of AMPK in slices of rat midbrain. But as an unexpected finding, we found that diazoxide currents also increased over time when pipettes did not contain A769662; although currents also increased significantly to 300% of control, this was significantly less than the increase observed when A769662 was present ($P < 0.01$, t-test). Moreover, superfusing the slice with the AMPK blocking agent dorsomorphin (30 μM) significantly reduced diazoxide current to 38 ± 7% of control, whether or not A769662 was present in pipette solutions. Control experiments showed that repeated applications of the

GABA-B agonist baclofen evoked outward currents that were not altered by the presence of either A769662 or dorsomorphin over 90 min of recording. Moreover, diazoxide currents did not increase over time in subthalamic nucleus neurons when pipettes contained A769662. We conclude that AMPK activation augments the function of K-ATP channels in midbrain dopamine neurons. Our findings that AMPK activation did not alter diazoxide currents in subthalamic neurons or GABA-B currents in dopamine neurons suggest that AMPK exerts actions that are specific for types of neuron and ion channel.

Title: T-type calcium channels control non-linear dendritic integration in vulnerable subpopulation of substantia nigra dopamine neurons

Authors: *R. C. EVANS, Z. M. KHALIQ;
NINDS, NIH, Bethesda, MD

Abstract: Dopamine neurons burst in response to rewarding stimuli and pause in response to reward omission. Recent *in vivo* studies suggest that these bursts and pauses interact with each other, with pauses facilitating rebound bursts. One possibility is that hyperpolarization during the pause modifies intrinsic conductances and alters dendritic integration, enabling bursts in response to incoming excitatory input or disinhibition. However, little is known about how hyperpolarization affects dendritic excitability and synaptic integration in substantia nigra pars compacta (SNc) neurons. Using two photon calcium imaging and whole cell recording, we found that hyperpolarization modulates intrinsic conductances, facilitating a strong depolarizing rebound in SNc dopamine neurons. When we drove a 20Hz triplet of action potentials from a range of membrane potentials (-50mV to -90mV), we saw a long lasting afterdepolarization (ADP), and a concomitant large dendritic calcium transient emerge with increasing hyperpolarization. For example, the calcium amplitude in response to the triplet driven from -80mV was four times larger than the calcium amplitude in response to the same triplet driven from -60mV (-60mV: mean dG/Gs=0.031 n=42; -80mV: mean dG/Gs=0.133 n=94; p<

0.000001). In addition, we found that at -80mV, the size of the ADP correlated well with the size of the calcium transient (r=0.75, n=114). Applying TTA-P2, we found that the ADP and corresponding calcium transients depend on T-type calcium channels. Additional experiments along with computational modeling suggested that the high input resistance and tightly coupled dendrites characteristic of SNc dopamine neurons facilitate the generation of the ADP. Specifically, increasing membrane conductance by activation of GIRK potassium channel with baclofen, a GABAb agonist, eliminated the ADP. To test the effect of hyperpolarization on synaptic integration, we stimulated excitatory inputs onto the SNc dopamine neurons at increasing frequencies. We found that hyperpolarization increased the sensitivity of SNc neurons to input frequency, shifting the dendritic integration pattern from a linear to a non-linear mode. Lastly, we performed post-hoc immunostaining on recorded cells. We found that the hyperpolarization induced ADP is prominent in the calbindin negative subpopulation of SNc neurons, but substantially smaller in the calbindin positive subpopulation. Because a large ADP corresponds to a large global calcium influx, this novel characteristic may represent an increased calcium load and thus contribute to the selective vulnerability of the calbindin negative neurons in Parkinson's Disease.

Title: Ionic mechanisms of the post-burst pause in dopamine neuron subpopulations

Authors: *R. A. TARFA[1,2], Z. KHALIQ[1];
[1]NIH/NINDS, Bethesda, MD; [2]Neurosci., Brown Univ., Providence, RI

Abstract: Dopamine neurons (DA) contribute to a range of behaviors such as reward, motivation, and movement, which raises the question of whether functional differences exist between dopamine neuron subpopulations. Here, we tested heterogeneity in the firing properties and underlying ionic conductances of retrogradely-labeled mesostriatal (MS) and mesoaccumbal (MA) dopamine neuron subpopulations located in the substantia nigra (SNc) and ventral tegmental area (VTA). During goal-directed behaviors, dopamine neurons fire bursts of spikes

quickly followed by pauses. Therefore, we examined the ionic mechanism underlying high-frequency firing and the subsequent pauses. First, we compared firing evoked from fixed membrane potentials (between -65 and -70 mV) and found that MA and MS neurons displayed similar maximal spike rates. However, comparing the amplitude of the after-hyperpolarization (AHP) immediately following high-frequency spiking, we found that AHPs were significantly larger in MS neurons compared to MA neurons. Furthermore, AHPs were completely blocked by apamin, a blocker of small-conductance calcium-activated (SK) potassium channels, suggesting a more dominant role of SK channels in shaping the post-burst pause in MS neurons. *In vivo* experiments comparing the burst-pause sequence in dopamine neuron subpopulations have observed relatively longer pauses following bursts in MA dopamine neurons. We next examined the latency to the first spike in response to current injections evoked from fixed potentials (-70 mV). We found significantly longer latencies in MA versus MS neurons. In a similar comparison between spontaneously active VTA and SNc neurons, we found that the delay to first spike (i.e. rebound delay) following a brief (500 ms) hyperpolarizing current injections was typically longer in VTA versus SNc neurons. Bath application of AmmTX3 in both VTA and SNc neurons dramatically reduced the length of the rebound delay, consistent with a prominent role of A-type potassium currents. Past work has shown that A-type potassium currents contribute to the latency of first spike and rebound delays in midbrain dopamine neurons. We found that A-type potassium currents decayed significantly more slowly in MA dopamine neurons (avg inactivation time-constant, at -40 mV: 98.4 ± 12.21 ms, n = 13) as compared to the MS neurons (avg time-constant, at -40mV: 36.8 ± 6.0 ms, n = 10). Altogether, our findings suggest post-burst pauses in dopamine neurons result from the interaction of SK, A-type and H-currents, with SK and H-currents playing a more dominant role in the SNc neurons while A-type currents are more important in shaping pauses in VTA neurons.

Title: Influence of timing on integration of excitatory synaptic input during tonic firing in substantia nigra dopamine neurons

Authors: *T. A. HAGE, Z. M. KHALIQ;
NINDS/NIH, Bethesda, MD

Abstract: Dopamine neurons of the substantia nigra pars compacta display ongoing firing of action potentials (APs) at low rates both *in vivo* and in acute slices. As a result, excitatory synaptic inputs must be integrated on an ever changing membrane, unlike the stable resting potentials of typically silent neurons. There are multiple mechanisms by which the ongoing activity of dopamine neurons could influence synaptic inputs. First, synaptic and voltage-sensitive ion channels (e.g. NMDA receptors and low-voltage activated Ca channels) are more likely to be strongly activated towards the later phase of the spike cycle where the membrane potential nears AP threshold. Second, APs during tonic firing of dopamine neurons reliably backpropagate throughout the dendrites and produce large AP-evoked conductances that decrease membrane resistance and may shunt synaptic potentials. Using whole-cell recording, 2-photon Ca imaging and glutamate uncaging in acute mouse brain slices, we tested the influence of the timing of synaptic input relative to the phase of tonic firing. We find that the amplitude of glutamate-evoked synaptic Ca influx is nearly twice as large in the late phase of tonic firing, near AP threshold (phase = 0.75-1, $\Delta G/GS = 20.2 \pm 2.1\%$) than in the early phase, shortly following an AP (phase = 0-0.25, $\Delta G/GS = 10.6 \pm 1.5\%$). The amplitude of synaptic Ca influx in response to glutamate uncaging during the middle phase of the firing cycle (0.26-0.74) was intermediate ($\Delta G/GS = 15.7 \pm 1.4\%$). We measured the effect of glutamate uncaging on the timing of the subsequent AP as a function of the phase of tonic firing. We observe a U-shaped relationship in which synaptic input shortly following an AP has little effect on the timing of the next AP - likely due to weak synaptic strength ($2 \pm 4\%$ decrease in ISI). Synapse activation in the late phase of tonic firing also has little effect on the timing of the subsequent AP ($1 \pm 3\%$ decrease in ISI) despite increased synaptic strength, as the membrane voltage is already near AP threshold. Synaptic activation during intermediate phases of tonic firing significantly decreased the ISI by $12 \pm 3\%$. Ongoing experiments are aimed at determining the contributions of specific ion channels to shaping excitatory synaptic inputs during different phases of tonic firing.

Title: Optogenetic stimulation of the Subthalamic nucleus modulates downstream dopaminergic neurons in the Substantia Nigra pars compacta via endocannabinoids

Authors: *P. S. FREESTONE, K. L. TODD, Y. SUN, J. LIPSKI;
Univ. of Auckland, Auckland, New Zealand

Abstract: Endocannabinoids (eCBs) are cannabis-like substances produced by the brain which regulate synaptic transmission in a retrograde fashion by inhibiting presynaptic neurotransmitter release. We have recently shown a novel mechanism regulating GABAergic transmission onto dopaminergic neurons in the Substantia Nigra pars compacta (SNc) mediated by eCBs. Production of eCBs was initiated by spillover of glutamate, yet the source of the glutamatergic input was not determined. The Subthalamic nucleus is a major glutamatergic nucleus of the basal ganglia circuitry and plays a crucial role in the indirect and hyperdirect pathways of this network. The present study investigated the effect of the STN on the activity of dopaminergic neurons in the SNc, with focus on the role of eCBs. CD-1 mice expressed either channelrhodopsin (ChR2) or halorhodopsin (HR) under the CaMKIIα promotor after injection of viral (AAV) constructs into the STN. Neuronal activity was monitored using whole-cell and single-unit electrophysiological recordings from horizontal midbrain slices (300 μm thick) containing the SNc, STN and SN pars reticulata (SNr) after 4 - 8 weeks expression. The STN was selectively illuminated using a digital mirror device and a variety of stimulation patterns (constant on, 5 - 100 Hz, or Theta-burst; 30 sec duration, 4 ms pulse). Light activation of the STN in slices obtained from ChR2-expressing mice evoked a biphasic increase in dopaminergic neuron firing. The initial increase was reduced by bath application of CNQX (10 μM), while the delayed response was unaffected. In HR-expressing STN, a biphasic inhibition of firing was observed. The response supports an underlying glutamate driven disinhibition mediated eCBs, requiring further characterization using specific pharmacological tools.

Title: Role of co-released glutamate from dorsal raphe serotonin neurons in substantia nigra

Authors: *H. ZHANG[1], L. CHEN[2], Q. QIN[3], L. ZHI[3], C. B. DIVITOA,[4], S. CHOI[6], Y. WANG[2], R. P. SEAL[5];
[1]Neurosci., Dept. of Neurosci., Philadelphia, PA; [2]Fudan Univ., Shanghai, China; [3]Thomas Jefferson Univ., Philadelphia, PA; [4]Univ. of Pittsburgh, Pittsburgh, PA; [5]Univ. of Pittsburgh, Philadelphia, PA; [6]Columbia Univ., New York, NY

Abstract: The serotonergic system is involved in the regulation of mood, aggression, sleep, and numerous other behaviors. Accumulating evidence suggests that a subset of raphe serotonin neurons may release glutamate as a cotransmitter to communicate with target neurons, however, this ability is still controversial and its roles wait to be elucidated. Dopamine (DA) neurons in the substantia nigra (SN) pars compacta plays key roles in movement and dysregulation of DA transmission has been strongly implicated in movement disorders such as Parkinson's disease. The other component of SN, SN pars reticulata (SNr) is a key basal ganglia output nucleus critical for movement control. In addition to excitatory inputs from the cortex and subthalamic nucleus, SN neurons are prominently innervated by serotonin neurons in the dorsal raphe (DR), however, up to date; the exact role played by the serotonin system in the control of midbrain SN neurons is still unclear. Here we use an optogenetic approach to investigate whether glutamate is co-released in SN and how serotonin and the co-released glutamate modulate the midbrain SN microcircuit. We selectively activated the serotonergic axons by expressing the light-activated cation channel channelrhodopsin-2 (ChR2) in genetically defined serotonin neurons in the raphe of wild-type (WT) and vesicular glutamate transporter 3 (VGLUT3) KO mice by injecting a virus encoding a cre-dependend ChR2-mcherry fusion protein into the dorsal raphe nucleus of Sert-Cre mice (> 2 month old). We performed whole-cell patch-clamp recordings in SN 3-8 weeks after surgery. We found that excitatory post-synaptic potentials (EPSCs) could be evoked by photo-stimulation of serotonergic terminals in the SN in the WT mice whereas was absent in the VGLUT3 KO mice. Serotonin terminals co-releasing glutamate mainly targeted GABA neurons in the SN and increased their firings upon activation. These data suggest that serotonergic neurons in dorsal raphe are capable of release glutamate in SN and may provide a fast sub-cortical control of SN microcircuits.

Title: Model of the interaction of the axonal and somatic spike generating mechanisms in nigral dopamine neurons

Authors: *C. C. CANAVIER;
Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: The action potential in midbrain dopamine neurons has two separable components, an axon initial segment (AIS) component and a somato-dendritic (SD) component. The AIS component can be isolated using antidromically evoked spikes while holding the soma hyperpolarized. The maximum firing range in these neurons is limited by depolarization block caused by the failure of the SD component. In order to model the temporal separation of these two components, we started with an existing model of a dopaminergic pacemaker neuron (Kuznetsova et al. 2010) with a morphology (Vetter et a.l 2001) downloaded from www.neuromorph.org and implemented in the simulation package NEURON. We then added an axon hillock and axon initial segment connected to a primary dendrite at variable distances from the soma. The NaV and delayed rectified channel density were larger in the AIS than elsewhere, and in some simulations, the half activation and inactivation of the NaV current were shifted in a hyperpolarized direction in the AIS to lower the threshold. The model reproduces many features of the published experimental data, including a latency between the spike in the axon-bearing dendrite (ABD) and that in the soma, as well as the near simultaneous spikes throughout the soma and nonABD dendrites. The AIS component is much more prominent in the model for antidromic compared to orthodromic spikes, such as those that occur during pacemaking *in vitro*. For some parameter settings we observed action potential reflection, which involves a second spike in the ABD driven by the SD in the rest of the cell (Gentet and Williams 2007). We incorporated a second, slow component of NaV channel inactivation in order to better capture entry into depolarization block. The results are highly dependent on the passive properties of the model neuron as well as the geometry and other parameters of the axon. The model can be used to understand back propagation of spikes during simulated *in vivo* firing patterns.

Title: Cerebellar modulation of substantia nigra

Authors: *S. G. KEE, K. KHODAKHAH;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The graceful, precise, and well-timed movements of the human body are coordinated by a complex system of interconnected brain regions. Two subcortical structures, the cerebellum and basal ganglia, are responsible for fine-tuning motor output. Dysfunction of these structures is associated with a number of neurodegenerative diseases and movement disorders, including Parkinson's disease (PD), Huntington's disease, dystonia, and ataxia. Both structures are known to form a number of closed-loop circuits with the cerebral cortex, which, until recently was believed to be the primary site of interaction between these two brain areas; however, reports of reciprocal disynaptic connections between basal ganglia and cerebellum have challenged this view. There is anatomical and functional evidence in the literature that supports a connection from the cerebellar nuclei to the dopamine neurons of the substantia nigra pars compacta, by which the cerebellum can alter dopamine levels in the striatum. Here, we test the hypothesis that the cerebellum can modulate the substantia nigra through a direct, monosynaptic connection. To test this hypothesis, Channelrhodopsin (ChR2) was expressed in cerebellar nuclei neurons and an optrode was used to record from single units in substantia nigra while simultaneously activating cerebellar fibers in substantia nigra. Immunohistochemistry confirmed that cerebellar fibers expressing ChR2 were present in the tyrosine hydroxylase-positive region of the substantia nigra, corresponding to the pars compacta, but limited in the nearby parvalbumin-positive region of the substantia nigra, corresponding to the pars reticulata. Preliminary electrophysiology data suggest that neurons in the substantia nigra are excited in response to optogenetic activation of cerebellar fibers in substantia nigra. Taken together, these data provide support for an additional pathway capable of relaying information directly between the cerebellum and basal ganglia.

Title: A new role for midbrain dopaminergic neurons during temporal judgments

Authors: S. SOARES[1], B. V. ATALLAH[1], T. S. GOUVÊA[1], T. MONTEIRO[1], *J. J. PATON[2]; [1]Champalimaud Fundation, Champalimaud Ctr. for the Unknown, Lisboa, Portugal; [2]Fundacao Champalimaud PT507131827, Lisbon, Portugal

Abstract: Encoding the passage of time is critical to behavior and cognition. Although classically referenced as key structures for reward based decision making and motor behavior, the basal ganglia (BG) are critical for encoding time on the scale of seconds. Yet, little is known about how distinct components of BG circuit contribute to the encoding of time. Here we probe the role of a critical component of the BG, midbrain dopaminergic (DAergic) neurons. We measured and manipulated the activity of DAergic neurons in mice performing a temporal discrimination task. In this task, mice learned to judge the delay between two tones as shorter or longer than a 1.5s boundary, reporting their judgements by entering one of two nose ports in order to earn a reward. To characterise the response properties of midbrain DAergic neurons during this task, we expressed GCaMP6f specifically in these neurons and recorded bulk fluorescence signals in awake, behaving mice. We observed large phasic responses tied to various task events, such as delay onset, delay offset and reward delivery. Notably, the amplitude of the response to delay offset was larger when stimuli were judged as short than when they were judged as long, regardless of whether the subsequent choice was correct. This suggests that short temporal judgements are correlated with higher midbrain DAergic activity. To test whether this relationship is causal, we photo-activated these neurons using channelrhodopsin-2 during task performance. This manipulation resulted in a horizontal shift in the psychometric curve towards shorter choices. Our results are consistent with the interpretation that activating midbrain DAergic neurons slows the animal's internal representation of elapsed time, suggesting a novel and non-classical role for midbrain DAergic neurons in time encoding.

Title: Loss of Gad67 in neurons expressing dopamine Drd1a receptors prevents the development of l-DOPA-induced dyskinesias in a mouse model of Parkinson's disease

Authors: *J.-J. SOGHOMONIAN[1], K. ZHANG[2], C. CHAMMAS[2];
[1]Anat. and Neurobio., [2]Boston Univ. Sch. of Med., Boston, MA

Abstract: L-DOPA-induced dyskinesias are a major detrimental side effect of l-DOPA administration in patients with Parkinson's disease. The objective of this study was to determine the contribution of the Gad67 isoform of the GABA-synthesizing enzyme glutamic acid decarboxylase in striatal neurons on dyskinesias induced by l-DOPA in a 6-hydroxydopamine-mouse model of Parkinson's disease. Mice with a floxed Gad1 exon 2 (Gad1=gene encoding for Gad67) were bred with mice expressing Cre-recombinase under the activity of the promotor for the dopamine Drd1a receptor, which is predominantly expressed in striatal direct pathway neurons, or under the activity of the promotor for Gpr88, an orphan G-protein coupled receptor predominantly expressed in direct and indirect pathway striatal neurons. Mutant mice with a deletion of Gad1 exon 2 in Drd1a or Gpr88-expressing neurons had a prominent decrease in Gad67 levels in the striatum and the substantia nigra but not in the cerebellum or the cerebral cortex, a finding consistent with evidence that these proteins are highly and predominantly expressed in the striatum. Mice with a Gad67 deficiency in Drd1a-expressing neurons were impaired on the pole test and the Rotarod suggesting that a deficit in GABAergic inhibition in the direct pathway impairs motor coordination and balance. In contrast, mice with a Gad67-deficiency in Gpr88-expressing neurons had a performance comparable to control littermates. Gad67-deficient and control littermate mice were lesioned with 6-OHDA in the medial forebrain bundle on one side of the brain. Three weeks post-surgery, mice were injected once daily for 10 days with l-DOPA. Control littermate mice or mice with a Gad67 deficiency in Gpr88-expressing neurons developed abnormal involuntary movements (AIMs) soon after the onset of l-DOPA administration. In contrast, mice with a Gad67 deficiency in Drd1a-expressing neurons did not exhibit AIMs in response to l-DOPA. These finding indicate that Gad67 in direct pathway striatal neurons plays a key role in motor control in the dopamine-intact mice and in l-DOPA-induced dyskinesia in the dopamine-deficient brain. We also conclude that the additional loss of Gad67 in indirect pathway neurons cancels out the effects of Gad67 loss in direct pathway neurons.

Title: Intrinsic choice reflexes in the sensorimotor striatum

Authors: *A. J. GRUBER[1], R. THAPA[2], P. BANKS[2];
[1]Dept. of Neurosci., [2]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The propensity of animals to switch choices immediately after unexpectedly poor reinforcement outcomes is a pervasive strategy across species and tasks. We report here that such lose-switch responding rapidly decays in rats and is blocked by corrupting the negative reward prediction error signal transmitted by dopamine in the sensorimotor striatum. Moreover, we found that decaying lose-switch responding emerges in humans when subjects are given a cognitive load and must presumably rely on motor systems for task performance. These data reveal an important but underappreciated role of motor-related systems in rapid choice adaptation. We propose that this immediate lose-switch responding is aptly described as an instinctual choice reflex due to its predictably rapid decay and ubiquity despite being a sub-optimal strategy in the present task. In addition to solving simple ethological tasks, we speculate that this mechanism could cease animals' current response policy when outcomes are poor so that computationally expensive behavioural control systems can implement an improved strategy.

Title: Juvenile onset of stereotypy with loss of BDNF signaling in D1R expressing striatal neurons

Authors: ***M. ENGELN**[1], R. CHANDRA[1], A. LA[2], T.-C. FRANCIS[1], M.-K. LOBO[1]; [1]Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD; [2]Univ. of Maryland, Col. Park, College Park, MD

Abstract: Imbalance between D1- vs. D2-receptor containing medium spiny neuron (MSN) basal ganglia output-pathways is implicated in stereotyped disorders including Tourette Syndrome (TS). Surprisingly, there is little information on the molecular role of MSN subtypes in TS or other stereotypy disorders. We have a mouse model carrying a deletion of TrkB (the BDNF receptor) in D1-MSNs (D1-Cre-flTrkB mice), in which a subset of mice display involuntary stereotypic behaviors beginning around 3 weeks of age. Consistent with an impaired GABAergic system in TS, these mice display a decrease in striatal GABA-A subunits accompanied by reduced inhibition in striatal D1-MSNs. We first characterized repetitive behaviors in D1-Cre-flTrkB mice with stereotypy (S), or with no stereotypy (NS), and D1-Cre control mice. Complete turns, head tics, rearing, and grooming are assessed weekly from ages 3 to 8 weeks. Since the transcription factor, early growth response 3 (Egr3) is regulated by BDNF and Egr3 transcriptionally regulates a subset of GABA-A subunits, we are examining striatal Egr3 mRNA in all groups. We found that D1-Cre-flTrkB-S mice display more complete turns at all ages compared to D1-Cre-flTrkB-NS and control mice. D1-Cre-flTrkB-S mice exclusively display head tics, which decline from juvenile to adult ages. Our preliminary data demonstrates decreased Egr3 mRNA in the striatum of D1-Cre-flTrkB mice. To investigate if this change is specific to D1-Cre-flTrkB-S mice we are using D1-Cre-flTrkB-RiboTag mice to measure Egr3 levels in D1-MSNs and chromatin immunoprecipitation to examine Egr3 transcriptional regulation of GABA-A subunits in these mice. In addition, we overexpress Egr3 in D1-MSNs with AAV-DIO-Egr3-eYFP to rescue these stereotyped behaviors. Our findings demonstrate that D1-MSNs through dysfunctional BDNF signaling play a role in juvenile onset of stereotypy behaviors. The enhanced stereotypy behaviors potentially occur through reduced inhibition in D1-MSNs via altered Egr3 regulation of GABA-A subunits. Our ongoing studies can provide novel insight into the cell subtypes and molecular mechanisms underlying stereotypy disorders.

Title: Optimizing functional MRI sequences at 7 Tesla for subcortical nuclei

Authors: *B. U. FORSTMANN[1], M. KEUKEN[1], R. TRAMPEL[2], G. DE HOLLANDER[1]; [1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: The substantia nigra (SN) and subthalamic nucleus (STN) are thought to be important, distinct nodes in a cortico-basal ganglia loop implementing cognitive functions such as perceptual decision-making and cognitive control. The STN is the main target of deep brain stimulation (DBS), a popular and effective treatment of Parkinson's Disease. This treatment can lead to serious side-effects and the underlying mechanisms are not well-understood. Ultra high-resolution functional MRI could help elucidate both the function of the STN in the healthy population, as well as lead to a better understanding of the side-effects of DBS because these might be related to functional subdivisions within the STN. However, deriving a functional MRI signal from these subcortical nuclei remains a challenge. Anatomical specificity requires a very high spatial resolution due to the small size and close proximity of the two nuclei. In addition, the signal-to-noise-ratio is hampered by the fact that the SN and STN show highly elevated concentrations of iron, which lead to greatly reduced baseline T2* values. Also, the nuclei lie deep in the brain, far from, and approximately equidistant to the different receive elements of a multi-channel array coil. The resulting increased g-factor reduces the performance of parallel imaging sequences and ultimately the signal-to-noise ratio in those regions. We present a set of functional imaging studies at ultra-high field (7T), measured while participants performed the stop-signal paradigm. Different spatial resolutions, echo-times, and acceleration factors were acquired in an effort to optimize signal-to-noise ratio and anatomical specificity of functional MRI in the iron-rich human basal ganglia including the SN and STN.

Support: The effect of normabaric hyperoxia treatment on energy metabolism and dopaminergic gene expression in basal ganglia following everetraumatic brain injury in mouse model of C57BL/6J (Account no: 1001/PPSP/813032 Universiti Sains Malaysia).

Title: Normobaric hyperoxia treatment following fluid percussion injury in striatum of mice improved locomotors activity through neuroprotection and enhancement of dopaminergic system

Authors: *S. MUTHURAJU, J. ABDULLAH, M. RAFIQUL ISLAM;
Univ. Sains Malaysia, Kota Bharu, Malaysia

Abstract: Objective: Fluid percussion injury (FPI) is most substantial method to mimic closed traumatic brain injury (CTBI). Majority of accident caused CTBI which leads to increase mortality rates in developing countries. However, sustainable therapeutic approach has not been established yet. Therefore, the present study was designed to evaluate the impact of normobaric hyperoxia treatment (NBOT) on striatum associated locomotors activity and dopamine genes after FPI. Methods: Locomotors activity has been assessed using a new computerized well recognized behavior tool called IntelliCage. Animals were divided four groups such as Group I control (n=15), Group II sham (n=15) (only cannula implanted), Group III FPI (n=15) and Group IV FPI with NBOT (n=15). Animals were habituated in IntelliCage for 4 days following transponder implanted in mice neck region on 5th day. Locomotors activity of all four groups of animals has been assessed for 5 days for 6hr (9am-3pm) before inducing FPI. On 6th day, cannula was implanted on striatum, on 7th day FPI was performed in Group III (kept in normal environment) and IV (immediately exposed to NBOT for 3hr). Locomotors activity was assessed at 1st, 7th, 14th, 21st and 28th days following FPI in IntelliCage for 6hr. At the end of the behavior experiment, neuronal morphology and dopamine receptors (D1 and D2), Dopamine transporter (DAT) and Vesicular monoamine transporter (VMAT) were also assessed. Results: The data suggested that FPI significantly impaired locomotors activity of mice as compared to control and sham in terms of less number of visits in all four corners of IntelliCage in associated with downregulation of dopamine genes. The immediate exposure to NBOT improved locomotors activity in terms of increased number of visits in all four corners as compared to FPI and upregulated dopamine genes and minimized neuronal damage. Conclusion: Taken together these results concluded that normobaric hyperoxia exposure could improve the locomotors activity of mice following fluid percussion injury in striatum through prevent neuronal damage and enhancement of dopaminergic neurotransmission. The present study suggested that NBO treatment could be possible therapeutic approach for improving dopaminergic neurons as well as

locomotors activity following closed traumatic brain injury victims. Key words: Traumatic Brain injury, Normobaric Hyperoxia Treatment, IntelliCage, Locomotors activity, Striatum, Dopamine. E.mail: brainsciences@gmail.com

Title: Functional imaging of dopaminergic projections in dorsal striatum with single-axon resolution in behaving mice

Authors: *M. HOWE[1,2], D. A. DOMBECK[2];
[1]Neurosci., Northwestern Univ., Chicago, IL; [2]Northwestern Univ., Evanston, IL

Abstract: Dopamine signaling in the striatum has long been recognized as critical for regulating movement on immediate timescales, and for driving learning-related plasticity over extended timescales. Current theories of dopamine function, derived primarily from midbrain electrophysiological recordings in the midbrain SNc and VTA, propose that dopamine neurons homogenously transmit phasic (hundreds of ms) signals to unpredicted rewards or reward-predictive cues. These signals are believed to enhance representations of environmental stimuli or actions that lead to reward, driving future goal-directed learning and behavior. Regulation of ongoing movement, on the other hand, is believed to be enabled by the ongoing tonic or slowly varying (several seconds) firing within these same neurons. Recent electrophysiological and voltammetric recordings in different striatal subregions have called these theories into question, but lack the combination of fine (micron scale) spatial resolution, striatal projection target specificity, and large sampling region necessary to adequately assess functional dynamics across populations of dopamine axons projecting to specific striatal subregions. To overcome these limitations, we have developed a new approach based on two-photon imaging of genetically encoded calcium indicators to measure dynamics across the dopaminergic projection population to dorsal striatum with single axon resolution in behaving mice. We are applying this new imaging method to test existing models of dopamine signaling. Preliminary data suggests that locomotion related signaling may be present within the projection population and may be

separate from the reward signaling projection population. Such a finding would require revisions of current models of the dopamine signaling dynamics in the striatum responsible for movement regulation and reinforcement learning.

Title: Contributions of the globus pallidus to action selection and proactive inhibition

Authors: ***B.-M. GU**, C. LU, S. BIDWELL, J. BERKE;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Basal ganglia networks provide important gating mechanisms that facilitate adaptive behavioral control. This control includes action suppression, which is essential to achieve flexible, non-impulsive behavior. The indirect pathway through the globus pallidus (GP; GPe in primates) is often considered a "No-Go" pathway, but how exactly it contributes to action suppression is not well understood. One proposal (Aron 2011) is that GP contributes to "proactive" behavioral inhibition, also called action restraint. This is manifest as greater preparedness-to-stop, for example in proactive versions of the Stop-signal task. We have started to assess the behavioral functions of GP using precisely-timed optogenetic manipulations in rats. In order to test GP contributions to both action initiation and proactive inhibition, we first developed a modified version of our existing Stop-signal task (Leventhal et al. 2012; Schmidt et al. 2013). Rats initiate trials with a nosepoke, wait for an instructive Go cue (a tone indicating either Go-left or Go-right), but on some trials a subsequent Stop cue (white noise) indicates that they must remain in the initial location. In the modified, proactive version, distinct starting nosepoke locations are associated with different Stop probabilities (0%, 25%, 50%). As intended, on Go-only trials rats show reaction times that scale with Stop probability, indicating that they are appropriately engaging proactive inhibition mechanisms. In our initial optogenetic

experiments we used Arch to briefly reduce GP activity on one side, either just before the Go cue, together with Go cue onset, or just after the Stop cue. So far we have found that GP suppression during Go cue processing interferes with normal contraversive action selection, and analysis of reaction times suggests that this occurs through biasing a competition between ipsiversive and contraversive choices.

Title: Expectations of reward omission selectively modulate striatal fast-spiking interneurons

Authors: *A. MOHEBI[1], J. R. PETTIBONE[1], M. A. FARRIES[1], J. D. BERKE[1,2,3];
[1]Psychology, [2]Neurosci., [3]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: The striatum plays critical roles in motivated decision-making, and in particular dorsal-lateral striatum is thought to store the values of particular actions. These values may be used for selecting and invigorating actions, and are updated by dopamine fluctuations that convey abrupt changes in reward expectation (reward prediction errors). This feedback allows choices to adapt towards the most rewarding options. Striatal medium spiny projection neurons (MSNs) express either lower-affinity dopamine D1 or higher-affinity D2 receptors, so may be differentially sensitive to either rapid increases (D1) or decreases (D2) in dopamine. It has therefore been suggested (e.g. Collins & Frank 2014) that D1-MSN values reflect the recent history of successful outcomes while D2-MSN values reflect the history of reward omissions. Separate storage of these “positive” and “negative” reward expectations may facilitate behavioral

flexibility across different motivational states. We investigated whether separate sets of striatal neurons are indeed modulated by expectations of reward, and of reward omission. We recorded single-units from rat striatum during performance of a trial-and-error (2-armed bandit) left/right choice task. Neurons were separated into presumed MSNs and presumed fast-spiking interneurons (FSIs) based on previously established criteria (e.g. Gage et al. 2010). Firing rates of each cell were regressed against the decision variables of a modified actor-critic reinforcement learning model, which separately tracked positive and negative reward expectations for each action. Unexpectedly, we found that a disproportionate number of FSIs were modulated by negative reward expectation. This modulation was present throughout the trial for some FSIs, but reached a peak (>35% of FSIs) around the moment of choice execution during which FSIs are especially active (Gage et al. 2010). Much less modulation was observed by positive reward expectations, or for MSNs. Although the functional significance of these observations remains to be determined, one possibility is that FSIs are particularly involved in restraining actions that have resulted in worse outcomes than expected.

Title: Neuromodulation and adaptive decision-making in frontal cortex and striatum

Authors: *J. R. PETTIBONE[1], A. MOHEBI[1], A. HAMID[2], J.-M. T. WONG[3], R. T. KENNEDY[3], J. D. BERKE[1,2,4];
[1]Psychology, [2]Neurosci., [3]Chem., [4]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Computational models of adaptive choice typically involve both specific variables, such as the learned values of particular actions, and more global parameters such as reward rate, learning rate or uncertainty. It is widely hypothesized that in the brain such global decision parameters are signaled by neuromodulators such as dopamine, noradrenaline, serotonin and

acetylcholine (e.g. Doya 2002). However, direct evidence for this remains quite sparse. Furthermore, there is evidence that a given neuromodulator may provide different signals, either in distinct subregions that participate in competing behavioral strategies (e.g. dorsal-medial vs. dorsal-lateral striatum) or in distinct yet cooperating brain structures (e.g. prefrontal cortex and dorsal-medial striatum). We have been investigating the computational contributions of neuromodulators to adaptive choice, using microdialysis coupled to HPLC-MS. This method allows us to sample a wide array of neurochemicals simultaneously, each with 1-minute resolution. Samples are taken from rats during performance of a stochastically rewarded two-armed bandit task, and compared to decision parameters estimated using a Bayesian reinforcement learning algorithm. In our initial study we have sampled from the nucleus accumbens and found a selective relationship between dopamine and reward rate, which helps determine motivation to work (engage in activities that are not inherently rewarding, but may lead to rewards). We are currently sampling from other brain regions including medial frontal (prelimbic) cortex and dorsal-medial striatum, to test whether each neuromodulator provides a consistent computational signal.

Title: Chemogenetic control of motor behavior in the non-human primate: DREADD-mediated silencing of the substantia nigra pars reticulata

Authors: *B. L. AGUILAR, C. ELORETTE, M. N. HUIZENGA, P. A. FORCELLI, L. MALKOVA;
Georgetown Univ., Washington, DC

Abstract: Classic approaches to focal brain manipulation in non-human primates have primarily relied on lesion techniques, and more recently focal microinjections of drugs to transiently suppress neural activity. While these techniques have been enormously informative, the former does not allow for repeated within-subject assessments, and may allow for compensatory

neuroadaptation in the post lesion period. The latter approach minimizes some of these confounds but is technically challenging. Moreover, repeated microinfusions may cause tissue damage. Designer receptors exclusively activated by designer drugs (DREADDs) allow for the selective activation of DREADD-expressing neurons by otherwise inert compounds. Because DREADD constructs may be delivered virally, only a single surgery and brain penetration is needed to produce life-long sensitivity to systemic administration of DREADD-activating compounds (e.g., CNO). While this approach has been extensively deployed in rodents, it remains understudied in primates. Here, we targeted the substantia nigra pars reticulata (SNpr), a key basal ganglia output structure for DREADD-mediated inhibition. We have previously reported (Dybdal et al., 2013, Holmes et al., 2012) that unilateral inhibition of SNpr induces profound locomotor and postural abnormalities, as well as limb dyskinesias. The importance of this structure in movement disorders, coupled with the relative ease of behavioral measures of nigral inhibition led us to select SNpr as a pilot target. We injected AAV-hSyn-HA-M4D(Gi)-IRES-mCitrine into the substantia nigra of 3 macaques during an MRI guided stereotaxic surgical procedure. We allowed a minimum of 1 month post-operative recovery before behavioral testing. Each animal was tested with a series of vehicle injections and at least 3 CNO sessions. The primary behavioral output was contraversive quadrupedal rotations (QR). In each animal, the frequency of QR was increased by CNO administration. A mean 60% increase in rotation rate ($P<0.05$) was observed. Post-mortem histological confirmation of virus injection was performed on two animals. Histological analysis showed sparse labeling within the reticulata and compacta of the SN. Histological assessment of a third subject is underway. A fourth subject is currently in progress using an alternative serotype of AAV to increase neural coverage, as well as dual injection of M4-DREADD and Kappa Opiod Receptor DREADD (KORD) allowing independent silencing of two separate neural populations. These results demonstrate the efficacy of DREADD-mediated silencing in the non-human primate and open the door to further studies employing this methodology.

Title: Inverse incentive learning on the bar test in rats following injection of haloperidol into the nucleus accumbens

Authors: *L. N. SCHIMMEL[1], C. DI PROSPERO[1], R. J. BENINGER[2];
[1]Ctr. for Neurosci. Studies, [2]Ctr. for Neurosci. Studies, Departments of Psychology and Psychiatry, Queen's Univ., Kingston, ON, Canada

Abstract: Inverse incentive learning is the loss by stimuli of their ability to elicit approach and other responses. Repeated pairings of injections of a dopamine (DA) receptor antagonist (e.g., haloperidol) with environmental stimuli gradually reduces their incentive value observed as a loss of motor engagement with the environment. c-Fos results implicate several brain regions including the nucleus accumbens (NAc). We examined the role of the NAc in inverse incentive learning by bilaterally infusing haloperidol and testing rats on the horizontal bar test. During the 13-day training phase paired rats were bilaterally infused with haloperidol (10 μg/0.5 μl/side) into NAc 1 h prior to placing them with their forepaws resting on a horizontal bar in a specific environment. Unpaired control rats were infused with saline and similarly tested. Unpaired rats were centrally injected with haloperidol and paired rats with saline 1 h later in their home cage. On the test day all rats were treated with saline prior to the bar test. The dependent variable was descent latency. Groups did not differ at the beginning of training but the paired group showed progressively longer descent latencies over days while the unpaired group did not. On the saline test day, the descent latency of the paired group was longer than that of the unpaired group. Results implicate the NAc in the neuronal mechanisms underlying inverse incentive learning.

Abstract: The Motor thalamus plays a key role in movement control, linking cerebellum and basal ganglia to the cerebral cortex. Large amounts of thlamocortical axons projects to different areas of the cerebral cortex. Axonal processes from ventromedial motor thalamus terminate in layer 1 (e.g. Arbuthnott et al. (1990)Neuroscience, 38, 47-60). However, how the thalamic activity changes during motor behavior is unknown. The main goal of this project is to visualize *in vivo* activity of the axons projecting to layer I of the motor cortex in head-restrained mice under the following conditions: isoflurane anesthesia, awake and following systemic haloperidol (0.6mg/kg, i.p.). All animal experiments were approved by the OIST Institutional Animal Care and Use Committee (IACUC) in an Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC International) accredited facility. To visualize *in vivo* activity of thalamocortical axons to layer 1 a mixture of AAV1/2-hSyn-GCamP6f and AAV1/2-hSyn-TurboRFP viral vectors was delivered directly into the motor thalamus of 21 days old C57BL/6J mice. Two weeks later, a chronic cranial window with a silicon access port was placed over the motor cortex, as previously described (Roome, C.J.& Kuhn, B. 2014, Front Cell Neurosci. 8, 379), and two silver wires were placed next to the window for electrocorticography (ECoG) recordings. After a couple of days of acclimatization in a head restrained configuration, calcium transients of thalamocortical axons on layer 1 and ECoG activity were recorded. A custom-built microscope that combines bright field and two-photon resonant-scanning microscopy (31 frames/s, MOM, Sutter) was used to record calcium transients. Animals were filmed during every experimental condition to check vital signs and track locomotion. Our experimental configuration allowed us to detect different populations of Layer 1 axons. One synchronizes their activity during the spontaneous march of the animal becoming quiet under isoflorane anesthesia, while others synchronize their activity during the anesthesia but not during the march. Interestingly, both of them change their activity under the dopaminergic antagonist.

Title: Investigating activity of fast spiking interneurons in dorsolateral striatum

Authors: *J. KULIK, K. COFFEY, A. PAWLAK, M. WEST;
Rutgers Univ., Piscataway, NJ

Abstract: Numerous studies have shown that certain types of striatal interneurons might play a crucial role in selection and regulation of striatal output. Among these, striatal Fast-Spiking Interneurons (FSIs) are parvalbumin positive, GABA-ergic interneurons that constitute less than 1% to the total striatal population. FSIs display a strong medial<lateral distribution gradient across the striatum, which suggests that they are important for regulation of motor functions subsumed within the lateral striatum. It is becoming increasingly evident that these sparsely distributed neurons exert a strong inhibitory effect on Medium Spiny projection Neurons (MSNs), the principal neurons of the striatum. MSNs in lateral striatum receive direct synaptic input from regions of cortex representing discrete body parts. Individual MSNs show phasic increases in activity during touch or movement of specific body parts. In the present study we sought to determine whether FSIs, identified by their electrophysiological properties, display body part sensitivity similar to that exhibited by MSNs in the striatum. Body part sensitivity of individual recorded neurons was assessed using a sensorimotor exam in which each individual body part was stimulated and responses of the neuron were observed and quantified. A large proportion of identified FSIs displayed patterns of activity related selectively to stimulation of a discrete body part. Those patterns of activity were often similar to those that are displayed by typical MSNs in the lateral striatum. Some FSIs displayed patterns of activity different from those described for MSNs, such as a dramatic decrease in firing during movement of the related body part. Together these results serve as evidence that striatal FSIs process information related to discrete body parts and participate in control of motor output by the striatum.

Title: Exploring body part sensitivity of optogenetically identified D1 and D2 receptor expressing medium spiny neurons in the dorsolateral striatum of the mouse

Authors: *K. COFFEY[1], M. NADER[2], M. WEST[3];
[1]Rutgers Univ., Piscataway, NJ; [2]Psychology, [3]Rutgers, Piscataway, NJ

Abstract: The dorsolateral striatum (DLS) of the mouse is a large structure situated at the base of the forebrain and is associated with a variety of functions including control of voluntary motor movements, sensory-motor integration, procedural learning, and habits. Dysfunction of the dorsal striatum is also associated with a number of diseases such as Tourette syndrome, obsessive-compulsive disorder, psychomotor stimulant addiction, Parkinson's disease, and Huntington's disease. The DLS is thought to be functionally organized in order to support sensorimotor processing. First, the DLS is hypothesized to contain two opposing pathways, defined by their dopamine receptor expression. The D1 pathway, or the “direct” pathway, is thought to be responsible for generating movement while the D2, or the “indirect” pathway, is thought to be responsible for inhibiting movement. Further, the DLS is known to be somatotopically organized, and it has been repeatedly shown to process single body part movements and sensation (Kunzle 1975, 1977, 1978; Selemon and Goldman-Rakic 1985). Moreover, the dorsolateral striatum contains patches of neurons that together represent all parts of an animal’s body (Carelli and West 1991). This is because the DLS receives direct topographical projection from the primary somatosensory and motor cortices. The present study seeks to explore the relationship between these two functional organization schemes. We utilized optogenetics coupled with electrophysiological recordings in the awake behaving mouse to identify D1 and D2 receptor expressing medium spiny neurons (MSNs) in the DLS. We then performed “body exams” in order to determine the body part sensitivity of individual MSNs. Differences or similarities between D1 and D2 neurons will be explored with regards to single body part processing.

Title: Relationship between the cerebellar dentate nucleus, VA/VL and VM thalamus and motor cortex in the generation of high gamma oscillation during L-DOPA-induced dyskinesia in Parkinson’s disease

Authors: *C. DELAVILLE, H. BERMUDEZ CABRERA, A. J. MCCOY, J. R. WALTERS; NIH NINDS, Bethesda, MD

Abstract: The neural mechanisms and circuitry involved in L-DOPA-induced dyskinesia (LID) remain unclear. Recently, high gamma frequency oscillations (70-120 Hz with a distinct peak around 80 Hz), referred to as finely-tuned gamma (FTG) in patients, have been observed in the motor cortex (MCx) and correlated with the emergence of LID in a rodent model of Parkinson's disease (PD). Recent studies suggest that there are also changes in cerebello-thalamo-cortical networks occurring in PD and LID and that continuous cerebellar stimulation has an antidyskinetic effect in PD patients with LID, possibly due to modulation of this pathway (Koch et al., 2007). The cerebellar dentate nucleus (Dn) is an essential structure for the control of movement and sends ascending projections to the cortex via the ventromedial/ventrolateral (VA/VL) thalamus. To investigate the contribution of the Dn and VA/VL thalamus in the generation of high gamma oscillations during LID, we used the hemiparkinsonian rat model and recorded chronic activity in the Dn, VA/VL and ventromedial (VM) thalamus and MCx during LID followed by the local inactivation of the Dn using muscimol. As expected, after dopamine cell lesion, a strong high beta peak appeared in the MCx (4X increase in total power around the peak relative to control) and in the VM (10.7X). However, this 28-36 Hz oscillation was not present in either the Dn or VA/VL (1.2X and 1.2X, respectively). After chronic L-DOPA treatment, a substantial high gamma-FTG-like band appeared in the MCx (18X), VM (16.3X) and modestly in VL (3.2X) but not in Dn (0.9X). As expected, VM thalamus LFPs were coherent with MCx in both the high beta range after dopamine depletion and the high gamma range during LID. In contrast, VA/VL activity was not coherent with MCx in the high beta range but was significantly coherent with the MCx in the high gamma range after chronic L-DOPA treatment. Dn LFP activity was not coherent in the high beta and high gamma ranges with MCx, VA/VL or VM thalamus in any condition. Inactivation of the Dn by local injection of muscimol during LID did not significantly change the effect of L-DOPA on high gamma power and coherence between MCx, Dn, VA/VL or VM. However, this local Dn inactivation during LID significantly decreased the degree of phase locking of VA/VL spikes to their own LFP, filtered between 70 to 120 Hz without affecting the phase locking of VM neurons to their own LFP. These results indicate that the Dn contributes to coordinated VA/VL spiking activity in the high gamma range but does not impact either the expression of LID or high gamma-FTG like activity in the MCx and VM.

Title: Does the parafascicular nucleus participate in transmission of oscillatory activity in motor circuits in hemiParkinsonian rat?

Authors: *E. BRAZHNIK, N. NOVIKOV, A. J. MCCOY, J. R. WALTERS;
Neurophys/Pharmacol Section, NIH NINDS, Bethesda, MD

Abstract: Exaggerated beta range oscillations in the basal ganglia are a prominent characteristic of Parkinson's disease (PD). However, the neural mechanisms and circuitry underlying these oscillations remain unclear. The motor thalamus receives inhibitory input from basal ganglia and transmits activity to the motor cortex (MCx), and is implicated in the control of movements. We observed that loss of dopamine is associated with robust increases in high beta range local field potential (LFP) oscillations in the ventromedial thalamic nucleus (VM) (Brazhnik et al. SfN 2011). The parafascicular thalamic nucleus (Pf), which receives inputs from the basal ganglia, cortex and cerebellum, provides feedback to the subthalamic nucleus and striatum, and may also contribute to the exaggerated oscillatory activity in the basal ganglia-thalamocortical circuit in PD. The present study explores this hypothesis. Electrodes were implanted into the Pf, substantia nigra pars reticulata (SNpr), dorsal striatum and MCx in in one group of rats and into the VM, SNpr and MCx in a second group. LFPs and spike activity were recorded in rats during epochs of rest and walking on a circular treadmill before and after 6-OHDA-induced dopamine cell loss and during L-DOPA-induced dyskinesia. Recordings from electrode bundles in the ventrolateral part of Pf showed very modest, but noticeable (from selected wires) 30-36 Hz range activity and low coherence with SNpr and MCx LFPs on day 21 postlesion. Pf spiking showed modest synchronization with local LFPs in the beta range (24 % spike trains were significantly correlated after dopamine cell lesion relative to 12% in control), but not with MCx and striatal LFPs. In contrast, recordings from the VM showed a 3-5 fold increase in VM LFP power and VM LFP coherence with both MCx and SNpr in the 30-36 Hz range after dopamine loss, relative to controls. Along with this, VM spikes were highly synchronized with both thalamic and cortical LFPs (82% and 65% spike trains, respectively). Chronic treatment with L-DOPA evoked dyskinesia and significantly increased power in the high gamma band (90-120 Hz, peak ~100 Hz) in all recordings from MCx and VM, but only in 15% of recordings from Pf. In addition to observations that inhibition of the VM by muscimol reduced both high beta and L-DOPA-induced high gamma rhythms in the basal ganglia-thalamocortical loop (Brazhnik et al. SfN 2011, 2013), these results support the view that the enhanced beta oscillations which emerge following dopamine loss are generated in the basal ganglia-thalamocortical network with the VM, not the Pf, as a critical element of the circuit.

Title: Ventromedial thalamus is critical for expression of cortical narrow band high gamma oscillations but not L-DOPA-induced dyskinesia in hemiParkinsonian rats

Authors: *K. B. DUPRE, C. P. DODGE, C. DELAVILLE, E. BRAZHNIK, N. I. NOVIKOV, J. R. WALTERS;
Neurophys/Pharmacol Sec, NIH NINDS, Bethesda, MD

Abstract: Chronic treatment with the dopamine (DA) precursor levodopa (L-DOPA) in Parkinson's disease (PD) frequently causes severe motor complications known as L-DOPA-induced dyskinesia (LID), the causes of which are not fully understood. Interestingly, robust increases in cortical narrow band high gamma activity, also referred to as finely-tuned gamma, appear in PD patients following L-DOPA and coincide with LID in hemiparkinsonian rats. As L-DOPA is thought to reduce basal ganglia inhibitory output to the thalamus, a logical hypothesis is that reduction of this inhibition would increase excitatory thalamic output to the motor cortex, inducing exaggerated cortical high gamma and, in turn, dyskinesia. However, infusion of the GABA A receptor agonist muscimol into the ventromedial (VM) thalamus prior to systemic L-DOPA prevented the expression of cortical narrow band high gamma activity without affecting LID (Brazhnik et al. 2013 SfN abstract). To further explore this apparent dissociation between thalamocortical high gamma activity and LID, rats with unilateral DA cell lesions were subsequently injected with L-DOPA once daily for 7 days to induce stable dyskinesia. LFPs and neuronal activity were recorded from chronically implanted electrodes in the motor cortex and cannulatrodes in the VM thalamus, which enabled monitoring of VM thalamus spiking and LFP activity following local drug infusions. Similar to our previous work, L-DOPA caused dramatic increases in narrow band high gamma (70-110 Hz with a peak ~90 Hz) LFP power in, and coherence between, the motor cortex and VM thalamus in conjunction with dyskinesia. Muscimol (but not saline) infused into the VM thalamus during peak dyskinesia eliminated high gamma activity in both brain regions without impacting dyskinesia. Phase locking of VM thalamus spikes to both their own and motor cortex LFPs in the high gamma range was increased

during dyskinesia (when high gamma power was high) and decreased following muscimol (when high gamma power was low). In contrast, phase locking of motor cortex pyramidal neurons to their own LFP was increased following muscimol when high gamma LFP power decreased. Our findings suggest that the VM thalamus is generating and/or propagating exaggerated high gamma activity in the motor cortex during LID. However, this thalamocortical high gamma activity does not appear to be responsible for causing dyskinesia. Furthermore, our results question the assumption that the thalamus is a critical nucleus for precipitating the expression of LID. Thus, the functional correlate of narrow band high gamma activity during LID in PD, as well as the mechanisms responsible for dyskinesia, remain elusive.

Title: Long-term effects in cortical evoked potentials in response to GPi-DBS in childhood generalized dystonia

Authors: *E. ARGUELLES[1], N. H. BHANPURI[2], M. BERTUCCO[1], T. D. SANGER[1]; [1]USC, Los Angeles, CA; [2]NorthShore Univ. HealthSystem, Skokie, IL

Abstract: Dystonia is a movement disorder characterized by involuntary muscle contractions and abnormal postures. Dystonic symptoms have been associated with basal ganglia dysfunction and increased cortical excitability. Deep brain stimulation of the internal segment of the globus pallidus (GPi-DBS) is a common treatment for severe dystonia, despite an incomplete understanding of its mechanisms of action. We hypothesize that GPi-DBS reduces cortical excitability, disrupts the abnormal information flow through the pallidothalamocortical loop, and reduces transcortical long-latency stretch reflexes. An essential component of this hypothesis is that DBS has an effect on cortex that could be mediated by anterograde trans-synaptic pathways from GPi via thalamus. We measure the effects of DBS on cortical activity by recording changes

in scalp EEG evoked by 9hz DBS. We previously showed that the DBS evoked potentials (DBSEPs) amplitude in contralateral paracentral leads at 20msec after stimulation correlates with clinical improvement in children with primary and secondary generalized dystonia, and they may therefore provide a measurement of the modulatory effect of GPi-DBS in cortex. Because clinical effects often occur after months of starting stimulation, we now investigate whether progressive changes in efficacy are reflected in progressive changes in the transmission of DBS pulses from GPi to cortex. We recorded DBSEPs for 8 pediatric patients with generalized dystonia at 1, 3, 6 and 12 months after DBS implantation. We analyze the cortical activity in response to GPi-DBS by examining the DBSEPs for different stimulation contact pairs and voltages. DBSEP amplitude is highly sensitive to variations in scalp impedances, therefore we use the DBSEP voltage gain (the rate of increase in evoked potential amplitude relative to increase in stimulation voltage) as a more reliable indicator of how well a stimulation contact pair can selectively recruit neurons in and around GPi that have connections to cortex. Our results indicate that while the cortical response to GPi-DBS is larger for the most effective contact pairs, changes in DBSEP voltage gain over time do not correlate with overall clinical improvement. Indeed, for a subgroup of patients that showed clinical improvement of motor function after one year of implantation, DBSEP voltage gains remained low throughout the study. This suggests that changes over time in the effect of DBS are not mediated by changes in conduction of stimulation from GPi to cortex. Other mechanisms, such as plastic changes within the basal ganglia or cortex, must therefore be the cause of the gradual improvement in dystonia following GPi DBS.

Title: Testing the role of ventral tegmental area inputs to Area X in vocal plasticity

Authors: *L. XIAO, G. CHATTREE, T. F. ROBERTS;
Dept. of Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Brain circuits associated with the basal ganglia are involved in the learning and execution of a wide range of behaviors. In songbirds, the output of the basal ganglia pathway plays an important role in implementing changes in vocal behavior during song learning. Further, this circuit plays a critical role in biasing motor output in response to reinforcement learning paradigms, such as those using pitch contingent disruptive auditory feedback. A longstanding, idea is that the ventral tegmental area (VTA) provides a reinforcement signal that helps instruct adaptive changes in song performance through its projection onto the striatopallidal portion of the song circuit (Area X). We have begun to test this idea using pitch contingent optogenetic manipulation (pCOM) of VTA axon terminals in Area X. We find that pCOM of VTA axon terminals in adult zebra finches is sufficient to elicit graded changes in the pitch of an optogenetically targeted syllable over the course of hours and days. Pitch contingent optogenetic silencing of VTA terminals result in changes to syllable pitch that function to minimize optogenetic silencing of the circuit. This adaptive shift in syllable pitch away from frequency ranges being targeted by light are reminiscent of the behavioral changes associated with pitch contingent disruptive auditory feedback. In contrast, pitch contingent optogenetic stimulation of VTA terminals elicit changes in song syllables that function to maximize optogenetic stimulation. For example, targeting optogenetic stimulation only to the lower pitch 'registers' of a syllable results in a significant decrease in the mean pitch over the course of hours and days. These preliminary findings support the idea that VTA provides a positive valence signal to Area X important for instructing vocal plasticity.

Title: Effects of enriched housing on the expression of novelty-shuttling induced Fos-LIke Immunoreactivity in the cingulate cortex and basal ganglia

Authors: *W. M. STRUTHERS, S. P. MEDRANO, K. ANSELL;
PSYCHOLOGY, Wheaton Col., Wheaton, IL

Abstract: Previous research has indicated that environmental enrichment (EE) that includes complex housing conditions with varied objects provides enhanced sensory, motor, cognitive and social opportunities that influence brain development and behavioral responses. In our lab this has been demonstrated in a previous study where young male rats housed in enriched conditions display reduced novelty-induced Fos-Like Immunoreactivity (FLI), a marker for neuronal activation. Novelty-shuttling is the process of placing animals in repeated novel environments, and the cingulate cortex and basal ganglia have been implicated as brain regions involved in the processing of and response to novel challenges. While much of the research on environmental enrichment targets young animals, little has been done to investigate its impact on adult animals. In this study adult male rats were housed in a Marlau cage for 5 weeks with the enriched housing conditions varied every 3-4 days, or in standard housing conditions with a single cage-mate (SH). At the end of this time frame all animals were placed through a novelty shuttle procedure (30 minutes in an open field with three novel objects, followed by 30 minutes on an Barnes Maze) and then placed in a holding cage for one hour. They were then perfused and their brains processed for FLI. There was a significant increase in novelty shuttling induced FLI in both groups when compared to non-Novelty Shuttled controls. This increase was tempered in the number of cells displaying FLI in the striatum and cingulate cortex of EE males when compared to SH controls. These results suggest that enriched environment can impact adult neural responses in addition to that seen in early development.

Title: The timing mechanism in the hundreds of milliseconds is disrupted by a D2 agonist

Authors: ***K. YC**, L. PRADO, H. MERCHANT;
Cognitive Neurobio. LAB-B15, Inst. de Neurobiologia, UNAM, Queretaro, Mexico

Abstract: Studies in rodents and humans have shown that the dopaminergic system is deeply involved in the perception and production of time intervals in the range of seconds. For example, time is overestimated or underestimated in response to the administration of D2 agonists or antagonists, respectively. However, little it is known about the role of D2 in the milliseconds range. Thus, in the present study we analyzed the effect of systemic administration of a D2 agonist on the tapping behavior of Rhesus monkeys performing a Tapping Synchronization Task (ST), and a serial reaction time control task (CT). In each ST trial, the monkeys synchronized their tapping with a metronome to produce five isochronous intervals, and seven target intervals (350-950ms) were presented pseudorandomly. We measured the variability and accuracy of the produced intervals, as well as the stimulus-response asynchronies. We found that dose-dependent increase temporal variability with the D2 agonist (quinpirole), with a complete loss of the scalar property of interval timing at the largest dose (0.05mg/kg). These effects were accompanied with a dose-dependent switch from under- to overestimation of the produced intervals. In addition, stimulus-response asynchronies showed a large increase at the largest dose of quinpirole. In contrast, during the CT the reaction times were not affected by the systemic administration of the D2 agonist. These results suggest that the D2 receptor system is involved in temporal processing in non-human primates, where high systemic doses the quinpirole profoundly disrupts the timing mechanism governing the tapping synchronization to a sensory metronome. The present data support the notion that high levels of D2 agonist produce a change from a time-predicting to a stimulus-reacting behavior during the ST.

Title: Anticipatory grip force adjustments as an emerging feature of coordinated feedback control

Authors: ***F. CREVECOEUR**[1], J.-L. THONNARD[1], P. LEFEVRE[1], S. H. SCOTT[2]; [1]Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Queen's Univ., Kingston, ON, Canada

Abstract: Suppose that someone bumps into your arm at a cocktail party while you are holding a glass of wine. Such perturbation will engage rapid upper-limb motor responses including the stretch reflex (~20ms) followed by sophisticated, goal-directed feedback responses (long-latency, ~50ms-100ms; early voluntary, >100ms). While such responses can rapidly compensate for the perturbation, it is also clearly desirable in this context that they do not destabilize the grip or spill the wine. Whether and how grip force control during object manipulation is coupled with upper-limb feedback responses to mechanical perturbations remains unknown. We investigated this issue by applying mechanical perturbations on the upper limb of healthy humans while asking them to hold an object stable between their thumb and index fingers (precision grip). We used a perturbation paradigm known to elicit robust and important modulation of upper-limb muscle responses dependent on whether the perturbation pushes the hand towards or away from the goal target. We leverage this paradigm in the context of object manipulation to measure the moment when feedback control of grip force reflects knowledge of upper-limb motor commands. Surface recordings of muscle responses highlight coordinated upper-limb and grip feedback responses in ~60ms. Importantly, target-dependent modulation of muscle responses was observed at the same time in upper-limb and hand muscles. The simultaneous expression of flexible feedback in shoulder and hand muscles cannot be explained by the hypothesis that grip force results from forward models predicting the consequences of motor commands, as this framework implies measurable delays between target-dependent modulation in shoulder and hand muscles (15-20ms). Instead, our results suggest that apparently predictive grip force control is also partially mediated by simpler coordination of motor systems embedded in the feedback control policy.

Title: Texting on the go: Multi-muscle activation patterns during a dual-task performance

Authors: *P. K. ACHARYA, A. AMEDEE, J. AMEDEE, S. A. WINGES;
Kinesiology, Louisiana State Univ., Baton Rouge, LA

Abstract: Since the first mobile phone prototype was unveiled in 1973 it has become an increasingly integral part of the modern society with more than 6 billion users with applications including video calling, internet browsing, reading, and texting. Most common among young adults, the average number of text messages sent per day often exceeds 100 on average. Texting is a repetitive tapping task accomplished by precise tapping of the thumb(s) using a one- or two-handed method. Text messages are commonly composed while people sit, stand, or walk and require that the thumb make precise dynamic combinations of flexion/extension, abduction/adduction and rotation movements to move across the keypad. Precisely coordinated patterns of muscle activation are necessary to move the thumb while maintaining hand and arm posture during this task. The purpose of this study was to compare multi-muscle activation patterns of the upper limb during a texting task while subjects were standing or walking on a treadmill. The specific hypothesis was that muscles used to stabilize the arm and hand posture to hold the phone would be affected by walking in both the amplitude and temporal domain while no change would occur in intrinsic thumb muscles. Ten healthy college students performed a one-handed texting task using iPhone 3GS. The task incorporated four different repetitive sequences of taps that spanned the texting keyboard, a pangram sentence, and a short phrase more likely to be sent as a text message. Kinematics of the thumb and whole body movement were recorded along with activity from 12 different muscles: abductor pollicis brevis, flexor pollicis brevis, first dorsal interosseous, adductor digiti minimi, extensor pollicis longus, extensor carpi radialis, flexor carpi radialis, extensor carpi ulnaris, biceps brachii, triceps brachii, medial deltoid, trapezius. Subjects were capable of performing the tasks with minimal errors. Accuracy i.e. whether the correct text symbol registered, was not adversely affected by walking on the treadmill and in several cases, subjects had fewer errors while walking on the treadmill compared to standing. Thus the repetitive stepping motion of the treadmill appeared to improve their performance. Differences between in the magnitude of muscle activity were observed for all muscles including the intrinsic thumb muscles during the typing tasks. However the nature of the change i.e., whether walking resulted in increases or decreases in magnitude between standing and walking, varied among subjects. Proficiency was one factor that may have contributed to the differences between subjects but could not explain the difference completely.

Title: Sense of effort: right and left hand sensitivity to proprioceptive feedback

Authors: *Y. ACOSTA-SOJO, B. J. MARTIN;
Univ. of Michigan, Ann Arbor, MI

Abstract: The contribution of sensory feedback to the sense of effort is still debated. A recent study indicated that in a contralateral force-matching task the influence of reference hand vibration was significant for left hand matching of the right hand reference force. However, this effect was negligible when matching in the reverse condition. In addition, a difference in muscle proprioceptive sensitivity between males and females has been observed in another study. Hence, the aim of the study was to understand the sensitivity of the left and right hand sensory systems to vibration induced changes in force control and correlated changes in electromyographic (EMG) activity. Ten strongly right-handed young adults (5 males and 5 females, aged matched), free from any neurological disorders, participated in this pilot study. In this experiment, participants were asked to grasp fixed horizontal cylinders instrumented with strain gauge transducers and exert 20% of their maximum voluntary contraction (MVC) force with the right or left hand. It was required to establish the reference force level and maintain that force for about 12 seconds with or without visual feedback of the force level. Five seconds after stabilization of the exertion a 60 Hz vibration was applied to the distal tendons of the finger flexor muscles. EMG activity was recorded from each hand finger flexor muscles and normalized to each hand 100% MVC. Changes in force and EMG activity were quantified for each hand. The preliminary results show that the vibration-induced increase in EMG activity is significantly greater for the left than the right hand. This increase tends to be greater for females than males, however it did not reach significance as the number of subjects in each group is still small. These results suggest that the gain of the sensory system is greater for the left than right hand, which confirms previous results concerning position sense.

Title: Task specific stability of abundant systems: structure of variance and motor equivalence

Authors: *D. J. MATTOS[1], G. SCHÖNER[2], V. ZATSIORSKY[3], M. LATASH[3];
[1]Kinesiology, Penn State Univ., State College, PA; [2]Inst. für Neuroinformatik, Rühr Univ. Bochum, Bochum, Germany; [3]Dept. of Kinesiology, The Pennsylvania State Univ., University Park, PA

Abstract: Task specific stability allows reorganizing elements after perturbations, while being motor-equivalent with respect to values of salient performance variables. Our main goal was to test a hypothesis that self-triggered transient changes in performance of a steady-state task would result in motor equivalence. A secondary goal was to estimate effects of removing visual feedback on the amount of reorganization of motor elements. Healthy subjects performed two variations of a four-finger pressing task requiring accurate production of total force (FTOT) and moment (MTOT). In the Jumping-Target task, a sequence of target jumps induced transient changes in either FTOT or MTOT. In the Step-Perturbation task, the index finger was lifted by 1 cm for 0.5 s using the "inverse piano" device. Visual feedback could be frozen for one of these two variables in both tasks. Deviations in the space of finger modes (hypothetical commands to individual fingers) were quantified in directions that did not change FTOT and MTOT (ME component) and in directions that changed FTOT and MTOT (nME component). The changes in performance led to an increase in both the ME and nME components. After the sequence of target jumps leading to the same FTOT; MTOT combination, the changes in finger modes had a large ME component. Without visual feedback, a large increase in the nME component was observed without consistent changes in the ME component. Results from the Step-Perturbation task were qualitatively similar. These findings suggest that both external perturbations and purposeful changes in performance trigger a reorganization of elements of an abundant system, leading to large ME motion. These results are consistent with the principle of motor abundance corroborating the idea that a family of solutions is facilitated to stabilize values of important performance variables.

Title: "Time" as a sensorimotor control problem: performance limits of human auditory--motor entrainment

Authors: *E. W. SAMSON[1], R. W. NICKL[2], M. M. ANKARALI[3], N. J. COWAN[3];
[2]Biomed. Engin., [3]Mechanical Engin., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: To living systems, time is a hidden state (Ankarali 2014; Carver 2013). It is therefore remarkable how effectively animals -- particularly humans -- can synchronize to auditory and other external cues. This requires a nervous system that can both model the environment (Wolpert 1995) and, in the presence of variability, use feedback control to correct timing errors (Repp 2005). To study how humans use feedback control to entrain to a metronome, we designed a virtual-reality sensorimotor synchronization task. The metronome consisted of auditory cues (10 ms pulses at approx. 3500 Hz), with a base inter-pulse interval of 0.3 s. Experiments consisted of trials where temporal "jitters" were imposed on the metronome. Participants held the handle of a user control device ("haptic paddle") and tapped on virtual haptic wall that imitated tapping on a tabletop. We identified tapping events from reaction forces applied to the hand by the wall. Jitters consisted of single- or sum-of-sinusoid variations of timing with amplitudes of 20 ms at each frequency. Seven frequencies were investigated between 0.06 Hz and 1.5 Hz. These jitters allowed us to perturb the metronome in a structured way, yet resulted in jitter sequences that seemed random (particularly in sums of sines) to subjects during the experiment. Both metronome jitters and user "tap" signals were recorded in real time. We estimated the entrainment controller using system identification methods (Ljung 1999), taking inputs as applied jitters, and outputs as deviations of tapping times. We characterized the controller by computing discrete-time frequency response functions from the discrete Fourier transforms of the input and output signals (Roth 2011). Humans respond most strongly to slowly varying auditory signals and responses were consistent across individuals up to 1.5 Hz. Sensorimotor bandwidth was approximately 0.5 Hz. A comparison of estimates from single-sine and sum-of-sine jitter perturbations suggests that the controller is quite linear at low frequencies, consistent with our hypothesis. Second-order transfer functions provide a good approximation to frequency responses, implying that a subject's current response depends on behavior in previous cycles, i.e. multiple jitters may be kept in working memory to plan the next tapping time. This tapping paradigm is a potentially valuable method to study inherent timekeeping because the movement is already learned (thus adaptation is unnecessary), it requires relatively simple movements that generate reduced motor noise, and the mechanical system (the "haptic paddle") can be modeled as possessing a single degree of freedom.

Title: Pantomime hand-to-mouth movements suggest different sensory control systems mediate arm transport versus mouth shaping during feeding

Authors: *J. M. KARL[1], D. J. QUINLAN[1], K. M. STUBBS[1], I. Q. WHISHAW[2], J. C. CULHAM[1];
[1]Western Univ., London, ON, Canada; [2]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Pantomime reach-to-grasp movements are kinematically different from real visually-guided reach-to-grasp movements. These differences may be due, at least in part, to the inefficient coordination of arm and hand movements in the absence of online visual guidance. Withdrawing the hand to place an object in the mouth is a natural and common movement; however, it differs from other reaching actions in that it develops exceptionally early, relies almost entirely on somatosensory guidance, and may be mediated by a single cortical circuit that controls the arm, hand, and mouth. Given these differences, we hypothesized that hand-to-mouth movements may not be subject to the same real vs. pantomime dissociation as visually-guided reach-to-grasp movements. The present study used frame-by-frame video analysis and linear kinematics to analyze hand and mouth movements as participants withdrew the arm and hand to place either real or imagined food items into the mouth for eating. Preliminary results indicate that aspects of arm transport: trajectory, duration, and peak velocity are similar regardless of whether the hand-to-mouth movement is real or pantomimed. Mouth aperture also consistently scales to the size of the food item, but is smaller in the pantomime condition and reflects the smaller hand aperture initially used to grasp imaginary compared to real food items. The results suggest that different sensory control systems mediate arm transport (proprioception) versus mouth shaping (manual haptics) during both real and pantomime feeding actions and thus, the neural substrates that support the two may be at least partially dissociable.

Title: Arm geometric properties contribute to the non-uniform arm position sense across a horizontal workspace for both sighted and visually-impaired subjects

Authors: *K. OH[1,2], B. I. PRILUTSKY[1,2];
[1]Applied Physiol., [2]Ctr. for Human Movement Studies, Georgia Inst. of Technol., Atlanta, GA

Abstract: It has been reported that the precision of arm position sense is non-uniform across a horizontal workspace. The reasons for this non-uniformity are poorly understood. Since the muscle spindles are major contributors to arm position sense and because the non-linear geometric transformation from small changes in hand position to changes in joint angles (and thus in spindles' length) depends on arm posture, we hypothesized that (1) the geometric arm properties could contribute to the non-uniform precision of arm position sense and (2) this contribution would be similar between individuals with normal and impaired vision given their similar arm geometry. To test the first hypothesis, we conducted a Jacobian-based geometric analysis of a plane, two-segment kinematic chain representing the human arm. The geometric analysis revealed theoretical distributions of the precision error of hand position for any given arm configuration. The predicted precision error distributions were nearly orthogonal to the experimentally measured arm stiffness ellipses (Flash, Mussa-Ivaldi, 1990). The analysis also predicted the non-uniformities in arm position sense reported in the literature, thus supporting the first hypothesis. To test the second hypothesis, we measured precision of hand and joint angle position sense in two groups of right-handed subjects: normal vision group (n=10) and visually-impaired group (n=7). In the first experiment, a robot moved the subject's right hand to one of four targets in random order, and the subject matched the joint angles of the left arm to those of the right arm. In the second experiment, the subject matched the hand movement distance and direction from the initial position. The experimental distributions of the precision error for 4 targets were qualitatively similar to the predicted distributions regardless of the tasks and groups of subjects. Also, the direction of the maximum precision error was not statistically different between the two groups of subjects, whereas the magnitude of error was greater in the visually-impaired group. Thus, it can be concluded that arm geometric properties contribute substantially to the non-uniform precision of arm position sense across the horizontal workspace in individuals with normal and impaired vision, and that the direction of the maximum precision error depends on arm geometry. The larger precision errors in arm matching tasks in visually-

impaired individuals might indicate a contribution of visual experience in the precision of arm position sense.

Title: Neuromuscular control in Clarinetists: does thumb-rest position matter?

Authors: *S. A. WINGES[1], K. E. YOUNG[2];
[1]Kinesiology, [2]Music, Louisiana State Univ., Baton Rouge, LA

Abstract: Repetitive static loading has been linked to cumulative overuse injuries. This is of particular importance to musicians whose skill relies on properly supporting their instrument during practice and performance. The resulting musculoskeletal injuries tend to be lateralized for instruments where one arm is predominately responsible for instrument support. Clarinet players support their instrument with the right-hand thumb. Although the Clarinet only weighs ~0.9 kg, the cumulative static loading can cause discomfort in the thumb, wrist, elbow, and shoulder that may evolve into severe overuse injury and debilitating pain throughout the right upper limb. There is a debate among clarinet pedagogues, instrument makers, and the medical community about the most ergonomic position for the thumb rest. To date, no quantitative research has been conducted on the muscular component of this issue. The purpose of this study was to address the impact of thumb rest position on the neuromuscular control of clarinet playing. Surface electromyographic (EMG) recordings of superficial muscles that control the right thumb, wrist, and arm were taken during held note and finger exercises using three different thumb-rest position heights. We hypothesized that a high thumb-rest position would result in a significantly different balance of muscle activity than normal and low thumb-rest positions and that hand size would be a significant factor on muscle activity. Twenty clarinetists (13 female, 26.2 ± 9.578

years old) were divided into groups by hand size (16.54 ± 8.33 mm long) and experience level (12 students, 8 professionals). They performed ten held notes and ten exercises on each of the three thumb-rest positions with five minute breaks between. The notes and exercises were chosen to be inclusive of specific elements of playing. There were significant main effects of rest position on the amplitude of muscle activity recorded from the biceps brachii, abductor pollicis brevis, abductor pollicis longus, extensor carpi radialis and flexor carpi ulnaris. Main effects of hand size on EMG were limited to the triceps brachii. Opposing muscles had contrasting patterns of activation regardless of hand size; therefore, there is no conclusive evidence that altering the standard position for thumb rests would be beneficial everyone, although on a case-by-case basis it may be useful. Interactions between variables such as the exercise, thumb-rest position, and hand size enrich the understanding of the biomechanics of clarinet playing.

Title: Interlimb Asymmetries are attenuated in unsupported vs supported reaching movements

Authors: *R. L. SAINBURG[1,3], J. E. SCHAFFER[2];
[1]Penn State Univ., University Pk, PA; [2]Kinesiology, Penn State Univ., University Park, PA; [3]Neurol., Penn State Col. of Med., Hershey, PA

Abstract: Our previous studies have elaborated substantial asymmetries in motor performance between the dominant and non-dominant arms of healthy adults, which have been extended to the hemispheres through studies in stroke patients. Whereas the dominant hemisphere appears specialized for predictive control associated with fast, efficient, and smooth trajectories, the non-dominant arm appears specialized for impedance control that often leads to increased final position stability and accuracy. We now test whether these differences are altered by the dynamic context of supporting the arm against gravity. We propose that this condition results in increased stiffness, which can enhance impedance control for the non-dominant arm, as well as reducing the effect of intersegmental dynamics on asymmetries. Healthy young volunteers performed unimanual dominant and nondominant arm reaching movements under two

conditions: 1) With the arm supported by an air-sled, which removed the effects of gravity and 2) With the arm unsupported. Our preliminary results support the prediction that interlimb differences in coordination and accuracy are reduced under 3-D reaching conditions. Furthermore, consistent with our hypothesis, non-dominant arm movements achieved the final position with greater accuracy under 3-D conditions, as compared with 2-D conditions.

Title: Modifying multi-muscle coordination by targeted assistance of hand muscles

Authors: *S. LEE[1], B. VERMILLION[1], D. KAMPER[2];
[1]Biomed. Engin., Catholic Univ. of America, Biomed. Eng., Washington, DC; [2]Biomed. Engin., Illinois Inst. of Technol., Chicago, IL

Abstract: The problem of muscle redundancy arises in human movement production, as the central nervous system (CNS) needs to select particular muscle coordination patterns out of an infinite set of possible combinations (Bernstein, 1967). Coordination of the hand muscles, in particular, is a complex neuromechanical process due to the high number of degrees-of-freedom to be controlled, the large number of muscles involved, and the complex biomechanics of the multiarticular musculotendon units. While some studies indicated that certain dimensionality reduction processes are involved in the coordination of hand muscles (e.g., employing a smaller number of muscle modules, Overduin et al., 2008; scaling fixed coordination patterns across different fingertip force levels; Valero-Cuevas, 2000), others have demonstrated by analyzing the within-trial variability structure of muscle coordination that hand muscle activation patterns can be modulated in relation to task requirements (Kutch et al., 2008; Valero-Cuevas et al., 2009). This suggests that multi-muscle coordination can be modulated. In this study, we explored feasibility of a novel technique to provide peripheral sensation in order to modulate coordination of the hand muscles. Specifically, we provided targeted assistance to hand muscles by pulling

exotendons, whose geometry and kinetic function emulate those of targeted hand muscles (Lee et al., 2014), by electric motors. We then examined if muscle coordination is affected by peripheral sensory inputs induced by these exotendons. Six subjects participated in a pilot experiment in which they were instructed to produce isometric dorsal fingertip force equivalent to 50% of their maximum voluntary force. Activities of three task-related muscles, extensor digitorum communis (EDC; agonist), flexor digitorum superficialis (FDS; antagonist), and first dorsal interosseous (FDI; synergist) were recorded during force production while two types of external assistance conditions were applied: 1) EDC assistance; and 2) FDI assistance. Targeted assistance of the EDC muscle primarily led to an increase in the activation of the antagonist of the targeted muscle (i.e., 27.6% increase in FDS activation) with a small decrease in both EDC and FDI activations during task performance. FDI assistance exclusively reduced the activation level of FDI, by over 40%. FDS activity increased to a much smaller extent (8.7% increase in FDS activation). The outcomes of this study indicate that coordination of hand muscles performed by CNS is affected (and can be modulated) by peripheral sensory inputs (e.g., internal normal/shear forces in finger joints) produced by exotendons.

Title: Distinct influence of hand posture on cortical activity during human grasping

Authors: *M. A. PEREZ[1,2], J. C. ROTHWELL[3];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [3]Sobell Dept. of Motor Neurosci. and Movem, Univ. of Pittsburgh, London, United Kingdom

Abstract: We recently showed that subcortical circuits contribute to control the gain of motor cortical inputs to spinal motoneurons during precision grip of a small object. Here, we examine whether the involvement of the motor cortex could be revealed by grasping with different hand postures. Using noninvasive cortical, cervicomedullary, and peripheral nerve stimulation we examined in humans motor-evoked potentials (MEPs) and the activity in intracortical circuits (suppression of voluntary electromyography) and spinal motoneurons (F-waves) in intrinsic hand muscles when grasping a 6 mm cylinder with the index finger and thumb while the hand was held in the neutral position or during full pronation and supination. We demonstrate that the size of cortically evoked MEPs in the first dorsal interosseous, but not in the abductor pollicis brevis and abductor digit minimi muscles, was reduced to a similar extent during grasping with the hand pronated or supinated compared with the neutral position. Notably, the suppression of MEPs was present from the MEP onset, suggesting that indirect corticospinal pathways were less likely to be involved than direct connections. There was less intracortical inhibition targeting the first dorsal interosseous during hand pronation and supination compared with neutral and this negatively correlated with changes in MEP size. In contrast, cervicomedullary MEPs and F-waves remained unchanged across conditions, as did MEPs evoked during unopposed weak flexion of the index finger. Our findings reveal a distinct influence of the posture of the hand on the activity of cortical pathways controlling different hand muscles during grasping.

Title: Cortical contribution to different types of grip in intact humans

Authors: *T. TAZOE, M. A. PEREZ;
Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: The corticospinal system largely contributes to the control of hand function. However, evidence also supports the view that other systems are involved in the control of hand muscles. For example, studies in non-human primates demonstrated that cortico-motoneuronal cells fired more strongly during precision grip even though activity in the muscle tested was stronger for the power grip. Using transcranial magnetic stimulation over the hand motor cortex we examined motor evoked potentials (MEPs) and intracortical inhibition (suppression of voluntary electromyography, svEMG) in the first dorsal interosseous (FDI) muscle during isometric index finger abduction (control task), precision grip of a small cylinder between the index finger and thumb, and a power grip at matched levels of background electromyographic activity in the FDI muscle. We found that FDI MEP size decreases during precision grip (by 21.9±4.2%) and power grip (by 41.3±5.4%) compared with index finger abduction. Notably, the majority of subjects showed a similar MEP onset latency during index finger abduction and precision grip, whereas the MEP onset latency during power grip was delayed compared with index finger abduction (n=15/18, 0.58±0.11 ms) and precision grip (n=13/18, 0.64±0.14 ms), suggesting that other inputs are involved. svEMG decreased during precision grip by 25.8±11.4% and during power grip by 56.3±8.3%. A correlation was found between changes in svEMG and MEP size across conditions. Our findings indicate that precision and power grip exert a different influence on cortical circuits controlling the FDI muscle and support the view that power grip involves different neural sources than precision grip.

Title: Grip force responses after sudden and unpredictable increase in load force: The effect of load force direction

Authors: *K. C. LIMA, R. V. PEREIRA, P. B. DE FREITAS;
Univ. Cruzeiro Do Sul, São Paulo, Brazil

Abstract: Rapid grip force (GF) adjustments are needed to avert object slippage after unexpected increase in tangential load force (LF). Previous studies showed that when LF unexpectedly increased the central nervous system (CNS) used afferent information mainly from skin mechanoreceptors (i.e., FAI receptors) to trigger GF responses. Also, studies showed that when LF increased towards gravity, as an object tends to move downward, GF response initiated earlier than when LF increased against gravity and that the amount of GF applied just after the perturbation was based on the rate of LF change, which depends on the magnitude of perturbation. However, it is unknown if there would be a linear relationship between the amount of GF exerted and the magnitude of perturbation and if it is direction-dependent. Thus, the aims of the study were to investigate the effect of LF direction on GF response initiation (GFonset) and examine the effect of LF direction on the relationship between the magnitude of perturbation and the GF response. Eleven healthy and right-handed young adults were firstly asked to hold an instrumented object (m=132g) during 12 s, using the thumb and index finger of their right hand. The GF mean was calculated during this trial and used to determine the maximum and minimum values of GF allowed in the holding phase before perturbation (±50% of GF mean). Next, this object was suspended and kept stable by nylon threads fixed on the top and on the bottom of this object and by weights (367g each) fixed on the opposite extremities of these threads. The weights were linked to the threads by two electromagnets controlled by the experimenter. In this second condition, participants were asked to hold the object for 16 s and were warned that at any time the object could move either upward or downward, or stay at the same place. They were instructed to keep the object stationary after the perturbation. The GFonset, GF peak (GFpk), and acceleration peak (Apk), which determines the magnitude of perturbation, were calculated. No effect of direction was found for Apk. The GFonset was lower when the LF increased downward than when it increased upward (128.1±8.9 and 169.8±20.5ms, respectively). Moreover, while we found a strong positive correlation between GFpk and Apk for LF increasing in downward direction (r=0.87), no correlation was found for LF increasing in upward direction. These findings (low GFonset and strong GFpk and Apk correlation) indicate that the CNS is set to respond to perturbations towards gravity (default response) and when perturbation is not to this direction the CNS takes more time to respond (high GFonset) and do not adjust the amount of GF to the magnitude of the perturbation.

Title: Assessment of force coordination and neuromuscular quickness through an object manipulation task

Authors: *M. UYGUR[1], K. HABERLAND[2];
[1]Dept. of Hlth. and Exercise, [2]Mechanical Engin., Rowan Univ., Glassboro, NJ

Abstract: Hand function and neuromuscular quickness are two of the most important aspects of motor function that could be seriously affected by aging and neurological diseases. Deteriorations in these functions could increase the risk of falling and decrease the quality of life of an individual. Therefore, the assessment of these motor functions has crucial importance in clinical and rehabilitative settings. Hand function has been quantitatively evaluated through the coordination between grip force (GF; the perpendicular force) and load force (LF; tangential forces that overcomes the weight and inertia) during object manipulation tasks. Neuromuscular quickness, on the other hand, has been assessed through isometric force production tasks completed under instructions to produce quick force pulses to varying submaximal amplitudes. It has been shown that a positive, linear relationship exists between the peak value of the force pulse produced and the peak value of the corresponding rate of force development. The slope of this relationship is named as rate of force development scaling factor (RFD-SF), which is used as an index for neuromuscular quickness. The aim of our study is to develop a simple technique that assesses force coordination and neuromuscular quickness simultaneously and to test the effects of force production direction on these assessments. We hypothesized that the indices of force coordination (GF/LF ratio, cross correlation between GF and LF and the corresponding time lags) in brief force production tasks will be high and those indices will be similar between pulses completed in upward or downward directions. We also hypothesized that the RFD-SF obtained from GF and LF would be similar and that the force direction would not affect this relationship. Six male and six female healthy young adults were asked to hold an externally fixed GF-LF measuring device and to produce submaximal isometric force pulses by pulling up or pushing down on it. Results revealed high and similar indices of force coordination between pulses produced in each direction implying elaborate force coordination in both directions. Regarding the quickness indices of GF and LF, results revealed a higher RFD-SF of LF than of GF in both force directions indicating a quicker LF production than GF production. Results also indicated that there was no effect of force direction on RFD-SF obtained from either GF or LF, individually. Overall, these findings suggest that brief force production tasks should be further evaluated as clinical tests of hand function and neuromuscular quickness in various populations.

Title: Dexterous manipulation: Learning interference induces increase in effort

Authors: ***Q. FU**, M. SANTELLO;
Arizona State Univ., Tempe, AZ

Abstract: Previous studies have shown that learning of a multi-digit manipulation task induces interference on the learning of a subsequent manipulation task requiring opposite actions of the hand. Additionally, a given manipulation task can be performed with different combinations of digit forces due to biomechanical redundancy. However, little data exist about the adaptation of digit forces through learning of manipulation, and how such adaptation could be affected by motor interference. We addressed these questions through a novel experimental design based on velocity-dependent torque perturbations delivered by haptic devices. Subjects (n=6) were asked to grasp a sensorized grip handle by positioning their thumb, index, and middle finger on force/torque sensors and lifted the handle up to a target zone within 450-550 ms while preventing the rotation of the handle. Two haptic robots were connected to the left and right side of a grip handle to generate the perturbations in the opposite directions for manipulation contexts A and B. The experimental sequence started with 41 Baseline trials (no torque), followed by 66 A-trials then 58 B-trials on the same day. Subjects performed another 41 B-trials followed by 58 A-trials on the following day (i.e., A1B1B2A2). We found that learning in B1 was slower than in A1 on the first day, indicating that learning interference occurred. By measuring digit forces, we also found that subjects used more effort in the beginning of the block and gradually reduced the effort in both A1 and B1. Importantly, the initial increase of effort was greater in B1 than in A1. When subjects were tested on the second day with B2, they showed faster re-learning and no change in effort. Interestingly, subjects increased their effort when switching back to A2 significantly more than the initial increase in both A1 and B1, although the learning rate was the same as A1. This indicates that the increase in effort was not dependent on the actual error. Overall, our results suggest that learning interference at the switch of manipulation contexts

induces temporary increase in effort. The extent to which this effort increases may depend on the number of repetitions with manipulations during the pre-switch context.

Title: Monkeys can use continuous haptic feedback to stabilize an unstable cursor

Authors: *K. M. QUICK[1,2], J. MISCHEL[1,2], P. LOUGHLIN[1], A. BATISTA[1,2];
[1]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA

Abstract: Natural movements are typically guided by sensory feedback. To better understand the complex links between sensation and motor control, we developed a novel paradigm, the Critical Stability Task (CST), to study sensory feedback's role in motor control in primate neurophysiology studies. During the CST, monkeys made serial hand movements to keep a cursor centered on a target. In the absence of these hand movements, the cursor's unstable dynamics caused the cursor to drift from the target at an increasing velocity. The monkeys received either visual feedback or haptic feedback about the cursor position. During visual feedback, if the monkey saw the cursor drift right, the monkey tried to stabilize the cursor by moving its hand to the opposite position on the left, and vice versa. During haptic feedback, the monkey instead experienced the cursor position via two vibrating motors placed on the non-reaching arm. The difficulty of the CST was manipulated by changing the cursor's instability level across trials; a higher instability level caused the cursor to move faster, necessitating faster and more precise corrective movements to stabilize the cursor. A trial was successful if the monkey stabilized the cursor for 6 seconds. We determined the maximal instability level that monkeys could successfully stabilize for half the trials. This allowed a direct comparison of visual and haptic feedback performance. Our main finding is that monkeys can learn to use an

artificial sensory stimulus to shape a long-duration, continuous movement that stabilizes an instability. After several months, two monkeys could use haptic feedback to stabilize 2/3 of the maximum instability level that they stabilized using visual feedback. We also measured the sensorimotor lag between the feedback signals and the corresponding hand movements. We found that the sensorimotor lag was larger during haptic feedback than during visual feedback. This may in part explain the decreased performance during haptic feedback versus visual feedback. Interestingly, we also found that the sensorimotor lag could change with the degree of task difficulty: rather than applying their fastest achievable sensorimotor lag at all instability levels, monkeys used a longer sensorimotor lag at the easier, lower instability levels. The CST can complement classic point-to-point reaching paradigms in several ways: first, it will allow us to probe the neurophysiological mechanisms of continuous, feedback-driven movements. Second, it provides a way to quantitatively compare the effectiveness of different sensory feedback modalities. This will be important in the development of bidirectional brain-computer interfaces.

Title: Anthropometry of passive wrist stiffness

Authors: ***S. K. CHARLES**[1], S. D. GRIMSHAW[2], D. B. SEEGMILLER[3], A. L. PANDO[3], N. HOGAN[4], H. LEE[5,6];
[1]Mech. Inst. of Technol., Chicago, IL; [6]Sch. for Engin. of Matter, Transport, and Energy, Arizona State Univ., Tempe, AZ

Abstract: While decades of motor neuroscience studies have investigated how the neuromuscular system controls the inertial dynamics of shoulder and elbow (reaching) movements, recent studies have shown that the dynamics of distal joints (forearm, wrist, and fingers) are dominated by stiffness, not inertia. However, we do not know how joint stiffness varies between individuals, so it is not currently possible to accurately estimate an unimpaired individual's joint stiffness or to compare an impaired individual's stiffness to normative data to

determine the degree of impairment. The long-term goal of this study is to develop anthropometric regression equations to estimate individuals' passive wrist stiffness from easily measured characteristics. Here we present preliminary data from the initial cohort of subjects. Thirty-two young, healthy subjects participated in this study. Subjects' forearm and hand were attached to a rehabilitation robot (Interactive Motion Technologies, Watertown, MA) that slowly rotated the wrist in combinations of flexion-extension and radial-ulnar deviation. Subjects were instructed to relax as much as possible, and EMG measurements were used to exclude any measurements in which subjects were not sufficiently relaxed. Subjects' 2-by-2 stiffness matrices were calculated from recorded torque-displacement data by multiple linear regression. We computed for each stiffness matrix the area, anisotropy, and orientation of the associated stiffness ellipse, and regressed these ellipse parameters against subject characteristics (age, gender, BMI, height, hand and forearm lengths and circumferences, maximum voluntary torque, and movement direction). Since the height, lengths, circumferences, and torques are known to be highly collinear, we grouped them into a single latent variable termed "stature" determined by principal components analysis. Previous qualitative observations indicated that the area of the stiffness ellipse, which likely depends on muscle cross-sectional area, increases with body size, whereas the anisotropy and orientation, which reflect musculoskeletal geometry, are relatively stereotyped between subjects. We found that the latent variable stature, which represents body size, did have a significant effect on area ($p = 0.024$), but unexpectedly also on anisotropy ($p = 0.047$). We are currently working to increase the size and diversity of the subject population, but these preliminary results indicate that wrist joint stiffness varies in a predictable manner and can therefore be estimated from easily measured subject characteristics.

Title: Sensorimotor memory biases weight perception in a grip-lift task

Authors: *V. VAN POLANEN[1], M. DAVARE[1,2];
[1]Fac. of Kinesiology and Rehabil. Sci., KU Leuven, Heverlee, Belgium; [2]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: When lifting a series of objects, the previous lift influences the planning of fingertip forces for the next lift. For instance, grip force rates are higher after a heavy object has just been picked up compared to a light one. This effect is called sensorimotor memory. Here we investigated whether the order of lifting also affects perception of object weight. Twenty subjects were asked to grip and lift equally sized but differently weighted objects in a semi-randomized order. When the previous trial was a heavy object, peak grip and load force rates were higher and loading phases were shorter than when a light object was previously lifted. This sensorimotor memory effect was found during lifts of both light and heavy objects. Interestingly, weight estimation of an object was significantly lower when preceded by a heavy object compared to a light. This finding suggests that feedback mechanisms involved in force control influence perception of weight and a sense of effort might actually be perceived. A control experiment in which forces were passively exerted on a resting hand showed no perceptual biases due to presentation order. Moreover, the size of the sensorimotor memory effect correlated with the amount of perceptual bias in the grip-lift task, indicating that a larger sensorimotor memory effect was associated with a larger difference in weight estimation. These results were only seen for light objects. The absence of an effect for heavy objects might be explained by the Weber law and possible feedback corrective mechanisms that occur during the longer loading phase for heavy objects. Together, these results suggest that the control of grip force and perception of weight are linked.

Title: Maturation of grip force control in older children and adolescents

Authors: W. SCHERMER, M. CAMINITA, *S. H. BROWN;
Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Developmentally, studies have indicated that control of grip force matures by mid to late childhood (Blank and Hermsdorfer, 2009; Blank et al., 2000; Deutsch and Newell, 2001). In contrast, others have shown continued maturation into early adulthood, particularly in the control of high submaximal forces (Halder et al., 2007). Most studies examining the maturation of grip force have focused on submaximal forces which are typically higher than those required for many daily activities (Rice et al., 1998). Further, it is unclear whether maturation of grip force control is affected by the direction of force modulation (i.e. increasing or decreasing force). The purpose of this study was to examine the development of targeted force control as a function of submaximal force magnitude and direction in older children and adolescents. Typically developing, right-handed males were assigned to one of two age groups: 8-12y and 16-20y. Using hand-held dynamometers, participants produced visually-guided grip forces in response to a step change in a computer-displayed target force level. Tasks were performed with the dominant and non-dominant hand and varied in difficulty using two submaximal target forces (5%, 20% maximum voluntary contraction) and by altering the need to maintain a specific force level prior to and following a step change in target force. Once the force level was established, participants maintained a static target force for 4 sec. Dependent variables were time to reach the force target, rate of force change, and variability during force maintenance. Grip force control improved with age as seen by more rapid changes in force modulation and a reduction in static force variability in the adolescent group ($p<.01$). Regardless of age, static force variability was significantly greater at 5% compared to 20% MVC ($p<.01$). Older children took longer to modulate force regardless of force direction ($p<.01$). In both age groups, the need to control force prior to and at target acquisition did not affect force control. No differences were observed between hands across all tasks despite hand differences using functional measures of hand dexterity ($p<.05$). These results indicate that grip force control continues to mature into late adolescence with the generation of low submaximal forces providing a greater control challenge regardless of age. To what extent these findings reflect age-related differences in sensory processing of force-related sensory feedback and/or predictive force control strategies requires further investigation. **1924/2300**

Title: Finger tapping ability in the dominant and non-dominant hands

Authors: *T. AOKI;
Prefectural Uni of Kumamoto, Kumamoto-city, Japan

Abstract: The abilities of individual fingers during the performance of fast, repetitive tapping movements were compared between the dominant and non-dominant hands in ten healthy young males and females. All subjects were right-handed, as determined by the Edinburgh MRC Handedness Inventory (Oldfield 1971). The subjects completed two tasks. The first task (single-finger tapping) was to tap a force transducer for 7 sec as fast as possible using only one finger (the index, middle, ring and little fingers), while the another task (double-finger tapping) was to complete the same activity but tapping with two fingers alternately (the index-middle, middle-ring, and ring-little finger pairs). All conditions were performed by the dominant right and non-dominant left hands. The order of the tasks was randomized, and within each task the order of finger or finger pair was also randomized. In all tasks, the subjects were instructed to keep their "resting" (non-tapping) fingers in contact with the transducers. Tapping and non-tapping finger forces were measured using four force transducers. In the single-finger tapping, inter-tap intervals with the dominant hand were significantly shorter than the non-dominant hand in all fingers. Parallel changes were observed in the key-contact force of the non-tapping fingers during tapping. The sum of average forces over the entire 10-tap period for the three non-tapping fingers was significantly larger for the dominant hand in all fingers than the non-dominant hand. On the other hand, there was no significant difference between the dominant and non-dominant hands in all fingers for sum of the ranges of forces for the three non-tapping fingers. In the double-finger tapping, inter-tap intervals with the dominant hand were significantly shorter than the non-dominant hand in the index-middle and middle-ring finger pairs. Interestingly, significant difference between the dominant and non-dominant hands was not observed in the ring-little finger pair. Observed superior finger tapping abilities in the dominant hand in most of all conditions for right-handed adults can be due to effect of daily use on the development at the central nervous system. Similar finger tapping abilities between the dominant and non-dominant hands in the ring-little fingers may be attributed to less frequent combined use of the ring and little fingers for both of the dominant and non-dominant hands in daily activity.

Title: Effects of goal-directed mirror visual feedback on cortical excitability in the untrained hemisphere

Authors: *T. MANUWEERA[1,2], M. YAROSSI[1,2], S. ADAMOVICH[2], E. TUNIK[3];
[1]Rutgers Biomed. Hlth. Sci., Newark, NJ; [2]Dept. of Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ; [3]Rutgers Biomed. Hlth. Sci. - Sch. of Hlth. Related Professions, Newark, NJ

Abstract: In persons with hemiplegia due to stroke, mirror visual feedback (MVF) of movements performed with the unaffected limb, can recruit brain areas controlling the stroke-affected limb and aid recovery. Given evidence that goal-directed, relative to goal-free movements, elicit stronger bilateral activation, we ask here if goal-directed mirror training may likewise elicit stronger activation in the untrained (ipsilateral) M1. Following informed consent, 10 healthy subjects performed 4 blocks (B1-B4) of index-finger flexion movements using their dominant right hand, with feedback presented in a virtual environment. Each subject completed 4 protocols, randomly ordered: veridical feedback with (VG) and without (VF) a goal, and MVF with (MG) and without (MF) a goal. In the goal protocol (MG, VG), subjects moved to 3 targets (20º, 40º, 60º). In the no-goal protocol (MF, VF), subjects performed non-targeted flexion movements. Transcranial magnetic stimulation was used to elicit motor evoked potentials (MEPs) in the left first dorsal interosseous (FDI) and abductor digiti minimi (ADM) muscles prior to training and after each block to track cortical excitability in the untrained M1. Targeted movement kinematics without visual feedback were measured before and after training to assay learning. Separate rmANOVAs were used to analyze MEP amplitudes [Feedback (MG, MF, VG, VF), Block (Pre, B1-4)], and absolute angular error [Feedback (MG, MF, VG, VF), Time (Pre, Post) and Hand (Left, Right)]. For MEPs of the untrained FDI a significant ($p<.05$) main effect of Time, and a significant Time x Feedback interaction was noted. Post-hoc testing confirmed that the MEPs significantly increased relative to PRE in B3 (178%) and B4 (175%) for the MG condition only. No significant changes in MEPs were noted for the uninvolved ADM, suggesting a task-specific effect. Analysis of kinematics revealed no significant effects suggesting M1 excitability changes may reflect priming, rather than an interhemispheric transfer of information. To test the intra and interhemispheric drivers of M1 excitability in the MG condition, 5 subjects were tested using paired-pulse TMS-based measures of short intracortical inhibition (SICI), intracortical facilitation (ICF), and interhemispheric inhibition (IHI). Trends indicating decreased SICI and IHI were noted in the preliminary dataset. Our data suggest that performing goal-directed movements during MVF imparts the most robust M1 activation, and that this activation

is 1) task specific (e.g. muscle-specific), 2) may reflect a priming rather than an information-transfer effect, and 3) possibly mediated by SICI- and IHI-based mechanisms.

Title: Involuntary finger-thumb coupling during a pinching task

Authors: *D. G. KAMPER[1], C. L. JONES[2];
[1]Biomed Engin., Illinois Inst. Technol., Chicago, IL; [2]Biomed. Engin., Illinois Inst. Technol., Chicago, IL

Abstract: Highly individuated movement of the digits, especially for the index finger and thumb, is one of the hallmarks of human motor control. While great independence of movement is possible, tightly coordinated activity among the digits is required to achieve many activities of daily living. For example, the thumb tip and fingertip forces must balance each other when pinching an object, but both must also respond to perturbations to the object or its surface. As this coordination is incompletely understood, we ran a set of experiments to explore the coupling between the thumb and index finger during pinching movements. Accordingly, a cable-actuated finger exoskeleton (CAFE) was created to provide precise, strong, high-bandwidth perturbations to the index finger during dynamic movement. The CAFE is capable of independently actuating each joint of the index finger under force or position control. Neurologically intact participants were instructed to move their index finger and thumb from an extended posture with the hand open through a palmar pinching motion until fingertip and thumb tip made contact, and then back to the starting posture. Electromyographic signals were recorded with a combination of surface and intramuscular electrodes for 5 different muscles in the index finger and thumb. Kinematics for the thumb were recorded with an optical tracking system. The CAFE was employed to provide two types of perturbations to the index finger during either the opening or

closing phase of these movements. In the first group of experiments, the CAFE randomly rotated the MCP joint 40° into either flexion or extension at 600°/s during the pinching movement on selected trials. A total of 10 trials were performed for each of the four conditions: flexion/extension, closing/opening. An additional 20 trials were conducted where no perturbation was delivered. In the other group of trials, impedance of either the metacarpophalangeal (MCP) joint or distal and peripheral interphalangeal (IP) joints was suddenly increased to restrict further movement during either the opening or closing phase. Ten trials were conducted at each of the four conditions: MCP/IP, closing/opening, and twenty trials with no perturbation were randomly interspersed. Imposed displacement of MCP in the first set of trials produced stretch reflex activity in the perturbed finger muscles, but also a heteronymous reflex response in the non-stretched muscles of the thumb. Similarly, the sudden increase in joint impedance in the index finger led to reduced movement of the unperturbed thumb. In both cases, the degree of finger-thumb coupling varied with phase of movement.

Title: Synergy in a space of control variables during a finger force production task

Authors: *S. AMBIKE[1], D. MATTOS[2], V. ZATSIORSKY[1], M. L. LATASH[1];
[1]The Pennsylvania State Univ., University Park, PA; [2]Biomechanics and Movement Sci., Univ. of Delaware, Newark, DE

Abstract: We used the framework of the referent configuration hypothesis to explore the possibility that accurate performance can result from inter-trial co-variation among control variables that show relatively high variability. In particular, we assumed that force production by a finger in isometric conditions results from controlling the fingertip referent coordinate (R) and apparent stiffness (C) and is governed by the equation: force = R × C. Therefore, a hyperbolic function in the {R, C} space defines the solution space for the task of producing a certain force

(the uncontrolled manifold, UCM, for that task). We explored whether inter-trial variability in {R, C} was organized to keep deviations from the UCM low while allowing large deviations within the UCM. Subjects produced a specified constant force (25% of maximal voluntary contraction force) with a finger or all four fingers together by pressing downward on force sensor(s). Visual feedback on the instructed force was provided for the first 5 s and then removed while the subjects were instructed to keep performing the same action. Next, all fingers and sensors were gently raised (1 cm over 0.5 s), starting at an arbitrary time within a 2-s window, leading to an increase in the force. Subjects were instructed and trained to 'not interfere' with the external perturbation. Linear regression in the force-coordinate plane was used to estimate the apparent stiffness C and the intercept, which provided an estimate of R (referent position corresponding to zero force). R and C values computed across multiple trials displayed a hyperbolic distribution with consistently high R^2 values (> 0.9) for all task conditions and subjects. Further, we created a surrogate data set by shuffling the R and C values measured in different trials and re-computing the force (= R × C). Force production accuracy in the surrogate data sets was consistently smaller than in the actual sets confirming that the inter-trial co-variation in the {R, C} space was used to achieve accurate performance despite large variation in both R and C. Our results provide support for the referent configuration hypothesis and its more classical version - the equilibrium-point hypothesis. Note that R and C are produced by physiological control signals (thresholds of the tonic stretch reflex, λs) to the involved muscles, which are expected to covary to stabilize {R, C} to within their observed ranges. To our knowledge, this is the first experimental demonstration of hierarchical control expressed in terms of the fundamental control variables, such as {R, C}, and is an important step towards the analysis of synergies in the λ-space.

Title: Proximal and distal coding of sensorimotor parameters in the control of arm movements

Authors: K. REGNERY[1], N. NATRAJ[2], K. OH[2], B. PRILUTSKY[2], L. WHEATON[2], *J. C. MIZELLE[2];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Sch. Applied Physiol, Georgia Tech., Atlanta, GA

Abstract: Sensory feedback from the principal modalities (e.g., vision and somatosensation) are critical in the internal model framework, for estimation of the current state of the sensorimotor system, predicting future sensorimotor states given some motor command, and also for the on-line control of movement. The precise nature of how sensory feedback is used in coding the sensorimotor state has not yet been fully identified. More specifically, we sought to answer whether the sensorimotor state was estimated by the relative position of the end effector, or whether this estimation relied on the relative joint positions of the more proximal segments. As such, we designed an experiment where participants deprived of visual feedback performed a limb mirror-matching task with and without reduced sensory feedback from the end effector. A planar robotic apparatus moved the left arm from a constant starting postural configuration into one of four new postural configurations. Participants then actively moved the right arm to mirror this new postural configuration such that the elbow and shoulder joint angles of the right arm were equal of those of the left. In the first half of the experiment, participants had normal sensory feedback from the end effector of the left arm. For the second half of the experiment, we used ischemic deafferentation to reduce sensory feedback from the end effector (hand) of the left arm by inflating a blood pressure cuff placed on the distal forearm. Elbow and shoulder joint kinematics and the position of the middle fingertip were recorded for each experimental trial. Given the one-to-one mapping between finger position and the elbow and shoulder angles, virtual targets related to the expected fingertip location for each of the four postural configurations were also created, and errors between the actual fingertip position and these virtual targets were calculated. We observed similar elbow and shoulder kinematics regardless of deafferentation, but greater errors in finger location with reduced end effector sensory feedback. Thus, our results suggest a dual processing strategy, wherein proximal sensory feedback is sufficient to guide the finger to an approximate spatial location, and then sensory feedback from the end effector refines the spatial estimate. This study highlights the importance of sensory feedback from the end effector in sensorimotor state estimation for motor control and has implications for clinical populations suffering from reduced afferent sensory information.

Title: Cortical EEG oscillations can predict the variability of MEP amplitudes

Authors: *K. OGATA[1], H. NAKAZONO[2], S. TOBIMATSU[2];
[1]Grad Sch. Med. Sci, Kyushu Univ., Fukuoka, Japan; [2]Kyushu university, Fukuoka, Japan

Abstract: [Objective] Motor evoked potentials (MEPs) are obtained by transcranial magnetic stimulation (TMS) over the primary motor cortex (M1), but their amplitudes often vary stimulus by stimulus. We hypothesized that EEG oscillations just before TMS could predict MEP amplitudes. Thus, we evaluated the relationship between EEG oscillations and MEP amplitudes to determine the underlying mechanism of the variability of MEP amplitudes. [Methods] Twelve healthy adults were recruited in Experiment 1. EEGs were obtained at 19 locations (international 10-20 system), and EMGs were recorded from right FDI. Left M1 hotspot was stimulated by TMS with the intensity to obtain about 1 mV MEP amplitudes. Interstimulus interval was set at 5 - 7 s. MEPs and EEGs were recorded for 200 times in total for each subject under eyes-open (EO) and eyes-close (EC) conditions. EEGs were segmented between -500 and 0 ms of TMS onset, and the power values were calculated by wavelet analysis. EEG powers of 8 - 30 Hz were compared between the epochs of high and low amplitude MEPs. In Experiment 2, the influence of low TMS intensity was evaluated under EO condition. EEGs from 8 subjects were compared between the two conditions of different TMS intensities; high TMS intensity was set to elicit 1 mV MEPs as in Experiment 1 and low intensity was fixed at resting motor threshold. [Results] EEG powers of α and β range were enhanced at C3 when MEP amplitudes were larger in both EO and EC conditions (Experiment 1). When the EEG power difference of high/low MEPs was compared between EO and EC conditions, the power differences in α and low β range under EO was more increased than that of EC at frontal and parietal leads. On the contrary, EEG powers were reduced at C3 when MEP amplitudes were larger in the low TMS condition (Experiment 2). [Discussion] Our results (Experiment 1) demonstrated that the larger α and β powers at C3 could predict the larger MEP amplitudes in both EO/EC conditions. Modulation of visual cortices by EO/EC probably influences distant cortical functions including M1 in relation to vigilance, attention or anticipation. Decreased EEG powers for larger MEP amplitudes with low TMS intensity (Experiment 2) were in accord with previous studies, in which decreased EEG powers were considered to reflect only local M1 excitability. How do we interpret paradoxical results of Experiments 1 and 2? The higher TMS intensity becomes, the more activated areas involve. Therefore, we speculate that the enhanced inputs from surrounding areas to M1 induced by high TMS intensity produce the larger MEP amplitudes.

Title: Movement intermittency: visuomotor feedback loop or intrinsic rhythmicity?

Authors: *D. SUSILARADEYA, F. GÁLAN, K. ALTER, A. JACKSON;
Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: In tracking slow targets, humans are known to make periodic intermittent movement with a predominant frequency of 2 Hz, ranging from 1-4 Hz.[1] However, the mechanisms of this low-frequency rhythmicity in behaviour are not fully understood. Previously movement intermittency has been thought to be determined by sensorimotor loop delays, since artificially increasing these delays reduces the frequency of submovements. However, recent work has revealed an intrinsic rhythmicity within motor cortical networks at submovement frequencies around 3 Hz, including during sleep.[2] Therefore we re-examined the possibility of an intrinsic rhythmicity contributing to movement kinematics. First, we developed a novel 2D bimanual finger force tracking task with a target that followed circular trajectories with frequencies of 0.1 and 0.2 Hz. We observed a sharp peak in the power spectrum of the cursor speed at 2 Hz, irrespective of target speed or whether subjects made eye movements or fixated the centre of the screen. Tracking was associated with an increase in delta band (1-4 Hz) power in the electroencephalogram over sensorimotor cortex. This signal was coherent with cursor speed, at around 2 Hz. To investigate the role of visual feedback, we introduced delays of 100 ms, 200 ms, 300 ms and 400 ms. The main tracking frequency at 2 Hz shifted to a lower frequency as delay increased. Surprisingly, we observed a second higher frequency peak at twice the main frequency which became more prominent as delay increased. These data could be explained by a simple model in which intermittent movement commands arising from external visual feedback are filtered through motor circuits with intrinsic rhythmicity. We speculate that this intrinsic rhythmicity may help generate submovements with a kinematic profile appropriate for naturally-occurring feedback delays. References: 1. Vince MA. Title: Posterior parietal cortex informs self-action perception by integrating visual feedback about one's actions with internal movement-related cues from proprioception and forward models

Authors: M. J. ROTH[1,2], K. LAUER[1], M. SYNOFZIK[1], M. HIMMELBACH[1], *A. LINDNER[1];
[1]Hertie Inst., Tuebingen, Germany; [2]IMPRS for Cognitive and Systems Neurosci., Tuebingen, Germany

Abstract: Perception of one's own limb movements is not only informed by external (visual) information. It also relies on internal action-related information such as proprioception and efference copies of motor commands. An area that has access to these various types of information is posterior parietal cortex (PPC), rendering it an ideal neural substrate to inform self-action perception. In particular, it has been suggested that PPC represents forward models that enable predictions about sensory consequences of self-action based on efference copies. Such forward models are highly relevant for perception as they allow identifying sensory information that is self-produced. Moreover, they reliably inform perception about self-action without delays due to sensory processing and even in situations where external action-cues are unreliable or lacking. Here we tested the notion that PPC represents forward models for perception. To this end we contrasted performance between a group of 11 patients with lesions in PPC and a group of matched healthy controls: Subjects' task was to perform fast out-and-back pointing movements in a virtual reality setup, in which visual feedback about movements could be manipulated or omitted. Specifically, we acquired visual estimates of subjects' perceived pointing direction (i) in trials with veridical visual feedback, (ii) in trials with rotated visual feedback, and (iii) in trials without feedback. We also acquired visual self-action estimates in a passive pointing condition without feedback (iv) in which an experimenter was moving subjects' arms. Comparing this passive condition (iv) with the active case (iii) allowed us to infer the

respective contribution of forward models and proprioception on self-action estimates. Our experiments demonstrate that the reliability (the inverse of the variance) of self-action estimates significantly improved from passive to active pointing by a factor of roughly two, suggesting a contribution of both, proprioception and forward models to self-action perception. Interestingly, performance in both tasks (iii & iv) was indistinguishable between groups, questioning the notion of forward models for perception in PPC. Instead, in cases with rotated visual feedback (ii), patients self-action estimates relied to a significantly greater extend (about 1.7 times more) on that (manipulated) feedback as compared to controls. This suggests that the role of PPC in self-action perception is rather to integrate forward models and proprioception with visual information than to establish forward models in the first place. The latter might instead be a function of the cerebellum.

Title: Modulation of 5-30 Hz EMG-EMG coherence during grip force tasks with varying precision constraints

Authors: *R. TIBOLD[1], S. FARMER[1], M. DAVARE[1,2];
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London Inst. of Neurol., London, United Kingdom; [2]Movement Control and Neuroplasticity Res. Group, Biomed. Sci. Group, Dept. of Kinesi, KU Leuven, Leuven, Belgium

Abstract: Skilled hand movements involve functional interactions across an extensive parieto-frontal cortical network. The neural mechanisms by which these structures cooperate spatio-temporally are not fully understood. One way to investigate how these different areas interact is to analyse common oscillatory drive in the electromyogram (EMG) since oscillatory activity facilitates synchrony between neuronal ensembles. Here we varied the task precision constraints

to test whether different levels of activity in sensorimotor loops could alter the oscillatory interactions between the neural sources that underlie grip force control. To address this issue we quantified changes in EMG-EMG coherence between rectified surface EMG signals acquired simultaneously from first dorsal interosseous and abductor pollicis brevis while healthy individuals (n=9) performed visuomotor grip force tracking tasks at distinct force levels requiring either low or high precision. In a "force control" condition, subjects squeezed with their index finger and thumb a manipulandum with 2 force sensors (ATI mini40-E) to move a cursor on a computer screen along a predefined force target path by controlling their force. In a "position control" condition, two Phantom Desktop (Geomagic) haptic devices were attached to the index finger and thumb. Subjects had to vary their grip aperture to move the cursor along the target path whilst force exerted by the robots was kept constant. We found tracking performance improved as precision constraints increased in the position but not force control task, suggesting sensorimotor feedback loops acted more efficiently when processing position rather than force. A pooled coherence analysis with extended Chi^2 statistics revealed (1) a significant increase in the magnitude of coherence at 9-11 Hz frequencies when comparing high vs. low precision conditions and (2) a suppression of the coherence at 16-30 Hz frequencies for both precision levels in the position control task. There was an overall lack of coherence changes in the force control task. We suggest the increased common drive in the alpha-band is a signature of an enhanced oscillatory activity in cortical ensembles involved in sensorimotor control of position, but not force signals. It is plausible alpha-band oscillations implement generic filtration of neural activity interfering with high precision requirements, thus reallocating the computational resources on the control of grasp. These results are in line with the disengagement theory of task-irrelevant cortical regions achieved through "gating by inhibition" where the necessary information is routed to the task-relevant brain areas.

Title: Evidence for a transition in usage of cortical and subcortical structures during the learning process of human hand movement

Authors: *N. KIRKPATRICK[1], J. VALENTIN[2], E. J. PERREAULT[2], C. F. HONEYCUTT[1]; [1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [2]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: A startling acoustic stimuli (SAS) causes the involuntary release of certain planned movements in humans referred to as startReact. This technique has been used as a probe of motor planning for many actions such as reaching or grasping; however, other actions like individual finger movements are not susceptible to startReact. StartReact is only intact when subcortical (e.g. reticulospinal) structures are utilized during execution. Researchers have theorized this reliance on subcortical pathways for initiation precludes finger movements from demonstrating an intact startReact (Carlsen *et al.,* 2009) because such movements are predominately mediated by cortical structures. But, recent work couched in non-human primate work has revealed reticulospinal involvement in such tasks (Soteropoulos *et al.,* 2012). Accordingly, the underlying reasoning behind finger movement's inability to startReact remains elusive. Alternatively, startReact susceptibility could relate to task familiarity. The task previously used to evaluate startReact in finger movements was index finger abduction – an uncommon task requiring a large cognitive (cortical) burden to accomplish. We hypothesized index finger abduction would be susceptible to startReact after repetitive task training, during which this task would become more familiar and require less cognitive burden. 10 healthy adults practiced index finger abduction over the course of a 10-day training regime. Trials consisted of "ready" and "go" commands. SAS was implemented between the two commands in roughly 20% of trials. Latencies between SAS and FDI (index finger abductor) EMG activation were recorded. Using EMG activation of the right and left sternocleidomastoid (SCM), SAS trials were further classified as startle present (SCM+) and startle absent (SCM-). A movement is considered susceptible to startReact when the FDI latency during SCM+ trials is faster than during SCM- trials. We found FDI latencies between SCM+ and SCM- trials were similar on day 1 (Δ = 2.9±12.6ms) but demonstrated faster SCM+ latencies (average = 92.6±10.1ms) compared to SCM- latencies (average = 101.0±11.1ms) by day 10 (Δ = 8.4±4.2ms). These data indicate index finger abduction is receptive to startReact after repetitive training. This susceptibility is accompanied by enhanced performance of the task; reaction times for voluntary trials (without SAS) decreased from day 1 to day 10 (Δ = 58.9±33.2ms). These results suggest that subcortical structures become increasingly important as a motor task is learned. In this way, startReact may be a useful probe not only of the allocation of neurological resources, but also of the learning process itself.

Title: The role of movement in metacognition: the relationship between movement speed and confidence

Authors: *E. PALSER[1], A. FOTOPOULOU[2], J. KILNER[1];
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, Inst. of Neurol., London, United Kingdom; [2]Clinical, Educational & Hlth. Psychology, UCL, London, United Kingdom

Abstract: Previous studies have demonstrated that the confidence someone has in a decision they have made and whether or not that decision is correct are related. This is often referred to as metacognition. Furthermore, it is known that in such tasks participants' confidence ratings are correlated with the speed at which they reported their decision. Indeed, individuals can even estimate others' confidence levels from observing their movements while making a decision, with faster movements correlating with higher confidence. Currently, the mechanism by which we are able to correctly estimate our confidence in our decisions is not known. Recent work has shown that disruption of the motor system, specifically dorsal premotor cortex, significantly reduces metacognitive ability. This opens up the possibility that, at least in part, our confidence ratings of our own decisions are estimated from how we executed the action that indicated our decision. The link between cognition and action has been demonstrated in social psychology studies, where the adoption of high-power non-verbal displays (open, expansive postures) leads to increased reports of feelings of power and elevations in testosterone and reductions in cortisol, compared with subjects who adopted low-power displays (crossed limbs, contractive postures).

Here we tested the hypothesis that observation of our own movements modulates our estimate of our confidence in our decisions. 48 subjects (31 female, 17 male) with a mean age of 27 were recruited. Here we manipulated subjects' movement speeds using a movement priming task. They were then asked to make a binary decision on a perceptual contrast discrimination task, and indicate their response by moving an object to one of two containers. Subsequently, they reported their confidence in their decision using a numerical scale of 1-99, with 1 indicating minimum possible confidence, and 99 indicating maximum confidence. Preliminary analyses revealed that movement speed had a measurable effect on confidence. As expected, after the fast prime participants were quicker to indicate their decision and responded more slowly following the slow prime. For correct decisions there was no significant modulation in reported confidence ratings by the movement speed. However, for incorrect trials, as predicted, following the fast prime subjects significantly increased their confidence ratings compared to a decrease in confidence ratings subsequent to the slow prime. This finding suggests that humans obtain information about their confidence levels by monitoring their movement kinematics and that confidence can be manipulated by changing how subjects move.

Title: Interactions between different regions of ventral premotor cortex and contralateral M1

Authors: *K. L. BUNDAY[1,2], S. BETTI[3], J. M. KILNER[1], R. N. LEMON[1], G. A. ORBAN[2], M. DAVARE[1,4];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. degli Studi di Parma, Parma, Italy; [3]Univ. degli Studi di Padova, Padova, Italy; [4]KU Leuven, Leuven, Belgium

Abstract: Recent brain imaging studies investigating the neural network underlying action observation suggest that sub-regions of the ventral premotor cortex (PMv) are functionally

different from one another. For instance, monkey area F5a responds to observing actions in a more general way, such as viewing the hand alone performing a grasp, mimicking actions and robot actions. In contrast, area F5c is only active when the observer views a whole person performing an action (Nelissen et al., 2005). Due to these functional differences, we hypothesised that the effective connectivity profile of different sub-regions within human PMv would also differ. Here, using paired-pulse transcranial magnetic stimulation (TMS), we examined the connectivity between two sub-regions of PMv and the contralateral primary motor cortex (M1) and compared it to interhemispheric inhibition (M1-M1), as a control for electrical current spread to M1. The two different PMv sites were the caudal part of the inferior frontal gyrus (IFGc, cortical surface MNI coordinates: X=55, Y=14, Z=29) as frequently used in previous studies (Buch et al., 2010, Davare et al., 2010) and the recently identified putative human homologue of F5c (phF5c, MNI coordinates from the fMRI: X=38, Y=0, Z=40; see Ferri et al., 2015). Whilst subjects (n=9) sat at rest, a single TMS pulse was given over the left M1 alone (test pulse) or after a conditioning pulse over right IFGc, phF5c or M1 at an inter-stimulus-interval (ISI) of either 8 or 10 ms. The conditioning stimulus was applied either at a subthreshold (80% of resting motor threshold; rMT) or suprathreshold (120% of rMT) intensity. Twenty motor evoked potentials (MEPs) were recorded from the first dorsal interosseous (FDI) for each condition (2 conditioning intensities x 2 ISIs x 3 sites x 20 = 240 MEPs in total). We found that a subthreshold conditioning pulse over right IFGc, phF5c or M1 had no effect on contralateral M1 MEPs at either ISI. Conversely, suprathreshold pulses over right IFGc, phF5c or M1 differentially modulated contralateral M1 MEPs, such that for both ISIs phF5c conditioned MEPs were significantly increased compared to IFGc and M1, whereas IFGc conditioned MEPs, and to a greater extent M1 conditioned MEPs, were significantly decreased compared to phF5c. Our results indicate that phF5c has a net facilitatory influence on contralateral M1 compared to the neighbouring IFGc, which shows a net inhibitory effect on M1, in line with previous studies. Altogether these two distinct effective connectivity profiles could highlight different mechanisms by which phF5c and IFGc influence M1 during action observation.

Title: Quantifying the perception of self-movement: differences between the dominant and nondominant limbs

Authors: *L. C. BRAY[1], F. WOOD ORTIZ[1], E. MCKENNA[2], W. M. JOINER[1];
[1]Bioengineering, [2]Neurosci., George Mason Univ., Fairfax, VA

Abstract: There is evidence that state estimation of the limb (e.g., position and velocity) during movement is less accurate for the nondominant limb compared to the dominant arm (Hore et al. 1996; Sainburg 2005). In this study we aimed to quantify possible perceptual differences due to state estimation by examining (1) the extent to which human subjects accurately estimated hand location without visual feedback during arm reaching movements and (2) how this ability compared for movements of the dominant (right) and non-dominant (left) hand. Right-handed human subjects used a robotic manipulandum to make 15 cm shooting movements with no visual feedback of the hand position. After movement completion, feedback in the form of two white circles located 3 cm apart appeared at one of four possible locations into the movement (3, 6, 9 or 12 cm). The circles flanked the actual movement trajectory, but were horizontally shifted from trial to trial (a shift between -1.5 and 1.5 cm in 0.1 or 0.2 cm steps). The magnitude of the shift was randomly determined from a uniform distribution, with the largest shifts (± 1.5 cm) resulting in one of the cursors being presented exactly on the movement path. Subjects were required to indicate which of the two circles represented the actual completed movement trajectory by making a two-alternative forced choice decision using a joystick located on the robot handle. Based on these responses we created psychometric functions to determine the perceived movement trajectory at the four locations along the movement path. Our results show that the perceptual estimate (bias) matched the direction of the movement bias; left-handed movements had a rightward movement and perceptual bias, with the opposite true for right-handed movements. The variability of this perceptual estimate also increased with distance into the movement, but was significantly and consistently greater for movements of the nondominant hand ($P < 0.01$). This was true even though the movement variability was equivalent between the two limbs ($P > 0.58$ for all cases). These results suggest that the perceptual estimation of nondominant limb position (based on a combination of proprioceptive and efferent copy information) is a more variable process than equivalent estimates made for the dominant limb. We hypothesize that this difference in perceptual variability between the two limbs might diminish for passive movements, as the judgement of limb position should be based more on equivalent proprioceptive information rather than efferent copy.

Title: Tactile inputs distort perception of relative fingertip position

Authors: *D. SHIBATA[1], F. CHINELLO[2,3], D. PRATTICHIZZO[2,3], M. SANTELLO[4];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Dept. of Information Engin., Univ. of Siena, Siena, Italy; [3]Dept. of Advanced Robotics, Inst. Italiano di Tecnologia, Genova, Italy; [4]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: As we exert digit forces following contact with an object, the mechanical deformation of the finger pads elicits tactile afferent activity. The extent to which this tactile input alone might be used to estimate the relative position of the fingertips is unknown. We addressed this question by removing descending motor commands to generate digit forces while deforming the thumb and index finger pads by using a wearable haptic device. Subjects (n = 7) were asked to sense, remember, and match vertical and horizontal distances between the center of pressure (CoP) of the thumb and index finger pads (d_y and d_z, respectively). The digits were passively placed and held to a reference position (d_y = 0 mm, d_z = 64 mm) for 5 seconds. During this epoch, subjects were asked to sense the relative digit position while the haptic device exerted normal and tangential forces (*Fn*: 4.1-4.6 N and *Ftan*: 2.1-3.1 N, respectively) on each finger pad in either same (both up or down) or opposite (thumb-index: up-down or down-up) directions. After a 5-s break, subjects were asked to match the memorized d_y and d_z. We also examined effects of *Fn* magnitude exerted on the finger pads by using either the same range of *Fn* as for the above-mentioned conditions while exerting negligible *Ftan* (4.1-4.6 N, 0 ± 0.1 N), or negligible *Fn* and *Ftan* (< 0.1 N, 0 ± 0.1 N). Based on our prior work (Shibata et al. 2014), we hypothesized that estimation of d_y would be biased in the opposite direction of skin deformation, but only for the opposite digit *Ftan* direction condition. Subjects made systematic errors in reproducing d_y but only when the directions of thumb and index finger *Ftan* were opposite. Specifically, subjects positioned the thumb CoP lower than the index finger CoP when the *Ftan* of the thumb and index finger was directed upward and downward, respectively, and vice versa ($p < 0.05$). In contrast, d_z reproduction was accurate across all experimental conditions. These findings indicate that tactile input contributes to the biased estimation of relative digit position found when mechanical deformation of the fingertips is caused by the exertion of digit forces in opposite directions (Shibata et al. 2014). The relative contribution of tactile input and voluntary commands towards the biased estimation of relative digit position is currently being investigated.

Title: Correlation between central EEG rhythms and fMRI-BOLD responses in the sensorimotor area during a unilateral motor task

Authors: ***K. UEHARA**[1], H. HOSHINO[1], Y. MIZUNO[1], K. KITA[1,2], L. M. LI[3], Y. OGATA[1], T. HANAKAWA[1];
[1]Dept. of Advanced Neuroimaging, Integrative Brain Imaging Ctr., Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [2]Ctr. for Frontier Med. Engin., Chiba Univ., Chiba, Japan; [3]Div. of Restorative Neurosciences, Imperial Col. London, London, United Kingdom

Abstract: A simultaneous EEG-fMRI measurement allows us to achieve an understanding of human brain function with both high temporal and spatial resolutions. Such multimodal brain imaging technique might provide further information on neural mechanisms underlying motor control in humans. It is well known that EEG alpha (8-13 Hz) and beta (14-30 Hz) rhythms in the central areas are functionally related to sensorimotor events and are modulated by a motor task or somatosensory input from the peripheral limb. However, functional relationships between central alpha and beta rhythms and fMRI-BOLD responses during a motor task are still unclear. Therefore, the aim of the present study was to identify whether central alpha and beta rhythms were correlated with BOLD signals during a motor task and, if so, whether there was any difference in their correlational characteristics between the both EEG rhythms. Simultaneous EEG-fMRI measurements were performed with a 3.0-T MRI scanner and a 32-channel MR-compatible EEG cap in 21 young healthy right-handed subjects. We asked the subjects to perform a unilateral finger-tapping task with their right index finger at five different frequencies (0.25, 1, 2, 3 and 4Hz) paced externally by auditory cues. The motor task lasted for 20 s, interleaved with a resting period for 20 s, in a semi-randomized block design paradigm. For the analysis of the EEG signals, gradient artifacts arising from MR pulses and ballistocardiogram artifacts were removed from the raw EEG signals. We then performed time-frequency analysis of the alpha and beta band EEG signals from the C3 electrode, corresponding to the sensorimotor area contralateral to the task side. Specifically, we used a wavelet analysis to obtain power time-

series for every TR epoch (2.5 s), yielding mean alpha or beta power in each task/rest block as a parametric modulator of a task. For the EEG-fMRI integration analysis, we used a general liner model to evaluate correlations of C3 alpha and beta signals with BOLD responses. The C3 alpha rhythms were inversely correlated with BOLD responses in the contralateral primary motor cortex, somatosensory cortex, superior and inferior parietal lobules and ipsilateral cerebellum during the unilateral finger-tapping task; however there was no positive correlation between EEG rhythms and BOLD signals. We failed to find correlations of the C3 beta signals with BOLD responses. The present study indicates that C3 alpha and beta signals may differ with respect to their correlations with BOLD signals during the motor tasks. Central alpha signals seem to be more sensitive to detecting BOLD responses than C3 beta signals, at least during the present tapping task.

Title: Spatial variability in cortex-muscle coherence investigated with magnetoencephalography and high-density surface electromyography

Authors: *H. PIITULAINEN[1], A. BOTTER[2], M. BOURGUIGNON[1], V. JOUSMÄKI[1], R. HARI[1];
[1]Aalto Univ., Espoo, Finland; [2]Dipartimanto di Elettronca e Telecomunicazioni, Politecnico di Torino, Turin, Italy

Abstract: Objective Coupling between cortical magnetoencephalographic (MEG) signals with surface electromyography (sEMG) is referred to as cortex-muscle coherence (CMC). CMC is

strongest during isometric contraction but is, for unknown reasons, very weak or absent in about 20% of all individuals. Here, we aimed at evaluating whether the sEMG recording site or electrode derivation would explain some aspects of the CMC variability. Methods We used a novel non-magnetic high-density sEMG (HD-sEMG) electrode grid (36 mm × 12 mm; 60 electrodes separated by 3 mm) to record monopolar-sEMG signals from the right thenar simultaneously with 306-channel whole-scalp MEG recording from 14 subjects who kept for 4 min an isometric thumb abduction. CMC was computed using three HD-sEMG derivations (60 monopolar, 55 bipolar, and 32 Laplacian), and two derivations computationally produced from HD-sEMG signals to mimick conventional bipolar and monopolar sEMG recordings in terms of electrode diameter (9 mm) and inter-electrode distance (21 mm). Results Twelve out of 14 subjects showed statistically significant CMC in most of the HD-sEMG channels (on average 91-95% depending on the sEMG derivation), with maximum coherence (range across 12 subjects was 0.014-0.199 for monopolar derivation) at ~25 Hz. CMC was about a fifth stronger in monopolar than bipolar and Laplacian derivations (mean ± SD differences 19 ± 20% and 23 ± 11%, respectively). Moreover, the monopolar derivations resulted in the most uniform CMC distributions across the thenar (coefficient of variation: 19% for monoplar, 33% for bipolar, and 35% for Laplacian) and the most tightly clustered cortical sources in the hand area of the left rolandic cortex. Finally, the HD-sEMG derivations provided significantly stronger CMC than the conventional macroscopic bipolar (by 27 ± 28%, $p = 0.04$) and monopolar (by 19 ± 20%, $p = 0.02$) derivations. Conclusions These results demonstrate that the level of CMC, computed with respect to sEMG, depends on the sEMG-derivation but is not systematically affected by the recording site. The variability of the individual muscle anatomy therefore does not explain the large inter-subject variability in CMC level. Nevertheless, HD-sEMG recordings can facilitate detection of CMC. Monopolar sEMG resulted in strongest and most uniform CMC across the thenar and can thus be recommended for CMC recordings.

Title: Spontaneous rebound in implicit sensorimotor learning can occur in the absence of sensory prediction errors

Authors: *S. D. MCDOUGLE, K. BOND, J. TAYLOR;
Princeton, Princeton, NJ

Abstract: A popular model of human sensorimotor learning suggests that a fast process and a slow process work in parallel to produce the canonical learning curve (Smith et al., 2006). While a number of studies have pointed to potential neural substrates corresponding to these processes (Smith et al., 2006; Galea et al., 2011; Choi et al., 2014; Yang and Lisberger, 2014), a mechanistic account of the psychological underpinnings of the fast and slow process remains elusive. In a recent study (McDougle et al., 2015), we showed that explicit strategies and implicit learning map onto, respectively, the fast and slow processes put forth by Smith et al. (2006). Furthermore, we revealed that implicit learning itself can be subdivided, consisting of traditional trial-by-trial adaptation in addition to an operant process driven by repeated movements to unique regions of space. In the present study, we extend the investigation of the subcomponents of implicit learning, asking: What types of feedback drive the different components of implicit learning? And what are the different time-courses of these components? Here we show that implicit learning curves that closely match traditional cerebellar-driven, exponential adaptation curves can be produced using only abstract reward feedback in lieu of the standard spatial "sensory prediction error" feedback. Moreover, conventional markers of adaptation such as spontaneous rebound and aftereffects can also result from an operant subcomponent of implicit learning. We conclude that implicit motor learning is often a conflated measurement, consisting of both trial-by-trial calibration and operant directional biases. We suggest that future studies attempting to study single components of sensorimotor learning must isolate these subcomponents in order to skirt this conflation, by, for instance, varying the directions of movement or varying visual feedback.

Title: Validation of reaching movements made in a 2D virtual environment in typically developing children

Authors: *M. ROBERT[1,3], K. SAMBASIVAN[2,3], M. F. LEVIN[2,3];
[2]Sch. of Physical and Occup. Therapy, [1]McGill Univ., Montreal, QC, Canada; [3]Ctr. for Interdisciplinary Res. in Rehabil. of Greater Montreal, Montreal, QC, Canada

Abstract: The ultimate goal of rehabilitation is to improve movement kinematics which can be described at two levels: movement quality and motor performance. Measurement of change in movement quality and performance over time is also a method to identify motor learning. Motor learning is based on different principles which can be manipulated in treatment interventions by a therapist or through the use of interactive computer technology, such as virtual reality. Our aim was to compare the kinematics of movements in a physical environment to a similar virtual environment in typically-developing children. Participants (children; 8-17yrs) completed the Edinburgh Handedness Inventory to identify the dominant arm. They practiced reaching in the virtual environment to become familiar with the task. Then, they performed a series of 3 gestures (frontal, vertical and sagittal arm movements) in two environments: virtual and physical environments for a total of 6 gestures. 3D movement kinematics of the arm and trunk were recorded with 6 wireless electromagnetic sensors (G4, Polhemus, Vermont, 120Hz). Participants completed 15 trials of each gesture in each environment (45 trials per environment, for a total of 90 trials). The virtual environment consisted of an interactive game controlled by arm and hand movements (Jintronix, Montreal) projected on a computer monitor. Movements throughout the arm workspace were recorded with a Microsoft Kinect camera and projected into the game scene. Movements made in the virtual environment were less precise, slower and shorter in comparison to those made in the physical environment. In the virtual environment, participants used less trunk displacement in comparison to the physical environment. There were no significant differences between the two environments with respect to the range of motion of the elbow and the shoulder. Differences between movements made in each environment can be explained by less precise body position tracking in the virtual environment, decreased quality of the visual scene and differences in depth perception cues. The overall similarities of movements made in the two environments suggest that training in 2D game-like virtual reality environments may be feasible for motor rehabilitation of children.

Title: Movement strategies used in full body reaching tasks to targets in real-world versus virtual environments

Authors: J. COST, R. PROCTOR, S. T. LEITKAM, M. E. APPLEGATE, C. R. FRANCE, *J. S. THOMAS;
Ohio Univ., Athens, OH

Abstract: The purpose of this study was to determine if movement kinematics of healthy individuals performing full-body reaches are different in a real-world environment (RW) compared to two distinct virtual environments. Nineteen subjects (11 male, 8 female) aged 18-35 performed full-body reaching tasks to static targets. In the RW reaches, the subject was instructed to reach and place a dodgeball on the targets (i.e., a shelf located in the mid-sagittal plane). The targets were positioned such that the subject (with elbows fully extended and shoulders flexed to 90 degrees) could, in theory, reach each target by flexing the hips 15, 30, and 60 degrees. In the 3D-TV reaches, the subject wore 3D shutter glasses and was oriented to their avatar on the 3D-TV in the third person perspective. In the Oculus Rift (OR) reaches, the subject wore a head mounted display and was oriented to their avatar in the first person perspective. In each virtual environment, the target was presented as a virtual ball co-located to the RW target coordinates. Holding a dodgeball in both hands, the subject was instructed to reach and touch the virtual ball. In 3D-TV and OR reaches, the subject received both auditory and visual feedback that contact with the virtual targets occurred. The 6-DOF location of the trunk and limb segments was streamed from eight Vicon Bonita cameras running Vicon Tracker software to MotionMonitor. The anterior position (AP), mid-position (MP), and height of the centroid of the fingertips, as well as joint excursions of the ankle, knee, hip, lumbar spine, shoulder, and elbow were analyzed using mixed-model MANOVAs with environment (RW,3D-TV, Oculus), target heights (high, middle, low) and trials as within subject factors, and sex as the between subjects factor. There was an effect of environment on AP and ML fingertip position ($p<0.05$). Follow-up analyses indicated no differences in fingertip position between 3D-TV and OR but there were significant differences between RW and 3D-TV and between RW and OR. In general, excursions of the hip and spine were greatest for reaches performed in OR and progressively less for the same reaches made in 3D-TV and RW. There was an interaction of gender and environment for ankle and knee excursions ($p<0.05$). In RW reaches female and male subjects used an ankle plantar flexion-knee extension pattern, but in the 3D-TV and OR environments, females used an ankle plantar flexion-knee extension pattern while males used an ankle dorsiflexion-knee flexion pattern. These findings suggest that the presentation of the virtual environment has a clear influence on joint excursions even when the endpoint of the effector is quite similar.

Title: Effects of avatar presentation and display environment on game perception and lumbar motion in virtual dodgeball

Authors: ***M. E. APPLEGATE**, S. T. LEITKAM, J. COST, R. PROCTOR, C. R. FRANCE, J. S. THOMAS;
Ohio Univ., Athens, OH

Abstract: The purpose of this study was to assess both cognitive and physical responses to our newly developed game of virtual dodgeball in healthy adults aged 18-35. The game environment, developed using Vizard software, was a basketball arena in which the subject played dodgeball against four virtual opponents. The game was played in two distinctly different virtual environments. In the 3D-TV environment, the subject wore 3D shutter glasses and was oriented to their avatar on the 3D-TV in the third person perspective. In the Oculus Rift (OR) environment, the subject wore a head mounted display and was oriented to their avatar in the first person perspective. Virtual balls were launched in a randomized order from each of the four opponents to varying target locations in order to shape lumbar motion. The ball trajectories were set such that they would make contact with the subject's body anywhere from the mid-shank to the head. The subject scored points by successfully blocking and ducking launched balls. Game play consisted of three levels of difficulty, each with two sets of 15 launched balls. The levels progressively became more difficult by lowering the projected contact height of the launched balls. Body movements were streamed from Vicon Tracker to MotionMonitor, which parameterized game conditions (e.g., ball trajectories, scoring), communicated with Vizard, and recorded segment kinematics and game outcomes. Following each game, the subject completed the NASA Task Load Index. Cognitive data were analyzed using paired samples t-tests. For each game level, lumbar motion was analyzed using a repeated measures MANOVA; environment (3D-TV, OR), level (3), and sets (2) were the within subject factors. Perception of task success was significantly higher and frustration rates were significantly lower in the OR environment

compared to the 3D-TV environment ($p < 0.05$). Across all game levels, success rate in the OR environment was 85% compared to 69% for 3D-TV environment. Levels of engagement and immersion were also higher in the OR environment compared to the 3D-TV environment ($p<0.05$). Lumbar excursions increased at each level of game play ($p < 0.05$); lumbar motion in the OR environment ranged from 33.0-43.4 degrees, while lumbar motion ranged from 17.6-29.6 degrees in the 3D-TV environment. Adjusting parameters in virtual dodgeball increased lumbar motion in healthy subjects, and for each game level, lumbar motion was greater in the OR environment compared to the 3D-TV environment ($p<0.05$). Virtual environment is an important factor for both cognitive and motor behavior in the implementation of a gaming environment for research endeavors as well as treatment interventions.

Title: Performance asymmetries for left and right arms in 3D vary by visual condition and spatial location

Authors: T. A. AMEDEE[1], V. G. DONZE[1], A. PRZYBYLA[2], *J. M. HONDZINSKI[1]; [1]Kinesiology, Louisiana State Univ., Baton Rouge, LA; [2]Kinesiology, Pennsylvania State Univ., University Park, PA

Abstract: People often produce greater endpoint accuracy in normal room lighting when reaching toward remembered targets on a horizontal plane with the dominant right arm compared to the non-dominant arm. Interestingly, people can produce greater or similar endpoint accuracy when reaching toward remembered targets in darkness with the non-dominant arm compared to the dominant arm. Researchers blame asymmetric cortical control for these differences, suggesting that the right hemisphere possesses a more robust control strategy for such accuracy. In this study we questioned whether these hemispheric differences would also exist for 3D pointing movements primarily performed in vertical planes. We chose 3D movements as people often vertically undershoot remembered target locations when reaching with their dominant limb in darkness relative to an illuminated environment and in some cases can be more accurate without vision. Young healthy adults produced straight arm pointing movements to real targets

and remembered target locations in complete darkness (DARK) or normal room lighting (LIGHT). Gaze was anchored on target or remembered target locations during the pointing movement. Nine targets were located on a flat vertically oriented surface at a 1.5 m in front of subjects. Target levels included the shoulder and shoulder +/- 3o cm; three directly in front of each subject's midline and three 30 cm right and 30 cm left of midline. Subjects placed the hand of their extended arm on the thigh. Pointing movements were performed to each target in each visual condition. Pointing movements to each of 6 non-target locations in each visual condition were also performed to help ensure subjects did not memorize target locations. Movements of the shoulders, ankles, and the fingertip of the pointing limb were recorded at 60 Hz. Absolute 3D angular error for each remembered reach was determined relative to average reaches for real targets for a given target and subject. Subjects often ended pointing movements in the DARK vertically below those in the LIGHT thus the phenomenon of undershooting remembered target locations in darkness exists for both arms. In the LIGHT condition endpoint errors for the dominant arm were more often less than or similar to those for the non-dominant arm. In the DARK condition errors between arms varied among subjects, however, were commonly smaller for the non-dominant arm for targets below shoulder level left of midline. These data provide some evidence to support hemispheric specialization; specifically, that the right hemisphere offers significant control over 3D endpoint accuracy when vision is not available.

Title: Hybrid control of force and position in a sliding task

Authors: *D. DE SANTIS[1], C. PASQUINELLI[2], P. MORASSO[1], V. SQUERI[1], M. CASADIO[2];
[1]Robotics, Brain and cognitive sciences, Inst. Italiano Di Tecnologia, Genova, Italy; [2]DIBRIS, Univerista` di Genova, Genova, Italy

Abstract: A general question is to what extent position and force control are independent processes and/or in which manner they can be linked according to a common goal. This work aimed at investigating the mechanisms of motor control in a hybrid task that requires a concurrent control of force and position. With this purpose, seven subjects (30 ± 6 years old) were asked to slide a deformable virtual object for 15 cm along a haptic-rendered vertical wall using a 2-DOF manipulandum in three different experimental conditions: i) the mean sliding speed was imposed (0.14 - 1.25 m/s), but the object was unbreakable, making the contact force a free variable, ii) the object was fragile so that the maximum applicable force was constrained (1.5 - 4 N), but there was no imposed limit on the sliding speed, iii) the object was fragile and subject to a gravitational force (1.5 N) opposed to the sliding motion, with no constraint on the sliding speed. In order to characterize the strategy adopted by the subjects as a function of the constraints, the performance was quantified in terms of mean value (Fa) and variability (deviation from the mean - Fv) of the applied contact force, as well as in terms of average sliding speed (Vm). In the presence of an explicit velocity constraint, but no particular force constraint (condition i), the average magnitude of the force was independent of the speed of movement, while the force variability increased when moving at faster speeds (Vm < 0.1 m/s: Fa = 2.07 ± 1.03 N, Fv = 0.47 ± 0.24 N; Vm > 0.2 m/s: Fa = 2.48 ± 0.91 N, Fv = 1.11 ± 0.53 N). When a force constraint was explicitly introduced (condition ii), all the subjects reduced the average force from 2.13 ± 1.00 N to 1.04 ± 0.43 N and consistently decreased both their sliding speed and force variability proportional to the applied force. Fv was lower (0.30 ± 0.11 N) than before (0.47 ± 0.24 N) for matching average speeds, suggesting a dependency on Fa. When we introduced the gravitational force (condition iii), variability seemed to be a limiting factor: only the 3/7 subjects who changed sliding strategy succeeded for forces below 2.5 N. Instead of minimizing the force variability, they increased the speed so as to balance the effect of the gravity and apply a lower average force. Several studies tested the hypothesis that individuals improve their performance by seeking solutions that are robust to perturbations to reduce the influence of their intrinsic noise. The results of the proposed experiment seem to support this finding, suggesting that noise in the control of force may have acted as a constraining factor that induced the subjects to explore the space of possible solutions to minimize the impact of their variability.

Title: Toward identification of neural-pattern transition of limb selection using ongoing electroencephalogram

Authors: *K. AMEMIYA[1,2], J. IZAWA[3], J. USHIBA[1], R. OSU[4];
[1]Dept. Biosci. and Informatics, Keio Univ., Yokohama, Japan; [2]Japan Society for Promotion of Sci., Tokyo, Japan; [3]Fac. of Engineering, Information and Systems, Univ. of Tsukuba, Tsukuba, Japan; [4]Advanced Telecommunications Res. Inst. Intl., Kyoto, Japan

Abstract: Action selection, a process of choosing one from all possible conflicting motor plans, is central to generate motor movements in our daily life. For instance, selecting right or left arm in order to reach to a given target might request the brain to decide whether the selected hand is more valuable than the other option with taking account of the perceived target position. When the target is provided near the right hand, one might choose the right hand more whereas, when it is near the left hand, one should choose left hand more. A question is how these two options would compete together in the decision making process in the brain when the target is provides in between the right and the left hand. We hypothesized that neural activities prior to making decision might affect a competition process between two options so that the EEG signals would predict which option the brain would select near future. To test this hypothesis, we measured the whole head 64ch EEG (Active-Two, Biosemi system, Amsterdam) during subjects executing a reaching task. In this task, participants were required to reach with one hand to a target that appeared at a variable location on a semicircular array. We classified the limb selection with Support Vector Machine using EEG signals of the fixation period (2000 ms), which is preceded by target representation. In addition, we compared the decoding results between center target condition and peripheral target condition. We found that the classification accuracies of predicting limb reached to as high as 80% in case of center target condition. In contrast, the classification accuracies of same data only reached about 63% in case of peripheral target condition. In 7 out of whole 13 subjects, the variance of decoding accuracies was significantly different between two conditions. In addition, in order to know the transition of limb selection process, we divided fixation period into 4 time windows and averaged maximum decoding accuracy of each participants every 4 periods. Averaged maximum of decoding accuracy was also significantly different between conditions and in first and last period out of 4 time periods.

These results indicate that influence of ongoing activity on subsequent decision fluctuate time to time, but both time period of soon after the previous trials and time period right before the target presentation contribute to subsequent limb selection.

Title: Manipulation of movement preparation time reveals a target-selection component to use dependent learning

Authors: ***T. J. CARROLL**, E. POH, H. ALAVI, S. RIEK, W. MARINOVIC;
Sch. of Human Movement and Nutr. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: Movements tend to be biased towards the direction of previously executed actions, but it is unclear to what extent these effects are due to movement planning versus movement execution processes. Here we manipulated the predictability of target locations and the time available to process target location information, in order to dissociate between two potential sources of such systematic aiming errors: a) recent movement history and b) the expected location of the next target. In two experiments, aiming errors were measured for isometric wrist forces made toward targets presented occasionally (15-20% of trials) at angles at + 90° from the centre of a distribution of targets centred on 45° (Exp 1 SD = 7.5°; Exp 2 SD = 15°). Movement preparation time was controlled using the timed response paradigm (Exp 1) or a reaction time task (Exp 2). Aiming bias increased monotonically as probe target angle departed from the centre of the target distribution when movement preparation time was short, but not when movement preparation time was long. The sensitivity of bias to the timing of stimulus presentation suggests a mechanism related to movement preparation, rather than to movement execution. However the data do not distinguish between the potential influence of expected target location and movement history, because the most frequently repeated target was also the most probable next target. We therefore designed a third experiment to directly dissociate the influence of these two putative

sources of bias, by requiring subjects to perform a sequence of two movements on each trial. The first movement was made to one of three potential target locations at 25° (20% of trials), 45° (60%) or 65° (20%), whereas the second movement was made to a fixed-target, either at 0° or 45°, in separate blocks. When the fixed target direction was at 45°, aiming errors toward uncertain targets were biased toward the central, more probable target, and this effect was larger for short than for long preparation times. When the fixed target was at 0°, the distribution of errors toward uncertain targets was identical, but offset toward the second movement on the preceding trial. Moreover, this offset in bias was identical irrespective of the movement preparation time. This shows that a tendency to make errors toward the most likely next target interacts with a tendency for movements to be biased towards the most recently executed action. Moreover, these two sources of movement bias are dissociable on the basis of movement preparation time; bias due to movement history is insensitive to movement preparation time, whereas bias due to target selection is much greater when preparation time is constrained.

Title: Virtual reality display influences dynamic movement patterns in gaming-based research

Authors: ***S. T. LEITKAM**, R. PROCTOR, J. COST, M. E. APPLEGATE, C. R. FRANCE, J. S. THOMAS;
Ohio Univ., Athens, OH

Abstract: The purpose of this study was to determine if the type of display used in a virtual reality (VR) game affected the movement patterns used in performing a kinematically redundant dynamic task. A VR dodgeball game was played by 18 subjects (aged 18-35) on two distinctly different displays. In the 3D-TV display, the subject wore 3D shutter glasses and was oriented to their avatar on the 3D-TV in the third person perspective. In the Oculus Rift (OR) display, the

subject wore a head mounted display and was oriented to their avatar in the first person perspective. The subject scored points by successfully positioning the virtual ball held in both hands to intercept each launched ball. Thus, this task required both appropriate joint excursions and the correct timing of these excursions to block the launched ball. The impact locations were scaled to the anthropometrics of each subject to normalize the amount of theoretical lumbar flexion required to block each launched ball. For each subject, the impact locations of the launched balls were randomized, but identical for the games played in each display. Thus, in theory, the excursion patterns required to successfully block the launched balls in each display would be identical. The kinematics, as measured with Vicon Bonita cameras and MotionMonitor, were defined by angular excursions between a neutral posture and posture at time of intercept of the launched ball. Flexion of the ankle, knee, hip, lumbar spine, shoulder, and elbow were analyzed. In addition, the position of the centroid of the hands at intercept of the launched ball was extracted. Mixed-model MANOVAs were performed with display (3D-TV, OR) and projected impact location (high, middle, low) as within subject factors and sex as the between subjects factor. Joint excursions of the knee, hip, lumbar spine, and shoulder were greater in OR compared to 3D-TV ($p<0.05$). At intercept, the vertical and lateral hand positions showed no difference between the two displays, but the anterior hand position was on average 16.5 cm closer to the body in 3D-TV compared to OR ($p<0.05$). When playing dodgeball with the OR, for any given impact location, subjects chose to intercept the balls further away from their body compared to games played 3D-TV. Thus, display type resulted in angular excursions that were very different for successful intercepts of balls launched to the same location. These results together show that the type of display used in a VR game will have a significant effect on the kinematic patterns used to play the game. Specifically, greater overall angular movement is expected for VR games with first person perspective in comparison to 3D-TV games with a third person perspective.

Title: Movement kinematics while choking under pressure

Authors: *P. A. BUTCHER[1], T. G. OSBORNE[1], T. G. LEE[2], J. A. TAYLOR[1];
[1]Psychology Dept., Princeton Univ., Princeton, NJ; [2]Psychology Dept., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Performance typically improves with increased arousal or incentives, however, in some instances, if the incentive becomes too large, performance can dramatically decrease, an effect colloquially known as choking under pressure. Experimental investigations of choking under pressure have generally framed it as a discrete cognitive phenomenon, pointing to interplay between the executive function in the frontal cortex, and midbrain reward regions. However, it remains an open question as to the effect on movement execution. For example, is a basketball player who misses the game winning free-throw despite being an excellent free-throw shooter just releasing the ball too early or too late, or are the kinematics of the actual shooting motion changed? We investigated choking under pressure by manipulating monetary incentive in a reaching task, which required placing a cursor into a virtual target between 450 and 550 ms. At the start of each trial, participants (N=31) were informed that each trial was prospectively worth either $2, $5 or $20. At the end of the experiment one trial was picked at random and performance on that trial determined whether the bonus received _ a method purported to maintain consistent motivation. Heightened motivation should result in an increase in performance from low to mid incentives, but a decrease in performance from mid to high incentives would suggest choking under pressure. Importantly, the increase from low to mid incentive serves as an internal control to separate participants who are motivated by monetary incentive from those who are unmotivated. Thus, we separated our participant pool into motivated and unmotivated groups. We find that approximately half of the participants (N=16), were motivated by the increase from $2 to $5 and, importantly, on $20 trials, they displayed a precipitous drop in performance (i.e., choking). In contrast, the unmotivated participants showed no difference in performance on high value trials. Our primary focus was to identify what kinematic features of their movement had changed between $5 and $20 trials. However, despite comparing: reaction time, movement time, peak speed, position, and force, and consistent with previous literature (Lee et al 2014) we were unable to find a consistent kinematic signature of choking under pressure. This result presents a puzzle, how does a consistent difference in behavior, in this case impaired performance at high incentives, not result from a kinematic difference? Should these findings persist, one possible interpretation would be that impaired performance under pressure may be the result of processing involved in the selection of an action, but not in the execution.

Title: Explicit aiming strategies are fundamental to learning in a visuomotor adaptation task

Authors: *K. BOND, J. TAYLOR;
Princeton Univ., Princeton, NJ

Abstract: There is mounting evidence for the idea that performance in a visuomotor rotation task can be supported by both implicit and explicit forms of learning. The implicit component has been well-characterized in previous experiments and is thought to arise from the adaptation of an internal model driven by sensory prediction errors. However, the explicit contribution is less well-defined and previous investigations have relied on indirect measures such as dual-task manipulations, post-tests, and descriptive computational models. To address this problem, our lab developed a new method to directly assay explicit learning by having participants verbally report their intended aiming direction on each trial. While our previous research employing this method demonstrated the possibility of measuring explicit learning over the course of training, it was only tested over a limited scope of manipulations common to visuomotor rotation tasks. In a recent study, we sought to better characterize explicit and implicit learning over a wider range of task conditions (Bond and Taylor, 2015). Specifically, we tested how explicit and implicit learning change as a function of visual landmark configuration, training target number, and rotation size. We found that explicit learning was remarkably flexible, responding appropriately to task demands. In contrast, implicit learning was strikingly rigid, with each condition producing similar degrees of implicit learning. To further test the notion that explicit learning may be fundamental to learning in a visuomotor rotation task, we sought to determine if explicit learning was also responsible for structure learning (Braun et al. 2009). In a structure learning paradigm, the rotation magnitude changes frequently throughout training but has a zero mean. Following structure training, participants show faster learning of a novel, consistent rotation relative to participants without structure training. For our current experiment, we combined this paradigm with our method of assessing aiming strategies during training. We found that structure learning is almost entirely explicit, with little contribution from implicit learning. This evidence reinforces the conclusion that explicit learning is a fundamental, flexible element of learning in visuomotor adaptation tasks.

Title: Improvements in visual search contribute to visuomotor learning

Authors: *C. PERRY;
Exercise Sci., Univ. of South Carolina, Columbia, SC

Abstract: Christopher Perry1, Tarkeshwar Singh1, Kayla Goins1, Barbara Marebwa1,2, and Troy Herter1 1University of South Carolina, Columbia, SC, USA 2University of Trento, Trento, Italy Introduction: Visual search is used to gather visual information by actively scanning the visual environment with eye movements (overt visual search) and peripheral vision (covert visual search). Previous studies have shown that visual search can improve with practice and expertise in motor skills is linked to efficient visual search. While these findings suggest that improvements in visual search may contribute to motor learning, previous research has not directly tested this hypothesis. Here we examine the extent to which improvements in visual search contribute to the acquisition of a novel visuomotor skill. Methods: Eighteen young adults (20-31 years old) practiced a bimanual visuomotor task (Object Hit and Avoid Task) using an upper-limb robotic device (KINARM Endpoint Lab, BKIN Technologies, Kingston, Canada). In this task, objects (eight distinct geometric shapes) moved towards the subjects who used virtual paddles displayed on each hand to hit away two target shapes (Targets; n = 200), and avoid hitting the six distractor shapes (Distractors; n = 100). Each task trial lasted approximately two minutes, and the shape, location, and movement speed of individual objects was varied randomly to ensure every task repetition was distinct. Subjects completed six repetitions of the task once a week for six weeks. Object shapes assigned to Targets and Distractors varied weekly. Eye and hand movements were recorded to investigate the influence of visual search and limb-motor control on task performance. Results: Task performance, as measured by Targets hit and Distractors avoided, increased across all six weeks. Task performance improved rapidly during the first week (acute phase) followed by slower improvements over the over 5 weeks (chronic phase). We observed that acute improvements were more coupled to the number of targets that were overtly viewed with smooth pursuit and the number of targets that were successfully hit

following pursuit (overt success). Furthermore, chronic improvements appeared to be more linked to increases in success avoiding distractors and hitting targets that were viewed peripherally (covert success). Improvements in task performance did not appear to be coupled to changes in limb motor control. Conclusions: These results provide direct evidence that improvements in visual search can contribute to visuomotor learning. Our data also shows that both overt and covert visual search contribute to motor learning during acute and chronic phases, respectively.

Title: Moving Slowly is Hard for Humans

Authors: ***N. HOGAN**[1], H. MARINO[2], S. K. CHARLES[3], D. STERNAD[4];
[1]MIT, Cambridge, MA; [2]Res. Ctr. “E. Piaggio", Univ. of Pisa, Pisa, Italy; [3]Dept. of Mechanical Engin. and Neurosci. Ctr., Brigham Young Univ., Provo, UT; [4]Departments of Biology, Electrical & Computer Engin. and Physics, Northeastern Univ., Boston, MA

Abstract: Human dexterity exceeds that of modern robots, despite vastly slower 'hardware' (muscle) and 'wetware' (neural processing and transmission). Mounting evidence suggests this is due to using dynamic primitives, generated with minimal central supervision as attractors of dynamic neural networks. Dynamic primitives include discrete and rhythmic movements and imaging studies show that they evoke activity in substantially different brain regions. However, advantages of control using dynamic primitives may be offset by compromised versatility. We recently showed that unimpaired humans could not sustain discrete motions as duration decreased, and that could not be attributed to biomechanical limitations. This complementary study tested whether smoothly rhythmic performance could be maintained as movement period increased. Ten seated unimpaired subjects performed horizontal plane movements of their dominant hand between two target positions. Belts restrained shoulder motion; a brace discouraged wrist motion. Hand motions were recorded and displayed on a screen. Targets were displayed as large circles (5cm radius) to de-emphasize accuracy. Targets were located in a mid-sagittal plane specifying a movement distance of 28cm in the approximate center of the upper-limb workspace. Subjects were instructed to perform smoothly rhythmic back & forth movements between targets in synchrony with computer-generated sounds (1 per back & forth cycle) but without stopping at the ends, i.e. with no dwell time. Each trial began with 10 sounds at 1s intervals; then 25 sounds where each interval increased by 200ms; then 5 sounds at 6s intervals; then another 25 sounds where each interval decreased by 200ms; then 10 sounds at 1s intervals. Subjects performed this sequence twice with eyes open and twice with eyes closed. Subjects successfully executed this movement sequence. Remarkably, with eyes closed or open, the shape of their hand speed profile changed dramatically with duration, becoming visibly more irregular as movement slowed. Increased irregularity was accompanied by increased dwell time at the extremes of displacement; subjects did not sustain smoothly rhythmic motion. Measured velocity profiles were parsed into a sequence of overlapping submovements, each with a stereotyped shape (support-bounded lognormal). The number of submovements increased systematically with duration. These results show that it is hard for humans to execute smoothly rhythmic motions slowly, and this cannot be attributed to biomechanical factors. Instead they 'default' to using another dynamic primitive, and compose motion as a sequence of overlapping 'discrete' actions.

Title: The subjective value of effort explains preferred movement speed

Authors: *E. SUMMERSIDE, A. AHMED;
Univ. of Colorado, Boulder, CO

Abstract: In economics, it is well-known a reward's subjective value can differ from its objective amount. However, every reward requires an effort to obtain it and we currently do not have a good understanding of how effort costs are subjectively valued in healthy adults. In the current study we used an economic approach to quantify how individuals subjectively valued effort, where we quantify effort as the metabolic cost required to perform the movement. We then attempted to use these measures to explain the variability in movement preferences observed across individuals. Based on current theories in motor control, we hypothesized that individuals who exhibited greater sensitivity to effort costs would exhibit slower preferred movement speeds. Specifically, sensitivity to effort would be inversely related to preferred movement speed. Participants (n=20) visited the lab for two separate sessions. The first session involved performing seated 20cm out-and-back arm reaches. Metabolic rate was measured via expired gas analysis as participants reached against five resistances. In the second session, they were instructed to choose between a sure bet of performing a low effort reach or risk performing a higher effort reach. The risky choice was presented as a percentage value paired with one of the resistances. The percentage represented the chance of having to reach at the presented resistance for 5 minutes with the alternative outcome being to sit quietly for 5 minutes. Using the metabolic and individual choice data, the subjective value of effort (SV) was calculated based on Cumulative Prospect Theory (CPT): $SV(x) = x^{\alpha}$. Here, x is the metabolic cost, and α is the nonlinearity in effort valuation. An $\alpha > 1$ signifies overvaluation of effort, an $\alpha < 1$ signifies undervaluation and an $\alpha = 1$ signifies an objective valuation. In six participants, preferred reaching speed (m/s) was measured before the first session. A model-selection analysis revealed a significant distortion on an individual basis, with seven participants overvaluing effort. $\alpha > 1$, and eight undervaluing effort, $\alpha < 1$ ($p < 0.05$). We also observed a significant correlation between a participant's preferred reaching speed and their subjective valuation of effort ($R^2 = 0.67$, $p = 0.02$). Specifically, the greater a person's sensitivity to effort (increasing α) the slower they preferred to reach. Together these findings present a novel approach to quantifying effort costs that provide a unique window into how physical effort is considered when forced to decide between effortful movements and ultimately how those movements will be performed.

Title: Effort, reward, and vigor in decision-making and motor control

Authors: *R. SHADMEHR[1], H. J. HUANG[2], A. A. AHMED[3];
[1]Dept Biomed. Eng, Johns Hopkins Univ., Baltimore, MD; [2]Univ. of Michigan, Ann Arbor, MI;
[3]Univ. of Colorado, Boulder, CO

Abstract: Decisions depend on the reward at stake and the effort required. However, these same variables influence the vigor of the ensuing movement, suggesting that factors that affect evaluation of action also influence performance of the selected action. Here, we describe a mathematical framework that links decision-making with motor control. Each action has a utility that combines the reward at stake with its effort requirements, both discounted as a hyperbolic function of time. The critical assumption of our model is to represent effort via the metabolic energy expended to produce the movement. This energetic representation describes a parameterization of effort as a function of movement duration, mass of the limb, distance, and force, which we confirmed experimentally in reaching movements. The resulting model makes predictions regarding how these variables would affect decision-making and motor control. We found that the framework provided insights into the following observations: 1.Subjects not only preferred the more rewarding stimulus, but also moved faster toward it. 2.Subjects preferred to reach to the stimuli that required transport of a smaller mass, but did so with higher vigor than when forced to make the same amplitude movement with a larger mass. 3.Subjects were willing to perform actions that required greater effort, but only in exchange for greater reward. However, they moved with less vigor when forced to perform the less preferable action. 4.Increasing the duration that subjects had to wait before making a movement reduced the vigor of the ensuing movement. 5.In a task in which there were objective measures of reward and effort via their caloric values, subjects chose actions which were consistent with a utility in which reward and effort were both discounted by the duration of the action. 6.As the duration of generating an isometric force increased, the utility of effort did not continue to increase, but rather reached a

plateau. 7.Natural walking speed, and well as the speed of performing other actions, varied with the city in which people lived. Our main result is to show that a single mathematical formulation of action, a utility describing the goodness of the movement via effort, reward, and time, predicts both the decision that animals make as well as the vigor of the movements that follow. This framework accounting for choices that birds make in walking vs. flying, choices that people make in reaching and force production, and the curious fact that pedestrians walk faster in certain cities. We suggest that decision-making and motor control share a common utility in which the expected rewards and the energetic costs are discounted as a function of time.

Title: Predictability in the control of complex object dynamics

Authors: *D. STERNAD[1], I. ZUZARTE[2], N. HOGAN[3];
[1]Departments of Biology, Electrical & Computer Engineering, and Physics, [2]Departments of Bioengineering, Northeastern Univ., Boston, MA; [3]Mechanical Engineering, Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Numerous studies on reaching showed that humans compensate for the nonlinear inertial dynamics of the skeleton and imposed force fields. However, the dynamics of even simple objects can be vastly more challenging: fluid sloshing in a cup of coffee generates prodigiously complex forces. In addition, human limb dynamics interact with such object dynamics in highly counter-intuitive ways. How do humans predict and compensate for this complex behavior? Or do they preempt and avoid it? Previous research by our group showed that humans reduce the complexity of the hand-object interactions, rendering the behavior more

predictable. This study examined rhythmic motion of an object with internal dynamics with a focus on the resonance structure of the coupled hand-object system. The task of carrying a cup of coffee was simplified to the 2D cart-and-pendulum model and implemented in a virtual environment where a ball represented the liquid rolling in a semicircular cup manipulated by the subject. The dynamics of cup-and-ball interacting with the human limb include two resonant peaks and an anti-resonance, the latter determined only by the pendulum: periodic forces applied at this frequency yield zero cup motion. Subjects moved the cup-and-ball system rhythmically, at 8 different metronome frequencies between 0.7 and 1.2Hz; in 8 interspersed trials subjects were instructed to move at their preferred frequency. This same set of frequencies were performed with the nonlinear cup-and-ball system and a linearized version of the same system to understand the challenge due to the nonlinearity. Subjects were free to choose their cup and ball amplitude. We hypothesized that humans choose strategies to maximize predictability by avoiding anti-resonance and seeking resonance of the coupled hand-object system. Because lower forces have less noise and afford more precise control, moving at resonance reduces required forces and increases precision and predictability; the converse applies to anti-resonance. An additional option (applicable to the nonlinear model) is to avoid nonlinearities by choosing the smallest possible ball motion to linearize the system. Results showed that in self-selected frequencies subjects adopted one of the two resonance frequencies. The amplitude of the ball movement became smaller with practice. In the paced trials subjects synchronized with the metronome, although the variability depended on the frequency: the closer to anti-resonance, the higher the variability. These results present first insights into how human dexterously control complex objects, which is of high clinical significance as many daily activities involve object manipulation.

Title: Exploring a more functional task for studying upper extremity motor control

Authors: *C. R. HENGGE, J. R. PIERCE, K. E. TEW, S. Y. SCHAEFER;
Utah State Univ., Logan, UT

Abstract: The paradigm of point-to-point reaching has been widely used to study upper extremity motor control in a number of typical and clinical populations. Although it is viewed as a proxy for goal-directed movements, it may be limited in its approximation of how arm and hand movements are controlled in the real world. We have begun to develop a functional motor task that adds manipulation, tool use, object transport, and executive function to the established 'gold standard' of point-to-point reaching. Thus, the purpose of this study was to determine the construct validity of our functional task in a sample of healthy adults. In this case, the existing method against which we compared our task was a targeted reaching task. In two different tasks, 28 adults (mean±SD age: 20.4±2.2 years) performed planar out-and-back movements of 16 cm in three different directions (45°, 90°, and 135°) relative to constant start location along midline using their nondominant arm. In the 'gold standard' reaching task, participants moved a digital cursor sequentially between targets that were virtual squares displayed on a computer screen, veridical to the planar workspace. In the functional task, participants manipulated a spoon to transport beans sequentially between targets that were actual cups anchored to the planar workspace. In both tasks, the primary measure of performance was movement time, which indicated the time to complete five repetitions to each target. Mean performance on the functional task was not correlated with that of the reaching task (Spearman's rho = -0.039; p=.84). The variable of movement time was, however, highly sensitive and specific to performance on each task, as the area under the Receiver Operating Characteristic (ROC) curve was 0.95. Additional measures of performance, such as cumulative hand distance (rho = .04; p=.83) and inter-repetition interval (rho = 0.0016; p=.99), were also poorly correlated between the two motor tasks. These results demonstrate a lack of construct validity between the functional task and the established point-to-point reaching paradigm in healthy human participants, thereby suggesting that 1) the functional task may recruit different neural mechanisms recruited to perform the additional aspects of the functional task (e.g. object manipulation) and 2) these mechanisms may be measurable by psychophysical experimentation. Thus, the functional task tested in this study may be used in the future as a relevant proxy for studying real-world upper extremity motor control.

Title: Age differences in muscle activation patterns supporting arm stabilization

Authors: *L. A. MROTEK[1,2], M. C. BENGTSON[2], T. STOECKMANN[2], C. GHEZ[3], R. A. SCHEIDT[2,4];
[1]Dept Kinesiology, UW-Oshkosh, Oshkosh, WI; [2]Marquette Univ., Milwaukee, WI; [3]Columbia Univ., New York, NY; [4]Northwestern Univ., Evanston, IL

Abstract: Sensorimotor function often becomes degraded with aging and this change has been linked to a decline in whole-body postural stabilization and concomitant increase in fall risk. One way people avoid falls is to reach and grasp a railing or other object with which to stabilize the body. Success requires accuracy of the reach and efficacy of the stabilization effort. Here we emulate that scenario in an arm stabilization task that allows us to characterize neuromuscular control while minimizing fall risk. Three groups of healthy subjects (young: 18-29 yrs, n=4; middle: 30-59 yrs, n=3; older: 60-90 yrs, n=8) sat in front of a horizontal planar robot and grasped its spherical handle. Subjects were to stabilize the handle at a 1 cm dia. target location while the robot produced one of three types of force perturbations: a force vector rotating predictably in the x-y plane (0.2 Hz), unpredictable sum-of-sinusoid forces (1.1, 1.2, 1.65 & 1.75 Hz), and a combination of both. Subjects completed 18 trials of 60 s each. On half, subjects received real-time visual cues showing the target and feedback of the robot handle location; on the other half, no handle feedback was provided. We measured handle x-y position in each trial and computed kinematic error. We also measured electromyographic (EMG) signals from shoulder and elbow muscles. EMG signals were zero-mean rectified, low-pass filtered and normalized to MVC. Muscle pairs were used to calculate 2 measures of joint coordination at the shoulder and at the elbow: agonist / antagonist coactivity (CoA) and reciprocal activation (ReA). To evaluate the neuromotor response to the perturbations, we evaluated the power spectra of these EMG signals at the perturbation frequencies. As anticipated, subjects stabilized with more kinematic error without visual feedback than with visual feedback; no other age group or condition differences were found in the kinematic data. However, neural control strategy varied across age groups. Analysis of shoulder and elbow CoA power at high perturbation frequencies (>1 Hz) found that older adults allocated a larger percentage of their available EMG dynamic range to agonist/antagonist muscle coactivation than did the younger two groups. By contrast, younger adults demonstrated larger power in ReA, especially in the muscles controlling the shoulder at the lowest frequency (0.2 Hz). Thus, our results suggest that younger adults used a postural control strategy favoring reciprocal activation over coactivation in this task whereas

older adults used a coactivation strategy. Future studies are planned to explore factors contributing to this aging-related shift from reciprocal to coactive neuromuscular control.

Title: Effort discounting in reaching favors short-duration over short-distance movements

Authors: *P. D. MOREL[1], P. ULBRICH[1,2], A. GAIL[1,3,2];
[1]Cognitive Neurosci. Laboratory, Sensorimotor Group, German Primate Ctr., Göttingen, Germany; [2]Univ. of Göttingen, Göttingen, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Göttingen, Germany

Abstract: When deciding between alternative options, a rational agent chooses on the basis of the desirability of each outcome and the cost associated with each decision. In behavioral economics, this is conceptualized by the expected utility of each option, which can be discounted by unfavorable factors, such as the delay with which a reward is obtained. As different choices typically results in different actions, the effort associated with each action also has to be taken in account. In previous studies, a discounting of physical effort has been observed (Kurniawan et al. 2010) and characterized (Körding et al. 2004, Hartmann et al. 2013). However this physical effort discounting function has only been studied using isometric force productions, and not actual movements. In this study, we aim to characterize effort discounting during a decision between two alternative arm reaching movements. We asked if discounting minimizes movement-related variables that are linked to metabolic expenditure, to motor control costs, or to available sensory input. We tested which effort-related variables of an effortful movement were minimized by human subjects, comparing physical work, force level, impulse (force x duration) and other parameters. We tested for discounting-related movement parameters using a two-alternative forced-choice paradigm in which subjects had to choose between pairs of movements.

Movements were either of different durations, or of different amplitudes. Between trials we varied the friction-like resistive force against which each movement had to be performed with a robot manipulandum. During each trial, subjects experienced both of the alternative movements before expressing their choice by repeating the favored movement. This design allowed us to construct iso-effort curves, representing the force levels at which movements of different amplitudes or durations were deemed equivalently effortful. These iso-effort curves show that subjects are not sensitive to movement amplitudes, but base their choices on a non-linear combination of force and duration, even when temporal discounting was controlled for. We estimated this discounting as the product of duration by squared force. Moreover, subjects were sensitive to biomechanical factors, as arm flexions were preferred to arm extensions. Last, despite the variations in task performance between movements, the subjects did not systematically choose the reaches that had a higher chance of success. Our results show that humans mainly discount effort as a function of the duration of the movement and the force with which it is executed, which can be seen as a coarse approximation of muscle energy expenditure.

Title: Humans learn to compensate for altered mechanical efficiency of one limb, but fail to optimise force sharing between limbs

Authors: *M. ROUTSON[1], K. TUCKER[2], F. HUG[3], T. J. CARROLL[4];
[2]Univ. of Queensland, Sch. of Biomed. Sciences, Lab. of Motor Control and Pain Resear, [3]CCRE Spine, Sch. of Hlth. and Rehabil. Sciences, The Univ. of Queensland, Brisbane, Au, [4]Ctr. for Sensorimotor Neuroscience, Sch. of Human Movement Studies, The Univ. of Queensland, [1]The Univ. of Queensland, Brisbane, Australia

Abstract: Although humans appear to use motor patterns which minimise intuited movement costs such as effort or variability, it is yet to be determined how this behaviour arises. Our previous work (de Rugy et al, J Neurosci 32:7384-7391, 2012) shows that subjects fail to optimise coordination between muscles in response to real or virtual changes in wrist

biomechanics, which suggests that the nervous system favours habitual, rather than optimal, coordination. Here we tested responses to virtual muscle efficiency changes in a bimanual force sharing task, to circumvent the criticism that the CNS might be insufficiently flexible to dramatically alter coordination patterns among muscles acting at a single joint. In the bimanual task, subjects can flexibly produce all possible force combination ratios if instructed, so any departure from optimal behaviour cannot be attributed to inflexibility within the neural control system. Subjects exerted both unimanual and bimanual radial deviation forces in the sagittal plane to reach circular targets, in one of three conditions; an effort-focused condition (n = 10, 4 males) with force targets at 48-64% of MVC and target radius equal to 40% of the target amplitude, an error-focused condition (n = 9, 5 males) with targets at 24-32% of MVC and target radius equal to 4% of amplitude, and an intermediate condition (n = 11, 7 males) with targets at 24-32% of MVC and radius equal to 15% of target amplitude. Each experiment consisted of five blocks of 60 trials, and in the middle three blocks, the efficiency (ratio of force to cursor movement) of the right arm was doubled. When we withheld visual feedback in 25% of trials, subjects proved able to accurately acquire both bimanual and unimanual targets, indicating that they implicitly detected and localised the imposed efficiency change, despite receiving no explicit instruction. Post-experiment questioning confirmed that they remained consciously naïve to the gain change. Critically, in all conditions, subjects responded in bimanual trials to the change in movement costs either by increasing the force output of the weaker wrist, or by displaying no significant change in force sharing. Although these strategies achieved the task goal, they are inconsistent with predictions from optimal control theory that the stronger hand should be favoured in order to minimise the total force produced. Thus, the CNS fails to optimise movement output on a timescale over which it successfully adapts performance in response to changed movement costs, even when the system has ample flexibility to produce the required coordination.

[1]Sch. Engin., Harvard Univ., Cambridge, MA; [2]Dept. of Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Chunking refers to grouping components of a learning objective into small pieces, then learning the pieces separately. In memory tasks, chunking usually means grouping related items or ideas together to be recalled as a unit rather than as individual items. In this context, it has been shown to increase the effectiveness of capacity-limited working memory. In motor sequence learning, chunking usually refers to learning small subsequences before piecing them together. For example, one strategy for learning a piano piece would be to practice different phrases separately before playing the entire piece. Although chunking is generally thought to be a key component of implicit motor sequence learning, there is little direct experimental support. To examine chunk-based learning, we used a serial reaction time task in which subjects reacted to a cue as quickly as possible by pressing the corresponding key. With practice, subjects continually improved reaction times for an embedded repeating 12-item sequence, which they were unaware of, compared to trials presented in random order. Since the chunked subsequences should differ across individuals, we examined individual performance of the sequence using residual reaction times (RRTs) - computed as the average reaction time for each subject for each sequence element relative to the population average. We found clear evidence that most subjects consistently excelled at different sequence elements, and so we examined whether these differences were consistent with chunking. We examined three key predictions of chunking: (1) since the fastest RRT trials are likely part of a chunk, their neighbors are also likely part of a chunk and should therefore be faster than average; (2) since trials within a chunk have grouped improvement, there should be higher autocorrelation in the RRTs than in random noise . For both predictions, we found the data to be not significantly different from a no-chunking simulation with random noise RRTs, but strikingly different from simulations with chunking in which the chunk trials were just 30ms faster than non-chunk trials, with chunk lengths of 3-5 trials. Similar results were obtained for either 1 or 2 chunks in the sequence. Our findings show chunked improvements of just 30ms or more to be uncommon in serial reaction time learning. While we cannot reject chunking for improvements <30ms, models with sub-30ms effects could explain at

most 16% of the variance in RRTs, and are therefore unable to account for a substantial component of the learning behavior.

Title: Reward expectation increases reach vigor

Authors: ***A. A. AHMED**[1], A. NIKOOYAN[1], E. SUMMERSIDE[1], R. SHADMEHR[2]; [1]Integrative Physiol., Univ. Colorado, Boulder, CO; [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Selecting which movement to perform may be represented as an economic decision in which the expected reward is offset by the cost of the movement itself. A critical prediction of this hypothesis is that we will move faster towards more rewarding goals. Indeed studies have demonstrated, in both humans and other animals, that the vigor of saccades is greater when the target of the movement is paired with reward, than for non-rewarding targets. Here, we asked whether the vigor of reaching movements is also modulated by the expected reward. Subjects (N=14) made reaching movements while seated and grasped the handle of a robotic manipulandum. They used the manipulandum to control a cursor that was displayed on a screen mounted in front of them. The experiment consisted of making out-and-back reaching movements from a central home circle to one of four targets displayed on the perimeter of a 10cm invisible circle, centered at the home circle. The targets appeared at 45, 135, 225, and 315 degrees in pseudorandom order. Subjects were instructed to reach to the target at a self-selected velocity. To prevent corrective movements, the cursor was not visible on the outward movement away from the home circle. Importantly, subjects were not penalized for accuracy. In the first 100 trials, no targets were rewarded (baseline). The target would simply change color from orange to gray once the circle's perimeter was crossed. The following four blocks of 100 trials were REWARD blocks. In each block, one of the targets was rewarded once the perimeter was

crossed by creating a visual onscreen ‘explosion’, which was accompanied by a pleasant ‘beep’. The rewarded target did not change within each block and the order was randomized across subjects. The other targets in that block were not rewarded. To test whether reward increased movement vigor, we compared the average outward peak velocity to rewarded targets (R) with the average peak velocity to non-rewarded targets (NR) in the four REWARD blocks. We also compared movement duration, reaction time, movement extent and accuracy in a similar manner. We observed that peak velocity and movement extent were significantly greater towards the rewarded targets, compared with the non-rewarded targets ($P < 0.05$). Movement duration, and reaction time were also shorter towards the rewarded targets compared with the non-rewarded targets ($P < 0.05$). There was no significant effect of reward on accuracy. Therefore, people reach faster, further, and sooner toward stimuli that promise greater reward, highlighting a possible general role for reward in modulating movement vigor.

Title: Measuring proprioception and spatial-motor coordination in children with somatodyspraxia

Authors: *V. W. CHU, K. KRISHNAN;
Occup. Therapy, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Deficits in sensory processing, particularly in proprioception, can severely impact a child’s ability to learn new skills, presenting as dyspraxia and affecting activities of daily living. Traditionally, assessments of sensory processing and proprioception abilities have been primarily clinically and behaviorally based, focusing on problematic behavioral outcomes (Lane & Schaaf, 2010). More work is needed in the development of accurate assessments for proprioceptive deficits. The purpose of this study is to explore the use of a computer tablet to measure proprioceptive capabilities in the upper extremities. We postulate that deficits in proprioception leads to observable difficulties in spatial-motor coordination in children with dyspraxia. We recruited 5 children with somatodyspraxia (4 to 10 yo, mean: 7.6 yo) and 5 age-matched typically developing children (5 to 10 yo, mean: 7.5 yo) from the University of Illinois Hospital

and Health System and surrounding area. Informed assent and consent was obtained from the participants and their parents. We assessed spatial-motor coordination using a figure copying activity on a computer tablet in 2 conditions: active-active, passive-active. In the active-active condition, children were asked to copied shapes with vision of their hands. Immediately following the first attempt, the children were asked to repeat the figure without vision of their hand. In the passive-active condition, children's hands were moved passively to trace a figure, without vision of their hands. The children were then asked to draw the figure based on what they felt, without vision of their hands. Children were asked also to verbally identify the figure that they drew. The performance in the two conditions provides insights into the contribution of proprioception in spatial-motor coordination. Proprioception was further assessed through joint position sense of the elbow and wrist joint. Children in the dyspraxia group had more difficulty with drawing a figure with or without vision, showing larger geometrical and spatial errors. Children with dyspraxia also had more difficulty identifying the figures that were passively drawn. In the proprioception test, children in the dyspraxia group had more errors in the single joint angle matching tasks. The methods described in this study allow us to quantitatively characterize proprioceptive deficits. This study explores the relationship between quantitative direct measures of proprioception and measures of spatial-motor coordination through a drawing task, which could be done in a clinic setting, providing clinicians with another tool to improve clinical evaluation of somatodyspraxia.

Title: Cortical mechanisms underlying the integration of transport and grip components for grasping

Authors: *A. LE[1,2], S. MONACO[3], Y. CHEN[2], J. D. CRAWFORD[2];
[1]Univ. of Toronto Scarborough, Scarborough, ON, Canada; [2]York Univ., Toronto, ON, Canada; [3]Univ. of Trento, Rovereto, Italy

Abstract: Grasping is a fundamental skill that we need to interact with our environment. Research on this topic to date has largely emphasized the independence of the reach (transport) and manual grasp (grip) components of this behavior. However, to successfully grasp an object, the transport of the arm and hand must be closely coordinated with the grip. It is currently unknown how these components are integrated by the human brain to produce reach-grasp coordination. To investigate this, we used slow event-related fMRI to examine the neural circuits involved in the integration of reach direction and grasp orientation. Participants performed a cue-separation task in which they received (a) visual information about the object location and (b) auditory information about the grasp orientation, in two successive phases. In one condition, participants were first cued about the location of the object (left or right), and then after an 8 second delay, they were cued about the grasp orientation (horizontal or vertical), followed by another 8 second delay, after which the participants grasped the object. In another condition, the cues were given in the reverse order. We predicted that brain areas associated with reach-grasp integration would respond more strongly during the second delay compared to the first delay, because of the added integrative processes of visual information about the object's location into action planning. We performed voxelwise analyses and found evidence for such integration in the anterior intraparietal sulcus (aIPS), ventral premotor cortex (PMv), and primary motor area (M1) in the left hemisphere. The results suggest that the integration of reach with grasp orientation does not occur in separate, special-purpose brain areas, but rather within the well-known anterior dorsolateral grasp-network. These results are potentially significant in the clinic for correlating locations of brain damage with symptoms of reach-grasp coordination and for the design of rehabilitation strategies for such patients.

Title: The involvement of the wrist in hand preshaping during grasping

Authors: *L. F. SCHETTINO, S. TROUT, M. BARRETT, N. STEINBERG;
Psychology, Lafayette Col., Easton, PA

Abstract: During a reach-to-grasp movement, the shape of the hand changes based on target object shape (Santello & Soechting, 1998; Schettino et al., 2003), center of mass location (Lukos

et al., 2007) and behavioral goal (Craje et al., 2011). Coordination patterns of finger position and joint angle during a grasping movement have been previously described. However, the involvement of the wrist joint in hand preshaping and coordination has received less attention. Our study was designed to determine the extent to which wrist joint extension and deviation affect hand preshaping during a grasping task. Ten right-handed subjects grasped two objects of different shapes in two different orientations in two different placements: flat on a table or supported in mid-air. The two different object orientations required the ulnar deviation of the wrist to produce an effective grasp. Similarly, compared to table placement, the mid-air placement required an extension of the wrist to grasp appropriately. Electromagnetic tracking sensors (SR: 240 Hz) were positioned on the subjects' fingers and on the dorsum of the hand. We used principal component analysis to analyze the developing handshapes as the movement unfolded at 10% relative time increments in order to determine the effects of wrist deviation and extension on hand preshaping. Our results showed that the first and second principal components explained over 80% of the total variance. The first component identified the effects of wrist deviation on hand preshaping while the second component was mostly affected by object shape. Interestingly, wrist extension did not result in detectable handshape differences.

Title: The contributions of perception and prediction to changes in hand localization after visuomotor adaptation

Authors: ***B. M. 'T HART**, H. CLAYTON, D. Y. P. HENRIQUES;
Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Motor learning presumably results in changes in predictions about the sensory outcome of planned actions, which would in turn affect state estimates of limb position. To understand motor learning, access to these predictions - or how they change - would be desirable.

Several studies have asked participants to localize their invisible, trained hand with their untrained hand as a measure of state estimate that should be sensitive to changes in predictions of the sensory outcome of actions as a result of motor adaptation (Izawa & Shadmehr, 2012; Synofzik et al., 2008). However, estimates of limb position also rely on actually perceived limb position and although vision was removed in these studies, felt hand position - proprioception - was still available. Since our lab has shown that felt hand position is also recalibrated as a result of motor adaptation, it is likely that changes in localization result from changes in perceived hand position. We tested this by having 21 participants train with both aligned visual feedback and with a gradually introduced visuomotor rotation of 30°. Subsequently, they estimated the location of their hidden, trained hand with their seen, untrained hand after a movement. Crucially, this movement could be a passive hand displacement, controlled by a robot, or it could be actively generated by the participant. In self-generated movements, there is an efference copy, allowing predictions about upcoming sensory feedback, whereas passive hand displacements prevent such predictions. Both types of hand movement are sensitive to changes in perceived hand position though. Hence any changes in localization following passive displacement should be attributed to changes in perceived hand position. We found a significant change in hand localization following training with rotated feedback, both when the hand was placed passively as well as actively. The magnitude of the change when indicating the location of the unseen hand after it was displaced by the robot was over two thirds of the change measured with participants' self-generated hand movements. Consequently, predicted sensory consequences of movements are not solely responsible for changes in localizing the adapted hand after training with a perturbation. Instead, a large proportion of the changes recorded with localization appear to stem from changes in perceived hand position. Our results indicate the inherent problems with isolating predicted sensory consequences. Our results also stress the considerable contribution of felt limb position, or proprioception, to state estimates used in motor performance.

Title: Generalization of reinforcement based motor skill learning

Authors: *N. F. BERNARDI[1], M. CLARKE[1], D. J. OSTRY[1,2];
[1]Dept. of Psychology, McGill Univ., Montreal, QC, Canada; [2]Haskins Labs., New Haven, CT

Abstract: A large literature has assessed generalization of learning in the context of sensorimotor adaptation tasks, mostly showing that generalization is limited. Little is known about the characteristics of generalization when one learns a novel motor skill, for which initially there is limited sensory error information available and instead learning is heavily based on exploration and reinforcement. We developed an experimental analogue of this process. Participants make reaching movements without visual feedback of the hand to an unseen target location embedded within a visually presented bar that runs the width of the display screen. Movements that successfully end within the target zone are indicated by a reward signal, whereas no error information is provided for unsuccessful ones. Before and after the training, participants are tested for their ability to reach to target bars at 7 different orientations in the workspace: the trained orientation and 6 non-trained orientations, 3 on each side of the trained location and progressively farther away from it. We measure movement accuracy as the absolute error from a straight line joining start and unseen target position at movement peak velocity. Movement bias is quantified as the signed error from the same trajectory. Results show that participants significantly reduce movement error and eliminate the initial bias for the trained location. For the non-trained locations, similar to previous studies on generalization, no changes are seen for movement directions beyond 30 degrees from the trained target. However, for the closer targets, a pattern of generalization is observed that differs from the gradient commonly observed in motor adaptation studies. At all locations, movement bias changed in the same direction observed for the trained location, thus resulting in either decreased or increased bias depending on baseline scores. Consistent with the change in bias, movement accuracy increased or showed a tendency to decrease, respectively. The results are compatible with a view of generalization involving a global re-orientation of the representation of the workspace around the trained target. The characteristics of generalization in these early stages of motor learning differ from what has been previously described for motor adaptation in the shape of the generalization function, but is similarly limited in extent.

Title: Is implicit learning overestimated during an explicit aiming task?

Authors: *K. DAY[1], R. ROEMMICH[1], A. BASTIAN[1,2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Kennedy Krieger Inst., Baltimore, MD

Abstract: The mechanisms underlying motor adaptation are commonly studied using visuomotor rotation paradigms. Recent studies suggest that visuomotor learning involves two components: an implicit adaptation process driven by sensory-prediction error and an explicit process driven by target error. The implicit component has been derived previously by simply subtracting the subject's verbally reported aim (i.e., explicit component) from the target error on each trial. As this method relies upon a cognitive measure (reported aim) to explain a motor phenomenon (building of a forward model), whether this subtraction method accurately estimates the implicit learning process remains debatable. Here, we use direct and indirect measurements of implicit learning to understand how these learning processes interact during motor adaptation. Participants performed a visuomotor rotation paradigm (45 degree, clockwise rotation) consisting of 5 blocks—48 no rotation/no reported strategy trials, 8 no rotation/reported strategy trials, 320 rotation/reported strategy trials, 40 aftereffect trials, and 40 washout trials. Participants were placed in either an 8-target group with the target presented pseudorandomly at increments of 45 degrees or a 1-target group with the target always presented directly ahead of the starting position. Importantly, we also collected one catch trial every forty trials during the rotation block as a direct measure of the implicit learning process. During the catch trials, feedback was withheld and participants were instructed to aim directly at the target. Following the rotation block, participants were exposed to similar trials without feedback to evaluate aftereffects. Thus, we quantified the implicit process using two methods: by calculating the error in each catch trial over the course of adaptation (direct) and using the previously established subtraction method (indirect). We observed that the implicit process was consistently smaller when quantified by the direct method versus the indirect method. This finding prompted the obvious question—which result is more accurate? When quantified using the direct method, the implicit process was continuous with the motor output of the first aftereffect trial whereas the indirect method led to an implicit process that dropped sharply between the rotation and aftereffects blocks. These results suggest that the implicit component of learning can be assayed directly to provide additional insight into the interaction between the implicit building of a forward model and explicit aiming adjustments that we observe during motor adaptation.

Title: Quantifying performance and neuromuscular admittance during manual tracking of a visual target

Authors: *T. SOLIS-ESCALANTE[1], R. VAN DER VLIET[2], Y. YANG[1], A. C. SCHOUTEN[1], F. C. T. VAN DER HELM[1];
[1]Mechanical Engin., Delft Univ. of Technol., Delft, Netherlands; [2]Erasmus MC, Rotterdam, Netherlands

Abstract: Current neurorehabilitation can partially restore lost motor skills after brain injury (e.g. stroke). Understanding the mechanisms of motor skill learning could improve post-stroke rehabilitation. Practicing how to accurately execute a movement in the presence of (force) disturbances may offer a controllable scenario to evaluate skill learning. The goal of this work is to determine whether skill learning can be assessed when manually tracking a visual target in the presence of force disturbances, and whether the neuromuscular admittance of the forearm changes through the learning process. The neuromuscular admittance describes the dynamic relation between an external force and limb position, depending on visco-elasticity due to muscle (co)contraction and afferent feedback. Healthy volunteers (n = 7, right handed) practiced controlling a cursor using a robotic manipulator with movements of their right wrist. Their task was to track a moving target as accurately as possible (tracking behavior), while force disturbances were applied to the manipulator (disturbance behavior). The target movement (MS1) and the force disturbance (MS2) were designed as sums-of-sinusoids with mutually exclusive frequency components: MS1 contained 7 frequencies between 0.2 and 2.6 Hz, whereas MS2 contained 22 frequencies between 0.8 and 20 Hz. There were three training sessions in consecutive days. A training session consisted of 6 blocks of 15 trials (20 s), yielding 270 trials in total. Task performance was shown at the end of each trial. A skill score combined the time delay between the target and cursor (TAU), and mean squared error (MSE) between both trajectories. The score was normalized with the average performance from the first block. One participant was unable to conduct the task (excluded for analysis). The neuromuscular admittance was quantified with a Fourier-based spectral analysis. The admittance from each block was expressed as a frequency response function using the 5 trials with the best

performance, and validated with the mean variance-accounted-for (VAF) in a leave-one-out procedure. Tracking behavior: There was significant performance increase between the first two training days (t-test, $p = 0.004$), but not between the second and the third day ($p = 0.741$). Performance increase was related to reduction of TAU and stable MSE. Disturbance behavior: The average admittance did not change across blocks. However, the average VAF was 61%, suggesting that behavior among validation trials is not homogeneous. Thus the link between tracking behavior and disturbance behavior should be treated as time-variant.

Title: Learning vs. minding: how subjective costs mask motor learning

Authors: ***C. M. HEALY**[1], A. A. AHMED[1], M. BERNIKER[2];
[1]Univ. of Colorado, Boulder, CO; [2]Univ. of Illinois, Chicago, IL

Abstract: In trying to understand how people adapt their reaches, it is generally assumed that the amount of error is inversely proportional to how much a subject has learned. Sensibly then, smaller errors should indicate greater learning. This interpretation has helped advance our understanding of motor control in many ways. Interestingly, this idea implies that how much and how fast one learns varies with age, since older adults produce relatively larger errors. This apparent lack of learning relies on the assumption that a subject's objective is to exactly cancel the learned disturbance. Yet different objectives could result in varying errors but with the same amount of learning. We demonstrate how a controller that balances the trade-offs between subjective costs and error can produce equivalent control laws_and thus, trajectories_suggesting that different objectives can mask the true amount that a subject has adapted. To further test this hypothesis, we analyzed differences in how young and older adults adapted their reaches in a velocity-dependent curl field. We use an optimal control framework to produce theoretical trajectories to describe these reaches. While an internal model of the reaching dynamics directly reflects the true amount of adaption, metrics such as maximum perpendicular error, maximum

perpendicular force and force-velocity relationships within channel trials (adaptation index) can only infer this quantity. By comparing the internal model to the measured metrics of adaptation, we can determine how well these metrics capture the true adaptation process. Using channel trials, young adults were found to compensate for 84% of the curl field, while older adults compensated for only 65%. Using our model, trajectories with an internal estimate of 75% of the curl field gain were statistically indistinguishable from younger adult data, while trajectories with 70-75% were statistically indistinguishable from older adult data. These results call into question whether or not older adults actually adapt less than younger adults, or if they merely compensate less than young adults. Additionally, these results refine widely held assumptions regarding how to probe motor learning and which error metrics are appropriate. With further investigation into these topics, we may better quantify the learning process.

Title: Identification of a motor memory that is fully retained 24h after training

Authors: *A. E. BRENNAN, M. A. SMITH;
Harvard Univ., Cambridge, MA

Abstract: Long-term retention (LTR) is a fundamental goal of most motor training: from learning the violin to throwing a Frisbee, the intention of a practice session is generally to improve the skill for future recall rather than to perform better during the practice session itself. In fact, we have previously shown that achieving higher performance during a practice session can be experimentally dissociated from higher LTR. Here, we examine the mechanism linking training to LTR measured 24 hours later. . We previously decomposed learning into a temporally-labile fast process, which learns quickly but also forgets quickly, and a temporally-stable slow process, which learns more slowly but also retains better. We have also previously

observed LTR to be a fixed fraction of the slow process. However, this observation could arise in two distinct ways: (1) slow process adaptation could be partially consolidated so that only a fraction remains 24h later; or (2) slow process adaptation could be composed of distinct components, one of which is retained over 24h and one of which is not. These two possibilities would lead to different strategies for optimizing LTR from a training session, with a focus on improving consolidation yield in the first case versus on directing training to specifically target LTR-stable learning in the second case. . Here we were motivated by the observation that repeated movements without error appears to cause slow process adaptation to decay substantially but not completely. We wondered whether this corresponded to distinct parts of the slow process that had different retention properties. We therefore compared the 24h retention of a 200-trial force-field training session that either was or was not followed by 500-trial error clamp trials. . In the group without error clamp exposure, 61±7% of slow process adaptation was retained 24h later. In contrast, only 30% of slow process adaptation remained after error clamp exposure, but 116±22% of this remaining adaptation was retained 24h later, corresponding to full retention. The sharp difference in 24h retention ($p = 0.02$) suggests slow process adaptation is composed of a long-term stable component of motor memory that is completely retained after 24h and a long-term unstable component that decays with repeated error clamp trials. . Future work will investigate why error clamp exposure reduced the total learning retained after 24h: whether the long-term stable component decays partially with error clamp trials, the long-term-unstable component is partially retained 24h later, or there is a 3rd component that is fully retained but decays with error-clamp trials.

Title: Can flexibility of reaching movements be increased through training?

Authors: R. M. BONGERS[1], I. TUITERT[2,1], M. M. SCHOEMAKER[1], *L. J. MOUTON[1]; [1]Univ. of Groningen, Univ. Med. Ctr. Groningen, Groningen, Netherlands; [2]Aix-Marseille Université, Inst. des Sci. du Mouvement, Marseille, France

Abstract: The current study examined whether flexibility of a reaching movement can be increased through a variable practice intervention. Flexibility in motor behavior is defined as

accomplishing the same action goal with different joint coordination patterns. The question was whether practicing the use of a larger range of joint coordination patterns in an intervention resulted in more flexibility after the intervention. The pretest, on day 1, and the posttest, on day 3, consisted of 30 trials of 30cm reaching movement over an obstacle (height: 10cm, placed at one third of the movement distance). The intervention, on days 1 to 3, consisted of 200 reaching movements per day over one of 10 different obstacles (heights: 5-9cm and 11-15cm, steps of 1cm) in quasi-random order. The pretest, intervention and the posttest were analyzed with the UCM method. With the UCM method we partitioned variability in joint angles over repetitions of reaching movements in two types of variability: a) goal equivalent variability (GEV): variability in joint angles that does not affect the end-effector position, and b) non goal equivalent variability (NGEV): variability in joint angles that results in variability of the end-effector position. The ratio over GEV and NGEV implicates the flexibility of a movement. Results showed that during the intervention GEV was lower compared to the pre- and posttest while NGEV was higher. Comparison of pre- and posttest showed a decrease of both GEV and NGEV after the intervention, however flexibility (GEV/NGEV) did not change. This implies that over training joint angle variability becomes smaller while flexibility was maintained. This conclusion does not support our expectations because we aimed to increase flexibility through an increase of the joint angle ranges exploited during the intervention. Future studies will exploit whether the same effects are observed when a test task is used that is less overlearned.

Title: Visuomotor adaptation generalizes partially in head- or eye-centred coordinates

Authors: ***E. POH**[1], G. WALLIS[1], A. DE RUGY[2], S. RIEK[1], T. J. CARROLL[1];
[1]The Univ. of Queensland, St Lucia, Australia; [2]Univ. de Bordeaux, Bordeaux, France

Abstract: Humans can adapt to visual feedback that distorts the normal relationship between visual target direction and the direction of hand movement. This process called visuomotor

adaptation is thought to occur via a recalibration of the brain's spatial mapping between the visual environment and the issued motor command. How such maps generalize to untrained conditions may reflect the coordinate systems in which visuomotor remapping is represented We previously used an isometric wrist force aiming paradigm to assess the degree to which a new map between a visual target direction and isometric wrist force generalizes across different head roll angles (Poh et al, SfN 2013). When a 30° rotation of the visual feedback was introduced gradually, the generalization pattern was partially shifted (25%) relative to the degree of head roll, consistent with a representation that combines head/eye- and body-centred coordinate systems. However, because the experiment was performed in full lighting, salient cues drawn from the edges of the monitor provided allocentric information as to where the target is relative to the extrinsic world. This resulted in conflicting allocentric and eye/head-based information of target position at the generalization head posture, such that expression of generalization in head-centred coordinates is reduced. Here we examined if the shifts in the generalization pattern can be accentuated by aligning all visual information with respect to head orientation. To achieve this, subjects were trained in the dark and provided with allocentric cues in the form of a rectangular frame surrounding the stimulus that were congruent with the degree of head roll in each of the two postures. A 30 ° visuomotor rotation was imposed in steps of 0.5° for a single force direction (120 trials) with the head rolled either +30° or -30 from midline such that the training target was aligned with the sagittal axis of the head. Generalization was assessed without visual feedback to 13 targets, in a range of ±90° from the head-aligned target in each posture. We observed a 40.1% shift when head position was shifted to the generalization head position. This indicates that allocentric cues may marginally enhance the extent of head-centred generalization, and confirms that a representation of target direction in head- or gazed based coordinates does not fully account for generalization of isometric visuomotor rotation learning. These results add to evidence that multiple coordinate systems (eye, head object-centred) are involved in generalization of sensorimotor learning.

Title: Spatial and attention abilities are more predictive of motor learning in younger adults compared to older adults

Authors: T. J. SHELAT[1], M. R. BROWN[1], V. MYRTHIL[2], *J. LANGAN[3];
[1]Rehabil. Sci., [2]Univ. at Buffalo, Buffalo, NY; [3]Rehabil. Sci., Univ. At Buffalo, Buffalo, NY

Abstract: BACKGROUND: Previous work has explored relationships between cognitive and motor performance. For example, proprioception using a joint matching paradigm has been shown to have a positive relationship to spatial working memory abilities. We aimed to further this line of research examining the relationship between motor learning and cognitive abilities such as spatial abilities and attention. OBJECTIVES: The purpose of this study was to: 1) Investigate the relationship between cognitive abilities (spatial memory and attention) and motor learning and 2) Compare these results between younger adults (YA) and older adults (OA). METHOD: Participants (YA=19; OA=24) completed a paper-based spatial assessment (card rotation task) and two computer-based assessments examining attention (reaction time) and motor control (a chase task using the computer mouse). Adding a motor control task allowed us to investigate if these cognitive abilities have similar associations across motor tasks. Subsequently, participants were asked to perform a motor learning task using a video game in which they adjusted their grip pressure to hit a sequence of six targets on a screen. To move to the next target, the pressure had to be maintained for 750 milliseconds. Targets for right and left hands were never the same. The pressure required to meet any given target never exceeded 21% of a participant's maximum strength. This sequence of six targets was repeated 60 times with each hand. We analyzed correlations between the end performance in which the participants performed the learned task bilaterally and the other assessments: spatial, attention and motor control. End performance was determined by the average amount of time to complete the six target sequence bilaterally in the last five trials of the session. RESULTS: OA did not show a significant relationship between end performance and the other assessments. However, YA did show a statistically significant correlation between end performance of the learned task and both spatial abilities and attention. Those who had a higher percentage correct in the spatial task, had lower times in completing the target sequence. Also, lower reaction times were associated with better end performance of the learned task. The correlation between end performance and motor control did not reach levels of statistical significance and only attention was related to performance of the motor control task, not spatial abilities. CONCLUSION: Spatial and attention abilities are associated with better end performance of a learned motor task in YA. This suggests cognitive abilities are used differently by YA compared to OA in learning a new motor task.

Title: Adaptation to neural noise manipulation in voluntary movement control

Authors: *C. J. HASSON, O. GELINA, G. WOO;
Dept. of Physical Therapy, Movement and Rehabil. Sci., Northeastern Univ., Boston, MA

Abstract: Neural noise plays an important role in human movement control. It is known that neural control signal variability increases with amplitude (i.e. is signal-dependent), and motor variability induced by neural noise can be suppressed with antagonistic muscular co-activation. However, what remains unclear is how humans adapt to changes in neural noise, which can occur through various disease states and may accompany aging. To investigate this issue, we manipulated neural noise in ten healthy young adults, who used a myoelectric virtual arm to perform a goal-directed task. Neural noise was manipulated by adding or reducing the variability of the myoelectric signals driving the virtual arm. The task was to flex the virtual arm past a waypoint 45° away and return to the starting position with speed and accuracy. On one day subjects practiced the task for 4 blocks of 60 trials. The next day, subjects performed a series of isometric contractions at different effort levels to determine muscle-specific coefficients of variation (CV). Subject then practiced the task for 60 trials without manipulations. In the next 4 practice blocks, neural noise was increased and decreased in alternating blocks without subjects' knowledge. The order of the manipulation blocks was not randomized so noise adaptations across blocks could be assessed. Before each manipulation block of 45 trials, subjects performed 15 trials without manipulation. Neural noise was increased by adding noise to subjects' muscle activity signals to increase the CV by 100%. Noise was reduced by low-pass filtering the muscle activity signals, reducing the CV by 30%. Task performance was assessed by speed and accuracy, and antagonistic co-activation quantified by the overlap between biceps and triceps muscle activity linear envelopes. Task performance and co-activation with each noise manipulation was compared to the immediately preceding block of 15 non-manipulated trials. The results showed that initially, subjects responded to increased neural noise by increasing antagonistic co-activation, with speed and accuracy unchanged. With practice under increased noise, antagonistic co-activation decreased; speed and accuracy was maintained. In response to decreased neural noise, subjects initially decreased their antagonistic co-activation, moved slower, and were more accurate. However, with practice, performance became worse (i.e. slow and inaccurate), and antagonistic co-activation increased. These results suggest that humans can adapt to increased neural noise to maintain task performance without elevated antagonistic co-activation, and that decreasing neural noise is not necessarily beneficial.

Title: Individual behavioral marker for identification of explicit awareness during sequential motor learning

Authors: ***R. LAWSON**, L. WHEATON;
Applied Physiol., Georgia Inst. of Technol., Atlanta, GA

Abstract: The learning of motor skills required for daily function in a rehabilitative setting often utilizes practice sessions involving multiple repetitions of the desired movements. While the value of simple repetition has been well established, it has been suggested that continued practice, in which explicit awareness of the movement pattern develops, can result in overlearning of that pattern, resulting in a reduced ability to generalize to new or more complex tasks. This study evaluated the potential for an individualized performance threshold to provide an indication of the development of explicit awareness during the learning of a serial reaction time task (SRTT). Subjects were exposed to varying levels of difficulty in the SRTT to examine the generalizability of the threshold. Results showed that subjects reaching performance below threshold indicated explicit awareness of sequence, while those failing to reach threshold were unable to repeat the sequence. These results suggest that a behavioral marker based on individual baseline performance may provide an accurate measure of when explicit awareness has developed.

Title: Robust use-dependent learning in reaching movements without error or reward feedback

Authors: A. S. BAINS[1], *N. SCHWEIGHOFER[2];
[1]Neurosci., USC, Los Angeles, CA; [2]Univ. So California, Los Angeles, CA

Abstract: Previous work has suggested that repetition of a learned movement induces bias towards that movement when executing similar movements (Han et al 2008, Classen et al 1998, Diedrichsen et al 2010, Verstynen and Sabes 2011). Such use-dependent learning is thought be a slow process rooted in long-term potentiation in the motor cortex (Han et al 2008, Verstynen and Sabes 2011, Galea and Celnik 2009). Here, we test the hypotheses that use-dependent learning 1. has a slow time course and requires extensive training; 2. does not require feedback from the environment; and 3. is relatively resistant to time-based forgetting and to washout. Two subject groups took part in a two-day experiment. Subjects used a pen and tablet to reach to targets displayed on a horizontal screen which also acted to hide the subject's hand from view. Reaches were made without online feedback and trials were terminated once endpoint velocity fell below 25 mm/s. Group 1 was provided with endpoint error and score feedback after each trial, while Group 2 was shown only endpoint error on 20% of trials. Subjects trained by repeating 476 reaches in a single direction during Day 1 and another 238 at the beginning of Day 2. Over the first 100-200 trials during Day 1, both groups slowly developed a bias towards the repeated direction, measured using probe trials located 90° away from the repeated direction. This bias was still apparent at the beginning of Day 2, though it partially decayed by 3.0° ± 1.3° in Group 1 and 0.7° ± 0.5° in Group 2 from levels of 4.4° ± 1.6° and 2.7° ± 0.9° (mean ± SEM), respectively, at the end of Day 1. Additionally, after Day 2 training, the bias did not fully washout when subjects executed 203 reaches in random directions with error and score feedback available. Instead, the bias showed a partial washout of 1.7° ± 1.3° in Group 1 and 3.4° ± 1.3° in Group 2 from levels of 3.9° ± 1.4° and 5.2° ± 1.6° (mean ± SEM), respectively, at the end of Day 2 training. These results demonstrate that use-dependent learning 1. has a slow time course , 2. can be induced without error or reward (score) feedback, and 3. can last over 24 hours and is relatively robust to washout. Our results underline the potential importance of use-dependent learning as an independent mechanism of motor learning that may be harnessed in developing rehabilitation strategies after stroke or other motor impairments. In particular, use-dependent learning may lead to the "entrenchment" of compensatory movements in affected individuals: after such compensatory movements are "used" numerous times, it is difficult to re-train "normative movements", even with full feedback, as suggested by our washout paradigm.

Title: Evidence for a rapidly evolving internal estimate of environmental variability in grip force control

Authors: ***A. M. HADJIOSIF**, M. A. SMITH;
Harvard Univ., Cambridge, MA

Abstract: Grip forces (GFs) are known to adapt to changes in expectations about environmental dynamics. However, we recently found that GFs are, in fact, 3-fold more sensitive to environmental variability than to the expected value of environmental dynamics (Hadjiosif & Smith, 2015). Here, we investigate the mechanism underlying this exquisite sensitivity. . The sensitivity of GF to environmental variability might arise from control directly based on an internal estimate of environmental variability. But it could also arise from asymmetric trial-to-trial adaptation that responds more strongly to unexpectedly high load forces than low ones, without requiring an internal estimate of environmental variability. Such an asymmetry would increase the GF levels associated with a given load force environment, because the GF decreases associated with unexpectedly small loads would be outweighed by GF increases associated with unexpectedly large loads. Critically, in higher variability environments where both very small and very large loads are more frequent, the effect of this asymmetry would increase, due to the increased gap between the small and large loads experienced, resulting in a systematic increase in GF control with load variability. . Here we use a trial-by-trial analysis of the changes in GF during exposure to a stochastic environment to distinguish between these possibilities. Asymmetric trial-by-trial adaptation that could support systematic variability-driven responses would predict larger increases than decreases in GF control following equal-amplitude increases vs decreases in load. However, GF adaptation driven by an internal estimate of environmental

variability would predict adaptive increases in GF control for *both* increases and decreases in load, with adaptive decreases in GF predicted only when expected loads are experienced. . We examined data from an experiment in which participants (N=51) used a precision grip to maintain grasp of a virtual object during 10cm point to point reaching movements. This object was perturbed by a viscous curl force field, whose strength, b, could randomly vary from one trial to the next, centered around zero. We found adaptive increases in GF control both when b>>0 *and* b<<0. These responses were both higher than when b=0 ($p < 0.001$ in both cases). In fact, the adaptive increases were essentially identical for b>>0 and b<<0 ($p = 0.44$). These data are at odds with asymmetric adaptation to high vs. low loads, but in line with an internal estimate of variability that evolves from one trial to the next, suggesting that motor system maintains a rapidly evolving internal estimate of the uncertainty about environmental dynamics.

Title: Evolution of limb kinematics during fine motor skill acquisition in rats

Authors: ***T. JOHN**[1], D. ELLENS[2], M. GAIDICA[2], S. PENG[3], D. LEVENTHAL[4];
[1]Biomed. Engin., [2]Neurol., [4]Neurology/ Biomed. Engin., [3]Univ. of Michigan, Ann Arbor, MI

Abstract: The evolution of skilled movements has been studied using motion capture techniques in human subjects. To understand the neural underpinnings of motor skill acquisition, however, similar detailed kinematic analyses of fine animal movements is needed. Rodent skilled reaching, in which rats or mice are trained to reach for and grasp a food pellet, has been used for over two decades to study motor control. However, the task requires extensive human supervision to both run the task and analyze data. Furthermore, reaches are usually scored on a semi-quantitative scale, providing limited insight into how the reaching movement develops over time. We developed an apparatus that allows automated high throughput training and unsupervised

kinematic analysis of rat skilled reaching. Reaches early in the learning process were characterized by variability in paw trajectories, whether the animal successfully grasped a food pellet or not. As task proficiency improved, reaches took on a more stereotyped trajectory, again independent of reach success or failure. Importantly, variability in early reach trajectory was correlated with the degree to which reaching proficiency improved. This supports the notion that motor variability during task acquisition is important to explore potential movement strategies, so that the optimal strategy can ultimately be adopted. These results provide insight into how motor skills develop, and why some subjects become more successful than others.

Title: Learning a visuomotor adaptation task without adaptation when the arm is visible

Authors: ***A. L. WONG**[1,3], J. A. TAYLOR[3], J. W. KRAKAUER[1,2];
[1]Neurol., [2]Neurosci., Johns Hopkins Univ. Sch. Med., Baltimore, MD; [3]Psychology, Princeton Univ., Princeton, NJ

Abstract: Under typical situations, introduction of a visuomotor rotation promotes implicit adaptation. We have previously demonstrated that, curiously, this adaptation persists despite providing subjects with complete awareness of the cursor manipulation (i.e., by informing subjects where they should aim to solve the rotation) and despite good task performance, leading to a counterintuitive gradual drift of the hand away from the target. That is, subjects know that the cursor is rotated relative to the true hand position and have proprioceptive information about their actual hand location. Nevertheless, they experience an unavoidable sensory-prediction error (i.e., derived by a forward model) between the expected outcome of the motor command sent to the hand and the observed movement of the cursor, which drives implicit adaptation. Here, we asked if additional visual information about true hand position, provided via direct vision of the limb, negates or can overcome sensory-prediction errors during a visuomotor rotation. Thus, vision, proprioception, and knowledge of the position of the hand are all congruent; solving the

rotation then becomes akin to playing a game. In this situation, subjects quickly recognize the presence of the cursor manipulation and formulate an aiming strategy to overcome the rotation. This aiming strategy is initially formulated independently for each target, but eventually becomes generalized into a single common strategy (e.g., "aim to a location clockwise from the target"). Furthermore, when subjects re-aim their hand, the amount of drift away from the target that they experience is dependent upon the certainty with which they can localize their hand position. Therefore, unlike knowledge or proprioception, vision of the hand can uniquely eliminate implicit adaptation in response to a hand-cursor visuomotor mismatch by providing direct evidence that there is no sensory-prediction error between the motor command sent to the hand and the observed consequences of that movement. This supports the argument that motor performance during adaptation tasks reflects the interaction between explicit strategy and implicit adaptation; thus, when implicit adaptation is impaired or suppressed, subjects can use explicit strategy to maintain good behavior.

Title: Decision making during motor learning: investment in learning and reward optimization

Authors: *J. B. MOSKOWITZ[1], D. J. GALE[1], D. M. WOLPERT[2], J. P. GALLIVAN[1], J. R. FLANAGAN[1];
[1]Queen's Univ., Kingston, ON, Canada; [2]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: In our daily lives we often must decide whether it is worth investing in learning a new skill (e.g., learning to play the guitar). This relies on weighting the costs/benefits associated with learning, the outcome probabilities, as well as prior knowledge. Successful evaluation depends on our ability to estimate our own learning parameters (e.g., our rate of learning and its variability) and the duration over which we have the opportunity to exploit this learning (e.g., a day or a lifetime). To our knowledge no work has explored the extent to which individuals can track their own learning and exploit this information to make optimal decisions related to future rewards. We examined this question by engaging subjects in a target-directed reaching task using a planar robotic manipulandum. After an initial practice phase, we applied a 45 degree visuomotor rotation to participants reaches. This adaptation block was short (30 trials) such that

participants did not fully adapt to the rotation. In a subsequent decision phase, subjects decided how many points they would like to receive for hitting and missing the target, respectively, for a future block of adaptation trials. Subjects made three separate point-assignments for future blocks that were short, medium, or long in trial length, respectively. At the end of the experiment subjects received a payout contingent on how many points they accrued during the study. Because learning curves are generally well-approximated by an exponential, we hypothesized that subjects should, in theory, be able to predict their future performance based on their performance during the short adaptation block and thus determine a point-assignment that should maximize their reward (i.e. optimal decision). On average, we found that participants selected point-assignments that were in the direction of optimal. That is, subjects chose riskier point-assignments (more points assigned to hitting than missing the target) the greater the length the future block was, suggesting that participants predicted their performance would improve over longer learning horizons. Furthermore, the results suggest that optimal point-assignments were easier for participants when their task performance was at the extremes (i.e., very poor or very good), but more difficult when their performance was mediocre. Taken together, these findings suggest that individuals can exploit information about their own learning in order to effectively guide decisions about future reward.

Title: Artificial vestibular cues enable dual motor adaptation

Authors: *L. P. SELEN, J. L. RUDOLPH, W. P. MEDENDORP;
Radboud Univ., Donders Inst. for Brain, Cognition and Behavio, Nijmegen, Netherlands

Abstract: When two opposing force field perturbations are presented sequentially, there is substantial interference between the associated motor memories. However, if contextual cues are

associated with each perturbation interference is reduced and subjects can readily adapt to both (see Howard et al., 2012, 2013). In a recent study we had subjects adapt to two opposite accelerating environments and showed that interference between motor memories is reduced (Sarwary et al., 2013). We attributed this reduction in interference to the availability of vestibular information that dissociated the two environments. Here we have a deeper look into this claim by investigating whether artificial vestibular signals can serve as a cue dissociating between two opposing perturbations. Subjects were asked to make two stage reaching movements on a robotic manipulandum. During the first stage of the reach a velocity dependent current was applied to the vestibular afferents through Galvanic Vestibular Stimulation (GVS). The sign of this current determined the direction of the curl-force field (CW or CCW) during the second stage of the reach. In a small fraction of trials the force field was replaced by an error-clamp. This allowed us to determine the force expression during the second stage of the movement induced by the GVS-cue in the first stage of the movement. Subjects do adapt to both force force fields as indicated by the increase in force expression in the error-clamps in opposite directions for the two vestibular cues. However, they never learn to fully compensate for the force fields, indicated by adaptation indices of about 0.5. We conclude that vestibular information does serve as a cue that enables adaptation to two opposing force environments at the same time. However, the arbitrary mapping between vestibular information and movement parameters probably prohibits full adaptation. Howard, I. S., Ingram, J. N., Franklin, D. W., & Wolpert, D. M. (2012). Title: Training of the non-dominant arm leads to substantial and durable changes in performance

Authors: *A. DUNN[1], C. CHOPICK[1,2], R. SAINBURG[1,2];
[1]Kinesiology, Pennsylvania State Univ., State College, PA; [2]Neurol., Pennsylvania State Univ. Col. of Med., Hershey, PA

Abstract: Our previous studies have shown substantial asymmetries in motor performance between the dominant and non-dominant arms of healthy adults. Whereas the dominant arm appears specialized for predictive control associated with fast, efficient, and smooth trajectories, the non-dominant arm appears specialized for impedance control that leads to robustness in the face of unexpected perturbations. Functional tests of unilateral upper extremity performance, such as the Jebsen-Taylor Hand Function Test (JTHFT) show substantial performance asymmetries, with the dominant arm tending to perform a range of unimanual upper extremity activities roughly 20% faster than the non-dominant arm. Whether these performance asymmetries are amenable to modification through practice is not well-understood, although it is clear that individuals who have experienced a partial or complete dominant hand amputation largely switch their dominance over time, which is associated with increased activation of ipsilateral cortex (Philip BA, Frey SH (2014)). We now ask whether general training of predictive control using virtual reality, in combination with training of real-world coordination, can lead to significant improvements in speed and coordination of the non-dominant arm, as tested using the JTHFT. Our preliminary results suggest substantial and durable improvements in coordination and performance of the trained non-dominant arm. These results have substantial implications for dominance retraining in individuals with unilateral dominant-arm impairments, such as amputation and stroke.

Title: The role of attention in visuomotor and force field adaptation

Authors: *E.-M. REUTER[1,2], T. J. CARROLL[1], J. BEDNARK[2], R. CUNNINGTON[2,3];
[1]Sch. of Human Movement and Nutr. Sci., [2]Queensland Brain Inst., [3]Sch. of Psychology, Univ. of Queensland, Brisbane, Australia

Abstract: Attention is a crucial and well-studied aspect of cognition, but little is known about how it relates to processing and adaptation in the motor system. To learn a new visuomotor transformation visual attention is needed [1]. However, how attention changes throughout successful adaptation, and how motor adaptation affects spatial attention, remain open questions. In a series of experiments we tested groups of 20 healthy right-handed participants during visuomotor or force field adaptation. We used behavioural and/or EEG measures of attention and motor function to probe the effects of the sensorimotor perturbations. In Exp. 1 we investigated how visual attention changes throughout visuomotor adaptation to smaller (60°) and larger (120°) screen cursor rotations, using steady-state-visual-evoked-potentials (SSVEPs). In Exp. 2 we characterized the consequences for spatial attention of i) adaptation to persistent sensorimotor perturbations and ii) exposure to random perturbations that do not result in motor adaptation. The effects of the training were assessed pre-adaptation, 5-minute, and 30-minute post-adaptation via Visual Temporal Order Judgment and Visual Attention Dual-Task tests. Results of Exp. 1 showed that participants' performance improved over time in all conditions ($F(1,19) = 43.82$, $p < .001$, $\eta p^2 = .70$) and was influenced by the degree of rotation ($F(1,19) = 84.53$, $p < .001$, $\eta p^2 = .82$). We found that SSVEP EEG power, reflecting attention to the visual stimulus, decreased with improved performance for smaller rotation, but did not change with performance for larger rotation ($F(11,209) = 2.53$, $p = .04$, $\eta p^2 = .12$). The findings from Exp. 1 suggest that visual attention to the cursor decreased as performance increased, and that this is influenced by the difficulty of the new transformation. This might reflect a reduced reliance on visual attention for easier rotation, but continued reliance on attention to visual feedback of action for the more difficult rotation. Results of the ongoing Exp. 2 will indicate whether the interrelation between attention and motor adaptation is bi-directional. Reference: [1] Taylor, J. A., & Thoroughman, K. A. (2007). Divided attention impairs human motor adaptation but not feedback control, Journal of Neurophysiology, 98(1), 317-326.

Title: Time course of reach adaptation and proprioceptive recalibration during visuomotor learning

Authors: *J. E. RUTTLE[1], E. CRESSMAN[3], D. HENRIQUES[2];
[1]York Univ., Bolton, ON, Canada; [2]York Univ., Toronto, ON, Canada; [3]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Training to reach with rotated hand-cursor feedback, results in changes or adaptation of these hand movements during training, which continues to persist when the perturbation is removed (reach aftereffects), as well as changes in felt hand position, which we refer to as proprioceptive recalibration. The rate by which motor and proprioceptive changes arise throughout training is unknown. Here, we aim to determine the timescale of these changes and their relationship in order to gain insight into the processes that may be involved in learning. We measured reach aftereffects (no-cursor reaches) and perceived hand position after every 6 reach-training trials with a 30 rotated-cursor to 3 radially located targets. To assess proprioceptive recalibration, the right adapted hand was passively moved to one of the three target sites by a robot, and its perceived location was indicated by the left untrained hand. Participants trained with both a clockwise and a counter-clockwise cursor rotation in sessions a week apart to determine if the original training led to any retention or interference of these motor and sensory changes. Results suggest that both motor and proprioceptive recalibration occurred simultaneously and immediately after only 6 or 12 rotated-cursor training trials (13.08 & 4.50 respectively) and did not increase much or at all with further training. Moreover, there was no retention or interference present one week after training. This suggests that the implicit changes in both motor and sensory systems do not simply reflect changes in performance made with a cursor during training.

Title: Persistence of a neural representation following repeated adaptations to and repeated deadaptations from a novel visuomotor rotation

Authors: *S. BAO, J. WANG;
Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: When humans adapt their voluntary reaching movements to a systematic visuomotor perturbation, a neural representation that is associated with the novel condition, called an internal model, is thought to develop in the cerebellum. The adapted performance returns to baseline rapidly once the external perturbation is removed, and this procedure is called deadaptation. There are two opposite ideas about the mechanisms that underlie deadaptation: (1) the process of deadaptation results in the decay of motor memory that is associated with the internal model; and (2) the internal model is not decayed during this process, but rather allows the nervous system to have two distinct visuomotor transforms: the original visuomotor transform (related to baseline performance) and the novel visuomotor transform (related to adapted performance). In the present study, we attempted to test the two ideas by having individuals adapt to a novel visuomotor rotation and de-adapt from the rotation repeatedly. That is, our subjects first adapted to a visuomotor rotation; deadapted from the rotation; readapted to the rotation; deadapted from the rotation again; and readapted to the rotation once more. We hypothesized that if the internal model developed during initial adaptation was decayed following deadaptation, the extent of savings observed following the first deadaptation period would be similar to that following the second deadaptation period. Alternatively, we hypothesized that if the internal model remained intact following deadaptation, the extent of savings should be greater following the second deadaptation period than following the first deadaptation period. Results showed that the extent of savings observed during the second adaptation period was significantly greater than that observed during the first adaptation period, and the extent observed during the third adaptation period significantly greater than that observed during the second adaptation period. This finding indicates that the extent of savings continues to improve across multiple adaptation periods, which suggests that the internal model continues to be improved for better performance even after repeated deadaptation periods. This finding provides support to the idea that an internal model associated with a novel visuomotor transform is not decayed following a period of deadaptation, but rather allows the nervous system to contain both the original and a novel visuomotor transform simultaneously.

Title: Exploring the value of practice in motor adaptation

Authors: *S. K. COLTMAN[1], L. E. BROWN[2];
[1]Psychology, Trent Univ. Dept. of Psychology, Peterborough, ON, Canada; [2]Trent Univ., Peterborough, ON, Canada

Abstract: Given that variability and performance have an inverse relationship, one question that we must address is, “What should we practice?” Practice provides an opportunity to learn to control highly variable movements as a novice with the goal being that precision will increase. We designed an experiment to examine the effect of constant versus variable practice, to assess which leads to greater precision when adapting a simple visually guided reaching movements. The experiment consisted of a 2-practice task (vary distance, vary direction) by 2-test task (vary direction, vary distance) between subjects design. Participants used their right hand to make simple point-to-point movements from a constant start position to one of three possible targets varying in direction or distance. All four groups practiced over 144 trials and tested over 144 trials, with focus for the analysis limited to the first 12 trials of testing to capture the effect practice condition on performance. Data was analysed from end-point variability, measured as the standard deviation of all end points, and movement time, measured as the time between initiation and cessation of movement. The results indicated that when the test task was to vary direction, greater precision was achieved when practice was to vary direction over distance, without compromising time. On the other hand, when the test task was to vary distance, there was no one task that was more beneficial to achieve greater precision, however, participants were able to significantly reduce time when practicing to vary distance over direction. So far, these results indicate that people should practice what they intend to perform. Subsequent analyses may reveal the role of functional and non-functional variability experienced during practice on test performance.

Title: Visuomotor adaptation and deadaptation with one arm result in savings during subsequent visuomotor adaptation with the other arm

Authors: *J. WANG, A. D'AMATO;
Dept Kinesiology, Univ. of Wisconsin, Milwaukee, WI

Abstract: Savings refers to a phenomenon in which individuals learn a motor task faster when exposed to the same learning condition again later. It has been suggested that savings is related to model-free, as compared with model-bsed, learning. However, savings is frequently observed following interlimb transfer of motor learning, which is thought to involve model-based, but not model-free, learning. In the present study, we explored the phenomenon of savings by examining how unlearning of a motor task with one arm would influence retention of the motor task with the same arm or with the other arm. A group of subjects experienced three experimental sessions: (1) adaptation to a 30-degree rotation during targeted reaching movements with the left arm; (2) deadaptation from the rotation with the left arm; and (3) readaptation to the rotation with the right arm. Another group of subjects experienced three sessions that were somewhat different: (1) adaptation to a 30-degree rotation with the left arm; (2) deadaptation from the rotation with the right arm; and (3) readaptation to the rotation with the left arm. Our general working hypothesis was that if the deadaptation caused the internal representation developed during initial training to be decayed, no savings would be observed during readaptation; and that the pattern of readaptation should be similar regardless of which arm was used during the deadaptation and readaptation sessions. Our results indicated that savings was observed in both subjects groups. Specifically, the former group showed savings during readaptation with the right arm following deadaptation with the left arm, which indicates that the deadaptation session did not cause the internal representation developed during initial training with the same arm to be decayed. The latter group showed savings during readaptation with the left arm following deadaptation with the right arm, which indicates that the deadaptation session did not cause the internal representation developed during initial training with the other arm to be decayed. Interestingly, the latter group also showed that the savings observed at the first few trials of the readaptation session was also associated with substantially low performance errors, which has not been observed in previous studies. Our findings collectively suggest that internal representations developed following visuomotor adaptation involve some aspects that are effector independent and other aspects that are effector dependent; and that the nature of savings can vary depending on whether it involves model-based learning, which is effector independent, or model-free learning, which is effector dependent.

Title: Individual ability of motor imagery can determine the suitable attentional strategy under motor learning

Authors: *T. SAKURADA, M. HIRAI, E. WATANABE;
Jichi Med. Univ., Tochigi-Ken, Japan

Abstract: It has been shown that the motor learning performance can be affected by various cognitive factors such as directing attention and motor imagery ability. Most previous studies on motor learning have shown that directing the participants' attention externally, such as on the outcome of the body movement, can be more effective than directing their attention internally, such as on body movement itself. However, to our best knowledge, there are no findings regarding the effect of attention manipulation on motor learning performance, depending on individual's motor imagery ability. To clarify the individual differences, we first assessed individual motor imagery ability by using the Movement Imagery Questionnaire (MIQ-R) and classified participants into 2 groups on the basis of their scores. After that, the participants performed a simple motor learning task such as tracing a trajectory with visuomotor rotation. We introduced 3 experimental conditions (No Attentional Instruction condition, Internal Focus Attentional condition and External Focus Attentional condition). We defined the movement error as an index to evaluate the transition of motor performance and calculated the aftereffect size to evaluate the degree of motor learning in a wash-out trial. When the participants were required to direct their attention internally, the aftereffects of the motor learning task in the participants good at kinesthetic motor imagery were significantly higher than those of the participants good at visual motor imagery. Conversely, when the participants were required to direct their attention externally, the aftereffects of the participants good at visual motor imagery were significantly higher than those of the participants good at kinesthetic motor imagery. Furthermore, we found a significant correlation between the aftereffects of motor learning and the differential scores between visual and kinesthetic motor imagery abilities. These results suggest that individual intrinsic motor imagery ability can be related to the suitable attention strategy during a motor

learning task and the suitable attentional strategy under motor learning can be changed individually. Therefore, we should evaluate the individual differences to conduct motor learning tasks effectively such as using a simplified assessment for the purpose of applications in the sports and clinical fields. Our current findings can contribute to the first step in promoting tailor-made motor learning or rehabilitation programs.

Title: Development of collaborative strategies in physical human-human interaction

Authors: V. THEKKEDATH CHACKOCHAN, I. TAMAGNONE, *V. SANGUINETI; Univ. of Genoa, Genoa, Italy

Abstract: Physical human-human interaction plays an important role in our life experience and is the basis of many daily activities. If two partners have different goals, but a perfect knowledge of their respective goals and internal state, they may negotiate a joint strategy. However, it is unclear how the development of collaborative strategies is affected by lack of this information. To explore this we developed an interactive learning paradigm in which each subject sat in front of a computer screen and grasped the handle of a haptic interface. The two subjects could not see each other and were not allowed to talk. They were instructed to perform reaching movements with the same start and target position, but through different via-points. The haptic interfaces generated a force proportional to the difference of the two hand positions, so that the two subjects were mechanically connected. During movements the haptic interaction force was continuously displayed. At the end of each movement each subject received a 0-100 reward, calculated as a function of the minimum distance of their movement path from his/her own via-point and the average interaction force. Both subjects were instructed to aim at maximizing their score. They were also encouraged to maintain an approximately constant movement duration. We focused on two different scenarios: (i) visible via-point: each subject can see his own via-point but not his/her partner's. (ii) hidden via-point: no via-points were displayed, so that the score was the only information available to learn the movement and to develop a cooperation strategy. During a familiarization phase the interaction forces were turned off and each subject

performed on their own. In a later phase the two subjects were mechanically connected. They had the option to establish a collaboration - negotiating a path through both via-points, which would lead to a minimization of the interaction forces and a maximum score for both - or to ignore each other - each partner only focuses on their own via-point and on maximizing his/her own score. In the 'hidden' scenario, collaboration also affects the exploration of the space of the possible actions. In the analysis, we specifically focused on the temporal evolution of the trajectories (trial-by-trial variability), the scores and the magnitude of the interaction force. In both the visible and hidden scenarios, the subjects pair generally converged to a collaborative strategy, characterized by a minimization of the interaction forces. Lack of knowledge of partner's state (no visual feedback on interaction forces) reduced the trend toward collaboration.

Title: Investigating reward-based regulation of task-relevant motor variability in rats

Authors: *Y. R. MIYAMOTO, A. DHAWALE, M. A. SMITH, B. P. ÖLVECZKY; Harvard Univ., Cambridge, MA

Abstract: Motor variability can be equated with action exploration, a key ingredient of trial-and-error motor learning. The motor system is known to actively modulate its variability, consistent with the need for high-variability exploration when rapid learning is called for and low-variability exploitation when precision is desired for good performance (Tchernichovski et al. 2001; Kao et al. 2005; Wu et al. 2014; Pekny et al. 2015). Here we investigate how variability is regulated by reward in task-relevant dimensions, and the timescales involved. We studied 4 rats trained to press a small 2-d joystick downward with their paws, with a reward based on joystick trajectory angle. Animals were trained 2 to 4 times a day, in 30 minute sessions, amounting to 100,000+ trials over the course of a few months of training. To ensure that rats were continually

challenged to adapt motor output, we periodically shifted the rewarded joystick angle to a new value as the rats successfully adjusted to the target angle. The rats were able to perform this task proficiently; the rats' average error was 8 degrees from the target, much smaller than the size of typical target angle shifts, which ranged up to 50 degrees. When we examined the rats' behaviors following rewarded trials, we found that they systematically decreased joystick angle variability compared to pre-reward baseline trials ($p < 0.0001$), indicating a propensity to modulate task-relevant variability based on reward. To examine the relationship between reward and variability further, we administered reward randomly with different probabilities {0.1, 0.35, 0.7}, uncoupling it from performance in occasional blocks of 75 contiguous random-reward trials. We found that variability in press angles was larger on blocks with low reward rates and vice versa ($p < 0.0001$); in addition, we characterized the time-scale over which reward rates are integrated to influence variability, and found an exponential fit to the data to have an average time constant of 8.7 trials (99% CI: [6.5, 11.0]). In contrast, preliminary analysis suggests that the variability of task-irrelevant features, such as press velocity and path curvature, was not sensitive to these reward manipulations ($p = 0.26$, $p = 0.57$). Thus, the motor system may selectively modulate variability along the dimensions of motor output that are essential for the task, and do so by integrating reward information on a short, multiple-trial timescale.

Title: The training duration influences the magnitude of motor adaptation retention, but not the magnitude of savings following a 24-hour break

Authors: *K. P. NGUYEN[1,2], L. C. BRAY[2], L. ALHUSSEIN[2], E. A. HOSSEINI[3], W. M. JOINER[2];
[1]NIH, Bethesda, MD; [2]Dept. of Bioengineering, George Mason Univ., Fairfax, VA; [3]McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: There is growing understanding of the influence the training schedule exerts on different features of motor adaptation (retention, transfer, generalization and stability). Here, we were interested in the influence of training duration on the retention and savings (readaptation) of

a learned motor adaptation following a 24-hour break period. We trained subjects to make point-to-point reaching movements when perturbed by a position-dependent force-field in two experimental sessions completed over two consecutive days. The perturbation was suddenly applied, but the duration of training was either long (160 trials) or short (15 trials). Consistent with previous findings (Joiner and Smith, 2008) the training duration had a marked influence on the retention of adaptation on the second day of training with an approximate 74% decrease in retention with the shorter training duration. However, following the first trial of force-field exposure on the second day, the magnitude of savings was comparable for both training durations ($P = 0.51$). This was also true when the initial training on the first day was followed by a washout period ($P = 0.83$); the magnitude of savings was reduced by an equivalent amount for both training durations (> 20% in both cases). When we represented these results in a position/velocity gain-space (the amount of the observed temporal force pattern associated with limb position and velocity) there were differences in the orientation of the respective gain-space learning trajectories. In general, the initial trajectory for learning on the second day was closer to the task-relevant position axis than on the first day for the long training schedules. However, the specificity of the applied force pattern on the second day was affected by both the washout period and training duration. That is, the learning trajectory on the second day was farther from the position axis for the short training conditions and when training was followed by a washout period on the first day. Collectively, these data imply that motor adaptation retention and the specificity of the savings are both influenced by training duration, but the magnitude of motor adaptation savings is independent of the exposure duration. These differential effects on motor adaptation retention and savings may reflect the stability and reengagement of implicit and explicit learning mechanisms.

Title: Savings requires prior history of error, not repetition of successful movements

Authors: *L.-A. LEOW[1], A. DE RUGY[2], S. RIEK[3], W. MARINOVIC[4], T. J. CARROLL[5]; [1]Sch. of Human Movement and Nutr. Sci., Brisbane, Australia; [2]Univ. de Bordeaux, Bordeaux, France; [4]Sch. of Human Movement and Nutr. Sci., [5]Sch. of Human Movement And Nutr. Sci., [3]The Univ. of Queensland, Brisbane, Australia

Abstract: When we move, perturbations in the environment often elicit discrepancies between predicted and actual movement outcomes. We readily adapt our movements to correct these prediction errors, and this learning can show savings. That is, after initially adapting to a perturbation and then executing movements in an unperturbed environment (washout), re-adaptation to the original perturbation can be faster. Recent data suggest that when we learn, we increase our sensitivity to the errors we experience, and that savings results from improved trial-by-trial corrections of previously experienced errors at subsequent learning (Herzfeld et al., 2014). An alternative theory suggests that savings occurs when an action that successfully reduces errors is reinforced through repetition, and this reinforced action is more rapidly selected at subsequent learning (Huang et al., 2011). Here, in a factorial design, we sought to dissociate how prior experience of error and repetition of successful movements affect savings. The perturbation was a rotation of visual feedback of hand position. All conditions contained the following blocks: A1: 30° CW (clockwise) rotation, Washout: no rotation, B: 30° CCW (counterclockwise) rotation, and A2: 30° CW rotation. Savings was assessed in B. Conditions were as follows: NoErrorNoRepetition, NoErrorPriorRepetition, PriorErrorNoRepetition, PriorErrorPriorRepetition. In all the NoError conditions, the A1 CW rotation was gradually imposed and gradually removed, such that the same CCW errors as B were never previously experienced. In all the PriorError conditions, the A1 rotation was abruptly imposed and abruptly removed, such that the same CCW errors as B were only experienced after the rotation was abruptly removed. In all the PriorRepetition conditions, target location was manipulated to induce repetition of a successful movement, such that the movement solution to hit the target was the same throughout A1 to B. In all the NoRepetition conditions, target location was manipulated such that the movement solution to hit the target never repeated before block B. Error x Repetition ANOVAs on rate constants of exponential fits on block B directional errors showed significant main effects of Error ($p=.03$), no significant main effects of Repetition, and no significant Error x Repetition interaction (all $p>0.05$). Hence, prior experience of errors appears both necessary and sufficient for savings, whereas reinforcing a motor action via repetition appears neither necessary nor sufficient for savings.

Title: A rapid-response-selection model of motor skill: learning to produce low-latency responses to arbitrary visual stimuli

Authors: *R. M. HARDWICK, J. W. KRAKAUER, A. M. HAITH;
Dept. of Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: Motor skill involves not only selecting appropriate actions and executing them well, but also being able to do so with a low latency. For instance, two goalkeepers can be equally skilled in executing dives to block a shot, but one who is faster to initiate the appropriate dive is more likely to make a save. Despite the importance of response latency, most models of motor learning overlook this critical component of skill. Here we examined human subjects' ability to initiate accurate responses at low latency in an abstract motor skill task, and examined the degree to which this could be improved with practice. Participants first learned an arbitrary association between symbolic cues and movements to spatial targets. Once these associations were established, we determined the speed-accuracy trade-off, between preparation time and response accuracy, using a timed response paradigm (Ghez et al., Exp Brain Res, 1996) in which participants initiated movements at a precise time within each trial. We manipulated the amount of preparation time allowed to initiate a response by varying the time of presentation of the cue relative to the time of movement onset. Participants exhibited a clear speed-accuracy trade-off, with the proportion of correct responses increasing monotonically as a function of preparation time. Critically, training led to an improvement in this speed-accuracy trade-off, reducing the preparation time required to initiate a correct response. We compared behavior to a control condition in which stimulus-response relationships were non-arbitrary (arrows cued the appropriate target). Participants had superior speed-accuracy trade-offs for this non-arbitrary condition, but performance did not change with training. In addition, we compared the speed-accuracy trade-off established in the timed response condition to performance in a choice reaction time condition (i.e. when participants were instructed to move to the correct target as soon as possible after cue presentation). Notably, reaction times in this condition were greater than appeared necessary based on the speed-accuracy trade-off. These results demonstrate that arbitrary visuomotor associations can be viewed as a skill that can be improved with practice over days, and could therefore serve as a useful model of general motor skill acquisition. The ability to initiate accurate responses at low latencies is an important aspect of motor skill, can be enhanced through training, and is not adequately assessed using choice reaction time measures alone.

Title: Interference between motor memories developed through learning with different arms

Authors: ***N. KUMAR**, P. K. MUTHA;
Indian Inst. of Technol. Gandhinagar, Ahmedabad, India

Abstract: Learning of a new motor task B shortly after learning another task A is thought to interfere with consolidation of the memory of A. This has been typically demonstrated in studies in which A and B are opposing visuomotor mappings or force perturbations, and are learned with the same arm. The memory for A is generally examined 24 hours after it is initially learned, and similar initial errors and identical rate of learning at these two times are indicators that the intervening learning of B interfered with consolidation of A. Interference presumably arises because the neural substrates mediating learning of A and B are common, which is not surprising because A and B are of the same type and the same arm is used to learn both. However, recent behavioral, neuroimaging and patient studies indicate that regardless of the arm used, the neural substrates mediating motor learning may be the same, and lateralized to the left brain hemisphere. If this is true, then interference between A and B should be observed even if they are learned with opposite arms. Here we tested this idea by having human subjects first adapt to a counterclockwise 30 degree visuomotor rotation (A) and then to a clockwise rotation of the same magnitude (B) with the opposite arm. After 24 hours, subjects were re-tested on A while using the same arm they used during initial learning. We observed complete interference: subjects showed no memory of A and learned at the same rate upon re-exposure as during initial learning. In contrast, we observed protection of the memory of A in control subjects, who learned A and were re-tested on it 24 hours later without learning B; these subjects showed a smaller initial error as well as a faster rate of re-learning. Thus, learning of B prevented consolidation of A even though they were learned with different arms. To the best of our knowledge, such interference between two motor memories, each of which is developed using a different arm, has not been shown before. Our findings lend further support to the idea of a common, possibly lateralized neural substrate for motor learning independent of the arm used to perform the task.

Title: Predicting BCI accuracy with alpha band analysis

Authors: *A. W. AREF[1], J. E. HUGGINS[2];
[2]Physical Med. and Rehab / Biomed. Engin., [1]The Univ. of Michigan, Ann Arbor, MI

Abstract: Brain-Computer Interfaces (BCIs) provide a direct communication pathway between a user's brain and an external device. They can enable communication for people with severe motor impairments. This study used off-line analysis of recorded data where the BCI was used for letter-by-letter spelling. The selections on the BCI display are flashed randomly, and the BCI makes selections based on the event-related potentials in the user's EEG reaction to each flash. To operate the BCI, the user needs to actively attend to selections on the BCI display. Studies have shown that activity in the EEG alpha frequency band (8-13Hz) is negatively correlated with the user's attention to the current task [1]. In this study, recorded EEG from 25 subjects using the BCI was analyzed to determine the correlation between alpha band power and accuracy of BCI selections. For each subject, recorded data included configuration data and BCI use while copying text with correction of errors. Subjects generated at least 23 characters per sentence, 3 sentences per day, for 3 days. The alpha power during the training run was used as the baseline for each subject. Evaluations were made on multiple time-scales (whole-sentence scale and character-by-character scale). The alpha power during each whole sentence was calculated and compared to the spelling accuracy of each sentence. Also, the alpha power before, during, and after each character selection was calculated and compared to the accuracy of each character (1 for correct and 0 for incorrect). The alpha power calculated before and during each character was deemed statistically significant for correct versus incorrect characters with p-values of 0.0018 and 0.00017, respectively. The alpha power before and during the selection of the character showed the most significance, and thus can be used to possibly predict the accuracy of the selection. Classification methods using the alpha power before and during each character as features to predict the accuracy of individual characters, can be used to predict the accuracy of future selections and to block selections that are likely to be inaccurate. 1. Title: Silent speech recognition system using single-trial EEGs: A silent season BCI

Authors: *T. ITOH[1], H. YAMAGUCHI[2], A. YAMAGUCHI[3], T. YAMAZAKI[4], S.-I. FUKUZUMI[2], T. YAMANOI[5];

Abstract: Objective: The purpose of this study is to generalize our silent speech recognition system (SSRS) using single-trial EEGs previously proposed in terms of Japanese vowel recognition. Methods: During actual speeches (the learning phase) and silent ones (the decoding phase) of “haru”, “natsu”,”aki” or ”huju” in English pronunciation of Japanese, representing for seasons, 13-ch single-trial EEGs were recorded. In the learning phase, a relationship between spectrograms of speech signal and independent components (ICs), which are obtained by applying independent component analysis (ICA) to the EEGs, whose equivalent current dipole (ECD) source solutions are localized to the Broca’s area, is described by Kalman filters (KFs).In the other hand, the spectrograms are transformed into sequence of vowels and consonants by hidden Markov model (HMM). In the decoding phase, the EEGs during the silent speeches are inputted to the learned KFs and “silent spectrograms” are estimated by the KFs, then the HMMs, which the estimated spectrograms are inputted to output log- likelihoods with respect to vowel and consonant transition(s). Finally, by comparisons among the log- likelihood values from each HMM, it is determined which season was silently spoken. Results: As a preliminary result, the accuracy was 86% (“haru”), 29% (“natsu”), 43% (“aki”), and 100%(“huju”) for one subject . Conclusions: This study implies the possibility of recognizing and discriminating four kinds of silent speeches in Japanese. In future, we will obtain better accuracy.

Title: Control of a cursor in two dimensions with one single sEMG signal: Learning a novel motor skill

Authors: *I.-M. SKAVHAUG[1], K. LYONS[1], A. NEMCHUK[2], S. MUROFF[3], S. JOSHI[1]; [1]Mechanical and Aerospace Engin., [2]Psychology, [3]Human Develop., Univ. of California, Davis, Davis, CA

Abstract: We have designed a novel electromyography (EMG)-driven human-computer interface in which a user controls a cursor on a computer screen through low-level muscular contractions. The most novel aspect of our interface is that we create two control channels from one single EMG signal. Subjects achieve two-dimensional control of the cursor by manipulating their EMG power signal in order to simultaneously place a specific amount of power in two separate frequency bands. It is unlikely that this motor skill is needed in any natural body movement. We previously reported a pilot study showing that users can perform this skill using the auricularis superior muscle above the ear. The current study aims to formally study learning in this task from the initial encounter with the device to the end of several practice sessions. A secondary aim of our current study is to investigate this motor skill with a muscle innervated at the spinal cord, rather than the brain stem. 12 naïve able-bodied subjects completed eight one-hour long testing sessions in which they practiced moving a cursor to targets by contracting the extensor pollicis longus muscle located on the wrist. Performance measures included success rates, time-to-target (in seconds) and the percentage of time which the cursor spent in the desired section of the screen during any trial. We show that average subject success rates rapidly improved throughout the first three testing sessions and continued to improve throughout the remaining five sessions (however at a slower rate). At the end of 8 training sessions, the group achieved an 86% success rate for target hitting. Correspondingly, the time-to-target steadily decreased throughout all eight sessions. Most importantly, the percentage of time the cursor spent in the vicinity of the goal target increased significantly across the experiment for both successful and unsuccessful target hits, suggesting that with experience the subjects gained better control of the cursor's movement. Overall, we conclude that subjects significantly increase their ability to use our myoelectric interface throughout a relatively short training program of eight hours.

Title: Control of a cursor in two dimensions with one single sEMG signal: Effects of muscle fatigue

Authors: I.-M. SKAVHAUG, A. G. BARSZAP, *S. S. JOSHI;
Mechanical and Aerospace Engin., Univ. of California, Davis, Davis, CA

Abstract: Electromyography (EMG) has long been employed in prosthetics control, and more recently, EMG has also been utilized in Human-Computer Interfaces (HCI) for the disabled. A common concern relating to all EMG driven devices is the potential loss of performance due to fatigue. Here, we investigate the effects of fatigue on a single muscle-site EMG HCI, in which subjects navigate a cursor to targets by making low level contractions of a muscle. Subjects achieved two-dimensional control of a computer cursor by varying the power in two separate frequency bands (80-100Hz and 130-150Hz) of a single EMG signal. Two groups of four subjects (one group using a head muscle and the other group using a wrist muscle) completed 300 cursor-to-target trials (approximately 3 hours of use without breaks) during which we monitored performance. The wrist muscle group also returned for a second session, in which they completed an additional static fatigue-inducing exercise between each block of thirty trials. We did not observe any clear evidence of fatigue during the first session (for either group). During the second session (with fatiguing exercises) subjects' performance declined steadily towards the end of the experiment and we also observed an apparent difficulty in moving the cursor in the y-direction. This specific change in cursor trajectories was consistent with a shift of the median frequency towards the left in the power spectrum. This type of spectral compression has been reported previously in the literature for static isometric contraction (as opposed to our case which is a dynamic low level contraction). We conclude that fatigue is not a major concern

during normal use of our EMG-driven interface, but may be problematic after unlikely extreme and sustained use.

Title: Neurophysiological correlates of mind-wandering, towards a predictive BCI

Authors: *A. MARTEL[1], P. DOCKREE[2], I. ROBERSTON[3];
[2]TCD Sch. of Psychology, [3]TCD Inst. of Neurosci., [1]Trinity Col. Dublin, Dublin, Ireland

Abstract: Neuroscientific evidence has determined that our ability to remain attentive to a task, over a prolonged period of time, is subject to strong fluctuations. Recent electroencephalography (EEG) studies have identified neurophysiological signals reflecting inadequate task engagement preceding attentional lapses. Smallwood et al. (2008) investigated mind-wandering episodes on subjects performing the sustained attention to response task (SART) (Robertson et al. 1997), with thought probes and unveiled a significant reduction of the P300 amplitude during the reported mind-wandering episodes relative to the on-task periods. O'Connell et al. (2009) observed a modulation of the α-activity 20 s and of the P3 four to five s before a lapse of attention in a temporal expectancy task. Martel et al. (2014) found a decrease in P3 amplitude and increase in α-activity foreshadowing a miss by up to 10 s in a covert sustained attention task. Lapses of attention during mind-wandering episodes are the result of a withdrawal of attention from the task at hand towards internal, self-generated thought processes, or personal information such as memories (Smallwood et al. 2006). The present study recorded EEG, pupillometry, respiration and galvanic skin response (GSR) of twenty-six participants during a breath-counting task and a fixed version of SART with thought probes. During the breath counting-task subjects fixated on a cross while counting each inhalation from 1 to 9, pressing the left mouse button for 1 to 8 and the right button when reaching 9 before starting counting again. The SART presented participants with numbers from 1 to 9 sequentially and required them to respond for all numbers except 6, for which they were required to withhold response. Thought probes would randomly interrupt the task after 30 to 120 s on-task and prompt subjects to report whether their attention

was on-task, on thoughts related to the task, distracted by exogenous or endogenous stimuli, on planning or reminiscing, or on daydreams. Subjects were also instructed to interrupt the task if they caught themselves being inattentive. Preliminary results corroborate previous finding of P3 amplitude attenuation and differences in oscillatory activity between on-task and mind-wandering episodes. Additional analysis with Brain-computer interface (BCI) methods (SPoC - Dähne et al. 2014 & CSP - Blankertz et al. 2008) will determine whether mind-wandering episodes can be predicted in real-time and inform the participant for prospective use in a Neurofeedback training (NFT).

Title: Cortical incorporation of virtual legs in Spinal Cord Injured patients

Authors: R. MOIOLI[1], S. SHOKUR[2], S. GALLO[3], F. BRASIL[1], *E. MORYA[1], M. NICOLELIS[4,1,5];
[1]Edmond and Lily Safra Intl. Inst. of Neurosci., Inst. Santos Dumont, Macaiba, Brazil; [2]AASDAP, Sao Paulo, Brazil; [3]EPFL, Lausane, Switzerland; [4]Neurobiology, Biomed. Engineering, Psychology and Neurosci., [5]Duke Ctr. for Neuroengineering, Duke Univ., Durham, NC

Abstract: Spinal cord injury (SCI) induces spontaneous plastic reorganization of the body representation at cortical level. Here, we studied whether incorporation of a virtual body part related to an actual paralyzed leg could become part of a novel neurorehabilitation paradigm towards restoring mobility in paraplegic patients. Eight SCI paraplegic subjects (seven complete ASIA A and one incomplete lesion ASIA B) signed a consent form (IRB 364.027), and

underwent virtual reality walking sessions while their EEG was recorded. To perform this task they wore an immersive virtual reality head mounted display. Subjects observed legs of an avatar overlapped with their own as if they were continuation of their physical body. Tactile feedback from the virtual limbs was delivered using a haptic display attached to the subjects' forearm skin surface. Such feedback was delivered in accordance with the avatar walking. EEG recording was synchronized with the delivery of tactile feedback while the avatar walked. Visuo-tactile related cortical reorganization was detected in sensory-motor and multi-sensory brain areas. These findings are in accordance with previous observations during incorporation of an external body part. Therefore, we propose that sensory substitution (using the forearm to map feedback from legs) can be used to embed a new cortical representation of lower limbs, via assimilation of avatar limbs, and help in the process of neurorehabilitation of these patients.

Title: Inducing paraplegic patients to perceive distinct ground textures using tactile feedback generated by virtual feet

Authors: *S. SHOKUR[1], S. GALLO[2], R. MOIOLI[3], M. BOURI[2], E. MORYA[3], H. BLEULER[2], M. LAPORTA NICOLELIS[3,4,5];

For Neuroscienc, Macaiba, Brazil; [4]Neurobiology, Biomed. Engineering, Psychology and Neurosci., Duke Univ., Durham, NC; [5]Duke Ctr. for Neuroengineering, Durham, NC

Abstract: Spinal Cord Injury (SCI) induces bidirectional loss of communication between the brain and the body and between the brain and the external world. SCI patients neither control nor sense the body below the level of their injuries. We have proposed a solution for functional restoring sensory-motor control during locomotion for paraplegic patients (M.A.L. Nicolelis et al. The Walk Again Project: Using a Brain-Machine Interface for establishing a bi-directional Interaction between paraplegic subjects and a lower limb exoskeleton. Program No. 636.18/MM25. Neuroscience 2014 Abstracts. Wahsington, DC: Society for Neuroscience, 2014. Online). Eight SCI patients (seven with complete injury (ASIA A) and one with incomplete injury (ASIA B)) were trained to walk both in a simulated virtual environment and with a custom exoskeleton by imagining leg movements. Tactile feedback from the exoskeleton's feet surface was remapped on the patients forearm using arrays of mechanovibrators. Patients could rely on this tactile feedback to sense the position of the leg and the exo's contact with the floor. Here, we show how, by changing parameters of the tactile feedback, patients experienced the sensation of walking on different ground surfaces, such as: beach sand, a paved street or a grass field. For each patient, ten thousand combinations of tactile feedback were obtained by varying the amplitude, the duration and the time between vibrations. Patients were asked to select among all possible combinations the ones that corresponded to the sensation of walking on the aforementioned ground types while looking to an avatar walking on the corresponding ground or on a neutral black ground. The majority of the patients could find a combination of vibrotactile parameters that gave them a realistic sensation of walking on the selected ground. Patients' ground choices usually relate to the tactile sensation experienced at the very end of the stance phase. Overall, ground parameters were similar among groups of patients, suggesting that, despite being paralyzed for many years, patients shared similar representations of ground surface. We propose that future neuroprosthetics for locomotion will have to incorporate tactile feedback to achieve optimal performance and for provide patients with more realistic walking sensations. Abstract: Spinal cord injury (SCI) is considered a public health challenge, with devastating consequences on the subject himself. Here, we investigated the clinical effects of a novel neuroreabilitation program for paraplegic patients based on the concept of brain-machine interfaces (BMI). Eight subjects with chronic spinal cord injury (paraplegia) participated in the study, seven of them with complete injury (ASIA A) and one with incomplete injury (ASIA B). They pursued an intensive training for twelve months with activities included traditional physical therapy exercises, body-weight support (BWS) system for gait training (BWS ambulation on a treadmill and BWS ambulation on a fixed overground track), but also a brain-controlled robotic gait (or Brain Machine Interface BMI) training triggered by EEG and with the sensory support of tactile feedback. Patients' physical and emotional levels were assessed during twelve months. After 12 months of training, patients showed better control of intestinal function and improvements of the cardiovascular and neurological systems. Most patients also regained some muscular activities below the level of SCI. They also exhibited an increase of the somatosensory sensitivity below the level of SCI and an improvement in the zone of partial pain tactile sensation. As a result of this neurological improvement, three of the subjects moved from a complete (ASIA A) to incomplete (ASIA C) injury classification. These results suggest that chronic BMI utilization may lead to a degree of neurological improvement. Further studies are under way to clarify the potential mechanism underlying the neurological recovery observed here.

Abstract: By establishing direct communication between a subject's brain and external actuators, brain-machine interface (BMIs) have been heralded as potential new therapeutic alternatives for spinal cord injury (SCI). Here we tested a BMI in which EEG signals were decoded in real time to detect voluntary movement of legs and control a custom brain-controlled exoskeleton (EXO). Our EXO uses an hydraulic pump and transmission to ensure patient's balance and control of autonomous bipedal locomotion, without the need for auxiliary tools, such as crutches. Six SCI patients (five of them with complete injury (ASIA A) and one with incomplete injury (ASIA B)) participated in this study. They were instructed to imagine moving their left and right legs to control the forward stepping of the ipsilateral EXO legs. By alternating the left and right motor imagery, all patients became proficient in controlling the EXO during walking. This was achieved by using a shared-control mode of EXO operation in which, patients were in charge of high level walking commands, while the EXO calculated the low level kinematics and balance/stability control. Our results demonstrate the feasibility of using a brain-controlled EXO as an assistive walking device for SCI patients. Acknowledgments: The authors thank Alberto Santos Dumont Association for Research Support (AASDAP), Finep and the 156 people involved in this project.

Inst. of Neurosci., Macaíba, Brazil; [5]Neurobiology, Biomed. Engineering, Psychology and Neurosci., [6]Co-Director, Duke Ctr. for Neuroengineering, Duke Univ., Durham, NC

Abstract: Five spinal cord injury (SCI) patients (four with complete lesions and one with an incomplete lesion) were trained to use their cortical activity, recorded using EEG, to control the movements of virtual avatar legs seen from their first person perspective through a head mounted display. Every time the avatar feet touched a virtual floor, patients received tactile feedback describing that contact. Tactile feedback was delivered through three mechano-vibrating elements placed on each of the patient's legs; two on the knee and one on the hip. While our patients could not directly feel feedback on their leg skin, all of them reported feeling the vibrations when they were applied over the bone. EEG was recorded and decoded in real time while patients were instructed to imagine the avatar as part of their body and move the virtual left and right legs in an alternated sequence. Detection of leg motor imagery in the EEG was

used to trigger the movement of the corresponding leg on the avatar. Patients successfully learned to control both the avatar walking and stopping in this virtual environment. Following a session where a synchronous visuo-tactile feedback was delivered, two patients improved the ability to discriminate between different vibrator positions. Acknowledgments: The authors thank Alberto Santos Dumont Association for Research Support (AASDAP), Finep and the 156 people involved in this project.

Title: A longitudinal evaluation of SSVEP-BMI in patients with ALS

Authors: K. TAKANO[1], T. KOMATSU[1], M. NAGAO[2], K. KONDO[3], *K. KANSAKU[1,4]; [1]Sys Neurosci Sect, Dept of Rehab For Brain Funct, Res. Inst. Natl. Rehab Cent, Saitama, Japan; [2]Dept. of Neurol., Tokyo Metropolitan Neurolog. Hosp., Tokyo, Japan; [3]Dept. of Neurol., Yoka Hosp., Hyogo, Japan; [4]Brain Sci. Inspired Life Support Res. Center, The Univ. of Electro-Communications, Tokyo, Japan

Abstract: Brain-machine interface (BMI) or brain-computer interface (BCI) is an interface technology that utilizes neurophysiological signals from the brain to control external machines or computers. We have developed a P300-based BMI system to support daily activities of persons with disabilities, and found that green/blue chromatic and luminance flicker matrices improved the BMI performance (Takano et al., 2009). We showed that the P300-based BMI can be satisfactorily used by patients with spinal cord injury and amyotrophic lateral sclerosis (ALS) (Ikegami et al., 2011; 2014). We also showed that the use of high-frequency visual stimuli provided high classification accuracy in a steady-state visual evoked potential (SSVEP)-based BMI (Sakurada et al., 2015). In this study, we used a high-frequency SSVEP-based BMI system,

and tested the system for six months (longitudinal evaluation). We performed the experiments once every 1 or 2 weeks. To elicit SSVEPs, we prepared a light-emitting diode (LED) flicker using a visual stimulus apparatus with green/blue LEDs covered by a diffusion board. This system consisted of a PC, an EEG amplifier and 1-3 LEDs (34 to 54 Hz). Single channel (Oz) EEG data was recorded with in-house caps and solid-gel electrodes (Toyama et al., 2012). The EEG was digitized at a rate of 1024 Hz and stored. The SSVEP-based BMI performance was evaluated by calculating the power of the EEG data. Three ALS patients (2 males, 37-64 years old, ALSFRS-R = 0) participated in this study. One of the patients could not use the augmentative and alternative communication (AAC) devices and other patients were able to control conventional AAC devices. The mean accuracy of all experiments was 79.1% (n=3). At the first one-month measurement, the accuracy of each patient was 75.0%, 67.0% and 75.0%, respectively, and at the last one-month measurement, the accuracy of each patient was improved to 85.4%, 91.7% and 89.6%, respectively. Note that one of the patients could not use AAC devices but was able to use our system with practical accuracy (>70%). In this longitudinal evaluation, the ALS patients were able to use the SSVEP-BMI system satisfactorily. This suggests that the SSVEP-BMI system is beneficial in patients with ALS.

Title: Performance comparison of color and grey-white paradigms in undergraduates and older adults using the brain-computer interface

Authors: ***S. SPRAGUE**, D. B. RYAN, M. R. KELLICUT-JONES, T. L. STREET, E. W. SELLERS;
Psychology, East Tennessee State Univ., Johnson City, TN

Abstract: Amyotrophic lateral sclerosis and other neurodegenerative disorders can cause individuals to lose control of their muscles until they are unable to move or communicate. Brain-computer interfaces (BCIs) can provide an alternative method of communication that does not require muscle movement; however, BCI provides a slow form of communication. Therefore, many researchers focus on increasing speed and accuracy. One method for increasing the speed and accuracy of the BCI is by creating and manipulating the paradigms that control how the stimuli are presented. The aim of the present study is to compare the speed and accuracy of two different presentation paradigms in two non-disabled populations: traditional college aged students and those over the age of 45. The first experimental paradigm presents grey characters that change to white. The second paradigm presents color characters that temporarily disappear. Hypothesis 1: Younger participants would score better on performance measures than older adults. Hypothesis 2: Participants would score better on performance measures in the color paradigm than in the grey-white paradigm. We compared three performance measures: accuracy, speed, and bit rate. None of the three measures showed statistically significant differences by group, nor was the accuracy measure statistically significant by condition. On the other hand, both the young and older groups were able to make selections significantly faster in the color condition than in the grey-white condition. Moreover, both the young and older groups had higher bit rates in the color condition. Participants also completed a preference survey after each condition. The survey included three questions: I was able to focus on the target item; non-target items were distracting; and it was difficult to see all the target flashes. Participants used a Likert scale to indicate whether they strongly disagreed (1) with each statement or strongly agreed (7). Despite being able to make selections significantly faster in the color condition as well as higher bit rates, the survey items did not reveal a preference for one condition over the other. More data is needed in order to determine which paradigm is superior in both accuracy and preference.

Title: Utilizing visual attention and inclination to facilitate brain-computer interface design in an amyotrophic lateral sclerosis and college age sample

Authors: *D. RYAN[1], M. L. MORTON[2], E. W. SELLERS[2];
[2]Psychology, [1]East Tennessee State Univ., Johnson City, TN

Abstract: Thus far research has not addressed the issue of finding the optimal paradigm to fit an individual's visual attention abilities. Traditionally, in-home BCI applications rarely deviate from a "standard" paradigm. The norm to improve poor performance is a trial and error method, which is only employed in patient populations. This study proposes to identify the best paradigm for an individual by systematically manipulating flash type, stimulus size, and flash duration. We hypothesize that this method will reveal an optimal paradigm that outperforms a standard (control) paradigm. Additionally, the majority of BCI research is conducted with college age (18-22 years) participants. This is an issue because there are well documented changes in the ERP responses as a result of age (Braver et al., 2001; West, Schwarb, & Johnson 2010). Furthermore, there could be changes to the P300 and other ERP components as a result of ALS progression. To examine these changes and their potential influence on BCI performance, we have collected data from participants with ALS and from college age participants. The results from t-tests within participant groups showed that participants with ALS had a significant increase in BCI performance in the optimal condition over the standard condition. The college age participants did not show any significant performance differences between conditions. In a 2x2 repeated measures analysis (participant groups x conditions) we found a main effect of Accuracy, main effect of Logit transform of accuracy, and a main effect of Survey. These results show that the method used to examine the BCI performance and personal preference resulted in an optimal paradigm that was better by performance and preference measures compared to the standard paradigm. When examining the waveforms from the control condition (to keep stimuli consistent) we see that college age participants have stronger ERP amplitude responses than those with ALS. This stronger response allows the classifier to make higher accuracy discriminations between target and nontarget responses with less data (i.e., less flashes). Thus, higher amplitude ERP responses and BCI performance from younger participants do not accurately reflect the ERP responses and performance found in an ALS sample. Therefore, BCI research should shift its focus to an ALS population or at least age-matched control participants rather than college age participants.

Title: P300 brain-computer interface:comparing faces and size-matched non-face stimuli

Authors: ***M. R. KELLICUT**[1], C. M. COFFMAN[2], D. B. RYAN[2], E. W. SELLERS[2];
[2]Psychology, [1]East Tennessee State Univ., Johnson City, TN

Abstract: Non-invasive Brain Computer Interface (BCI) technology can restore communication for those who are no longer able to communicate to due loss of muscle control. Nonetheless, in comparison to other methods of non-muscular communication, such as an eye tracker, BCIs provide relatively slow communication. Therefore, it is important to implement techniques that can improve both accuracy and speed of BCI performance. One method of improving accuracy in BCI performance has been the presentation of familiar faces rather than the canonical presentation whereby the characters in an alphanumeric display change from grey to white. Previous studies have shown that in addition to the P300 event-related potential component faces elicits the N170 and N400 components. The addition of these components can increase the speed and accuracy with which items can be selected from the display. Previous studies have used face stimuli that are typically much larger than the items contained in the display. The purpose of the present study was to investigate the influence of image size and image content. Based on the results of previous studies, we predicted that faces would provide higher accuracy than non-face stimuli. To test this hypothesis we designed four conditions: large face stimuli, small face stimuli, large non-face stimuli, and small non-face stimuli. The familiar image of Albert Einstein sticking his tongue out was used as the face image. The non-face image was constructed using a crystalize filter (Photoshop CS5.5) and rotating it 180 degrees, thereby preserving the image content while making the stimulus unrecognizable as a face. The “checkerboard” paradigm was used to present stimuli and a Latin square design was used to determine the order of presentation: The preliminary data indicate there are no statistically significant differences between the four conditions. Nevertheless, mean accuracy in the small crystalized stimulus condition was higher than the small face, large face, and large crystalized conditions. Additional data will be collected to further test the hypothesis that face stimuli provide higher rates of speed and accuracy.

Title: How individual is low-voltage brain stimulation, rebound or entrainment? The influence of 10 Hz alternating current stimulation on the individual alpha rhythm

Authors: *S. SCHMIDT[1], L. HABERBOSCH[2], A. JOOß[2], A. KÖHN[2], M. SCHOLZ[3], K. OBERMAYER[3], S. A. BRANDT[2];
[1]Vision & Motor Res. Group, Berlin, Germany; [2]Neurol., Charité Universitätsmedizin - Berlin, Berlin, Germany; [3]Neural Information Processing Group, Univ. of Technol., Berlin, Germany

Abstract: Introduction: Alternating current stimulation (ACS) is an established means to modulate neural oscillations. Retinofugal alternating current stimulation (rtACS) is a novel and promising application of ACS. It has shown effects on neural oscillations outlasting the stimulation duration and allows investigation of stimulation effects in the well-circumscribed visual system. Neuromodulatory effects of ACS have been associated with significant behavioral and clinical impact, but the mechanism of action remains unclear and the notion of individualized stimulation unresolved. Possibilities include neuronal entrainment as well as rebound phenomena. A possible frequency peak shift from individual alpha towards the stimulation frequency would contribute to the discussion and support the notion of entrainment. The lack of a shift supports the notion of post-inhibitory rebound. Therefore, we investigated the alpha band peak before and after 10 Hz electric (rtACS) and photic stimulation ("photic driving"). Methods: To address this question, we stimulated 8 healthy subjects with "photic driving" or rtACS at a frequency of 10 Hz while recording EEG. Prior to stimulation, we assessed electrode impedances and phosphene thresholds and recorded a resting state EEG. We then applied rtACS in 6 blocks of 30s stimulation. We then assessed the spectral alpha power as well as the alpha peak frequency (individual alpha) over the occipital electrodes during baseline and 30s after stimulation and compared the two in a repeated-measure ANOVA. Results: A significant enhancement of α power was found during as well as after photic and electric stimulation. The alpha peak frequency changed by a mean 0.02 Hz (+/- 0.04) following rtACS and 0.03 Hz (+/- 0.05)) following photic driving. There was no evidence for a significant frequency peak shift or an association between stimulation frequency and alpha power change. Conclusions: The data at hand provides evidence against entrainment effects better in line with post-inhibitory rebound. Post-inhibitory rebound could provide stabilization and enhancement of an intrinsic frequency following a period of inhibition. Still, previous data suggest that post-inhibitory rebound is possibly not well equipped to explain neuromodulatory effects or photic

driving. As neural oscillators share features of both harmonic and relaxation oscillators, one mechanism of action may be a combination of both entrainment and rebound, where short periods of exogenous entrainment are followed by a rebound-like recruitment of similarly patterned endogenous oscillators.

Title: The stationary brain? -adaptive, feedback controlled electric stimulation, a case study-

Authors: *M. SCHOLZ[1], S. SCHMIDT[2], L. HABERBOSCH[2], A. JOOß[2], S. A. BRANDT[2], K. OBERMAYER[1];
[1]Univ. of Technol. Berlin, Berlin, Germany; [2]Dept. of Neurol., Charité-Universitätsmedizin, Berlin, Germany

Abstract: Our brain is a highly dynamic system. Transcranial and -orbital electric stimulation is a promising technique to help the beneficial reorganization of disease affected parts of the brain, from stroke to insomnia, visual to motoric deficits, spanning a wide field of possible clinical or even homecare applications. The used current could be DC (tDCS), AC (tACS) or random (tRNS) and is generally applied over 10-20min. Although the literature is somewhat controversial, common to most publications is a high percentage of “non-responders” and a static stimulation scheme, which is not adapted throughout the experiment. However, due to the intrinsic plasticity of the brain and its highly dynamic behavior, described but not precisely defined as “brain states” it seems likely, that the stimulation itself should change during the course of an experiment/treatment to reflect altered brain states and progress of learning. We address this here by using a new, selfadapting stimulation paradigm characterized by repeating short (~5s) cycles of stimulation and measurement. To be able to adapt the stimulus quickly on the fly, the following prerequisites must be met: i) a fast (under a second) evaluable state

variable, such as amplitude power in a specific frequency or cortico-muscular coherence, ii) a proof-of-principle that repeated short term stimulations have a comparable effect as 10min static stimulations and iii) a noise robust optimization scheme, such as evolutionary algorithms. As a testbed for this scheme, we used a well understood paradigm. Stimulating the optic nerve with 2 transorbital electrodes with 5-15Hz sine waves we analyze resulting alpha burst power in eyes open and closed conditions differentiating between rebound and entrainment, comparing it to classical long term stimulation. Since the Berger phenomenon is very stable and well understood, this scenario was chosen to show the reliability and robustness of such a closed-loop paradigm, because little is known about expected behavior and ground truth for other subsystems of the healthy brain. Where science still lacks a mathematical good description of the state trajectories of a healthy brain, things become even more speculative in the much more challenging field of stroke rehabilitation, where the brain is not normal or healthy. Even if we could reliably estimate which exact stimulus causes a specific behavioral change, it seems unjustified to assume that this will hold for a trauma induced change. With our proposed closed-loop approach not only subject specific differences but also such gross structural (brain) system changes could be successfully addressed as is the case in stroke restitution.

Title: Quantification of target population for communication brain computer interfaces in the Netherlands

Authors: ***E. G. M. PELS**, E. J. AARNOUTSE, M. J. VANSTEENSEL, N. F. RAMSEY; Brain Ctr. Rudolf Magnus, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: The target population for brain computer interfaces (BCI) for communication is predominantly described as locked-in syndrome (LIS) patients (Birbaumer et al 2008). From a BCI point of view, this population encompasses all patients with severe communication impairment due to severe paralysis regardless of the etiology. The medical definition of LIS is

exclusively defined by lesions in the ventral pons, not by the level of functioning or the needs of the patient (Meienberg et al 1979, Balami et al 2013). The constrained definition of LIS poses an obstacle for developers of communication BCIs and for other stakeholders like caregivers, families and companies, who stand to benefit from a more inclusive definition of the patient population for care, information and assistive technology development. Therefore we argue that in order to quantify the target population for BCIs all patients that function on the level of LIS (fLIS) should be considered, disregarding etiology. Efforts to calculate LIS prevalence before (Kohnen et al 2013; Snoeys et al 2013) only partially succeeded To estimate prevalence of fLIS, we sent out a letter to all, 8783, general practitioners (GPs) in the Netherlands covering the whole population (16 829 289; Statistics Netherlands, 2014) asking whether they were treating a patient with severe paralysis. The response rate was 15.5%, a subset of which responded affirmative. Those GPs were subsequently approached by telephone and asked to complete a questionnaire consisting of 22 items on the level of functioning, the cause of paralysis and the type of care and assistive technology used. After screening 11 patients were labeled with fLIS. An extrapolation of these results indicate a prevalence of 0.42 cases per 100 000 inhabitants. Moreover, the results of the questionnaires indicate, regardless of the cause of disability, care is similar, e.g. most patients are dependent on tube-feeding and most patients rely on homecare and artificial ventilation. Communication on the other hand showed a very diverse landscape. A wide range of alternative communication devices are used: eye trackers, mouth-stick, (spoken) letter boards and EEG/EMG device. The current research shows that there is a significant population in the Netherlands that functions on the level of LIS. Furthermore, care needed by patients is similar. Labeling the population by function and needs would help patients, caregivers and augmented alternative communication developers to gain coherence and visibility.

Title: EEG decoding of Arm reaching and hand movements

Authors: *F. SHIMAN[1,2,3], N. IRASTORZA-LANDA[2,3], A. SARASOLA[2,3], M. SPÜLER[4], N. BIRBAUMER[2,5], A. RAMOS-MURGUIALDAY[2,6];

Abstract: The ability of Brain-Computer Interface (BCI) systems to decode functional movement parameters based on electroencephalographic (EEG) data to control a robotic exoskeleton in post-stroke rehabilitation is of clinical importance. Most of the previous studies have addressed the classification of two or three classes mainly using imagery or motion or different limbs or within same limb for characterization of two classes. To date, there are not many studies exploring the decoding of functional hand movements from the same limb. We designed and developed an experiment to investigate functional upper limb movements attaching a newly developed exoskeleton to healthy volunteers upper limb. This study explores EEG decoding during a three-dimensional (3D) center-out arm reaching (four directions and Rest) and five hand movements (grasp, pinching, pointing, pronation, supination), all executed with the same limb. Nine healthy volunteers underwent EEG recordings in 4 sessions. Data was preprocessed and artifacts were eliminated. We used a 5-class BCI design to classify EEG signals related to four directions and Rest, and 6-class design for five different hand grasping movements and Rest based on a multi class extension of Spectrally Weighted Common Spatial Patterns (Spec-CSP) and a linear discriminant analysis (LDA) classifier. For illustrative purposes, we compared the r2 values as feature maps at individual frequencies and channel

locations between two tasks and performed also a topographical distribution analysis of Spec-CSP patterns of each condition-pair. Decoding accuracies were 39.5% (chancel level of 20%) and 24.6% (chance level of 16.6%) for the 5-class directional movements and the 6-class hand movements, respectively. The confusion matrices showed that space resolution (neighbored movements confused) and similar hand configurations were the main limitation for our decoding approach during direction and grasping movement respectively. These results were significantly above chance level and indicate that multiple functional movements classification from the same limb may be possible using EEG data, although further experiments are needed to leverage these results to a more functional level. We propose the combination of "less confused" functional movement and a probabilistic output method to improve functional upper limb movements classification using EEG data.

Title: Effective connectivity analysis of brain regions responsive to non-invasive vagus nerve stimulation in humans

Authors: *E. FRANGOS, B. R. KOMISARUK;
Dept. of Psychology, Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: We recently published fMRI evidence (Frangos et al., Brain Stimul., 2014, doi:10.1016/j.brs.2014.11.018) that a non-invasive approach to vagus nerve stimulation activates the classical central projections of the vagus nerve including regions that have a neuromodulatory role in pain, depression, and epilepsy. The present study was undertaken to analyze the connectivity pattern within networks that may mediate the therapeutic effects of vagal input. The analysis was performed with IMaGES (Independent Multisample Greedy Equivalence Search) using the fMRI timecourse data of healthy participants who underwent non-

invasive vagus nerve stimulation. Using this approach on brain regions that respond to, and modulate, pain (e.g., periaqueductal gray, anterior cingulate, insula, thalamus, and somatosensory cortex), we found that vagal input shifts the connectivity pattern in a "bottom-up" direction (i.e.,, lower brainstem regions to forebrain regions) compared to rest. This pattern persists into the post-stimulation period, which is consistent with the persisting effects of vagal stimulation. This analysis can provide insight on the underlying mechanism of action of vagus nerve stimulation and a basis for comparison with patient populations responsive to vagus stimulation.

Title: Neurofeedback training improves decoding accuracy in MEG/SSVEF

Authors: *H. ORA[1,2], K. KANSAKU[1,2];
[1]Sys. Neurosci. Sect., Dept. of Rehab. for Brain Funct., Res. Inst. of Natl. Rehabil. Ctr., Tokorozawa, Japan; [2]Brain Sci. Inspired Life Support Res. Ctr., The Univ. of Electro-Communications, Chofu, Japan

Abstract: A decoded neurofeedback method was recently proposed to lead brain activity to a target state by using functional magnetic resonance imaging (Shibata, et al., 2011). Real-time magnetoencephalography (rtMEG) is an emerging neurofeedback technology that could potentially benefit multiple areas of basic and clinical neuroscience, and we have applied an rtMEG system to perform decoded neurofeedback training of the MEG/steady-state visual evoked field (SSVEF). Eight able-bodied participants (age 33.8 years old, 7 females) participated in this study. We first conducted an SSVEF task (pre-training SSVEF task). In the task, the visual stimuli were displayed on a screen in front of the participant, and consisted of a circular checkerboard patch on the left and a circular checkerboard patch on the right. The checkerboard

patches flickered at 5Hz (left) or 6Hz (right). They were asked to attend to the left, right, or middle of the screen in the SSVEF task. A 306-channel Elekta Neuromag MEG scanner was used (Elekta Oy, Helsinki, Finland). We then constructed a sparse multinomial logistic regression (SMLR) decoder from the MEG signals during the SSVEF task of each participant. After constructing the decoder, an MEG neurofeedback training was conducted to improve the decoding accuracy for either right or left orientation. The orientation that showed lower decoding accuracy was selected as a target. In the training, a white fixation cross at the center of the screen was turned green for 5 second, then a green solid circle, whose radius indicated the score of the SMLR decoder, was presented. Participants were asked to "somehow regulate your brain activity to make the green solid circle bigger while the fixation cross is green". During the training, any flickering visual stimuli were not presented. After the training, the SSVEF task was used again to evaluate the training effects (post-training SSVEF task). The experiment for each participant was performed in one day. In the pre-training SSVEF task to construct decoders, accuracy for the target orientation was significantly lower than that for the non-target orientation ($p<0.05$). In the post-training SSVEF task, accuracy for the target orientation and for the non-target orientation were not significantly different. The degree of improvement of accuracy for the target orientation was positively correlated with mean score of the SMLR decoder during training ($p<0.05$). The results suggest that the decoded neurofeedback training performed in one day was effective for MEG/SSVEF, and the method may be useful to enhance robustness of steady-state visual evoked potential-based Brain-Computer Interface.

Abstract: Action understanding and action production are essential to developing socio-cognitive skills early in life. The neural basis of action understanding and the production of goal-oriented actions has been attributed to a postulated mirror neuron system (MNS) in human adults. However, little is known about the development of the MNS in human infants during unconstrained social interactions, in part due to the challenges associated with recording behavior and neural activity in freely behaving infants. To overcome these challenges, we propose a multi-modal neural decoding approach that integrates high-density scalp electroencephalography (EEG), inertial sensors and machine learning methods to study the emergence of the MNS in 6-24 month-old infants. Neural classifiers were trained to infer action intentions from time-domain features while the participants freely engaged in social interaction with an adult experimenter. EEG data was cleaned using Artifact Subspace Reconstruction (ASR), band-pass filtered in the delta (1 - 4 Hz) and alpha bands (6 - 9 Hz), and standardized. A neural classifier based on locality-preserving Fisher's discriminant analysis and Gaussian mixture models was deployed and cross-validated to infer behavioral output from scalp EEG in each infant. We applied the minimum Redundancy-Maximum Relevance (mRMR) algorithm to determine the channels relevant for classification of the behaviors displayed. Overall mean classification accuracies from a cohort of typically developing healthy infants (N= 9, age range = 6 - 23 months; 5 males/4 females) ranged from 59% - 95.5% (with 83.4% median accuracy), which was well above chance-level even when considering the number of classes used for classification. As expected, class number increased as a function of age from 3 at 6 months to 6 at 23 months, whereas imitation actions emerged around the age of 9 to 11 months. mRMR results showed that features most relevant to decoding included neural activity over fronto-central and posterior scalp areas occurring at lags 30 - 50 ms before movement onset attesting to their predictive nature. Overall, these findings show the feasibility of decoding behavior 'in action and context' during social interaction from noninvasively acquired delta and mu-band neural activity in freely behaving infants for the first two years of life. This research is supported by NIH NICHD Award PO1HD064653.

Title: Deciphering brain oscillations during motor rehabilitation tasks

Authors: *A. RAMOS MURGUIALDAY[1], N. BIRBAUMER[2];
[2]Inst. of Med. Psychology and behavioral Neurobio., [1]Univ. of Tubingen, Tubingen, Germany

Abstract: Stroke non-invasive Brain-Computer-Interfaces (BCI) coupled with robotic exoskeletons were recently and successfully used in motor rehabilitation of chronic stroke patients (Ramos-Murguialday et al 2013). Motor rehabilitation involves several motor actions during training that could influence and may limit the use of BCIs for this purpose. We investigated the neurophysiological correlates of an EEG-oscillations-driven BCI combined with a robotic orthosis to define, if existing, the specific oscillatory signature of the proprioceptive BCI-task. Controlling movements of a hand robotic exoskeleton using motor imagery of the same movement generates sensorimotor rhythm oscillations due to motor components common to stroke motor rehabilitation: passive and active movement and motor imagery or motor intention. We recorded EEG while 9 healthy volunteers performed five different motor tasks consisting of closing and opening of the hand: 1) motor imagery without any feedback and without hand movement, 2) motor imagery based BCI, which moves the orthosis proportional to the produced brain oscillation change and provides online proprioceptive and visual feedback of the hand moving (BCI-condition, see Ramos-Murguialday et al 2012), 3) passive and 4) active movement of the hand with feedback (seeing and feeling the hand moving) and 5) rest. During the BCI-condition (2) participants received contingent on-line feedback of the decrease of power of the sensorimotor rhythm which induced orthosis movement and therefore proprioceptive and visual information from the moving hand. We analyzed brain activity using time-frequency domain bootstrap based statistical comparisons and Morlet transforms. Activity during rest was used as reference. Significant contralateral and ipsilateral decrease of sensorimotor rhythm power was present during all motor tasks, largest in contralateral-post-central, medio-central and ipsilateral-pre-central areas identifying the ipsilateral pre-central cortex as an integral part of motor regulation. We identified EEG features (spatial-time-frequency) representing active and passive motor oscillatory signatures differentiating brain oscillations during motor tasks that could substantially optimize the design of novel motor BCI-based rehabilitation therapies. Furthermore, the BCI task presented brain oscillatory signatures not present in the other motor tasks indicating neural processes unique to the use of body actuators control in a BCI-context.

Title: Identification of the brain activity driving the lower muscles used during locomotion

Authors: ***S. TAKEDA**[1], S. KASUGA[2], J. USHIBA[3];
[1]Grad. Sch. of Sci. and Technol., Keio Univ., Kanagawa, Japan; [2]Dept. of Rehabil. Medicine, Keio Univ. Sch. of Med., Tokyo, Japan; [3]Dept. of Biosci. and Informatics, Keio Univ., Fac. of Sci. and Technol., Kanagawa, Japan

Abstract: Corticospinal tract (CST) plays an important role for voluntary control of foot movements during locomotion. In severe stroke patients, the ability for voluntary control during locomotion is markedly impaired because their CST is damaged. However, there are few rehabilitation measures to restore CST function for such disability. Recently, Brain-Machine Interface (BMI) system for stroke upper-limb rehabilitation has received much attention as an expected technology to restore CST function. In this system, when BMI detects characteristic brain activities such as a change in sensorimotor rhythm, a prosthesis assists to move a patient's paralyzed hand. Such processes are considered to help regain normal neural activities and enhance CST excitability accompanying intent for upper-limb movements, through multiple learning mechanisms. Thus we hypothesized that BMI system to enhance CST excitability may also be applied to repair voluntary foot movements. However, features of brain activities reflecting intent for foot movements have yet to be identified. In the current study, we aimed at identifying an electroencephalogram (EEG) biomarker reflecting voluntary activation of the rectus femoris, which is the muscle mainly used for the starting of walking, in both healthy individuals and stroke patients. In addition, we validated if this biomarker reflected CST excitability by using Transcranial Magnetic Stimulation (TMS). One hundred and twenty nine channels of scalp EEGs were recorded during either motor execution (experiment 1) or imagery (experiment 2) of foot movements from thirteen healthy individuals and five stroke patients in total. In experiment 1, to identify the EEG biomarker of activation of the rectus femoris, healthy individuals and stroke patients were asked to execute either right hip flexion or ankle dorsiflexion as a control in a random order. Healthy individuals showed event-related desynchronization (ERD) in the beta band (20-30 Hz) over the motor cortex (Cz) during right hip

flexion, while stroke patients did not. In experiment 2, to test CST excitability during motor imagery, healthy individuals were asked to imagine right hip flexion. TMS was randomly applied to the hotspot of right rectus femoris during imagery. We found that motor evoked potential induced by TMS was positively correlated with magnitude of beta ERD at Cz. These findings suggest that BMI training to modulate beta ERD in the motor cortex may help increase excitability of CST connecting to the rectus femoris, and improve voluntary control of foot movements in severe stroke patients.

Title: Amyotrophic lateral sclerosis and cognitive impairment alter optimal features for brain-computer interfaces

Authors: *A. GERONIMO[1], Z. SIMMONS[2], S. J. SCHIFF[3];
[1]Dept. of Neurosurg., Penn State Univ. Col. of Med., Hershey, PA; [2]Neurology, Humanities, Penn State Univ., Hershey, PA; [3]Engin. Sci. and Mechanics, Neurosurgery, Physics, Penn State Univ., State College, PA

Abstract: Brain-computer interfaces offer persons with amyotrophic lateral sclerosis (ALS) alternative means of communication. We identify ways in which personalization of feature selection benefits users on an individual level, and describe trends in optimal features that emerge when taking into account cognitive impairment, a major predictor of BCI performance. Twenty five patients with ALS and fifteen neurologically healthy control participants completed four sessions of electroencephalography-based brain-computer interface training with P300 and motor-imagery tasks. Participants were also given a cognitive screen to assess for possible cognitive impairment. Exhaustive optimization was carried out on the features produced during these sessions to identify the optimal spatiotemporal set of classification features for each

individual. Additionally, alternative task features of coherence, describing functional network connectivity, were assessed for classification utility in these groups. P300 feature space differed for controls and ALS patients as a whole. In controls, typical timing of task discriminable features occurred 300-400 ms after the visual stimulus, whereas time windows around 500 ms produced the lowest classification error in patients. ALS patients exhibited a wider distribution of P300 features in frontal electrodes, while in controls, discrimination between classes was exclusively found in centro-parietal regions. High performing users who produced lateralized power changes in response to motor imagery also displayed lateralized coherence changes. There were also individuals who demonstrated whole brain modulations of coherence which were hemisphere invariant and unassociated with changes in classical power features. There was a trend for the 14/25 patients with cognitive impairment to achieve better classification using coherence features than either cognitively normal patients or control participants. This study shows how the optimal features for BCI classification may change as a result of ALS as well as the cognitive impairment that often occurs with the disease. Effective use of BCI devices by individuals with ALS will rely on system personalization.

Title: Combined transcranial alternating current stimulation (tACS) and MEG: tACS-induced reduction in the auditory steady-state response

Authors: ***P. HYVÄRINEN**[1], S. D. CHOI[2], G. DEMARCHI[2], A. A. AARNISALO[1], N. WEISZ[2];
[1]Univ. of Helsinki and Helsinki Univ. Hos, Helsinki, Finland; [2]Ctr. for Mind/Brain Sci., Univ. of Trento, Trento, Italy

Abstract: Transcranial alternating current stimulation (tACS) is a noninvasive method used to rhythmically stimulate the brain. By investigating neural activity patterns and behavioral

performance before and after stimulation, previous studies have shown that tACS can modulate and entrain ongoing brain oscillations. However, simultaneous measurement of brain activity during the application of tACS has not been performed until very recently by Neuling et al. (under review), who successfully measured changes in visual areas during tACS. In order to better understand the mechanisms through which tACS induces its effects on the brain, it is important to study ongoing brain activity during stimulation. Recording brain activity and concurrently applying tACS is challenging, since the electrical currents produced by the stimulator exceed the level of neural activity by many orders of magnitude. When conducting electrophysiological measurements with electroencephalography (EEG) or magnetoencephalography (MEG), these stimulator currents manifest as major artifacts in the measured data. Artifacts hinder the analysis of genuine brain activity during stimulation, especially when working with the data in time-domain. Although beamforming suppresses the highly coherent artifacts remarkably and allows tracking changes in source-level activity, one can also use sinusoidal stimulating currents and inspect the measured data in the frequency domain where artifacts are limited to narrow peaks around multiples of the stimulating frequency. Thus, by choosing the frequency of sinusoidal tACS suitably, one can investigate brain activity in the frequency bands between artifact peaks. We measured the auditory steady-state response (ASSR) to a 41-Hz click train with MEG, both during sinusoidal 12-Hz tACS and without tACS. 18 healthy volunteer subjects participated in the experiment. tACS was applied through two saline-soaked 35 cm2 electrodes bilaterally over the temporal lobes, targeting the auditory cortices. We estimated source-level activity using an LCMV beamformer. A comparison of tACS and no-tACS conditions revealed a significant tACS-induced reduction in the ASSR in the right auditory cortex. This study is the first to simultaneously combine auditory MEG measurements with tACS. The study also demonstrates for the first time the real-time effects of tACS on ongoing auditory brain activity. The method described here can be applied to other sensory modalities as well as to clinical resting-state measurements.

Title: Development of an unsupervised and multiclass steady-state visual evoked potential based - BCI

Authors: *K. IKEMOTO, Y. ONO;
Meiji Univ., Kanagawa, Japan

Abstract: In order to facilitate the use of steady-state visual evoked potential (SSVEP) based brain-computer interface (BCI) as an easy-to-use assist device for the physically challenged people, we have previously proposed the unsupervised multi-class classification algorithm of SSVEP-BCI, which uses features both from spectrum power of raw EEG data and from averaged EEG signals. Our previously proposed algorithm adopts spectrum power in case that signal-to-noise ratio of the spectrum power is large enough, and otherwise adopts average EEG signals. The classification using spectrum power detects the frequency which gives the maximum peak-to-baseline amplitude of the spectrum power among the frequency bands corresponding to the flicker light stimuli. The classification using averaged EEG signals detects the frequency which gives the maximum peak-to-peak amplitude of visual evoked potential by dividing and averaging the raw EEG data with different cycles corresponding to the flicker frequencies. Both methods are applied to the data at each electrode (O1, O2, Oz) and majority voting among the results at three electrodes determines the final output of the classifier. To further increase the accuracy, we examined whether (1) a spectrum feature that incorporates the peak-to-baseline amplitude of the spectrum power at the harmonic frequencies of the flicker frequency in addition to those at the fundamental frequency, and/or (2) a winner-take-all fashion of classification in both algorithms depending on spectrum power and averaged EEG signals (classification based on the feature at a single electrode showing the maximum peak-to-baseline or peak-to-peak amplitude among three electrodes), could improve the accuracy of the classifier. The best accuracy (81.3%, N=32) was obtained when we incorporated the peak-to-baseline amplitude at the first and the second harmonics into features and selected the frequency at which the peak-to-baseline or peak-to-peak amplitude showed the largest value among the stimuli frequencies and electrodes. With this improved feature selection and classification algorithm, we could significantly improve the accuracy of the classifier compared to our previous algorithm (77.0%, $p<0.01$).

Title: Chronic musculoskeletal pain and its effects on brain activation

Authors: B. D. EBBESEN, J. RASMUSSEN, S. GERVASIO, T. GRAVEN-NIELSEN, *N. MRACHACZ-KERSTING;
Aalborg Univ., Aalborg, Denmark

Abstract: Neurofeedback methods have a significant potential to reverse the maladaptive brain plasticity associated with pain conditions. Neurofeedback has been implemented for central neuropathic pain or migraines, while the patient is at rest or imagining a movement. Patients are trained to control specific waves (recorded using non-invasive electroencephalography - EEG) thereby reducing the pain. No current data is available for its potential use in the treatment of musculoskeletal pain. Since in these conditions, pain interacts with movement performance the initial aim of this study was to establish EEG signatures of chronic musculoskeletal pain (Lateral Epicondylalgia (LE)) and experimentally induced pain when a volunteer performs a movement. Pain patients with LE (n=6, age 46±10.7 years, 1 male) and healthy controls (n=6, age 26.5±6.2 years, 1 male) were asked to perform 30 repetitions of 3 movement tasks: index finger lift, grip force, and wrist extension. Continuous EEG (250 Hz sample rate) was measured from C3, F3, FC5, FC1, T7, Cz, CP5, CP1, and P3 and electromyographic (EMG) activity was recorded from the extensor carpi radialis brevis muscle. For each trial, EEG segments (+/- 2 s from EMG onset), were extracted and divided into preparation and execution phases. The power spectra within the alpha, beta, theta and gamma frequencies were extracted and compared between groups. The participants' subjective pain sensation was assessed on a visual analogue scale (VAS), pressure pain thresholds (PPT), and pain questionnaires. Compared with healthy controls, pain patients, as well as subjects with hypertonic saline injections compared with baseline showed an increased power of the alpha band in both the preparation (-0.4 to -0.05s) and execution phase (-0.05 to 0s). For the index finger task the mean difference was 8.2 Hz for preparation and 7.7 Hz for execution ($P<0.05$). Similar tendencies were seen for the other tasks. This was correlated to the VAS score ($R^2=0.62$ for the preparation phase and $R^2=0.61$ for the execution phase). Previous studies have demonstrated a decrease in alpha and increase in beta band power following saline-induced pain. In this pilot study the opposite trend was found for EEG monitored during movement execution. Results corroborate that pain interacts with movement performance and that this has an EEG signature. In addition, injection of hypertonic saline is further validated as an appropriate model to mimic musculoskeletal pain since the alterations in band power frequency followed the same trend as in chronic pain patients. The results will be a platform for full scale studies of neurofeedback techniques to manage chronic musculoskeletal pain.

Abstract: A number of theories to explain the mechanism of respiratory rhythm generation have been proposed, e.g., a pacemaker theory in which pacemaker neurons initiate inspiration and a network theory in which respiratory rhythm is generated by interaction of excitatory and inhibitory neurons. However, respiratory rhythm could persist under blockade of pacemaker currents or inhibitory synaptic transmission, suggesting that another mechanism is involved. Recently, we have discovered that a subset of astrocytes show periodic activation preceding inspiration in the pre-Bötzinger complex (preBötC) in medullary slices (Okada et al. 2012; Oku et al. 2015). These preinspiratory astrocytes have an intrinsic oscillatory property, although they

receive excitatory drive from neurons. We confirmed that astrocytes and neurons are anatomically closely coupled in the preBötC, collectively suggesting that inspiration could be triggered by interaction of astrocytes and neurons. Indeed, blockade of astrocytic metabolism which depletes glutamate in neurons suppresses respiratory rhythm. However, substitution of glutamine restores the rhythm. Further, respiration of spontaneously breathing animals is generally much faster than intrinsic oscillatory rhythm of astrocytes. Therefore, we could not simply conclude that every inspiration is triggered by astrocytes. Here we propose a model to explain the mechanism of respiratory rhythm generation under *in vitro* and *in vivo* conditions. In the respiratory center, rhythmogenic astrocytes and neurons, both of which could have intrinsic oscillatory properties and could be sources of tonic excitatory drive as well, are mutually coupled through astrocyte-astrocyte, astrocyte-neuron and neuron-neuron synapses. They are periodically and synchronously activated, and can together trigger inspiratory activities of downstream neurons. Astrocytes also modulate neuronal activity by buffering various ions and transmitters in the extracellular space. The nature of small-world network connectivity among astrocytes as well as chaotic characteristics of astrocytic activity could be the basis of irregularity and robustness of respiratory rhythm. In normal conditions, astrocytes are involved in respiratory rhythmogenesis and modulate neuronal oscillator's rhythm. However, in some pathological conditions, astrocytes could primarily trigger inspiration at a low oscillatory frequency. When astrocytic activity is inhibited, neurons alone could form an oscillator and trigger inspiration if sufficiently boosted. This astrocyte neuron network model of respiratory rhythm generation explains the previous observations.

Title: Neuromodulation of burst and burstlet rhythm generating mechanisms in preBötzinger complex (preBötC)

Authors: *X. SUN[1], K. KAM[2], M. SHAO[1], J. L. FELDMAN[1];
[1]Neurobio., Univ. California Los Angeles, Los Angeles, CA; [2]Cell Biol. and Anat., Rosalind Franklin Univ., North Chicago, IL

Abstract: The preBötC is essential for generation of respiratory rhythm. *In vitro* in rhythmic slices from neonatal mice (P0-P5), preBötC population activity consists of two separable components: small amplitude rhythmic burstlets that represent preinspiratory activity and that we hypothesize are rhythmogenic, and larger inspiratory bursts, threshold triggered by burstlets, that drive inspiratory motoneuronal activity (Kam et al., J. Neurosci. 2013). Our hypothesis predicts that perturbations that modulate burst frequency (*f*) will also similarly affect burstlet *f* and that modulating excitability can separately affect the ratio of burstlets to bursts. When bathed in ACSF at 3 mM K^+ and 1mM Ca^{2+}, preBötC activity was a mixed pattern of burstlets and bursts. Increasing K^+ to 9 mM or the addition of the neurokinin receptor agonist Substance P (SP, 500nM) did not significantly affect *f* while significantly increasing the ratio of bursts/burstlets, whereas Cd^{2+} (<50 μM) decreased the ratio of bursts/burstlets. In contrast, the μOR agonist DAMGO (30-100 nM) decreased both burst and burstlet *f* and decreased the ratio of bursts/burstlets. The depressant effects of DAMGO were reduced by high K^+ and SP. We suggest that perturbations in preBötC neuronal excitability can alter the threshold for conversion of burstlets into bursts and that changes in *f* are reflected in changes to burstlet *f*. These data are consistent with distinct rhythm and pattern generating mechanisms within the preBötC, with rhythmogenesis being mediated by burstlets and a separable burst-generating mechanism being necessary for patterned output from the preBötC. Abstract: BACKGROUND: Blood gas and tissue pH regulation depend on the ability of the brain to sense CO2 and/or H+ and alter breathing appropriately. A specific group of neurons within the medullary retrotrapezoid nucleus (RTN), identified by Phox2b expression, are preeminent central respiratory chemosensory neurons, i.e., they directly sense CO2/H+ and adjust ventilation to rapidly regulate CO2 excretion and acid-base balance. However, the molecular mechanisms that mediate pH sensing within RTN neurons remain incompletely understood. Recent work from knockout mice suggests that the alkaline-activated TASK-2 (K2P5) background K+ channels account for pH-sensitivity in a subset of RTN neurons but also implied that other molecular sensors must also play a role. In insects, CO2 sensing involves G protein-coupled receptors (GPCRs). Interestingly, a group of proton-activated GPCRs has been identified in mammalian systems, although their specific physiological roles remain to be elucidated. OBJECTIVE & METHOD: Here, we use a combination of genetic loss-of-function, cellular pharmacology and molecular biology, *in vitro* and *in vivo* physiology, and RTN neuron-specific lentiviral re-expression and rescue, in order to identify GPR4, a proton-activated G protein-coupled receptor, as a molecular substrate for CO2/H+-dependent RTN neuronal excitability and breathing. RESULTS: In mice lacking GPR4, the enhanced breathing induced by raised CO2 was strongly reduced, and these mice were also more prone to apneic events. Mice lacking GPR4 showed a striking reduction in CO2 induced activation of RTN neurons *in vivo*, as determined by cFos expression. Likewise, RTN neuronal excitability and pH sensitivity *in vitro* were reduced by GPR4 deletion or receptor blockade, and modulated by intracellular application of GTP analogs. Finally, virally-mediated re-introduction of GPR4 into RTN neurons of GPR4-/- mice rescued CO2-stimulated cFos expression and ventilation, and returned apneic frequencies to wild type levels. Additional deletion of TASK-2, a pH-sensitive K+ channel expressed in RTN neurons, essentially abolished the ventilatory response to CO2 in double knockout mice. CONCLUSION: Taken together, these data identify GPR4 and TASK-2 as distinct, parallel and essential central mediators of respiratory chemosensitivity, and suggest new therapeutic options to regulate breathing.

Title: Mixed-mode oscillations and development of population bursts in the pre-Bötzinger complex

Authors: *B. BACAK[1], T. KIM[1], J. E. RUBIN[2], J. C. SMITH[3], I. A. RYBAK[1];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]Natl. Inst. of Neurolog. Disorders and Stroke, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Generation of rhythmic activities in neural structures, representing central pattern generators, involves complex dynamic synchronization of neuronal activity in large populations of neurons with endogenous bursting properties. Our theoretical and computational study focused on population activity that developed progressively with elevation of neuronal excitability in the pre-Bötzinger complex (pre-BötC), a medullary region known to be critically involved in the generation of the inspiratory phase of respiration. Progressive increase in extracellular potassium concentration in medullary slices containing the pre-BötC produces complex mixed-mode oscillations, characterized by amplitude modulation with large population bursts alternating with a series of small bursts (so-called “burstlets”). When the network’s excitability, which correlates with extracellular potassium concentration, is sufficiently high, only large amplitude bursts are observed. To study the generation of, and the relations between,

bursts and burstlets, we developed and analyzed two models: (a) a computational model of a network of 100 neurons, described in the Hodgkin-Huxley style, with bursting properties defined by the persistent (slowly inactivating) sodium current (INaP), sparse excitatory synaptic interconnections, and randomly distributed neuronal parameters, and (b) a reduced model consisting of three mutually exciting non-spiking neurons that allowed us to apply qualitative analytical methods for understanding key system behaviors. We show that the mixed-mode oscillations observed in the pre-BötC and similar systems can emerge within a single heterogeneous network due to recruitment and synchronization of multiple neurons involved in the generation of both bursts and burstlets. The resultant pattern of these mixed-mode oscillations depends on the distribution of neuronal excitability, sparsity and weights of network connections, and the neuronal properties underlying endogenous bursting (e.g., INaP). The latter should specifically provide a reduction of spiking activity within neuronal bursts with increasing burst frequency and a dependence of the after-burst recovery period on the burst amplitude. We conclude that the generation of mixed-mode oscillations observed in the pre-BötC *in vitro* does not require distinct sub-networks for rhythm generation and pattern formation.

Title: Neuronal TRPC3/7 channels play a critical role in breathing rhythm generation *in vivo*

Authors: *A. K. TRYBA;
Pediatrics, The Univ. of Chicago, Chicago, IL

Abstract: The mechanisms underlying disordered breathing patterns are poorly understood. The neural mechanisms that govern respiratory rhythm generation, including the cellular/ionic mechanisms and specific neurons of the respiratory control center are also not fully known. The pre-Botzinger Complex (Pre-BotC) is a brainstem region hypothesized to be an essential component of the respiratory network, playing a critical role in generating normal inspiratory breathing rhythms. Both *in vitro* (Ben-Mabrouk and Tryba, 2010; Ben-Mabrouk et al. 2012) and *in situ* experiments were used to start to identify ion channel targets that modify the bursting properties of pre-BötC neurons, including transient receptor potential (TRPC) channels. These

studies suggested that glutamatergic synaptic drive together with excitatory neuromodulators can activate TRPC3 and/or TRPC7 (TRPC3/7) channels to enhance inspiratory neuron bursting properties and stabilize inspiratory rhythms. Using *in vitro* brain slice preparations containing the pre-BotC, I made intracellular recordings dialyzing pre-BotC inspiratory neurons with selective TRPC3/7 antibodies, which reduced the inspiratory neuron drive potential (n=4), indicating that TRPC3/7 channel activation enhances inspiratory neuron bursting properties. In a novel approach to begin to define the role of TRPC3/7 channels in breathing pre-BotC *in vivo*, I stereotaxically injected a modified siRNA to selectively knock down expression of TRPC3 and TRPC7 channels in pre-BötC neurons of rats *in vivo*. I monitored rats' breathing using flow-through plethysmography and sleep/wake states using EEGs. Selectively interfering with TRPC3/7 protein production in neurons in the pre-BotC region results in repetitive sleep apnea, suggesting that TRPC3/7 channels play a critical role in breathing rhythm generation *in vivo* and that reduced availability of TRPC3/7 cannot be compensated for over several (~7) days of the study (n=7/7). In contrast, stereotaxic injection of non-targeting control siRNA sequences into the pre-BotC did not result in sleep apnea or other significant changes in breathing (n=7/7). For the first time, these data suggest that activation of TRPC3/7 channels in pre-BotC neurons plays an critical role in breathing, particularly during sleep. These data are also of interest, given that circulating levels of excitatory neuromodulators (e.g., Substance P, 5-HT) that can activate these channels are low during sleep and it appears that the respiratory system cannot compensate for selective reduction in availability of TRPC3/7 channels at that time. Enhancing TRPC3/7 in pre-BotC neurons may prevent disordered breathing.

Title: Combining constellation pharmacology with molecular genetics to classify neuronal cell types within the ventral respiratory column of mouse brainstem

Authors: *S. RAGHURAMAN[1], A. GARCIA[2], R. TEICHERT[1], J. RAMIREZ[2], B. OLIVERA[1];

[1]Dept. of Biol., Univ. of Utah, Salt Lake City, UT; [2]Ctr. for integrative brain research, Seattle Children's Res. Inst., Seattle, WA

Abstract: Constellation pharmacology is a methodology to identify and classify different neuronal cell types based on the sets (or constellations) of ion channels and receptors found in every cell type. We performed constellation pharmacology through calcium imaging to classify three major cell classes and subclasses within the ventral respiratory column (VRC) of mouse brainstem. Previous results published on these cell classes examined and confirmed that the cellular response profiles in an intact slice exhibited similar responsiveness as was found *in vitro* [1]. To further understand the physiological roles of these identified cell types, we performed constellation pharmacology on two different types of transgenic reporter mice that expressed tdTomato in genetically defined neuronal cell types. The cholinergic and glutamatergic neurons of VRC were labeled with tdTomato, with expression driven by promoters of the genes encoding choline acetyltransferase (ChAT) and the transcription factor Dbx1 respectively. Our results demonstrate that these cholinergic and glutamatergic cell types were a subset of our defined cell classes within VRC, thereby strengthening our classification. To further refine the definition of these cell classes, we used target-selective conotoxins that differentiated between complex molecular isoforms. For example, NMDA receptors that are found in various combinations of subunits are difficult to study due to the lack of target selective tools. Using conantokin-Rl-B, a peptide that selectively targets NR2B subunits of NMDA receptors, we identified its expression only in a specific subset of the defined cell types. Thus, this approach of combining constellation pharmacology with molecular genetics has provided a platform to classify cell types with crucial physiological roles in behavior and to generate hypotheses to test the roles of modulatory inputs to these defined cell classes in an intact system. Title: Optogenetic studies of population-specific roles of pre-Bötzinger complex glutamatergic neurons in respiratory rhythm generation

Authors: *H. KOIZUMI, M. TARIQ, B. MOSHER, R. ZHANG, N. KOSHIYA, J. C. SMITH; Cell. & Systems Neurobio. Sec, NINDS, NIH, Bethesda, MD

Abstract: The rhythm of breathing in mammals is generated within the pre-Bötzinger complex (pre-BötC), a circumscribed and functionally-specialized region of the ventrolateral medulla, involving cellular and circuit mechanisms that are not fully defined despite over two decades of investigation. The pre-BötC has a heterogeneous composition of rhythmically active excitatory and inhibitory interneurons, and it is generally assumed that glutamatergic neurons constitute the rhythmogenic kernel for inspiration. However, it has not yet been possible to directly demonstrate such causality in rhythm generation without methods to specifically manipulate activity of pre-BötC glutamatergic neurons. We now demonstrate this causality by leveraging optogentics with transgenic mice expressing Cre-recombinase in glutamatergic neurons promoted by the vesicular glutamate transporter 2 (VGLUT2) for conditional cell-type specific expression of Archaerhodopsin-3 (Arch, light driven outward proton pump) in neonatal medullary slices *in vitro* and in the functionally more intact juvenile/adult perfused brainstem-spinal cord preparations *in situ*. In these VGLUT2-Arch mice, optogenetic attenuation and loss of function of pre-BötC glutamatergic neurons caused rapid and reversible disruption of inspiratory rhythm generation in a site-specific manner. We further analyzed, by whole-cell patch-clamp recordings, the relationship between the laser-induced (2-10 mW) neuronal membrane hyperpolarization of functionally identified glutamatergic pre-BötC inspiratory neurons vs. the frequency of inspiratory bursting activity generated in medullary slice preparations *in vitro*. The results showed a monotonic reduction of inspiratory burst frequency as a function of membrane hyperpolarization, consistent with a membrane voltage-dependent mechanism underlying inspiratory rhythmogenesis. These results provide a more definitive demonstration of the molecular/neurotransmitter phenotype specification of the essential rhythmogenic neurons in the pre-BötC.

Title: Functional mapping of genetically-defined neuron populations in central control of respiratory physiology

Authors: *J. SUN, R. RAY;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The perpetual rhythm of breathing is essential for survival and emerges through the interactions of a highly redundant and anatomically complex array of neuronal networks. As a result, central respiratory circuits are challenging to study, and the underlying causes of congenital respiratory disorders and diseases including Rett Syndrome, Congenital Central Hypoventilation Syndrome, and Sudden Infant Death Syndrome remain unclear. A necessary step toward diagnosis and treatment of respiratory dysfunction is identifying the roles of specific populations of neurons within the central respiratory circuitry. Here we use acute, non-invasive, and reversible pharmaco-genetic methods to precisely perturb (hM4D) and stimulate (hM3D) genetically-defined developmental and neurotransmitter-based populations in the adult mouse brainstem. hM4D and hM3D are modified G-protein coupled receptors that are biologically inert until activated by administration of the synthetic ligand clozapine-N-oxide (CNO), which causes neuronal silencing via hyperpolarization or stimulation via burst firing, respectively. By expressing these receptors in a conditional Cre and/or FLP recombinase-responsive manner, we can target widely-dispersed and developmentally critical populations, resulting in high spatial resolution and bypassing embryonic or neonatal lethality. In combination with whole-body plethysmography, we are able to accurately measure respiratory parameters under room air, hypercapnic (5% CO_2), and hypoxic (10% O_2) conditions in conscious and unrestrained mice. Our data demonstrate that genetically defined segments of the developing hindbrain called rhombomeres contribute to the functional organization of the adult respiratory network, differentially affecting respiratory rate, tidal volume, oxygen consumption, and waveform patterns when they are perturbed or stimulated under different breathing conditions. We also show that neurotransmitter expression defines populations with distinct respiratory roles. Together, these data set the stage for intersectional mapping of dual-gene expressing subpopulations to further refine neuron subtypes involved in respiratory homeostasis and expand our understanding of the intricacies of central respiratory circuits.

Title: Medullary raphé neuron responses during central chemoreceptor perturbations and functional connectivity within the respiratory brain stem

Authors: K. E. ICEMAN, S. C. NUDING, L. S. SEGERS, *B. G. LINDSEY, K. F. MORRIS; Dept. of Mol. Pharmacol. & Physiol., Univ. of South Florida Morsani Col. of Med., Tampa, FL

Abstract: Different classes of medullary raphé neurons are hypothesized to function as sensors of central CO_2: mildly CO_2-stimulated serotonergic (5-HT) neurons, robustly CO_2-stimulated non-serotonergic neurons, and inhibitory neurons that are themselves CO_2-inibited. These raphé neurons are proposed to function together in a "push-pull" manner to enhance breathing during central chemoreceptor stimulation via excitation and disinhibition of target neurons within the raphé and other brainstem respiratory regions. To address the hypothesis that CO_2-responsive raphé neurons form such functional connections, we used multi-array recording and cross-correlation methods to evaluate spike train data from the medullary raphé nuclei, ventral respiratory column (VRC), and pontine respiratory group of 6 decerebrate, vagotomized, neuromuscularly-blocked cats. Phrenic activity, blood pressure, end-tidal CO_2, and arterial blood gas measures of O_2, CO_2 and pH were monitored. Thirty-nine percent (26/67) of the raphé neurons recorded changed firing frequency during selective stimulation of central chemoreceptors (injection of CO_2 saturated saline via vertebral artery). When the 26 neurons were tested with hypocapnia induced by hyperventilation, 46% (12/26) had a response opposite to the injections, 46% (12/26) had no response, and 8% (2/26) had the same response. Offset peak and trough features in correlograms triggered by raphé neurons with target cells in the raphé, VRC, and pons support a "push-pull" model: CO_2-stimulated and CO_2-inibited raphé neurons excite and disinhibit target neurons, respectively. The results support the hypothesis that chemoresponsive raphé neurons modulate respiratory drive during conditions of altered CO_2 via local circuits within the raphé and through parallel connectivity with the VRC and pons.

Title: Optogenetic activation of leptin-receptor expressing NTS neurons increases respiratory motor output in mice

Authors: Z. CHANG, A. S. KOWAL, G. SEKERKOVA, K. E. MCKENNA, M. MARTINA, *D. R. MCCRIMMON;
Dept Physiol., Northwestern Univ. Feinberg Schl Med., Chicago, IL

Abstract: Administration of the anorexigenic hormone leptin to rodents increases energy expenditure with a parallel increase in respiratory motor output so that arterial blood gas and acid-base balance are maintained. This occurs at least in part through activation of CNS neurons that express the long form of the leptin receptor (LepRb). LepRb expressing neurons are concentrated in several CNS regions, most notably in the hypothalamus and brainstem. Of these, activation of LepRb neurons in the nucleus of the solitary tract (NTS) has been linked to respiratory motor stimulation. We have initiated studies to characterize the NTS LepRb neurons contributing to respiratory stimulation using mice that express channelrhodopsin-2 (ChR2) in LepRb neurons. Mice were anesthetized and a optical fiber (200-300 um diameter) conducting 473 nm wavelength light was used to activate the ChR2-LepRb neurons. Light intensity was maintained below 3 mW to avoid nonspecific activation or damage to tissue in the vicinity of the fiber. For stimulation, trains of light pulses at 5, 10, 20 and 50 Hz (≤10 ms pulse width) were used. In parallel control experiments in mice not expressing LepRb-ChR2, these stimulus parameters did not elicit any change in respiratory motor output. In contrast, when the NTS region of mice expressing ChR2 in LepRb neurons was optogenetically activated, there was a progressive increase in respiratory motor output, consisting primarily of an increase in the peak amplitude of integrated phrenic nerve activity with little change in the number of phrenic bursts per minute. The magnitude of the increase in the peak amplitude of phrenic nerve bursts was

directly dependent on the stimulus frequency, with a maximum of about a doubling in amplitude. Current studies are using retrograde tracing and immunohistochemistry to identify candidate neurotransmitters within NTS LepRb neurons that project to neurons within brainstem regions that contain respiratory neurons. We are grateful for the support from NIH grants HL122921 and HL095731.

Title: Perinatal fluoxetine exposure affects the serotonergic drive of the respiratory rhythm *in vitro*

Authors: *K. A. BRAVO[1], J. EUGENÍN[2], I. LLONA[1];
[1]Univ. De Santiago De Chile, Santiago, Chile; [2]Univ. de Santiago de Chile, Santiago, Chile

Abstract: Serotonin (5HT) is a proliferation and differentiation factor at gestational period, being 5HTergic maternal tone important for overall embryonic brain development (Bonnin and Levitt Neuroscience 197(2011)1-7; Neuropsychopharmacol 37(2012)299-300). Administration of selective inhibitors of 5HT reuptake during pregnancy alters 5HT levels, which we propose may lead to modification of neural circuitry with functional effects on central chemosensory responses (Alwan and Friedman CNS Drugs 23(2009)493-509). We previously found that, at the postnatal day 8 (P8), perinatal fluoxetine exposure decreased: 1) the ventilatory responses to hypercapnia, 2) the recruitment of neurons expressing c-Fos induced by hypercapnia at the raphe and NTS nuclei, and 3) the respiratory response induced by hypercapnic acidosis in medullary slices. In the present work we extend our study to other postnatal ages and we investigated the effect of perinatal fluoxetine on 5HTergic drive on respiratory network. Osmotic minipumps were implanted to CF-1 dams on day 5 of pregnancy, to deliver fluoxetine (7mg Kg-1 day-1) for up to 28 days. Plethysmographic head-out recordings were done in adults (P40) mice breathing

either air or air enriched with 10% CO2. Fictive respiratory activity was recorded from ventral respiratory column with suction electrodes and exogenous 5HT was delivered by superfusion, and respiratory frequency was evaluated by concentration-response curve. Fluoxetine exposure reduced the ventilatory response to hypercapnia from P8 to adulthood (P40). Prenatal fluoxetine reduced the maximal response to exogenous 5HT observed in concentration-response curves in P8 medullary slices. Our results indicate that perinatal fluoxetine exposure impairs chemosensory reflexes and it is associated to a reduction in the 5HTergic command during postnatal life.

Title: Pacemaker neurons in the respiratory network of embryonic mouse

Authors: ***M. THOBY BRISSON**[1], M. CHEVALIER[1], N. TOPORIKOVA[2];
[1]Univ. De Bordeaux, CNRS UMR 5287, BORDEAUX, France; [2]Biol., Washington and Lee Univ., Lexington, VA

Abstract: Breathing is a rhythmic motor behavior that is generated and controlled by neuronal assemblages located in the hindbrain. One such network, the preBötzinger complex (preBötC), plays a prominent role in generating the inspiratory phase of respiration. The status of this network at the time of its functional emergence during embryonic development has been recently described, but nothing is presently known regarding the existence and functional characteristics of preBötC inspiratory neurons that express pacemaker properties. We have aimed, firstly, to investigate the presence and properties of pacemaker neurons at embryonic stages, and secondly, to examine their potential role in respiratory rhythm generation and modulation at prenatal stages. To this end we combined multi-cellular calcium imaging with electrophysiological recordings of individual neurons in transverse brainstem slices obtained from mouse embryos (from embryonic day (E) 16 to 18). Patch-clamp recordings (n = 71) revealed the existence of heterogeneous pacemaker properties underlying three types of discharge pattern (long-lasting plateau-like bursts, short lasting-bursts and a mixed activity phenoptype). The effects of

pharmacological treatments associated with computational modeling indicated that this heterogeneity relies on distinct combinations of membrane conductances. The non-specific calcium-activated current (ICAN) plays a prominent role in the long-lasting, plateau-like discharge while the shorter bursting-like pattern relies more on the persistent sodium current (INaP). Furthermore we found changes in the respective proportion of the different pacemaker types during embryonic development, with the plateau-like bursting pacemakers being predominant at E16 while the bursting-like pacemakers being more prevalent at E18. Accordingly, rhythmogenesis is more affected by ICAN blockade at early embryonic stages and by INaP blockade at later stages. In addition, exogenous application of known neuromodulators of the respiratory rhythm (Substance P, DAMGO) revealed an intrinsic sensitivity of embryonic pacemaker neurons to these substances. Taken together our results provide the first description of pacemaker bursting properties in embryonic preBötC neurons, establish a developmental maturation of pacemaker properties and suggest an important role of pacemaker neurons in generating and governing activity of the prenatal respiratory network.

Title: Warfarin increases glial inflammation in healthy adult mice

Authors: *D. L. FEINSTEIN, A. SITU, N. MARANGONI;
Anesthesiol., Univ. of Illinois Chicago, Chicago, IL

Abstract: The commonly used anti-coagulant warfarin reduces clotting by inhibiting vitamin K recycling necessary for activation of gamma-glutamyl carboxylase (GGC), which carboxylates and activates clotting proteins. Since vitamin K and GGC have roles in other physiological processes including within the CNS, we tested the hypothesis that chronic treatment with warfarin would lead to alterations in indices of neuroinflammation. Adult healthy mice were treated with warfarin for up to 4 weeks, after which brain sections were examined for signs of inflammation, sulfatide content, and expression of genes relevant to vitamin K regulated processes. As a control, we compared the effects of warfarin to those of the anti-coagulant

dabigatran etexeliate (DE), which in contrast to warfarin does not reduce vitamin K levels but directly inhibits thrombin. Statistical comparisons were made by 1-way ANOVA and Student t-tests. We observed that after 4 weeks, warfarin, but not DE induced significant microglial and astroglial activation in different brain regions (cortex, cerebellum, and hippocampus) while in contrast DE showed trends towards reducing the basal levels of glial inflammation. Ultra HPLC analysis of samples measured after 1 week of treatment showed that warfarin, but not DE, reduced cerebellar levels of the C18:0 sulfatide. Quantitative PCR analysis showed that both warfarin and DE caused changes (both increases and decreases) in the expression of a panel of genes involved in vitamin K dependent processes, in different brain regions and with the largest changes in the cerebellum. These results suggest that warfarin, but no DE, induces alterations within the CNS including increased neuroinflammatory responses.

Title: Temporal expression pattern of microglia/ macrophage polarization after intracerebral hemorrhage

Authors: *S. SUKUMARI RAMESH[1], F. C. BONSACK[2], C. H. ALLEYNE[2];
[1]Neurosurg., [2]Dept. of Neurosurg., Georgia Regents Univ., Augusta, GA

Abstract: Intracerebral hemorrhage (ICH) is a fatal stroke subtype accounting for 15-20% of all strokes. Despite neurosurgical intervention and supportive care, the 30-day mortality rate remains 30-50%; with ICH survivors frequently displaying neurological impairments and requiring long-term assisted care. Notably, there is no effective treatment for ICH and the incidence of ICH is expected to grow over the next decades as a result of population aging and changes in racial demographics. Though, accumulating evidence demonstrates the role of neuroinflammation in secondary brain injury and delayed fatality after ICH, the phenotypic or functional characterization of microglia/macrophages, the cells that play key role in neuroinflammation, remains poorly defined after ICH. In the present study, ICH was induced in

CD1 male mice by collagenase injection method and immunofluorescence staining of brain sections for M1 and M2 markers was performed to characterize the phenotypic changes of microglia, 1 to 7 days post injury. Expression of M1 marker, CD16/32 was found to be increased in the peri-hematomal brain region 3 to 7 days post injury, peaking on day 5, in comparison to sham. In contrast, the expression of M2 marker, CD 206 was observed on post injury days 1 and 3 with a maximal expression on day 3. In addition, CD16/32 positive cells, remarkably co-localized with Iba1, indicating that the M1 marker expression is mainly confined to microglia/macrophages. Altogether, our results suggest the occurrence of an injury-induced dynamic shift of anti-inflammatory M2 to pro-inflammatory M1 microglia/macrophage after ICH and raise the possibility of targeting M1 microglia in ICH associated morbidity/mortality.

Title: PGJ2-induced Inflammation disrupts AMPA-receptor trafficking: implications for synaptic plasticity and memory processing

Authors: *J. A. AVILA[1,3], T. JEAN-LOUIS[2,4], M. KIPROWSKA[2,4], F. CHEUNG[2,4], P. ROCKWELL[2,4], P. A. SERRANO[1,3], M. FIGUEIREDO-PEREIRA[2,4];
[1]Psychology, [2]Biol., Hunter Col., New York, NY; [3]Psychology, [4]Biol., The Grad. Center, CUNY, New York, NY

Abstract: Inflammation has many detrimental effects on the nervous system, and can lead to cognitive impairment. However, little is known about the molecular mechanisms that underlie neuroinflammation-induced cognitive deficits. To address this gap in knowledge, we employed a cell-culture model of neuroinflammation in which rat E18 cerebral cortical cultures are treated with an endogenous neurotoxic product of inflammation, Prostaglandin J2 (PGJ2). Previous findings indicate that PGJ2 disrupts cellular homeostasis in neuronal cultures by decreasing protein turnover via a process that is regulated by the ubiquitin-proteasome system. Previous studies also show that spatial memory performance is positively correlated with the expression of the AMPA-receptor subunit GluA2 in the brain (Sebastian 2013 PLoS One. 8, e81121) and that

maintaining GluA2 levels within the synapse preserves a learned memory (Migues 2010 Nat. Neurosci. 13, 630-4). Thus, we hypothesize that inflammation could produce cognitive deficits by impairing the trafficking of GluA2 to and from the synapse. We performed immunocytochemistry on 10-DIV cortical-neurons and imaged neurons and their neurites by fluorescent microscopy. Images were quantitatively analyzed for levels of GluA2, PSD95 (a post-synaptic scaffolding protein), and their colocalization using ImageJ. Results showed that PGJ2 (1μM) significantly increased GluA2 and GluA2/PSD95 colocalization along neurites compared to controls. PSD95 levels were unchanged. Our results indicate that GluA2 levels increase at synapses after PGJ2 treatment due to a failure in their turnover that affects trafficking to and from the synapse. These results suggest that PGJ2 and inflammation have detrimental effects on synaptic homeostasis by disrupting protein turnover and blocking protein trafficking. Currently, our investigations are focusing on the mechanisms by which PGJ2 affects synaptic homeostasis, including the effects on protein kinase M zeta (PKMζ). This constitutively active enzyme is known to participate in the trafficking of GluA2 and is known to play a role in memory maintenance. These findings could explain why inflammation induces cognitive deficits.

Title: Contribution of lysophosphatidic acid receptor 2 and 3 (LPA2 and LPA3) to secondary damage following spinal cord injury in mice

Authors: *E. S. NOGUEIRA[1], I. FRANCOS-QUIJORNA[2], M. COLL-MIRÓ[2], J.-P. SALLES[3], O. PEYRUCHAUD[4], J. CHUN[5], R. LÓPEZ-VALES[2];
[1]Neurol., The Res. Inst. of the McGill Univ. He, Montreal, QC, Canada; [2]Biologia Celular, Fisiologia e Inmunologia, Univ. Autonoma de Barcelona, Bellaterra, Spain; [3]INSERM, CHU de Toulouse, Hôpital des Enfants, Toulouse, France; [4]Faculté de Médecine Laënnec, INSERM, Lyon, France; [5]Mol. and Cell. Neurosci., The Scripps Res. Institute, Dorris Neurosci. Ctr., La Jolla, CA

Abstract: Lysophosphatidic acid (LPA) is a pleiotropic extracellular lipid mediator with many physiological functions that signals through 6 known G protein-coupled receptors (LPA1-6). LPA1-3 share high homology in amino acid sequence and belong to the endothelial differentiation gene (edg) family LPA receptors, whereas LPA4-6 are genetically more distant and belong to the non-edg family LPA receptors. LPA mediates a wide range of LPA effects in the central nervous system, including neural progenitor cell physiology, astrocyte and microglia activation, neuronal cell death, and axonal retraction. Previous *in vivo* studies show that LPA is involved in the etiology of fetal hydrocephalus, as well as the development of neuropathic pain after sciatic nerve injury and cerebral ischemia. We previously reported that LPA plays an important role in the pathophysiology of spinal cord injury (SCI) by signaling through LPA1. Here we aimed at studying the contribution of the other two members of the edg family LPA receptors, LPA2 and LPA3, to secondary damage after SCI. We found that LPA2 and LPA3 mRNA levels are constitutively expressed in the spinal cord parenchyma and their transcripts are up-regulated after contusion injury. To dissect out the role of LPA2 and LPA3 in SCI, we induced contusion injury in LPA2 and LPA3 deficient mice. These experiments revealed that functional recovery, as well as myelin and neuronal sparing, was significantly enhanced in the absence of LPA2 signaling. The lack of LPA3, however, did not confer protection against functional deficits and tissue damage. Similarly, administration of OMPT, a LPA3 agonist, did not exert beneficial effects after SCI. To gain insight into the detrimental actions of LPA2 activation in spinal cord we performed *in vitro* studies. These experiments revealed that the detrimental actions of LPA2 signaling are mediated, in part, by activation of LPA2 in microglial cells. Overall, this study provide novel data demonstrating that LPA signaling via LPA2 contributes to tissue damage in SCI.

Title: Early life stress activates the innate immune system in the developing hippocampus

Authors: J.-C. DELPECH, L. WEI, J. HAO, R. K. LACHER, *A. KAFFMAN;
Psychiatry, Yale Univ., New Haven, CT

Abstract: Exposure to childhood abuse and neglect is associated with an increase risk for the development of several behavioral, emotional, cognitive and medical sequelae. These psychiatric and medical comorbidities present early in life, and in many cases, persist into adulthood and are associated with enormous clinical and economical burden. The molecular and cellular mechanisms by which early life stress (ELS) causes such diverse and severe clinical outcomes is currently poorly understood in humans. Using a mouse model of ELS, known as brief daily separation (BDS), we recently showed that exposure to BDS is associated with impaired hippocampal dependent memory in adulthood, and abnormal synaptic maturation and pruning during the juvenile period. Given that microglia cells play a critical role in guiding normal synaptic maturation and synaptic pruning, we tested whether exposure to BDS alters microglia function in the developing hippocampus. To test this hypothesis we collected microglia from the hippocampus of 14-day old (during the BDS period) and in 28-day old pups (one week after the last day of BDS). We found that BDS increased the number and modified the morphology of microglia in 14-day old but not 28-day old pups. We then examined the effect of BDS on gene expression in microglia harvested from the hippocampus of 14-day old BDS and control pups. Path analysis indicated that BDS activates many genes involved in phagocytosis, cell cycle regulation, and immune activation. These findings demonstrate that exposure to BDS causes a dramatic shift towards a phagocytic transcriptional programming in microglia cells present in the developing hippocampus. We propose that inappropriate activation of microglia early in life impairs normal synaptic maturation and pruning during hippocampus development. These synaptic abnormalities persist into adulthood leading to long-term cognitive and behavioral deficits in adult BDS mice.

Title: P75NTR mediates inflammatory responses by modulating differentiation of myeloid cells after TBI in mice

Authors: *S. LEE[1], N. SINGHAL[1], A. LIN[1], J. SACRAMENTO[1], B. CANOLLE[2], M.-N. CASTEL[2], S. DELBARY-GOSSART[3], B. FERZAZ[2], F. BONO[3], J. BRESNAHAN[1], M. BEATTIE[1];
[1]Neurolog. Surgery, Brain and Spinal Injury Ctr., UCSF, San Francisco, CA; [2]Sanofi R&D, Chilly-Mazarin, France; [3]Evotec, Toulouse, France

Abstract: Traumatic brain injury (TBI) leads to pro-inflammatory responses in both CNS and peripheral organs. The inflammatory responses may be involved in the subsequent development of clinical systemic inflammatory response syndrome, which eventually causes immune dysfunction and increases susceptibility to infection in chronic TBI patients (Keel and Trentz, 2005). Previously, we found that blocking the p75NTR signaling pathway by SARA, a selective p75NTR antagonist, preserves neuronal integrity and improves functional outcome after cortical contusion injury (CCI) TBI in rats. Strikingly, blocking p75NTR signaling reduces microglia activation as well as leukocyte trafficking into the injured brain (Lee et al., Neurotrauma 2014), suggesting p75NTR is involved in inflammatory responses after TBI. We used flow cytometry to examine the possible role of p75NTR in peripheral immune cell responses after TBI. *In vitro* studies using myeloid cells isolated from blood from WT mice demonstrated potent effects of LPS on differentiation of immature myeloid cells to mature myeloid cells and inflammatory macrophages ($CD11b^{+}F480^{+}Ly6C^{high}$). SARA treatment attenuated $CD11b^{+}F480^{+}Ly6C^{high}$ population, suggesting p75NTR is involved in differentiation of immature myeloid cells to inflammatory macrophages. SARA treatment also inhibited LPS-mediated increases in $Ly6C^{+}$ signal in splenocytes isolated from wild-type mice as well as reversed LPS-induced down-regulation of TCR, suggesting blocking p75NTR has beneficial effects on not only attenuation of inflammatory responses, but also preserve T cell function. Finally, we examined whether p75NTR mediates myeloid differentiation after TBI. Using a CCI-TBI model in C57Bl/6 WT mice, flow cytometric analysis showed that the population of mature macrophages ($CD11b^{+}F480^{+}$) and dendritic cells ($CD11b^{+}CD11c^{+}$) was significantly increased in the circulation as well as in the injured brain at 7 days after TBI. Interestingly, mice treated with

daily SARA (1 mg/kg i.p.) demonstrated reduced number of mature myeloid cells in both the circulation and the injured brain as well as reduced expression of pro-inflammatory markers in the spleen. Together, our new findings suggest that p75NTR mediates pro-inflammatory responses by modulating myeloid differentiation in the circulation., SARA, by blocking p75NTR, restores splenocyte T cell function and reduces myeloid differentiation. Such peripheral immuno-modulatory effect of SARA may contribute to its beneficial effects after cortical contusion.

Title: Chronic corticosterone primes the brain response to select neuroinflammatory agents by overexpression of Toll-like receptor 2 and S100A8: a potential role for microglia

Authors: *L. T. MICHALOVICZ, A. R. LOCKER, K. A. KELLY, D. B. MILLER, J. P. O'CALLAGHAN;
CDC-NIOSH, Morgantown, WV

Abstract: Neuroinflammation is commonly associated with chemically-induced neurotoxicity. We recently demonstrated that chronic exposure to the classic anti-inflammatory glucocorticoid, corticosterone (CORT), can markedly exacerbate, or “prime”, the neuroinflammatory response to select compounds (e.g., neurotoxicants or inflammogens). The mechanism by which this exacerbation is achieved is not yet understood. Here, we have exposed adult male C57BL/6J mice to several known neurotoxicants/AChE inhibitors/inflammogens that cause differential inflammatory responses following CORT pretreatment: methamphetamine (METH), 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), diisopropyl phosphorofluoridate (DFP), chlorpyrifos

(CPO), pyridostigmine bromide (PB), lipopolysaccharide (LPS), and polyinosinic:polycytidylic acid (PIC). While a single exposure to these agents increases the expression of inflammatory cytokines in the brain (with the exception of PB), chronic (4-7 days) exposure to CORT (200 mg/L) in the drinking water prior to treatment enhanced the METH, DFP, CPO, and LPS induced neuroinflammation. The extension of this CORT effect across these multiple models, including those that cause neuronal damage and those that do not, suggests that the glial rather than neuronal response to the compounds is important for the proinflammatory effects of CORT. Toll-like receptors (TLRs) have been strongly implicated in glial priming of the neuroinflammatory response. Thus, we investigated whether TLR expression was altered in the brain in parallel with enhanced neuroinflammation. TLR2 was positively associated with the CORT neuroinflammatory priming effect exhibiting significant overexpression in METH, DFP, CPO, and LPS treated mice, but was unchanged, or even downregulated, in MPTP, PB, and PIC treated animals. In contrast, TLR4 expression was largely unaltered by chronic CORT pretreatment. The S100 calcium-binding protein A8 (S100A8), which has been positively associated with neuroinflammation, showed a similar profile to TLR2 expression across the multiple models, as expression was increased with CORT pretreatment in the brains of METH, DFP, CPO, and LPS exposed animals. While TLR2 expression has been characterized in microglial and astroglial priming, S100A8 overexpression is found in activated microglia, suggesting that microglia may be a primary cell type involved in CORT priming. Our data identify TLR2 and S100A8 as potential biomarkers of CORT priming of the brain inflammatory response, making them potential targets for treating diseases associated with microglial priming, such as Gulf War Illness.

Title: Culturing adult mouse microglia

Authors: *A. D. GREENHALGH[1], B. W. MCCOLL[2], S. DAVID[3];
[1]McGill Univ., Montreal, QC, Canada; [2]The Roslin Inst. and Royal (Dick), Univ. of Edinburgh,

Edinburgh, United Kingdom; [3]Ctr. for Res. in Neurosci., Res. Inst. of the McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Microglia, the resident macrophages in the central nervous system (CNS) play a variety of roles during development, normal tissue homeostasis, defence against pathogen and response to injury and disease. Dissociated cultures of CNS cells has led to a greater understanding of all CNS cell types. A major caveat of such cultures is that cells are often isolated from perinatal animals. However, recent transcriptome data shows neonatal microglia have a significantly different profile to those isolated from the adult mouse, and that transforming growth factor beta (TGF-β) and Macrophage colony-stimulating factor (M-CSF) are needed for cultured adult microglia to retain their *in vivo* profiles. Here, we describe a simple protocol to extract and culture adult microglia with high purity using antibody-coated magnetic beads. We cultured isolated microglia from 12 week old mice in DMEM-F12 media containing FBS (10%) with combinations of recombinant M-CSF, conditioned media from L-929 cells (rich in M-CSF) or TGF- β, for 7 days. We find that L-929 conditioned media plus TGF- β provides the highest yield of microglia after 7 days in culture. Microglia under these conditions show a highly ramified morphology compared to those cultured in L929 media or M-CSF alone, and retain a similar transcriptional profile to freshly isolated microglia. These studies characterise an accessible protocol for the culturing adult microglia that allow the study of these cells in a variety of scenarios, including diseases of the adult CNS.

Title: Tonicity-responsive enhancer binding protein (TonEBP) regulates microglia activation and neuroinflammation

Authors: *D. KIM, H. KIM, B. LEE;
Univ. Ulsan, Ulsan, Korea, Republic of

Abstract: Activation of microglia, the resident macrophages of the central nervous system (CNS), is the hallmark of neuroinflammation in neurodegenerative diseases and other pathological conditions associated with CNS infection. Activation of microglia is often associated with neuronal death. Tonicity-responsive enhancer binding protein (TonEBP) is well known in the kidney as a transcription factor of Rel family such as nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kB). Not limited in the kidney, TonEBP is expressed in various tissues, including brain, heart and thymus. Particularly in the brain, TonEBP is predominantly expressed in neurons. However, no clear evidence has yet been available for detailed function of TonEBP in neuroinflammation. Our studies focused on a possible role of TonEBP in mediating CNS inflammation. For *in vitro* studies, mouse microglial BV2 cells were treated with 100 ng/ml lipopolysacchride (LPS). For *in vivo* studies, mouse hippocampal tissues were isolated from C57BL/6 TonEBP wild and TonEBP heterozygote mice intracerebroventricularly administered with LPS (2.5 μg). Expression of TonEBP, pro-inflammatory cytokines, cyclooxygenase-2 (Cox2) and inducible nitric oxide synthase (iNOS) was evaluated using western blotting, quantitative real time PCR and enzyme-linked immunosorbent assay (ELISA). LPS stimulation increased TonEBP expression in microglial BV2 cells and mouse hippocampus in a time- and dose-dependent manner. Knockdown of TonEBP resulted in a decreased level of pro-inflammatory cytokines such as tumor necrosis factor alpha (TNF-α), interleukin-1 beta (IL-1β), monocyte chemoattractant protein-1 (MCP-1) and interleukin-6 (IL-6), along with a significant decrease in iNOS and Cox2 expression and nitric oxide (NO) production. These results demonstrate role of TonEBP in mediating neuroinflammation in the microglia in response to LPS.

Title: Distinct neuroimmune responses to different TLR agonists in brain slice cultures

Authors: *J. Y. ZOU, F. T. CREWS;
Univ. North Carolina, Chapel Hill, Chapel Hill, NC

Abstract: The Toll-like receptors (TLRs), a family of pattern recognition receptors and the hallmark of the host innate immunity, are increasingly implemented in various aspects of the central nervous system such as neuronal development, neural plasticity, neurogenesis and brain injury as well as in alcoholism. The present study used an *ex vivo* model of organotypic hippocampal-entorhinal cortex (HEC) slice cultures to investigate neuroimmune responses to several TLR agonists including Pam3CSK4 (TLR2), Poly:IC (TLR3), LPS (TLR4), Imiquimod (TLR7) and ODN D-SL03 (TLR9). HEC slices, prepared from P7 neonates and maintained in cultures for 11days prior to any treatment, were treated with Pam3CSK4 (100ng/ml), Poly:IC (10ug/ml), LPS (100ng/ml), Imiquimod (1ug/ml) and ODN D-SL03 (10ug/ml), all concentrations determined by a concentration-dependent study, for 2, 8, 24, 48 and 72hrs. RT-PCR analysis indicates that cytokine TNFα and IL-1β mRNA levels were rapidly increased following treatments of TLR agonists, reaching peak at 8hrs (10-100 fold increase depending on agonists), and drastically reduced (more than 80% decrease) but remained sustained high level from 24 to 72hrs. Even with only one episode of treatment (24hrs) and then HEC slices were maintained in agonist-free medium for 72hrs, cytokine genes were persistently increased by 3-10 folds depending on agonists. Signaling molecules including MyD88 and NF-kB were activated at early time point (peak at 2hrs but remained high at 8hrs). NRLP3 inflammasome pathway appears to be involved in neuroimmune responses induced by TLR3, TLR7 and TLR9. Activation of TLRs triggered rapid release of nuclear protein HMGB1 into culture media, with 6-12 fold increase in response to stimulation of TLR4, 7 and 9 at 8hr time point. HMGB1 is able to form complexes with all TLR agonists and HMGB1-TLR agonist complexes significantly potentiated neuroimmune gene induction. Microglia play key role in early neuroimmune responses to TLR activation since blockade of microglia activation by minocycline (10ug/ml) abolished TLR agonist-induced cytokine gene expression. Activation of TLR 2, 3 4 and 7 up-regulates neuron-released fractalkine but downregulates microglia-expressed receptor CX3CR1 genes. In contrast, activation of TLR 2, 4, 7 and 9 downregulates neuron-released CD200 but up-regulates microglia-expressed CD200 receptor genes. Together, these results may facilitate our understanding of the process and progression of neuroimmune responses to activation of different TLRs in brain. (supported by NIAAA)

Title: Cobalt protoporphyrin up-regulates cyclooxygenase-2 expression through a heme oxygenase independent mechanism

Authors: *H.-Y. LIN, D.-Y. LU;
China Med. Univ., Taichung City, Taiwan

Abstract: Cobalt protoporphyrin (CoPP) is a potent HO-1 inducer and generally known to be cytoprotective in various cell types. However, the roles of CoPP in regulating inflammation are intricate. Little is known about the CoPP induced cyclooxygenase-2 (COX-2) expression and its downstream signaling in microglial cells. In current study, CoPP caused concentration- and time-dependent increases in COX-2 expression in microglial cells. Furthermore, CoPP resulted in the dissociation of Apoptosis signal-regulating kinase (ASK) 1 from 14-3-3 and which contributed to ASK1 activation. Transfecting cells with ASK1 siRNA reduced CoPP-induced COX-2 expression. YO-PRO-1 probe accumulation results indicated that CoPP induced P2X7 receptors activation in microglia. Treatment of cells with P2X7 inhibitors effectively reduced CoPP-induced COX-2 expression. Moreover, CoPP also increased ERK, JNK and p38 phosphorylation. The current study also found that CoPP induced protein inhibitor of activated STAT 1 (PIAS1) degradation in concentration- and time- dependent manners. Furthermore, CoPP also caused PI3- kinase, Akt and Glycogen synthase kinase 3α/β (GSK3α/β) phosphorylation. Administration with PI3-kinase/Akt inhibitors reversed CoPP-mediated COX-2 expression and PIAS1 degradation. PIAS1 is reported to be involved in modulating anti-inflammatory response through negative regulation of transcription factors. On the other hand, treatment with GSK3α/β inhibitors enhanced CoPP-mediated COX-2 expression and PIAS1 degradation. These results suggest that CoPP induces COX-2 expression through activating P2X7 receptors and ASK1/MAP kinases pathways. CoPP also induced PIAS1 degradation via PI3-kinase/Akt and GSK3α/β pathways to modulate COX-2 expression in microglial cells. Our study provides a new insight into the regulatory effect of CoPP on neuroinflammation.

Title: The effects of cadmium chloride on cell viability and inflammation in human astrocytes

Authors: *S. PHUAGKHAOPONG, D. OSPONDPANT, T. KASEMSUK, P. SATHAVORASMITH, P. VIVITHANAPORN;
Deparment of Pharmacol., Mahidol Univ., Bangkok, Thailand

Abstract: Cadmium is toxic to neurons and accumulates in the central nervous system. The exposure of cadmium is associated with neurodegenerative diseases such as Alzheimer's disease and Parkinson disease. However, the effects of cadmium on astrocytes remain unclear. Previous studies reported that prolonged exposure to cadmium induces inflammation in variety of tissues, including kidneys, liver and lungs, by increasing the expression of cyclooxygenase-2 (COX-2), interleukin 6 (IL-6), and interleukin 8 (IL-8). Herein we hypothesize that cadmium may cause neurodegenerative diseases by inducing cytotoxicity and inflammation of astrocytes. Thus, this study aims to investigate the effects of cadmium on the viability of astrocytes and the expression of COX-2 and cytokines/chemokines in U-87 MG and A172 human astrocytoma cells. Cells were treated with 0.1-100 μM of cadmium chloride for 6, 24 and 48 hours. Twenty-four hours after exposure to cadmium chloride, the median toxic concentration (TC50) measured by MTT assays are about 22.85 and 16.18 μM in U-87 MG and A172 astrocytes, respectively. Cell viability was decreased in a time- and concentration-dependent manner, compared to the mock-treated group. At 6-hour exposure, the non-toxic dose of cadmium chloride at 10 μM promoted the expression of COX-2, IL-6 and IL-8 assessed by real time PCR assays. In summary, the present results indicate that cadmium is toxic to human astrocytes and induces the production of inflammatory mediators i.e. prostaglandins, cytokines/chemokines. These direct toxic effects to astrocytes together with the up-regulation of inflammation may play a role in central nervous system dysfunction and contribute to the pathophysiology of neurodegenerative diseases.

Title: Status epilepticus induces lasting inflammatory changes in the hippocampus

Authors: *N. H. VARVEL[1], M. JUCKER[2,3], R. DINGLEDINE[1];
[1]Pharmacol., Emory Univ., Atlanta, GA; [2]Hertie Inst. for Clin. Brain Res., Tuebingen, Germany;
[3]DZNE-German Ctr. for Neurodegenerative Dis., Tuebingen, Germany

Abstract: The prolonged seizures of generalized status epilepticus (SE) trigger a series of molecular and cellular events that produce cognitive deficits and can eventually culminate in the appearance of spontaneous seizures, i.e. epilepsy. Initial known events include transient opening of the blood brain barrier (BBB) and reactive astrocytosis accompanied by activation of microglia, the resident brain macrophage. Between one and three days after SE circulating monocytes infiltrate the brain in a Ccr2-dependent manner. Inhibiting recruitment of these cells reduces the induction of IL-1β message by 50%. The goals of the present study were to utilize immunohistological approaches to examine the nature of blood brain barrier opening after SE and the innate and adaptive immune responses after systemic injection of the chemoconvulsant, kainic acid (KA). While peripheral Ccr2+ monocytes infiltrate the brain after SE, few CD3+ T-cells were encountered in the brain parenchyma. Only a few macrophages in each section were positive for hemosiderin by Prussian blue staining suggesting cerebral hemorrhage was not common after KA-induced SE. Fibrinogen staining was elevated in the KA-treated mice when compared to saline-treated controls. However, fibrinogen was confined to the vasculature and only rarely was observed in the parenchyma. On average 43,000 Iba1+ cells were counted in the control hippocampus. One day after SE, the number of Iba1+ cells in the hippocampus increased 2-fold and was further elevated 4-fold over controls at the three and 14 day time points. The Iba1+ and CX3CR1+ cells remained clustered around the sites of hippocampal damage up to 14 days after SE. Numerous markers of innate immune cell activation including CD11b, CD45, CD68 and CD169 were elevated in the hippocampus of KA-treated mice one and three after SE when compared to control hippocampi. Notably, these same indices of innate immune cell activation remained elevated when compared to saline-treated controls 14 days after SE. Taken together, these data argue against a generalized opening of the BBB immediately after SE and suggest that monocyte-dominated infiltration into the brain is regulated in part by Ccr2 signaling axis. Furthermore, our histological findings indicate that the neuroinflammatory response is mediated in part by central and peripheral innate immune cells of myeloid lineage with little evidence for an adaptive immune response at the time points examined.

Title: Chronic intermittent hypoxia associated oxidative stress and inflammation in male rats

Authors: *B. SNYDER[1], B. SHELL[2], J. CUNNINGHAM[2], R. L. CUNNINGHAM[2];
[1]Univ. of North Texas Hlth. Sci. Ctr., Ft Worth, TX; [2]UNT Hlth. Sci. Ctr., Ft. Worth, TX

Abstract: Sleep apnea is a common comorbidity in neurodegenerative diseases such as Parkinson 's disease and Alzheimer's disease. Increased inflammation and oxidative stress (OS) are hallmarks of both sleep apnea and neurodegeneration. The elevated OS associated with sleep apnea may be a mechanism leading to altered inflammatory profiles within specific brain nuclei. To examine the role of OS on inflammation in the brain, we used an animal model of chronic intermittent hypoxia (CIH) which mimics the hypoxemia experienced by sleep apnea patients. Adult male rats were exposed to 8 hours of 6 minute cycles of alternating room air oxygen and 8% oxygen levels during the light cycle for seven days. Plasma was assessed for OS and inflammatory markers. Also, inflammatory markers and OS were measured in five different brain nuclei: the substantia nigra (SN), hippocampus (H), entorhinal cortex (ETC), rostral ventrolateral medulla (RVLM), and the solitary tract nucleus (NTS). Our results showed that CIH is associated with increased circulating OS and inflammation. However, widely varying effects of OS and inflammation within different brain regions were observed in response to CIH. CIH had a significant protective effect in the hypothalamus, known for regulating homeostasis. A pro-inflammatory profile in the SN and ETC was observed as well as a significant increase in KC-GRO, a cytokine associated with recruitment of neutrophils and angiogenesis. This indicates that OS induced by mild hypoxemia is capable of having both protective and damaging effects on the brain. In regions associated with homeostasis, a protective effect of CIH was found. However, in brain regions associated with neurodegeneration, a damaging effect of CIH was observed, indicating that hypoxemia may be a contributor of neurodegenerative diseases.

Title: The danger-associated molecular pattern HMGB1 mediates the neuroinflammatory effects of methamphetamine

Authors: *M. G. FRANK[1], S. ADHIKARY[3], J. L. SOBESKY[2], M. D. WEBER[2], L. R. WATKINS[2], S. F. MAIER[2];
[2]Psychology and Neuoscience, [1]Univ. of Colorado, Boulder, CO; [3]NIDA, NIH, Washington, D.C., DC

Abstract: Methamphetamine (METH) induces neuroinflammatory effects, which may contribute to the neurotoxicity of METH. However, the mechanism by which METH induces neuroinflammation has yet to be clarified. A considerable body of evidence suggests that METH induces cellular damage and distress, particularly in dopaminergic neurons. Damaged neurons release danger-associated molecular patterns (DAMPs) such as high mobility group box-1 (HMGB1), which induces pro-inflammatory effects in microglia by signaling through toll-like receptor 4 (TLR4) or the receptor for advanced glycation endproducts (RAGE). Indeed, HMGB1 released from damaged neurons has been found to mediate neuroinflammation in models of seizure, ischemia, and traumatic brain injury. Therefore, we explored the notion here that METH induces neuroinflammation indirectly through the release of HMGB1 from damaged neurons, which then signals through TLR4 on microglia to induce a pro-inflammatory cytokine response. Adult male Sprague-Dawley rats were injected IP with METH (10 mg/kg) or vehicle (0.9% saline). Neuroinflammatory effects of METH were measured in nucleus accumbens (NAcc), ventral tegmental area (VTA) and prefrontal cortex (PFC) at 2h, 4h and 6h after injection. To assess whether METH directly induces pro-inflammatory effects in microglia, whole brain or striatal microglia were isolated using a Percoll density gradient and exposed to METH (0, 0.1, 1, 10, 100, or 1000 uM) for 24h and pro-inflammatory cytokines measured. To determine the role of HMGB1 in the neuroinflammatory effects of METH, animals were injected intra-cisterna magna with the HMGB1 antagonist box A (10 ug) or vehicle (sterile water). 24h post-injection,

animals were injected IP with METH (10 mg/kg) or vehicle (0.9% saline) and 4h later neuroinflammatory effects measured in NAcc, VTA, and PFC. METH induced robust pro-inflammatory effects in NAcc, VTA, and PFC as a function of time and pro-inflammatory analyte measured. In particular, METH induced profound effects on interleukin-1 beta (IL-1) in NAcc (2h) and PFC (2h and 4h). Exposure of microglia to METH *in vitro* failed to induce a pro-inflammatory response, but rather induced significant cell death as well as decreases in cytokines at the high concentrations of METH. Pre-treatment with the HMGB1 antagonist box A blocked the neuroinflammatory effects (IL-1) of METH in NAcc, VTA and PFC. The present results suggest that HMGB1 mediates, in part, the neuroinflammatory effects of METH and thus may alert CNS innate immune cells to the toxic effects of METH.

Title: The effect of sevoflurane in systemic inflammation-induced cognitive dysfunction

Authors: *W. LEUNG[1], O. T. W. NG[2], S. S. Y. CHENG[2], C. H. L. HUNG[2], J. M. T. CHU[1], R. C. C. CHANG[2], G. T. C. WONG[1];
[1]Dept. of Anaesthesiology, [2]Dept. of Anat., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: With longer lifespan and medical advancement, about half of the population over 65 may have undergone operative procedures with anaesthesia and subsequently be more prone to post-operative cognitive dysfunction (POCD). Upon surgical procedures, systemic inflammation is elicited and the production of peripheral cytokines would prime the microglia after direct entry across the blood-brain-barrier. Subsequent neuroinflammation could affect cognitive functions leading to POCD. Risk factors of POCD are not limited to age, but also the modulatory effects of anaesthetic agents. The effect of a commonly used inhalational anaesthetic agent, sevoflurane remains unclear. To demonstrate the modulatory effect of sevoflurane on systemic inflammation-induced cognitive dysfunction, 3-month-old of young and 18-month-old of aged mice were subjected to sevoflurane exposure and administration of lipopolysaccharides. After treatment, the

results from the Morris water maze showed an increase in the latency to find the hidden platform in both young and aged mice, implying its effect on spatial memory. Modulations in the expression level of presynaptic, postsynaptic and synaptic vesicle membrane proteins within different brain regions were detected in Western Blot. Differential changes in both endocytosis and exocytosis of synaptic vesicles were detected by measuring the uptake and release of FM1-43, a lipophilic styryl fluorescent dye in synaptosome fraction of brain tissues. These results indicate that sevoflurane exerts its effect on systemic inflammation-induced cognitive dysfunction.

Title: The effect of immunosuppressive and immunomodulatory drugs in a cellular model of brain inflammation: involvement of nitric oxide-mediated neuronal death

Authors: C. NEVEU, E. ANDRIAMBELOSON, *S. WAGNER;
NEUROFIT, ILLKIRCH, France

Abstract: Neuroinflammation is now recognized as a critical process in different neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, stroke and multiple sclerosis. Microglia and astrocytes are key players in neuroinflammation since they release a wide variety of proinflammatory mediators, including nitric oxide (NO). In the present study, the potential neuroprotective effect of immunosuppressive (dexamethasone) and immunomodulatory (doramapimod) drugs was investigated in lipopolysaccharide (LPS) -stimulated microglia/astrocyte/neuron co-cultures, with special attention to the involvement of NO in the death of neurons. Stimulation of co-cultures with LPS produced substantial, sustained production of NO in the medium. Significant death of dopaminergic neurons was observed 5 days post-stimulation. Neuronal death was fully prevented by dexamethasone treatment but not by doramapimod although both drugs fully suppressed the production of NO. It is noteworthy that the antioxidant resveratrol markedly reduced NO production along with partial inhibition of neuronal death. These data indicates that inflammation-mediated neuronal death in

microglia/astrocyte/neuron co-cultures involves both NO-dependent and NO-independent pathways.

Title: Administration of IL-4 regulates macrophage polarization and reduces secondary tissue damage after spinal cord injury

Authors: ***I. FRANCOS-QUIJORNA**, A. MARTÍNEZ-MURIANA, R. LÓPEZ-VALES; Univ. Autonoma De Barcelona, Bellaterra, Spain

Abstract: Spinal cord injury (SCI) elicits an inflammatory response that comprises mainly microglia and peripheral blood macrophages. Several studies indicate that these cells contribute to tissue damage and functional deficits in several central nervous system disorders, including SCI. However, they have also shown to promote repair in other experimental paradigms. These paradoxically conflicting actions of microglia and macrophages may depend on the signals in the lesion milieu and the phenotype that they can adopt, “classical” M1 activation (pro-inflammatory and cytotoxic effects) or “alternative” M2 activation (anti-inflammatory and tissue repair effects). After SCI, microglial cells and macrophages display predominantly M1 phenotype, however, the factors that impede M2 polarization in SCI are not fully known. Answers to these questions are of high relevance for advancing therapeutics to treat SCI. In the present work we show that the expression of IL-4, one of the main M2 polarizing factor, is not induced in the contused spinal cord. To assess whether the lack of IL-4 accounts for the deficit in M2 polarization after SCI, we administrated mouse recombinant IL-4 into the contused spinal cord. We found that acute administration of IL-4 after SCI led to minor induction of M2 markers only in microglia. However, when IL-4 was given at 48 hours post-injury, the expression of Arg1 and CD206 was strongly induced in both, microglia and macrophages, adopting a hybrid M1/M2 phenotype that remained stable for at least four days. Interestingly, at 4 days post-injection (6

days post-injury), besides myeloid cells, we found an immune cell population (CD45high, CD11blow) that was only present in IL-4-treated animals. Further analysis on this immune cell subtype revealed that they were phenotypically compatible with resolution-phase macrophages, suggesting that IL-4 drives microglia and macrophage polarization towards a mixed M1/M2 as well as to a resolution-phase phenotype. We finally found that IL-4 led to beneficial effects in functional and histopathological outcomes after SCI, despite IL-4 was injected 2 days after lesion. Overall, our data indicates that the lack of IL-4 in the contused spinal cord impedes the shift in the polarization of microglia and macrophages in SCI, which leads to functional deficits and secondary tissue damage. We show that a single administration of IL-4 at 2 days after SCI is effective in reducing functional impairments and tissue damage. Our data suggest that treatment with IL-4 could be a new approach with a wide therapeutic window for the treatment of acute SCI, for which there are no effective treatment yet.

Title: The critical role of proteolytic relay through cathepsins B and E in the phenotypic change of microglia/macrophage

Authors: *N. JUNJUN[1], Z. WU[1], Y. HAYASHI[1], C. PETERS[2], K. YAMAMOTO[3], H. QING[4], H. NAKANISHI[1];
[1]Dept. of Aging Sci. and Pharmacol., Kyushu Univ., Fukuoka, Japan; [2]Albert Ludwigs Universitt Freibrug, Freiburg, Germany; [3]Proteolysis Res. Laboratory, Kyushu Univ., Fukuoka, Japan; [4]Beijing institute of technology, Beijing, China

Abstract: In spite of its clinical importance, little is known about the mechanisms underlying the phenotypic shift of microglia/macrophages. We herein show the critical role of a proteolytic

relay through cathepsins B (CatB) and E (CatE) as a phenotypic switch in microglia/macrophages. Hypoxic/ischemia (HI) caused extensive brain injury in neonatal wild-type mice, but not in CatB-/- mice. Furthermore, HI induced M1-like followed by M2-like polarization of microglia/macrophages in wild-type mice, but only M2-like polarization in CatB-/- mice. A specific CatB inhibitor CA-074Me prevented the activation of nuclear factor-κB (NF-κB) by inhibiting autophagic IκBα degradation following an HI-like injury. Rather surprisingly, CatE has been shown to increase the CatB expression after HI by the liberation of tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) from microglia through the proteasomal pathway. Thus, a proteolytic relay through the early CatE/TRAIL-dependent and late CatB-dependent pathways may play an essential role in the M1-like phenotypic polarization of microglia/macrophages.

Title: Lentiviral overexpression of interleukin-1β in the hippocampus induces neurogenesis-associated cognitive deficits in adult male rats

Authors: ***C. M. HUESTON**, C. S. Ó'LÉIME, D. A. KOZAREVA, J. F. CRYAN, Y. M. NOLAN;
Univ. Col. Cork, Cork, Ireland

Abstract: Adult neurogenesis within the subgranular zone of the hippocampus, which is integral for normal cognitive function, can be affected by inflammatory tone. Previous studies have demonstrated that elevated levels of the pro-inflammatory cytokine interleukin-1β (IL-1β) in the hippocampus, has detrimental effects on some aspects of memory and cognitive function, as well as a negative impact on the proliferation and survival of newly born neurons. Thus, the current study aimed to assess whether long-term increased expression of IL-1β through lentiviral mediated overexpression of the protein would alter performance in a series of hippocampal-dependent tasks including pattern separation, which has previously been demonstrated to be

dependent on hippocampal neurogenesis. A lentivirus overexpressing IL-1β (3.7x10^3 TU) or mCherry as a control was bilaterally injected into the dorsal hippocampus of adult male Sprague-Dawley rats (n = 10). Three weeks after injection a battery of behavioural tests were carried out, including spontaneous alternation in the Y-maze (a measure of working memory), the location recognition task (a measure of spatial memory), pattern separation in a modified location recognition task, and the open field test. Hippocampal tissue was collected 4 days following behavioural testing for analysis by real-time RT-PCR for changes in gene expression levels of IL-1β and neurogenesis-related markers. Increased mRNA expression of IL-1β was confirmed in the hippocampus following lentiviral IL-1β overexpression. IL-1β overexpression did not alter spontaneous alternations in the Y-maze test, or location discrimination in the location recognition task. In the pattern separation task, rats overexpressing IL-1β in the dorsal hippocampus were not able to pattern separate in the small separation condition, but were able to do so with a large separation, suggesting hippocampal neurogenesis-associated dysfunction. No change in locomotor activity was observed in the open field test. Analysis of the gene expression levels of neurogenic markers Ki67 and DCX, as well as expression of the nuclear receptor TLX, a neurogenesis regulator which has previously been shown to be reduced in response to IL-1β treatment *in vitro*, are currently underway. The current results indicate that long-term hippocampal exposure to the pro-inflammatory cytokine IL-1β has detrimental effects on the neurogenesis-associated pattern separation cognitive task. Thus, the ability to pattern separate may be more susceptible to the detrimental effects of chronic inflammation than other hippocampal-dependant functions such as working memory and location recognition memory.

Title: Intracellular acidification during the acute phase of neuroinflammation

Authors: *A. A. TYRTYSHNAIA[1], A. M. KLESCHEVNIKOV[2], M. KHOTIMCHENKO[1]; [1]Far Eastern Federal Univ., Vladivostok, Russian Federation; [2]Neurosciences, Univ. of California San Diego, La Jolla, CA

Abstract: Maintenance of the brain pH level within the physiological norm is an important component of the central nervous system homeostasis. pH levels strongly impact 3D-structure of proteins and other biological molecules, thus affecting functional activity of enzymes, receptors, and ion channels. In some conditions, the capacity of pH-regulatory system can be overcome by various pathological factors resulting in alterations of the brain acidity. pH changes are found in nervous tissue pathologies associated with neuroinflammation, such as Alzheimer's disease. We hypothesized that acute neuroinflammation may result in substantial shifts of the intracellular pH (pHi) levels, and that such pHi changes may contribute significantly to cognitive abnormalities in neurodegenerative disorders. To test this hypothesis, we developed an *in vitro* model of acute neuroinflammation. Measurements of intracellular pH levels were performed on transverse hippocampal slices using ratiometric pH-sensitive fluorescent dye BCECF. Hippocampal slices of 3 month old mice were incubated for 1 h in ACSF containing either LPS (1 μg/ml) or vehicle. After washing-out, the slices were stained with BCECF-AM (1 μM, 30 min at 32°C) and transferred to the recording chamber for measurements of pHi in pyramidal neurons of the CA1 region. We observed that pHi levels were not different in the LPS vs. Veh treated slices at 2-3.5 h after the treatment. However, at a later period (3.5-7 h) pHi levels were in Veh: 7.28 ± 0.05; in LPS: 6.92 ± 0.07, $p < 0.001$, showing a difference of about 0.36 pH units. To test if the LPS treatment induced neuroinflammation, densities of IL1β-positive neurons have been measured in the LPS and Veh-treated slices using immunohistochemistry. The density was in Veh: 312.66 ± 50.45; in LPS: 598.72 ± 77.44 cells/mm2, $p < 0.001$, confirming induction of neuroinflammation by '*in vitro*' treatment with LPS. To examine whether or not the effects of neuroinflammation on pHi levels could be observed *in vivo*, LPS or Veh were injected in 12 month old mice, and the levels of pHi were measured 8 h later. Again, pHi level was significantly reduced in slices from LPS vs. Veh -injected animals (Veh: 7.13 ± 0.03; LPS: 6.78 ± 0.08, $p = 0.001$). Thus, our results show that acute neuroinflammation causes a profound temporal intracellular acidification in the CA1 pyramidal neurons, which may affect neuronal and synaptic functions in pathologies.

Title: Microglia activation and monocyte recruitment in LPS induced neuroinflammation in mouse brain

Authors: *Q. CHEN[1], V. B. CHEUNG[2], C. HAN[2], S. MIYAKE[1], K. TAJINDA[1], H. ITO[1]; [1]Neuroscience, Astellas Res. Inst. of Ameri, Skokie, IL; [2]Master of Biotech. program, Northwestern Univ., Evanston, IL

Abstract: Neuroinflammation is not only a common characteristic in neurodegenerative diseases, but also associated with mental health conditions such as depression, bipolar disease, Schizophrenia and posttraumatic stress disease (PTSD), etc. Microglial cells are the resident immune cells in CNS which operate as critical effector and regulator of neuroinflammatory processes in the brain. The prolonged microglia activation has produced pro-inflammatory cytokines and other inflammatory mediators which disrupt the neuro-immune homeostasis in brain. In addition, in neuro-psychiatric diseases and neurological diseases, the immune-to-brain communication has been altered in pathological conditions such as inflammation and stress. The increased monocyte trafficking into the brain has further elevated pro-inflammatory cytokine levels and affected the innate immune function in brain which induces a wide range of detrimental effects in neuronal function. Therefore, targeting on the microglia activation and monocyte trafficking into brain will provide a novel approach for the treatment of neuro-immunological pathophysiology-involved neuropsychiatric and neurological diseases. In present studies, we established *in vitro* primary cultured microglia, primary microglia/ neuron co-culture systems. We investigated microglia M1 and M2 polarization by using LPS- and IL4-stimulated *in vitro* model and evaluated pro-inflammatory chemo-cytokine expression alteration by using qRT-PCR and multiplex ELISA assays. In the meantime, we studied the microglia activation and monocyte recruitment in endotoxin LPS-challenged neuroinflammation mice model. Acute and sub-chronic LPS systemic injection could induce the robust neuroinflammation phenotype in the brain. We also established microglia isolation protocol and developed flow cytometry assays to quantify microglia activation and monocyte trafficking in adult mouse brain. We demonstrated a significant increase in $CD11b^{+}CD45^{high}$ monocytes in the LPS-challenged brain samples. Furthermore, we are working to develop the flow cytometry assays to measure microglia activation marker in inflamed brain samples. These studies will help us to understand the microglia / immune cell mechanism in neuroinflammation and facilitate anti-inflammatory targets validation in neuropsychiatric diseases treatment.

Title: Characterization of the translocator protein (TSPO) ligand [^{3}H]PBR28 binding in BV2 microglial cell line homogenates and in rodent brain and spinal cord autoradiography

Authors: H. XIAO[1], *J. LI[2,1], M. MORIN[1], L. J. MARTIN[1], M. P. JOHNSON[1];
[1]Neurosci. Discovery, Lilly Res. Labs., Indianapolis, IN; [2]Eli Lilly & Co, Indianapolis, IN

Abstract: **BACKGROUND:** It has been well documented that the up-regulation of the translocator protein (18 kD) (TSPO) in microglia and astrocytes in response to lesions and/or neuroinflammation is directly associated with the degree of damage. Increased TSPO ligand binding has been investigated as a molecular *in vivo* sensor of neuronal damage and inflammation in patients with neurodegenerative diseases that are characterized by neuronal loss in discrete areas of the CNS. In addition, TSPO ligands show neuroprotective and anti-inflammatory effects in experimental models of peripheral neuropathies and traumatic brain injury. These ligands might therefore also be valuable for the treatment of neurologic diseases with inflammation-related pathophysiology. Here, we report TSPO expression in a cultured murine BV-2 microglial cell line and studied the effects of the TSPO ligand [^{3}H]PBR28 on microglial functions. We also use frozen section autoradiography to study TSPO radioligand [^{3}H]PBR28 binding in experimental neuroinflammatory models. **METHOD**: TSPO ligand [^{3}H]PBR28 saturation and competition binding assays were performed in murine BV-2 microglial homogenates. Autoradiography of [^{3}H]PBR28 binding for the activated microglial/astrocytes was assessed in sections of spinal cord from an animal model of experimental allergic encephalomyelitis (EAE) and after intrastraital Lipopolysaccharide (LPS)-induced neuroinflammation. **RESULTS**: TSPO was highly expressed in BV2 microglial cells line. High affinity binding of [^{3}H]PBR28 was detected in membranes prepared from BV-2 cells (Bmax = 7156 fmol/mg; Kd = 0.332 nM). Multiple known TSPO ligands potently displaced [^{3}H]PBR28 from BV2 homogenates. Autoradiograph of LPS-induced rat striatum lesions showed high intensity [^{3}H]PBR28 binding in the LPS-challenged hemisphere vs. saline injected hemisphere of rat brain. In an EAE model, autoradiography displayed a higher binding to grey matter with [^{3}H]PBR28 in EAE mouse spinal cord than in sham controls. **CONCLUSION**: [^{3}H]PBR28 has high binding affinity in murine BV-2 microglial cell membrane.

Autoradiography result suggested that TSPO was upregulated in glia with the EAE model and were also strongly induced after intrastriatal LPS-challenge in the rat.

Title: The Protein Phosphatase 4 complex is required for proper axotomy-induced glial immune responses

Authors: ***L. WINFREE**, M. A. LOGAN;
Junger's Ctr., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Neuronal damage induced by injury, stroke or neurodegenerative disease all elicit a swift immune response from glial cells, including upregulation of glial immune genes, directed migration to injury sites and glial clearance of damaged neurons through phagocytic engulfment. Collectively, these glial responses are critical for minimizing damage to the CNS. For example, proper glial clearance of degenerating neurons before they become necrotic attenuates broader inflammatory responses. Thus, it is essential that we understand the cellular and molecular mechanisms behind these important protective glial responses to assist efforts to therapeutically target glial cells in acute and chronic CNS conditions. To identify new molecular players that contribute to glial phagocytic function after injury, we are using a well-established acute axotomy assay in the powerful genetic model system *Drosophila melanogaster*. Through *in vivo* RNAi screening strategies, we have discovered that the evolutionarily conserved Protein Phosphatase 4 (PP4) serine/threonine phosphatase complex is required for proper glial clearance

of degenerating axons. The trimeric PP4 complex consists of one catalytic subunit (PP4c) and two regulatory subunits (PP4r2 and Falafel). We find that glial-specific knockdown of any of these subunits in the adult brain leads to delayed glial clearance of axonal debris after olfactory nerve axotomy. In addition, inhibition of the PP4 complex in adult glia leads to reduced recruitment of glial membranes to injury sites after axotomy, suggesting that defects in glial membrane dynamics may contribute to reduced phagocytic function in PP4-knockdown glia. Previous work has suggested that the PP4 complex regulates activation of the RhoGTPase Rac1 and is also required for proper cell migration *in vitro* (Martin-Granados, 2008). Importantly, Rac1 is essential for proper glial membrane recruitment and phagocytic clearance of degenerating axons in the adult *Drosophila* brain (Lu, 2014). Thus, we are now investigating the possibility that phosphatase activity of the PP4 complex directs Rac1-mediated glial migratory behavior in the context of innate glial immune responses to neurodegeneration. Collectively, this work highlights the importance of conserved serine/threonine phosphatase-dependent pathways as critical candidate effectors of glial immunity and also reveals a new family of molecules that could be targeted to harness the neuroprotective power of glial cells in the context of injury and neurodegenerative disease.

Title: Functional expression of the intermediate-conductance Ca^{2+}-activated K^+ channel, $K_{Ca}3.1$, in microglia isolated from human neocortical tissue

Authors: L. V. BLOMSTER[1,2], D. STRØBÆK[1], C. HOUGAARD[1], L. PINBORG[2], J. D. MIKKELSEN[2], *P. CHRISTOPHERSEN[1];
[1]Saniona, Ballerup, Denmark; [2]Neurobio. Res. Unit, Copenhagen University Hospital, Denmark

Abstract: Microglia are key players in neuroinflammatory processes and are considered to be cellular targets for development of drugs against neurological diseases. The $K_{Ca}3.1$ channel (*KCNN4*) has been suggested to participate in both pro-inflammatory and restorative

mechanisms of microglia cells. However, most studies are hitherto carried out using cell lines or primary rodent microglia cultures, while little is known about the presence and role of $K_{Ca}3.1$ in human microglia. Here we employ electrophysiological whole-cell measurements combined with selective pharmacological tools to study the functional expression of $K_{Ca}3.1$ in cultured human microglia. Cells were isolated from healthy brain neocortical tissue removed as part of neurosurgical treatment of epilepsy. Based on immunocytochemistry, the cultures contained 92% microglia, 1% astrocytes but no neurons or oligodendrocytes. The microglia were resting and responded to a lipopolysaccharide (LPS) challenge by the release of TNFα. A major fraction (84 %) of the cultured and unstimulated human microglia cells expresses functional $K_{Ca}3.1$ channels as demonstrated by a significant increase in the voltage-independent current at -40 mV upon application of NS309, a potent $K_{Ca}3.1/K_{Ca}2$ channel activator, followed by a significant decrease in response to NS6180, a highly selective $K_{Ca}3.1$ inhibitor (n=75). The "$K_{Ca}3.1$ window" thus defined as the delta current between full activation and full inhibition was estimated to be 239 ± 46 pA. Activation and inhibition of the $K_{Ca}3.1$ channel had a significant impact on the microglia cell membrane potential as measured by current clamp experiments. The resting membrane potential was -24 ± 17 mV and application of NS309 induced a hyperpolarization of the membrane potential to -67 ± 13 mV. Subsequent co-application of NS6180 reversed this effect and restored the resting membrane potential ($p<0.001$, n=7). To activate the microglia the cell cultures were incubated with interleukin-4 (IL-4) or LPS for 2-4 days. IL-4 treated human microglia had a larger cell membrane area, as determined by whole cell capacitance (32 pF), compared to both unstimulated (20 pF, $p<0.001$) and LPS treated (24 pF, $p<0.05$) microglia ($n\geq18$). The fraction of microglia expressing functional $K_{Ca}3.1$ channels was unchanged after treatment with IL-4 or LPS. Microglia stimulated with IL-4 had only a small increase in the overall $K_{Ca}3.1$ current ($p<0.05$, n=28) which is quantitatively in contrast to previous findings in rat microglia. Taken together the data shows that $K_{Ca}3.1$ is functionally expressed on resting human microglia as well as on cells continuously challenged with standard pro- and anti-inflammatory stimuli.

Title: Modulation of Interleukin-10 immunosuppression by Tofacitinib (CP 690,550) in the mouse microglial cell line BV-2

Authors: *K. C. BRADLEY, J. RIVARD, A. JAMES, J. DAVID, L. BRANDENBURG, N. LEE, R. FUERSTENBERG, K. BRUMBAUGH, L. LEONG, G. WEGNER, K. REAGAN; R&D Systems, Inc., Minneapolis, MN

Abstract: The anti-inflammatory cytokine interleukin-10 (IL-10) is known to be necessary for down regulating pro-inflammatory responses toward pathogens. IL-10 inhibits the production of many cytokines downstream of its receptor via the JAK1/Tyk2-STAT3 signaling pathway. The small molecule Tofacitinib, CP 690,550, is a selective inhibitor of JAK family cytoplasmic tyrosine kinases. It has been shown to potently inhibit both JAK3- and JAK1-dependent STAT activation. Mouse microglial BV-2 cells are an established *in vitro* model for neuronal inflammation and have been reported to respond to IL-10 immunosuppression in a manner similar to primary mouse microglial cells. In this model, IL-10 pretreatment attenuates IL-6 and TNF-α secretion in BV-2 cells treated with interferon-γ (IFN-γ) and lipopolysaccharide (LPS) cells. In order to better understand the potential effects of inhibiting the immunosuppressive effects of IL-10, we examined the effects of Tofacitinib on the secretion of pro-inflammatory cytokines and activation of the JAK/STAT signaling pathway. The Mouse XL Cytokine Array was used to screen cell culture supernates from mouse microglial BV-2 cells with or without treatment with IFN-γ and LPS for six hours. We identified increased secretion of several cytokines upon IFN-γ/LPS treatment, including CCL3/4, CCL5, CCL12, CD40, CXCL2, CXCL9, CXCL10, G-CSF, ICAM-1, IL-1α, IL-1ra, IL-6, IL-27, SerpinE1, and TNF-α. The secretion of these cytokines were found to decrease by IL-10 treatment prior to IFN-γ/LPS treatment. We observed that Tofacitinib treatment attenuated the immunosuppressive action of IL-10 by restoring the secretion of CCL2, CCL5, G-CSF, CCL3/4, and CXCL2 to levels near IFN-γ/LPS treatment alone. Interestingly, NEDD8 E1 activating enzyme inhibitor MLN4924 inhibition of the Nuclear Factor-κB (NFκB) signaling pathway did not appear to abrogate IL-10 immunosuppression. Array results were confirmed by using a quantitative Luminex multiplex assay. Because Tofacitinib is known to inhibit JAK family kinases, we evaluated the tyrosine phosphorylation of their substrate STAT proteins. Western blot analysis revealed that Tofacitinib inhibited phosphorylation of Tyr701-STAT1 and Tyr705-STAT3 in a time-dependent manner in BV-2 cells treated with IL-10 and IFN-γ/LPS. While it is well established that LPS-induced

transcription of pro-inflammatory cytokines is regulated by mitogen-activated protein kinases and NFκB, the molecular mechanisms involved in IL-10 suppression of pro-inflammatory cytokine expression are largely unknown and may be affected indirectly by the action of Tofacitinib.

Title: Pesticide-induced mitochondrial dysfunction activates nlrp3 inflammasome signaling pathway in primary murine microglia

Authors: S. SARKAR[1], N. PANICKER[1], M. NEAL[1], H. JIN[1], A. CHARLI[1], *V. ANANTHARAM[2], A. KANTHASAMY[1], A. KANTHASAMY[1];
[1]Biomed. Sci., Iowa State Univ. of Sci. & Technol., Ames, IA; [2]Biomed Sci, Iowa Ctr. for Advanced Neurotoxicology, Iowa State Univ., Ames, IA

Abstract: The NLRP3 inflammasome signaling pathway has recently been recognized as a major player in neuroinflammatory insults in the CNS. Oxidative stress and mitochondrial dysfunction are also known to play a key role in pathophysiological processes of many neurodegenerative diseases, including Parkinson's disease (PD). To date, the relationship between mitochondrial defects and neuroinflammation is not well understood. In the present study, we show that neurotoxic pesticide-induced mitochondrial impairment amplifies the NLRP3 inflammasome proinflammatory cascade in primary microglia. Treatment of primary mouse microglia with LPS induced NLRP3 and pro-IL1β expression. Interestingly, exposure of LPS-primed microglial cells to the mitochondrial complex-1 inhibitory pesticides, rotenone and tebufenpyrad, activates the NLRP3 inflammasome and processing of pro-ILβ to IL-1β in a time and dose-dependent manner, indicating that mitochondrial impairment heightened the pro-

inflammatory response in microglia. Morphological analysis revealed that rotenone and tebufenpyrad significantly increased mitochondrial circularity and solidity in LPS-primed microglia as well as decreased mitochondrial perimeter relative to unprimed microglia, indicating the augmentation of mitochondrial fission during neurotoxic pesticide-induced inflammasome activation. Immunocytochemistry (ICC) revealed that rotenone and tebufenpyrad exposure induced mitochondrial superoxide production in LPS-primed microglia and ICC also showed co-localization of NLRP3 with mitochondrial superoxide in rotenone-treated LPS-primed microglia but not in rotenone-alone-treated microglia. Furthermore, following LPS-priming, more IL-1β was released during exposure tebufenpyrad than to rotenone, indicating that tebufenpyrad is a more potent activator of inflammasome signaling. Collectively, our studies demonstrate for the first time that mitochondrial impairment resulting from neurotoxic pesticide exposure can activate NLRP3 inflammasome signaling in microglia, further augmenting proinflammatory events in the brain. Our findings have important implications in the pathogenesis and progression of environmentally-linked PD.

Title: Sensory ganglia of injured adult mice have augmented populations of Iba1-immunopositive macrophages in the absence of functional p75 neurotrophin receptor

Authors: *L. J. SMITHSON[1,2], M. D. KAWAJA[3];
[1]Washington Univ. In St. Louis, Saint Louis, MO; [2]Ctr. for Neurosci. Studies, [3]Queen's Univ., Kingston, ON, Canada

Abstract: Peripheral nerve injury and disease trigger the activation and infiltration of immune cells (e.g., macrophages) in the affected nerve and associated sensory ganglia. These peripheral macrophages release various cytokines which can heighten the immune response and exacerbate injury (e.g., neuropathic pain) and disease progression (e.g., osteoarthritis). Neurotrophins such as nerve growth factor (NGF) are known mediators of inflammation and monocytic cell

infiltration. The neurotrophin receptor, p75 neurotrophin receptor (p75NTR) binds to all members of the neurotrophin family as well as cytokines with similar low affinity. Both neurotrophins and cytokines have been implicated in the pathophysiological features of sensory neuron dysfunction. The aim of this study was to determine whether the expression of p75NTR in adult mice affects the activation of macrophages in sensory ganglia after unilateral partial sciatic nerve ligation or unilateral injection of monosodium-iodoacetate (MIA) into the hind limb footpad. While wild-type (p75+/+) and p75NTR knockout (p75-/-) mice both displayed a significant increase in the density of Iba1-immunopositive macrophages in the ipsilateral lumbar dorsal root ganglia (DRG) at 1 and 2 weeks post-nerve ligation, only p75-/- mice exhibited a significant increase in the density in the contralateral DRG at 1 week post-injury as well. As for MIA-induced inflammation, p75+/+ and p75-/- mice both displayed increases in the densities of macrophages in the ipsilateral and contralateral DRG at 1 week post-injection; p75-/- mice (as compared to p75+/+ mice) exhibited a significant increase density in the ipsilateral DRG at 2 weeks after MIA injection. Effects seen in p75NTR-deficient mice are curious because macrophages in the mouse DRG (damaged or otherwise) do not express this receptor. Since sciatic nerve ligation and hind limb footpad inflammation both stimulate increased receptor levels by ganglionic glial cells (i.e., satellite and Schwann cells), we propose that p75NTR on these glial cells plays a role in restricting the activation and infiltration of macrophages in the sensory ganglia of adult mice. One possible mechanism may be through p75NTR-mediated sequestration of increased levels of neurotrophins and/or cytokines by glial cells, thereby minimizing macrophage activation and/or infiltration in the murine DRG following injury and inflammation.

Title: Primary microglia isolated from neonatal mice provide a model for the study of NLRP3 inflammasome and the effect of long-term hypoxia

Authors: *R. A. WICKENS[1], L. VER DONCK[2], S. J. BAILEY[1], A. B. MACKENZIE[1]; [1]Univ. of Bath, Bath, United Kingdom; [2]Dept. of Neuroscience, Janssen Res. & Develop., Janssen Pharmaceutica, Beerse, Belgium

Abstract: Microglia act as the primary immune cells of the brain and have inflammatory properties aimed at clearing infected or damaged tissue. Neuroinflammation is thought to play a key role in the pathology of many diseases, including Alzheimer's disease, Parkinson's disease and even psychiatric disorders such as depression (Amor, S. et al. 2010. Immunol. 129(2); 154-169). The NLRP3 inflammasome is a multi-protein complex responsible for caspase-1 activation and the production of inflammatory cytokines IL-1β and IL-18. Furthermore, while most *in vitro* studies use 20% O2, the O2 availability within the brain is thought to range between 0.5-7% O2 (Ivanovic, Z. 2009. J Cell Physiol. 219(2); 271-275). We have previously reported that NLRP3 inflammasome signalling is sensitive to acute hypoxia (4 hr; 5% O2) in a microglia cell line (Wickens, R. et al. 2013. pA2 Online. 11(3) 058P). Here, we have aimed to establish a primary microglia culture using mild trypsinization to study NLRP3 inflammasome expression in long term cultures under different oxygen conditions. Mixed glial cultures were obtained from neonate (P0.5) C57BL/6 pups and cultured in normoxic tissue culture conditions for 3 weeks (~20% O2/5% CO2). Astrocytes were removed via mild trypsin incubation (0.0625% w/v). Microglia were kept in conditioned media for 24 hours prior to testing. To study protein expression, cells were treated with lipopolysaccharide (E. Coli LPS; 0.1 μg/ml; ≤4hr) before cell lysates were collected for western blot. To study inflammasome activity, cells were primed with LPS (0.1 μg/ml; ≤4hr) prior to treatment with ATP (5 mM; 30 minutes) to assess IL-1β release by ELISA. All cells were CD11b+/GFAP-, confirming the presence of microglia. We observed a time-dependant increase in NLRP3 (4 hr, $p=0.06$) and proIL-1β (4 hr, $p<0.05$) expression following LPS stimulation, along with the expression of adaptor protein ASC and P2X7 in stimulated and unstimulated microglia. We then observed an LPS-dependant IL-1β release following cell stimulation with ATP (4 hr LPS, $p<0.001$). Furthermore, caspase-1 inhibition (Ac-YVAD-cmk; 10 μM) caused a significant reduction in ATP-induced IL-1β release ($p<0.05$), indicating the process is caspase-1-dependant. Together, these data suggest the presence of a functional NLRP3 inflammasome. These findings confirm the expression and activity of the NLRP3 inflammasome in neonatal primary microglia. The 3-week microglia culture provides a platform to study NLRP3 inflammasome signalling and the effect of chronic hypoxia, which will give a more accurate insight into microglia activation and inflammasome signalling within the brain and during neuroinflammatory disease.

Title: Central nervous system injury - newly observed abscopal effect of hind-limb radiation

Authors: *C. FEIOCK[1], M. YAGI[2], A. MAIDMAN[3], *A. RENDAHL[3], S. K. HUI[2], D. M. SEELIG[1];
[1]Vet. Clin. Sci., Univ. of Minnesota, Saint Paul, MN; [2]Therapeut. Radiology, Univ. of Minnesota, Minneapolis, MN; [3]Dept. of Statistics, Univ. of Minnesota, Saint Paul, MN

Abstract: Chemotherapy-related cognitive impairment (CRCI), otherwise known as "chemobrain" or "chemo fog," is a well-known phenomenon in cancer survivors, with approximately 30% of breast cancer survivors experiencing impairment up to 10+ years after treatment. The most prominent and enduring declines occur in learning and memory, attention, executive function, and processing speed, leading to severe disturbances in quality of life. However, these same deficits have also been described in cancer survivors who received radiation therapy only, or radiation in combination with chemotherapy (multimodal treatment), yet the consequences of non-brain directed radiotherapy (NBRT) have been poorly characterized and remain largely unstudied. While there have been several studies examining the mechanisms underlying the impact of chemotherapy on the development of CRCI, including the increased production of cytokines and reactive oxygen species, the biological consequences, and therefore mechanisms, of brain injury due to NBRT are unknown. In order to describe the functional and cellular effects of NBRT on the brain, adult female BALB/c mice were given a single-dose of 18-Gy orthovoltage ionizing radiation to the right hind limb. To assess the impact of NBRT on brain glucose metabolism, a subgroup of NBRT mice (n=3) were evaluated by FDG-PET 3 days post irradiation. To assess the longitudinal effects of NBRT, mice were sacrificed at 3-, 14-, and 30-days post irradiation and brains were examined by immunohistochemistry (IHC) for activated astrocytes (GFAP) and microglia (Iba1). The findings in NBRT mice were compared with: (i) mice treated with methotrexate (MTX), a chemotherapeutic agent associated with CRCI and (ii) untreated controls. As compared to untreated controls, FDG-PET imaging revealed decreased FDG uptake in all brain areas of NBRT mice and IHC showed a marked regional and global increase in the number of GFAP and Iba1 positive cells, indicating reactive astrocytosis and microgliosis, respectively, at all 3 sacrifice days. This increase in both GFAP and Iba1 positive cells was equal to the response seen following treatment with MTX alone, potentially indicating

a shared mechanism of CNS damage following either treatment, and also pointing to a potential for a compounding effect if both treatments are given together, as is seen in multimodal cancer treatment. Our initial findings indicate brain bystander effects associated with NBRT and support a role for its potential involvement in CRCI.

Title: Role of N-acylethanolamine acid amidase (NAAA) in (neuro)inflammation

Authors: *S. PONTIS, A. RIBEIRO, F. PALESE, N. REALINI, A. ARMIROTTI, D. PIOMELLI;
Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Fatty acid ethanolamides (FAEs) such as palmitoylethanolamide (PEA) and oleoylethanolamide (OEA) are lipid-derived mediators that potently inhibit inflammation and exert neuroprotective effects; their levels change during central nervous system (CNS) pathological conditions affecting the progression of the neuroinflammatory process. PEA and OEA are preferentially degraded by the intracellular cysteine amidase, N-acylethanolamine acid amidase (NAAA). We have previously demonstrated that NAAA inhibition normalizes PEA and OEA levels, which are severely reduced in several inflammatory models. Moreover our preliminary studies in mouse models of neuroinflammation suggest that NAAA mRNA and protein levels increase in activated microglia. To further characterize the role of NAAA in inflammatory diseases we generated conditional transgenic mice overexpressing NAAA (NAAA ki) in CD11b-positive cells. NAAA ki were obtained by crossing NAAA conditional knock-in heterozygous mice carrying a NAAA isoform-1 coding sequence within the Rosa26 locus with CD11b-Cre transgenic mice. NAAA ki mice display increased levels of NAAA mRNA and protein in the CNS and peripheral organs as demonstrated by qPCR and western blot analysis. Immunofluorescence analysis of lung sections shows increased levels of NAAA in macrophages from NAAA ki mice compared to WT littermates. Moreover, alveolar macrophages of NAAA ki mice display clear signs of activation: they are hypertrophic and show enlarged cytoplasm, nuclear decentralization and increased levels of iNOS. Analysis of CNS sections indicates that

NAAA expression is increased in Iba1-positive cells. In NAAA ki mice it is possible to identify two morphologically distinct types of Iba1-positive cells: (1) activated microglia expressing high levels of NAAA, which show large and ameboid shape; and (2) non-activated microglia with characteristic ramified form, expressing lower levels of NAAA. When challenged with intranasal LPS NAAA ki mice display higher inflammatory parameters - increased leukocyte migration into the lungs, TNF-alpha, IL-6 and MCP-1, compared to wt littermates - confirming that NAAA overexpression increases susceptibility to inflammatory stimuli. Preliminary studies on mouse models of Parkinson's disease (PD) (intrastriatal 6-OHDA injection) suggest that NAAA ki mice are also more sensitive to neuroinflammatory stimuli than wt littermates. NAAA ki mice may provide a valuable tool to elucidate the role of NAAA in PD and other neuroinflammatory conditions.

Title: Kinetic analysis of the translocator protein positron emission tomography ligand [18F]GE-180 in the healthy human brain

Authors: *C. L. FEENEY[1], G. SCOTT[1], J. RAFFEL[1], C. COELLO[2], A. GOLDSTONE[1], G. SEARLE[2], R. GUNN[1,2], D. SHARP[1];
[1]Imperial Col. London, London, United Kingdom; [2]Imanova Ctr. for Imaging Sci., London, United Kingdom

Abstract: Background The translocator protein (TSPO) is upregulated in activated microglia in response to inflammatory stimuli, making TSPO a good a biomarker for neuroinflammation (1). Positron emission tomography (PET) is used to image neuroinflammation by targeting TSPO. First generation radioligands, for example, [11C]PK11195, have been criticised for poor signal-

to-noise ratio and high nonspecific binding which can limit accurate quantification (2) [18F]GE-180 is a new TSPO radiotracer that demonstrates superiority to [11C]PK11195 in animal studies (3), and has the advantage of a longer half-life negating the need for an on-site cyclotron. Aim Our main objective was to evaluate the ability of [18F]GE-180 to quantify TSPO in brains of healthy human participants and to establish the best kinetic modelling approach. Our secondary objective was to determine whether there was any difference in binding between the high and mixed affinity binders (HABS and MABS), determined by a TSPO polymorphism that has been shown to affect binding of other TSPO tracers (4). Methods Ten participants (5 HAB, 5 MAB), 28-57 years old, underwent 90-min PET scans with arterial sampling after bolus injection of [18F]GE-180. One- and two-tissue compartmental models and Logan graphical methods were performed, enabling estimation of the volume of distribution (VT) in regions of interest (ROIs) in the brain. Results A two-tissue compartment model described the data well. The delivery rate constant (K1) was in the region of 0.1 mL/min across all brain regions. Average estimated VT values ranged from 0.3-0.6 ml/cm3. There was no significant difference in VT between HAB and MAB across all ROIs examined. Conclusion A two-tissue compartment model is an appropriate way to model the GE-180 PET signal. We found no clear evidence for a genetic effect of the TSPO polymorphism on binding. Investigation of [18F]GE-180 in clinical populations will be helpful in assessing fully the utility of the tracer for the investigation of activated microglia *in vivo*. References 1.Chen, M. Title: Brain endothelial cell tissue nonspecific alkaline phosphatase directs immunometabolic responses at the blood-brain barrier

Authors: *C. M. BROWN[1], S. JUN[2], W. WANG[1], C. THORE[3];
[1]Neurobio. and Anatomy, Box 9128, [2]Physiol. and Pharmacology, Box 9229, West Virginia Univ. Sch. of Med., Morgantown, WV; [3]Radiology, Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Brain microvascular endothelial cells (BMECs) form a network of cerebral microvessels that comprise the blood-brain barrier (BBB). The BBB preserves cerebral homeostasis, in part, by coordinating central and peripheral systemic inflammatory responses. Thus, preservation of the cerebral microvasculature is essential in acute and chronic neurological dysfunction. Histological staining of tissue nonspecific alkaline phosphatase (TNAP) activity is a well-characterized marker of cerebral microvessels, yet a physiological role for TNAP in BMECs and the BBB is unclear. The goal of this study was to determine a functional role for TNAP in BMECs that supports the preservation of cerebral homeostasis. We tested the hypothesis that acute systemic inflammation impairs TNAP activity in BMECs, leading to disrupted cellular metabolism in these cells, and, ultimately, impaired cerebral homeostasis. To test this hypothesis *in vivo*, female mice (8-12 weeks) were subjected to a moderate experimental sepsis model of acute systemic inflammation for 48h. Cerebral microvessels were stained for TNAP activity, followed by unbiased stereology to quantify the total length of TNAP-positive (TNAP+) microvessels in frontal cortex and striatum. Our results showed that experimental sepsis significantly reduced the number of TNAP+ cerebral microvessels in frontal cortex and striatum compared to their sham-injured counterparts. We then employed a human brain endothelial cell model of the BBB, hCMEC/D3 (D3) cells, to test our hypothesis *in vitro*. Treatment of D3 cells with a novel TNAP inhibitor suppressed TNAP activity. Similarly, lipopolysaccharide (LPS), tumor necrosis factor-α (TNFα), or interferon-γ (IFNγ) challenge to D3 cells also decreased extracellular and secreted TNAP activity. Since TNAP is known to regulate ATP metabolism in osteoblasts and chondrocytes, we tested whether inhibition of TNAP activity alters mitochondrial function in D3 cells. Assessment of BMEC bioenergetics with the Seahorse XF96 analyzer revealed that inhibition of TNAP activity suppressed oxygen consumption, maximal respiration, and glycolytic reserve in the presence of LPS, TNFα, or IFNγ. These results suggest a novel immunometabolic mechanism that supports a putative anti-inflammatory role for TNAP at the BBB. More importantly, these results also suggest the utility of exogenous TNAP administration as a therapeutic strategy to limit neurological dysfunction in acute and chronic systemic inflammation.

Engin., King's Col. London, King's Hlth. Partners, St Thomas' Hosp., London, United Kingdom

Abstract: The barriers of central nervous system (CNS) protect the brain from pathogens, potentially hazardous molecules and cells of the immune system. Dysregulation or breakage of the barriers may lead to harmful invasion of the CNS by pathogens and/or an activated immune system (e.g. during meningoencephalitis). The molecular mechanisms of physiological or pathological opening of the CNS barriers are yet to be elucidated. Here we show that peripheral administration of a synthetic bacterial lipoprotein and ligand for Toll-like receptor 2 (Pam3CSK4, PAM) induce massive infiltration of neutrophils and inflammatory monocytes to the cerebrospinal fluid (CSF) and brain of neonatal mice and rats as well as adult mice. In contrast, a TLR 4 ligand, LPS, did not cause leukocyte infiltration, although it elicited similar level of peripheral inflammation. Flow cytometry and immunohistochemistry studies revealed recruitment of inflammatory cells to choroid plexus following PAM administration suggesting it as one of the potential routes of leukocyte entry into the CSF and brain. RNA sequencing on choroid plexus of neonatal mice treated with PAM or LPS, revealed significant differences in expression level of hundreds of genes. Ingenuity Pathway Analysis (IPA) of data strongly predicted activation of integrin signalling (z-scores 3.12 and -0.2 for PAM and LPS respectively), Rho GTPase signalling (z-scores 3.0 and 0.18 for PAM and LPS respectively) and leukocyte extravasation signalling (z-scores 3.83 and 1.97 for PAM and LPS respectively) by PAM; the signalling pathways that may mediate adhesion, transmigration and extravasation of leukocytes through choroid plexus. Taken together, this study demonstrates a TLR2-mediated

leukocyte infiltration to the CNS through choroid plexus and suggests several potential underlying mechanisms that may facilitate the leukocyte trafficking.

Title: Retinal microglia and Müller glia crosstalk during BMP7 mediated gliosis

Authors: ***S. DHARMARAJAN**[1], T. MCCRAY[1], N. SHEIBANI[2], T. L. BELECKY-ADAMS[1]; [1]INDIANA UNIVERSITY-PURDUE UNIVERSITY INDIANAPOLIS, Indianapolis, IN; [2]Ophthalmology and Visual Sci., UNIVERSIY OF WISCONSIN, MADISON, WI

Abstract: **PURPOSE**: Retinal microglia are key players of the innate immune system of the central nervous system. Upon injury and damage, they become "activated", undergoing characteristic molecular and morphological changes. The primary retinal glial cells, Müller glia, as well as the retinal astrocytes also undergo activation, a process called reactive gliosis, following retinal injury. During reactive gliosis, several factors have been previously shown to be regulated, including bone morphogenetic proteins. Our lab has previously shown that BMP7 is able to trigger Müller cell gliosis, however the mechanism is unclear. In this study we aim to determine if BMP7 is able to trigger activation of retinal microglia, and whether this activation could lead to upregulation of factors which could potentially enhance Müller cell gliosis. **METHODS**: Mouse retinal microglial cells *in vitro* as well as mature mice were exposed to vehicle, lipopolysaccharide (LPS; a known activator of microglia), or BMP7 to test and compare activation. RT-qPCR was performed on RNA from treated microglial cells and mouse retinal tissue for markers of activation. Immunohistochemistry of microglial cells, retinal tissue sections and retinal flatmount preparations were also performed to assess changes in morphological characteristics. Conditioned medium from BMP7 treated retinal microglia was used to treat retinal Müller glial cells and its RNA was assessed via RT-qPCR for changes in gliosis markers. **RESULTS**: Mouse retinal microglia following LPS treatment *in vitro* showed an upregulation in RNA levels of inflammatory markers previously shown to be indicative of activation.

Morphological analysis of microglia *in vitro* as well as in mouse eyes injected with LPS intravitreally, revealed an increase in total cellular area as well as an increase in number of branch points. BMP7 treatment showed an increase in RNA levels of GM-CSF and BMP7 in the microglia, while an increase in INF-γ was observed in Müller glia. Furthermore, an increase in the morphological characteristics was also observed following BMP7 treatment *in vitro* and *in vivo*. Treatment of retinal glia with conditioned medium from activated microglia led to upregulation of some of the markers associated with gliosis, indicative of a positive regulation on retinal gliosis. **CONCLUSION**: Initial findings are indicative of crosstalk between reactive retinal glia and activated microglia. BMP7 does trigger activation of retinal microglia, and both microglia and Müller glia upregulate factors potentially playing a role in regulation of activation states of the two glial cell types.

Title: Phenotypic screening to identify small-molecule inhibitor of glia-mediated neuroinflammation: Target identification and biological effects of a novel compound

Authors: *G. SONG[1], Y. NAM[2], M. JO[2], J. KOO[3], S. PARK[3], K. SUK[2];
[1]Brain Sci. and Engin. Institute, Dept. of Pharmacology,, [2]Brain Sci. and Engin. Institute, Dept. of Pharmacology, BK21 Plus KNU, Kyungpook Natl. Univ., Taegu-City, Korea, Republic of; [3]Dept. of Biophysics and Chem. Biol., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Neuroinflammation is a key process for many neurodegenerative diseases. Therefore, targeting neuroinflammation by small molecules has been thought to be a potential therapeutic strategy. In this study, we have used microglia cell-based phenotypic screening system to identify a novel compound (N-carbamoylated urethane) as a potent anti-neuroinflammatory

agent. The compound inhibited LPS-induced pro-inflammatory cytokines, iNOS, and NO production showing anti-inflammatory effect in microglia. With a fluorescence-guided target identification method (FITGE), we have identified PPAR gamma as a target of the compound. PPRE reporter assay showed that the compound activated PPAR-gamma, but not PPAR-delta or alpha, confirming PPARgamma is a target protein of the compound. In fact, the anti-inflammatory effect of the compound was attenuated by PPAR-gamma knockdown or PPAR-gamma antagonist. In addition, the compound clearly increased the expression of PPAR-gamma-mediated anti-inflammatory genes such as arginase-1 in microglia as well as astrocytes. The anti-neuroinflammatory effect of the compound was also observed in LPS-injected mouse, demonstrating the therapeutic potential of the compound in neuroinflammatory diseases.

Title: The immune receptors dectin-1 and TLR2 are required for conditioning lesion-induced axon protection following spinal cord injury

Authors: *C. YOON[1], K. S. CARBAJAL[2], K. T. BALDWIN[1], B. M. SEGAL[2], R. J. GIGER[1]; [2]Holtom-Garrett Program in Neuroimmunology and Multiple Sclerosis Center, Dept. of Neurol., [1]Univ. of Michigan Sch. of Med., Ann Arbor, MI

Abstract: Under certain circumstances, activation of innate immunity promotes robust regeneration of severed axons following injury to the rodent optic nerve or spinal cord. The underlying molecular mechanisms, however, remain incompletely understood. Our laboratory recently identified that activation of the pattern recognition receptors dectin-1 and toll-like receptor 2 (TLR2) on myeloid cells triggers an inflammatory cascade that enables injured retinal ganglion cells (RGC) to extend lengthy axons that grow far beyond the lesion site in the adult

mouse optic nerve. In the current study, we hypothesized that dectin-1 and TLR2 also participate in the conditioning lesion (CL)-induced effects toward dorsal root ganglion (DRG) neurons that form the dorsal columns in the spinal cord. Histochemical studies show a decrease in macrophage infiltration into DRGs seven days following CL in both dectin-1-/- and dectin-1-/-;TLR2-/- mutant mice, when compared to wild-type controls. Flow cytometric analysis confirmed that following CL, neutrophil, dendritic cell, and macrophage accumulation in DRGs is reduced. Importantly, CL-induced neurite outgrowth of primary DRG neurons is reduced in mutants compared to CL-induced neurite outgrowth of wild-type DRG neurons. Specifically, neurite outgrowth, as assessed by NF200 immunolabeling, is significantly decreased both in dectin-1-/- and dectin-1-/-;TLR2-/- null cultures. Most noticeably, 5-weeks following spinal cord injury, axonal "die-back" in the injured dorsal columns is much more prominent in CL-dectin-1-/-;TLR2-/- mice compared to CL-wildtype mice. This suggests that activation of a dectin-1/TLR2-dependent immune response is required to protect dorsal column axons from "die-back". The long-term goal of this research is to identify the signaling pathways that are activated by the innate immune system to enable CNS axon regeneration following injury or disease. Title: Mitigating microglial-mediated neuroinflammation: the sur1-trpm4 channel regulates calcium-sensitive induction of inos

Authors: *D. B. KURLAND, J. A. STOKUM, V. GERZANICH, J. M. SIMARD; Neurosurg., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Microglia, the resident immune cells of the central nervous system, play a critical role in health and disease. Following injury, microglia upregulate inducible nitric oxide synthase (iNOS), and can exert neurotoxic effects by releasing large quantities of nitric oxide (NO). Expression of iNOS, and many other pro-inflammatory genes, is regulated in part by Ca2+ influx and Ca2+-dependent transcription factors, such as nuclear factor of activated T cells (NFAT). The expression of the non-selective cation channel Sur1-Trpm4 may be one molecular

mechanism by which microglia dynamically modulate Ca2+ influx. We hypothesized that microglial Sur1-Trpm4 plays a role in microglial-mediated neuroinflammation by regulating the calcium-sensitive induction of iNOS by controlling NFAT activity. To test this hypothesis, we evaluated microglial cells before and after stimulation by the Toll-like receptor 4 (TLR4) agonist lipopolysaccharide (LPS). Protein expression was evaluated by immunohistochemistry, western blot, and co-immunoprecipitation (Co-IP). Quantitative PCR (qPCR) was employed to evaluate gene expression. Functional Sur1-Trpm4 activity was evaluated electrophysiologically. Confocal microscopy and the calcium-sensitive fluorescent dye, Fluo-4, was used to dynamically measure intracellular calcium. Extracellular nitrite, a by-product of NO formation, was measured to evaluate iNOS activity. Glibenclamide and 9-Phenanthrol were employed to pharmacologically inhibit Sur1 and Trpm4, respectively. We found that microglia express functional Sur1-Trpm4 channels, whose activity modulated Ca2+ oscillations induced by TLR4 ligation. Inhibition of Ca2+, Sur1-Trpm4 or NFAT all significantly abrogated the induction of iNOS. The activation of NFAT induced by TLR4 ligation was modulated by inhibition of Sur1. Our results strongly support our hypothesis that Sur1-Trpm4 regulates the calcium-sensitive induction of iNOS by controlling NFAT activity. These observations have impactful therapeutic implications. Inhibition of Sur1-Trpm4 using the well-tolerated sulfonylurea glibenclamide (a.k.a. glyburide) may be a promising approach to limit the deleterious effects of microglial-mediated neuroinflammation.

Title: High-fat-diet induced obesity increases nociceptive responses and spinal glial activation

Authors: Y.-Q. GUO[1], J. LEI[1], M.-Q. LIU[1], *K.-Y. FU[2];
[1]Ctr. for TMD & Orofacial Pain, Peking University School & Hospital of Stomatology, China;
[2]Peking Univ. Sch. & Hosp. of Stomatology, Beijing, China

Abstract: Altered nociceptive responses are frequently seen in obese individuals. However, animal experimental evidence is lacking and molecular mechanism is less known. Low grade chronic inflammation of obese individual may contribute to increased nociceptive activity. Microglia are the central immune and inflammatory cells and has been well implicated in the generation and maintenance of pain hypersensitivity. In this study, we aimed to investigate nociceptive behaviors, spinal glial activation and associated proinflammatory adipocytokines expression with high-fat-diet induced obese mice. Chow-diet (CD) mice and high-fat-diet (HFD) mice were fed with 10% kcal% fat and 45% kcal% fat (Research Diet D12450J, D12451) post weaning, respectively. Pain responses to mechanical and thermal stimuli were recorded at age of 6, 8, 10, 12 weeks, together with body weight and glucose, triglyceride, cholesterol in blood. Then lumbar spinal cords were collected at the age of 12 weeks when the HFD mice overweighed the CD mice by 30% in average. Hypersensitivity to von Frey hairs was recorded at the age of 12 weeks in the HFD mice, while no difference with responses to heat stimulation. Microglia (recognized by Iba1) and astrocytes (recognized by GFAP) became activated in the spinal cord from the obese mice with increased fluorescence intensity and morphological changes identified by immunohistochemistry, while no statistical difference for the levels of Iba1 and GFAP using western blotting between the HFD mice and CD mice. mRNA expression of proinflammatory adipocytokines including IL-1β, IL-6, IL-8, TNF-α, and MCP-1 in spinal cord and plantar tissue were significantly upregulated in the HFD mice. In conclusion, the proinflammatory adipocytokines level increased with obesity, together with glial activation and hypersensitivity to mechanical stimulation. Further investigation will be needed to understand the connection between neuroinflammation, glial activation and hypersensitivity to nociceptive stimulation in HFD mice.

Title: Microglial inflammasome formation in obese and diabetic models

Authors: *S. PUGAZHENTHI[1], A. TYAGI[2];
[1]Res. Services-151, Denver VA Med. Ctr., Denver, CO; [2]Med., Univ. of Colorado, Aurora, CO

Abstract: Inflammasome, a multiprotein cytosolic complex, is generated in response to infection, cellular damage and metabolic dysregulation. Its formation leads to activation of caspase-1, followed by proteolytic cleavage and secretion of IL-1β and IL-18. Cellular stress-induced sterile inflammasome formation sets in motion the vicious cycle of neuroinflammation, a central player in cognitive decline of the aging population. A growing number of studies have reported that obesity in mid-life is a predictor of mild cognitive impairment in old age. Brain inflammation in obese individuals is being considered as secondary to peripheral inflammation originating from macrophages. The possibility of microglial activation in response to saturated fatty acids has not been fully investigated although this pathway in hypothalamus is documented. Increased fatty acid uptake by the brain in metabolic syndrome has been demonstrated. To determine the mechanism of central inflammation in obesity and diabetes, we performed pathway specific gene expression profiling with hippocampal samples of mice fed high fat diet for 5 months and of Zucker diabetic rats, a model for type 2 diabetes. Significant elevation of several oxidative stress pathway genes including iNOS, regulatory protein for NOX enzymes (p41NOX), dual oxidase-1, and myeloperoxidase was observed. The inflammatory pathway genes induced were GM-CSF, a growth factor that increases the proliferation of microglia, IFN-γ, P-Selectin, E-Selectin, CCL4, CCL6, CCL7 and CXCL10. Immunoblot analysis revealed the cleavage of caspase-1 and IL-1 beta in these brain samples. Cultured BV cells, a mouse microglial cell line, exposed to palmitic acid secreted IL-1β, a marker for inflammasome formation which was inhibited by caspase-1 inhibitor. Mitochondrial respiration measured by high resolution respirometry using Oroboros Oxygraph-2k decreased in these cells. The combination of obesity and type 2 diabetes (T2D) is a serious health problem, which is projected to afflict 300 million people worldwide by 2020. While improved glycemic control has extended the life span of diabetic patients, it has revealed their susceptibility to aging-associated cognitive decline. Cognitive dysfunction and decrease in brain volume has been reported in chronic T2D patients. While studies in obesity research have focused on macrophages of the periphery, microglial activation of the CNS has remained mostly in the domain of Alzheimer's research. Our findings could bridge these two domains to develop a consensus approach to reduce inflammation in periphery and CNS in aging-associated disorders.

Title: Role of exosomes in microglia communication and inflammation

Authors: *J. C. UDEOCHU[1], S. VILLEDA[2];
[1]UCSF, San Francisco, CA; [2]Univ. of California, San Francisco, CA

Abstract: Microglia, the resident immune cells of the brain, have an important role in maintaining homeostasis through constant surveillance of the brain parenchyma. This homeostatic function is facilitated by the ability of microglia to rapidly sense and respond to physiological and pathological alterations. Although cytokines, purines, and trophic factors have been implicated in microglia responses, it is unclear what other mediators of communication are used by microglia. Bulk transfer of protein, RNA and lipid cargo, via membrane bound extracellular vesicles (EVs), has recently emerged as a conserved mode of cell communication in various cell types. Seminal work in this field has established exosomes, 30-150nM sized EVs, as regulators of activation and cytokine production in peripheral mononuclear cells (PMCs). While there is evidence for microglia exosome secretion, it is unclear if exosome transfer mediates intercellular communication in microglia. Thus, we hypothesized that bulk transfer of protein and RNA message via exosomes plays an important role in microglia-microglia communication and inflammatory activation. We have used a combination of *in vitro* and *in vivo* approaches to characterize microglia-derived exosomes and microglia responses to exosome stimulation. Exosomes were purified from media of primary mouse microglia and BV2 microglia cell line cultures, and characterized for stereotypical morphology and size using electron microscopy and nanoparticle tracking analysis. The functional role of exosome-mediated communication was investigated by examining changes in the ability of microglia to phagocytize opsonized latex beads after exposure to exosomes *in vitro*. We detected that exosome stimulation of microglia significantly enhances microglia phagocytosis. Correspondingly, analysis of microglia-derived exosomes by mass spectrometry identified various proteins implicated in phagocytosis. Additionally, exosome stimulation increased gene expression of inflammatory mediators such as IL1β and TNFα in microglia. Interestingly, total cellular mRNA levels were also reduced in exosome-stimulated groups relative to control, raising the prospect of exosome-RNA mediated transcriptional repression. Ongoing experiments are focused on elucidating mechanisms underlying the observed phagocytic enhancement and transcriptional repression in exosome-stimulated microglia. Together, our data indicate that bulk transfer of protein and RNA via exosomes regulates phagocytosis and inflammatory responses in microglia, positioning exosome-mediated communication as a critical regulator of physiological processes in microglia.

Abstract: Phagocytosis is an essential component of the brain regenerative response that remains poorly explored. We have discovered a universal response of surveillant, ramified

microglia to apoptotic challenge induced by inflammation or excitotoxicity *in vitro* and *in vivo*. Microglia resorted to different strategies to boost their phagocytic output and compensate for the increased number of apoptotic cells, thus maintaining phagocytosis and apoptosis tightly coupled. Unexpectedly, this coupling was chronically lost in a experimental and human mesial temporal lobe epilepsy (MTLE), a major neurological disorder characterized by seizures, excitotoxicity, and inflammation. Importantly, the phagocytosis/apoptosis uncoupling correlated with the expression of microglial pro-inflammatory, epileptogenic cytokines, suggesting its contribution to the pathophysiology of epilepsy. The phagocytic blockade was not directly mediated by glutamate receptors on microglia but by the disruption of local ATP microgradients caused by the hyperactivity of the hippocampal network, which reduced microglial motility and surveillance, and prevented the efficient targeting of apoptotic cells. Finally, the uncoupling led to an increase in the number of apoptotic newborn cells in the neurogenic niche that was not due to decreased survival but to delayed cell clearance after seizures. These results demonstrate that the efficiency of microglial phagocytosis determines the dynamics of apoptosis, and urge to routinely assess the microglial phagocytic efficiency in neurodegenerative disorders.

Title: Mast cells and maternal allergy regulate early life programming of offspring social, affective and hyperactive behavior

Authors: *K. M. LENZ[1,2,3], S. PLATKO[2], A. GALAN[1];
[1]Psychology, [2]Neurosci., [3]Group in Behavioral Neuroendocrinology, The Ohio State Univ., Columbus, OH

Abstract: Perinatal inflammation increases risk for neurodevelopmental disorders, including autism, schizophrenia and ADHD. Autism and ADHD are four times more common in males than females, and there are significant sex differences in onset, severity, and symptoms of schizophrenia. We aim to understand how sex differences in the brain's innate immune environment regulates sex-specific brain development, and ultimately, sex-specific programming of behavior by inflammatory events. Mast cells are innate immune cells, largely associated with peripheral allergy, that are present in the brain of both rodents and humans. Mast cells secrete serotonin, histamine and cytokines, yet their role in brain development is unknown. We have found that thousands of mast cells reside in the developing rat brain, with over 90% situated in or near the hippocampus, thalamus, and amygdala. Males have 40% more mast cells in the brain than females during the neonatal period; by adulthood both males and females have only a few hundred brain-resident mast cells. The goal of these experiments was to determine whether the mast cell population in the neonatal brain regulates the development of social behavior, mood, and impulsivity/attention that are impacted in many neurodevelopmental disorders. We induced mast cell activation during development using prenatal allergic immune challenge on embryonic day 15, and found that it led to significantly increased total mast cells and the percent of activated mast cells in the brains of pups, effects that persisted to postnatal day 4. We then tested juveniles and adults on various behavioral tasks, beginning with juvenile social play behavior post-weaning, which shows a significant sex difference (males > females) at baseline. Males that experienced allergic challenge *in utero* engaged in less social play behavior than control males; in contrast, allergic challenge females showed increased social play behavior relative to control females, indicative of a masculinized phenotype. On the open field test, both allergic challenge males and females showed increased time in the center in the open field than controls and increased locomotion, indicating decreased anxiety and hyperactivity. Currently underway experiments will determine the effects on allergic challenge on adult social interaction, social memory, and attention, as well as assessing the effects of allergic challenge on immediate early

gene expression throughout the limbic system. Together these studies show that mast cells may play a key role in the early life programming of sex differences in brain and behavior following early life perturbations.

Title: Effects of the oxytocin agonist, carbetocin, on sickness behaviours and immune responses in male mice

Authors: *J. M. DELEEMANS, K.-P. OSSENKOPP, M. KAVALIERS;
Dept. of Psychology, Western Univ., London, ON, Canada

Abstract: The nonapeptide, Oxytocin (OT), is implicated in the modulation of reproductive functions and social behaviours, and has also been shown to influence stress response and immune system function. The present study investigated effects of the OT agonist, carbetocin, on behavioural responses and pro-inflammatory cytokine function associated with sickness behaviour in adult male CD-1 mice. To evaluate whether OT is involved in the onset of an immune response and expression of sickness behaviours, adult male mice received either a low (10mg/kg) or high (20mg/kg) intraperitoneal injection of carbetocin, followed 15 minutes later by either saline vehicle or 75μg/kg lipopolysaccharide (LPS), a bacterial endotoxin mimetic, to initiate an immune response. Mice were then tested for 30 minutes in a Dark-Light paradigm to assess locomotor and anxiety related behaviours. Following behavioural testing, animals were euthanized and blood samples were collected for later measurement of Tumor Necrosis Factor Alpha. Mice displayed sickness-like behaviours as shown by reduced locomotor activity and increased anxiety, indicated by increased time spent in the dark chamber, along with reduced number of Dark-Light transitions. The behavioural data showed that OT did not attenuate sickness behaviours in mice treated with LPS. However, in mice treated with carbetocin and then saline, anxiety-like behavior was attenuated and exploratory locomotor activity was augmented, which is consistent with previous studies showing that OT has anxiolytic effects. These results suggest that in male mice carbetocin does not suppress acute phase anxiety and locomotor related sickness behaviours, with immune measures pending.

Title: Reversibility of neuroinflammation and impaired hippocampal function in high fat diet-induced obesity

Authors: ***A. DEY**[1,2], S. HAO[1,2], A. M. STRANAHAN[1];
[1]Neurosci. and Regenerative Med., [2]Med. Col. of Georgia, Georgia Regents Univ., Augusta, GA

Abstract: Obesity increases rates of age-related cognitive decline and dementia, but the mechanisms have yet to be identified. In rodents, high-fat diet consumption (HFD) is associated with deficits in hippocampal function and inflammation in the central nervous system, but basic questions surrounding these processes have yet to be addressed. Specifically, the question of whether consumption of a low-fat diet (LFD) reverses brain inflammation in dietary obesity has never been examined, and as a consequence, the reversibility of cognitive and synaptic deficits remains open to speculation. In this study, we examined the metabolic, neuroimmune, and cognitive consequences of diet reversal. Male mice were fed HFD for 3 months, which was the earliest time point when neuroinflammation and synaptic dysfunction were detected in pilot studies. Half of the HFD mice were then switched to LFD (HFD/LFD) for an additional 2 months, or continued to consume HFD throughout this period (HFD/HFD). An additional set of mice were maintained on LFD throughout the experiment (LFD/LFD). HFD/LFD mice had lower body weights than HFD/HFD mice, but analysis of fat pad weights revealed that HFD/LFD mice still exhibit greater adiposity relative to LFD/LFD mice. Inflammation in visceral adipose tissue was evident in HFD/HFD mice based on immunohistochemical detection of macrophage markers in the epididymal fat pads and analysis of proinflammatory cytokines in adipose tissue using western blotting and ELISA. HFD/HFD mice also had elevated levels of circulating inflammatory cytokines, including TNFa and IL1b. Diet reversal attenuated macrophage accumulation and inflammatory cytokine expression in epididymal fat from HFD/LFD mice, and reduced circulating levels of TNFa and IL1b. HFD/HFD mice had more

cells that expressed the microglial marker IBA1, and many IBA1-positive cells co-expressed MHCII, a marker of classical activation. Diet reversal prevented increases in the number of hippocampal microglia and blocked induction of MHCII in IBA1-positive cells. Attenuation of local inflammation in the hippocampus of HFD/LFD mice was accompanied by normalization of dentate gyrus long-term potentiation (LTP), dendritic spine density, and spatial recognition memory. Taken together, these findings indicate that dietary obesity reversibly impairs hippocampal function, and that synaptic deficits may be attributable to microglial activation. Future studies will be needed to identify the signaling mechanisms for reinstatement of hippocampal function with diet reversal, and to determine whether synaptic deficits and neuroinflammation in obesity are interrelated or independent processes.

Title: Inflammation induces changes in the reward system through a prostaglandin dependent and a prostaglandin independent mechanism

Authors: M. A. SOTOMAYOR[1], *C. GOMEZ[1], A. OCHOA[1], *C. GOMEZ[3], M. D. PÉREZ[2], L. A. MÉNDEZ[2], J. A. LÓPEZ[4];
[2]Pharmacol., [1]Natl. Univ. Mexico, Mexico, Mexico; [3]Med., La Salle Univ., Mexico, Mexico; [4]Natl. Inst. of Psychiatry, Mexico, Mexico

Abstract: The field of neuro-immunology provides new insight into the function of the nervous system, linking inflammation to depression and neurodegeneration among others, however the precise relationship has not been completely determined. The aim of this study was to explore the influence of peripheral inflammatory processes over the response of the reward system to pharmacological and nutritional reinforcers. Place preference: We tested the reinforcement of morphine in the place preference model, in a 3 compartment box with different color and textures, time spent by the animal in each compartment was assessed before, and after 4 conditioning sessions in which a compartment was paired with morphine, while the other one was paired with saline, time spent after conditioning sessions minus time spent before conditioning sessions was calculated. After habituation the animal was subjected to deafferentation of the right hind paw, a week later conditioning sessions with a subcutaneous

administration of morphine (5 mg/kg) began (control group). Peripheral inflammation group: The same as control group, but 24 hours previous to conditioning sessions, carrageenan (carr) 750µl was injected in the denervated paw. Pharmacological modulation of inflammation: The same as the inflammation group, but after carrageenan injection the animal received ibuprofen (ibu) 0.6mg/ml in the drinking water, and 15 minutes prior to conditioning sessions ibu 50mg/kg, i.p. Rats develop a significant place-preference for the morphine paired side ($p=0.001$) with an average increase of 174 seconds (sec), rats that were pretreated with the inflammatory stimuli did not show this place preference with an average increase of 11.6 sec ($p=0.003$); when we administered ibu (a prostaglandin synthesis blocker), the animals didn't only recovered the reward response, but it was greatly increased with an average of 497.7 sec ($p<0.005$). Two bottle choice: Two groups of rats with prior deafferentation of the right hind paw, one without any inflammatory stimulus, the other with an intraplantar injection of carr 750µl, had free access to two bottles, one with tap water, the other one with tap water plus saccharine 4mmol; total liquid consumption and percentage of tap water vs saccharine (sac) water were measured for 11 days. Rats had a significative decrease in sac water consumption inversely correlated with paw diameter (Pearson test=-0.55), this decrease was reverted as the inflammatory process was resolved (the paw diameter returned to normal). The evidence above suggests that inflammatory stimulus inhibit the reward response to pharmacological and nutritional rewards by a prostaglandin-mediated pathway.

Title: Associations between polymorphisms in immune-related genes and autistic-like traits in a Swedish population

Authors: ***N. STRENN**[1], D. HOVEY[1], L. JONSSON[1], H. ANCKARSÄTER[2], P. LICHTENSTEIN[3], A. EKMAN[1];
[1]Pharmacol., Sahlgrenska Acad., Gothenburg, Sweden; [2]Dept. of Forensic Psychiatry, Sahlgrenska Academy, Univ. of Gothenburg, Gothenburg, Sweden; [3]Dept. of Med. Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden

Abstract: Background: Autism spectrum disorders are a complex group of neurodevelopmental disorders which are characterized by impairments in social interactions and both verbal and nonverbal communication as well as by unusual repetitive behaviour. The immune system has been suggested to be of importance for the development of neuropsychiatric symptoms; for example, elevated levels of cytokines and the inflammation-related transcription factor nuclear factor kappa-B (NFKB) have been reported in both blood and brain tissue of autistic individuals. Objectives: The aim of this study was to investigate possible associations between single nucleotide polymorphisms (SNPs) in several immune-related genes, amongst others, NFKB and NFKB inhibitor-like protein 1 (NFKBIL1) and autistic-like traits in a Swedish population of twins. Methods: The subjects in this study (n=12426, 9-12 years old) are from "The Child and Adolescent Twin Study in Sweden" (CATSS). Their parents participated in a telephone interview where the children were assessed by the Autism-Tics, ADHD, and Other Comorbidities Inventory (A-TAC) where autistic-like traits are measured using a continuous scale. DNA was extracted from saliva samples and polymorphisms were genotyped. Statistical analyses were performed in the SAS 9.3 (SAS Institute, Inc., Cary, NC) softwear. Results: Four out of the five investigated SNPs (NFKB: rs4648022; NFKBIL1: rs2230365, 2239707 and rs2857605) showed significant associations with the A-TAC total autistic-like traits score. Conclusions: To our best knowledge, polymorphisms in the genes encoding NFKB and NFKBIL1 have not previously shown to be associated with autism. These proteins may be involved in neuronal development and our findings support the hypothesis of the immune system being important in the aetiology of neuropsychiatric symptoms.

Abstract: Backgrounds: Recent studies have shown that not only neurons but astrocytes contain a considerable amount of γ-aminobutyric acid (GABA), which can be released and activate the receptors responsive to GABA. GABA from reactive astrocytes has been implicated in epilepsy, sleep, memory and cognition. The mechanism underlying the astrocytic release of GABA in depression is poorly understood. The purpose of this study is to test whether gliotransmitters from astrocytes may play a role in etiology of depressive-like symptoms.**Methods:** After rat recombinant IL-1β was infused into 3rd ventricle (100 ng, ICV) or paraventricular nucleus (10 ng, i.PVN) of the hypothalamus (PVN), the rats were tested for depressive-like behaviors in elevated plus maze, open field test and tail suspension test. Expression of glial fibrillary acidic protein (GFAP) and GABA were investigated using the immunofluorescence. Next, the systemic or intracerebral injections of L-α-aminoadipate (L-AAA, 0.5, 5 mg/rat, s.c. or 250 nmol/μL/bilateral into the PVN), a specific astrocyte toxin or bestrophin-1 channel blocker 5-Nitro-2-(3-phenylpropylamino) benzoic acid; (NPPB, 40 mg/kg, i.p. or 300 nmol/μL/bilateral in to the PVN) was pretreated before IL-1β ICV or i.PVN injection and depressive-like behaviors and GABA and GFAP expression in the PVN were measured. Finally, extracellular GABA release was measured using *in vivo microdialysis* in order to examine the role of astrocytic GABA in IL-1β induced depressive behaviors.**Results:** I.c.v infusion of IL-1β (100ng) induced depressive-like behaviors and activated the glial fibrillary acidic protein (GFAP) in the PVN and hippocampal dentate gyrus (DG). However, astrocyte inhibition by systemic L-AAA reduces depressive behaviors and the GFAP expression in the PVN. Injection of IL-1β (10ng) into the PVN produced markedly depressive behaviors and increased release of GABA from astrocyte. Local injection of L-AAA or blockade of Best1 channel by systemic NPPB, specific Best1 channel blocker, decreased depressive behaviors, but not changed the GABA expression in the PVN. Finally, IL-1β injection into the PVN release GABA measured by *in vivo microdialysis,* and treatment of L-AAA or NPPB decreased IL-1β-induced gliotransmitter GABA release. **Conclusion:** The present results demonstrated that release of gliotransmitter GABA in the brain may modulate the interleukin 1β-induced depressive responses. These results suggest that selective inhibition of astrocyte or astocytic GABA release may serve as an effective therapeutic strategy for treating depression.

Title: T cell maternal immune activation leads to deficits in prepulse inhibition and sex-specific deficits in spatial learning in adult offspring

Authors: ***N. W. FOX**, H. M. DEITCH, Z. S. WITTER, A. W. KUSNECOV;
Rutgers Univ., Piscataway, NJ

Abstract: Prenatal maternal immune activation (MIA) is a risk factor for several psychopathologic disorders, including bipolar disorder, autism, and schizophrenia. Most research has focused on using toll-like receptor (TLR) agonists such as lipopolysaccharide (LPS) or the synthetic viral genome analogue polyinosinic:polycytidylic acid (poly I:C) as experimental immune activators. Little is known about how T cells, necessary for successful clearance of both viruses and intracellular bacteria, may influence the neurodevelopment of a gestating fetus. To this end, we challenged pregnant female C57Bl/6J mice on day E12.5 of gestation with 200 ug/kg of purified staphylococcal enterotoxin A (SEA) to oligoclonally activate maternal T cells. After successful birth and weaning, both male and female adult offspring (N = 7-12 / sex / treatment) from SEA and Saline-treated mothers were tested for spatial navigation in a water radial arm maze (wRAM) and for deficits in acoustic sensorimotor gating, as measured by prepulse inhibition (PPI). In the wRAM, after eight days of hidden platform training, female offspring from SEA mothers took significantly longer to find the escape platform ($F(1, 83) = 6.50$, $p < 0.05$). Females from SEA mothers also swam further prior to reaching the platform ($F(1, 83) = 3.68$, $p = 0.058$). There were no differences in swim speed between SEA treatment and control animals. For male offspring, there was no observed difference in either swim distance or latency to find the escape platform, though males from SEA-treated mothers swam significantly slower ($F(1, 149) = 6.17$, $p < 0.05$). When these offspring were tested for PPI, offspring from SEA mothers had less percent inhibition over two days of testing ($F(1, 27) = 5.36$, $p < 0.05$), suggesting a stable deficit in sensorimotor gating due to maternal immune challenge with SEA. These data suggest that specific T cell activation during pregnancy compromises neurobehavioral development of the offspring. Title: Temporal changes in LPS-induced microglial cell activation in adult and aged mice

Authors: *R. A. KOHMAN, A. M. LITTLEFIELD, S. E. SETTI, P. R. FREEMAN; Psychology, Univ. of North Carolina Wilmington, Wilmington, NC

Abstract: The brain's resident immune cells, microglia, can express distinct forms of activation including the classic pro-inflammatory (M1) and alternative anti-inflammatory and neuroprotective (M2) phenotypes. Prior work has shown that at distinct time-points after a stroke or traumatic brain injury microglia express different phenotypes, indicating a time-dependent shift in activation (Hu et al., 2012; Wang et al., 2013). Further, normal aging has been shown to prime microglia towards the M1 phenotype. As a result, aged subjects show an abnormal neuroinflammatory response to an immune challenge when compared with adults. Presently unknown is how these age-related changes in microglia activation differ across time. The current study evaluated whether adult and aged mice show differential temporal profiles of microglia activation following an immune challenge. Aged (18-20 months) and adult (6-5 months) female C57BL6/J mice were administered a single intraperitoneal injection of the bacterial endotoxin lipopolysaccharide (LPS) or saline. Alterations in locomotor and anxiety-like behavior were assessed 1, 2, 3, or 7 days following LPS or saline exposure. Immediately following behavioral testing, hippocampal samples were collected. Hippocampal expression of genes associated with the M1 and M2 microglia phenotypes is currently in progress. Preliminary data indicate that aged mice show prolonged behavioral deficits following LPS administration relative to adult mice. We predict that aged mice will show prolonged LPS-induced expression of proinflammatory cytokines relative to adults, in agreement with prior reports. Further, the current data will determine whether the onset and duration of an anti-inflammatory response is altered in aged subjects.

Title: Behavioral phenotyping of male and female IL1-R1 null mutant mice reveals sex-specific impairments in the Morris Water Maze and Porsolt Forced Swim Test

Authors: *J. A. JOHNSON[1], S. N. RESCH[1], A. PEREZ[1], S. D. CROLL[2,3];

Abstract: IL1-R1 null mutant mice (IL1-R1 KO) have reduced signaling in the interleukin-1 (IL-1) pathway, making them a convenient model for testing the importance of IL-1 in either the development or maintenance of mouse behaviors. Prior research has revealed impaired cognitive and emotional processes in adult male IL1-R1 KO mice, including impaired spatial learning and memory and decreased anxiety. We tested both male and female IL1-R1 KO animals and wild-type (WT) animals on an array of behavioral tests, including retesting at an older age for spatial learning and memory. Animals were sacrificed and their brains were measured for neuroanatomical abnormalities and differences in hippocampal vascular investment. Our findings were consistent with prior findings of impaired spatial learning and memory performance for male IL1-R1 KO animals, as well as reduced anxiety-type responses in multiple behavioral tests. Female IL1-R1 KO mice were less affected, and showed no behavioral impairment in the Morris Water Maze. We found increased depressive-type behavior in the Porsolt Forced Swim test, but only in female IL1-R1 KO animals. All animals were retested at a later age in the MWM to determine if the observed sex-based differences in impaired spatial learning and memory would persist or increase with age. We found impaired spatial memory performance for aged IL1-R1 KO animals, and although older male KOs showed poorer performance in the water maze than female KOs, the difference between sexes no longer achieved statistical significance. Neuroanatomical evaluation revealed no gross differences in cortical or hippocampal structure. However, IL1-R1 KO animals had significantly reduced vascular investment in the hippocampal region, a finding that significantly correlated with impaired spatial memory performance in older animals ($r = .535$, $p = .027$). Our findings suggest that disruption of normal IL-1 activity can influence vascular density in the hippocampus and also alter hippocampally-mediated behavior, including spatial learning and memory. Our findings also reveal sex-dependency of these effects,

suggesting the possibility that male and female animals suffer different behavioral consequences of IL-1 signaling deficiency.

Title: Increased social approach in adult mice raised under germ-free conditions: Implications for neurodevelopmental disorders

Authors: *H. RAITH, T. ARENTSEN, Y. QIAN, R. DIAZ HEIJTZ;
Karolinska Institutet, Stockholm, Sweden

Abstract: Environmental influences during early life can have a profound impact on brain development and later life structure and function. One such environmental factor is the gut microbiota (the microorganisms that inhabit our intestines) that over evolutionary time has adapted to coexist with mammals. A growing number of studies have recently revealed that the gut microbiota has much wider effects on host physiology and development than originally believed, including the developmental programming of brain and later-life behavior. We have previously shown that adult NMRI mice raised under germ-free (GF) conditions display increased motor activity and decreased anxiety-like behavior compared to mice with normal gut microbiota (specific-pathogen-free, SPF). To further access the influence of the gut microbiota on social approach behavior, we subjected adult GF and SPF Swiss-Webster mice to a three-chambered sociability approach test. In addition, we included other tests for motor activity and

anxiety-like behavior that were used in our previous studies with NMRI mice. In the present study, we demonstrate that adult Swiss-Webster mice display increased sociability, as well as increased motor activity and reduced anxiety-like behavior compared to Swiss-Webster SPF mice. These mice also show alterations in the expression of synaptic-related plasticity molecules (e.g. BDNF) in key regions involved in social behavior (e.g., amygdala). Our results suggest that the postnatal microbial colonization process initiates signaling mechanisms that affect neuronal circuits involved in social behavior, motor control and emotional responses.

Title: Lipopolysaccharide administration induces sustained sex-dependent monoaminergic neurochemical alterations in the mouse brain

Authors: *J. P. SENS, E. SCHNEIDER, E. BIRMINGHAM, J. MAUCH, A. FRANCESCHELLI, C. THELEN, P. M. PITYCHOUTIS;
Dept. of Biol. & Ctr. for Tissue Regeneration and Engin. (TREND), Univ. of Dayton, Dayton, OH

Abstract: The innate immune response is an important component of the immune system that serves to isolate and prevent further infection from pathogenic organisms. A component of the response manifests as sickness symptoms (i.e. decreased locomotor activity, anorexia) and depressive-like neurobehavioral outcomes (i.e. anhedonia, social withdrawal, alterations in central monoaminergic neurotransmission) that are prefaced by complex immune-to-brain communication pathways that ultimately result in proinflammatory cytokine production within the brain. Indeed, patients that suffer from chronic inflammatory diseases, such as rheumatoid arthritis, have an increased risk of developing major depression. Despite the greater prevalence of major depression in women, the role of sex in the neuroimmunology of depression remains elusive. Of note, the proinflammatory agent lipopolysaccharide (LPS) has been shown to activate the innate immune machinery that leads to depressive-like neurobehavioral alterations in rodents. Herein, we investigated whether acute immune stimulation with LPS induces sex-dependent

serotonergic and dopaminergic neurochemical responses in limbic brain regions implicated in the pathophysiology of major depression, namely the prefrontal cortex (PFC), the hippocampus (HIPP), the amygdala (AMY) and the striatum (STR). Mice were injected with LPS (0.83 mg/kg) or saline (0.9% NaCl), and were sacrificed at two different time-points; at 6h (i.e. when sickness symptoms reach their plateau) and at 24h post-LPS administration (i.e. when sickness symptoms are alleviated but depressive-like symptoms are still evident). *Ex vivo* neurochemical responses were assayed with high performance liquid chromatography (HPLC) with coulometric detection. Collectively our data showed that LPS administration induced sex-dependent serotonergic and dopaminergic neurochemical effects at both time-points. Our efforts now focus on how these neurobiological alterations ultimately play out in an effect on basic behavior. With a higher prevalence of affective disorders in women, an understanding of the neurobiological mechanisms of sex differences underlying this inflammatory model of depression is imperative to delineate the neuroimmunological substrate in the appearance, course and outcome of these conditions.

Title: Conditional elimination of p38α mitogen activated protein kinase provides evidence for a cell autonomous role of kinase signaling in SERT regulation and serotonin-linked behaviors following immune system activation

Authors: *N. L. BAGANZ[1,2], K. L. LINDLER[1], C. B. ZHU[3], J. T. SMITH[1], M. J. ROBSON[1], H. IWAMOTO[1], E. DENERIS[5], W. A. HEWLETT[6], R. D. BLAKELY[1,4,2];

Abstract: Central serotonin (5-HT) neurotransmission and peripheral immune system activation have been linked to multiple neuropsychiatric disorders, including depression, anxiety, schizophrenia and autism. The antidepressant-sensitive 5-HT transporter (SERT, SLC6A4) is a critical determinant of synaptic 5-HT inactivation and is tightly regulated by multiple signaling pathways, including those initiated by proinflammatory cytokines such as interleukin-1β (IL-1β), interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α). We have shown that systemic native immune system activation via i.p. injection of lipopolysaccharide (LPS) rapidly elevates CNS SERT activity and 5-HT clearance. Moreover, IL-1β can rapidly stimulate SERT activity in raphe nerve terminal preparations *ex vivo*, effects attenuated by pharmacological p38 MAPK inhibition. Because inflammatory cytokine signaling pathways are widely expressed, the role of p38 MAPK signaling in CNS 5-HT neurons in SERT regulation and attendant behavioral responses requires the use of conditional gene manipulation strategies. We engineered mice that afford elimination of p38α MAPK in 5-HT neurons (p38α5HT-) and used these animals and p38α5HT+ littermates to interrogate SERT regulation by peripheral LPS administration. p38α5HT- animals are viable and display no overt growth/behavior abnormalities and express normal levels of SERT protein and 5-HT transport activity. Consistent with pharmacological studies, however, midbrain synaptosomes from p38α5HT- animals fail to increase SERT activity in response to IL-1β application. Although LPS-treated p38α5HT- animals display normal elevations in central and peripheral inflammatory cytokines and plasma corticosterone, they fail to demonstrate elevations in midbrain SERT activity, and they lack typical depressive or anxiety-like behaviors characteristic of acute serotonergic manipulations. Our studies provide evidence for a critical role of 5-HT neuron p38α signaling in the translation of immune activation to SERT regulation and changes in behavior.

Title: Exercise improves postoperative cognitive decline in rats with metabolic syndrome by rectifying inflammation resolution and the microbiome

Authors: *X. FENG[1], S. VACAS[2], L. KOCH[3], S. BRITTON[3], M. MAZE[2];
[1]Anesthesia and Perioperative Care, [2]Anesthesia and Perioperative care, Univ. of California, San Francisco, San Francisco, CA; [3]Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Previously, we demonstrated that neuroinflammation induced by surgery causes cognitive decline (1,2). In a rat model of Metabolic Syndrome (MetaS), we have identified deficiencies in the resolution of inflammation following aseptic trauma (3,4). Here, we report on the role of exercise on acute postoperative memory decline in MetaS. Male low capacity runner (LCR) and high capacity runner (HCR) rats (4 months) were exercised 5 days/week for 6 weeks immediately prior to surgery. Following exercise, rats were trained in the trace-fear conditioning (TFC) paradigm 30 min before surgery. On day 3 after surgery, the rats were tested for freezing behavior; hippocampi were harvested for protein level of IL-6 and mRNA level of Il-6, Netrin-1, Hmgb-1, markers for pro-resolving macrophages (Arg1, Mrc2, Pparg, and Chi3l3) and pro-inflammatory macrophages (Nos2, Ccl2, Tnfa, and Itgax); stools were collected 1 day before and 3 days after surgery for 16s RNA sequencing of microbiome. LCR rats had less contextual freezing behavior than HCRs; however, exercise eliminated this difference. Hippocampal neuroinflammation was significantly activated in LCR+non-exe+surgery group than in HCR+non-exe+surgery; again, these differences were rectified by exercise. Furthermore, exercising the LCR rats rectifies their abnormal microbiome which becomes indistinguishable from the un-exercised HCR rats after. Pre-operative exercise may reverse the postoperative behavioral phenotype and normalize dysregulated inflammation-resolution. A: Freezing time in rats after exercise, TFC and tibia fracture. Title: Basolateral amygdala astrocyte activation via DREADDs modulates ethanol consumption

Authors: *S. A. MARSHALL[1], T. E. THIELE[2], D. T. LYSLE[2];
[2]Dept. of Psychology and Neurosci., [1]Univ. of North Carolina, Chapel Hill, NC

Abstract: The role of the astrocytes in alcohol abuse has generally focused on neuroinflammation and its contributions to neurodegeneration, but astrocytes also play an integral role in modulating neuronal functions. Recent evidence indicates that astrocyte activation within the nucleus accumbens decreases the motivation to self-administer ethanol in dependent animals, but the actions of astrocytes in other regions and in non-dependent animals remains elusive. This study examines astrocyte activation within the basolateral amygdala (BlA) using the "drinking-in-the-dark" (DID) paradigm. The DID model is uniquely suited to study binge-like alcohol intake in non-dependent rodents. Male C57BL/6J mice were bilaterally infused with AAV8-GFAP-hM3D(Gq) or control virus within the BlA. This virus induces expression of Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) selectively on astrocytes. DID cycles consisted of three days of two hour access to 20% ethanol or 3% sucrose and a fourth day, or test day, where mice were given four hour access to ethanol or sucrose. Mice underwent four 4-day DID cycles. On the first two test days, ethanol consumption was measured after clozapine-N-oxide (CNO) administration. CNO specifically binds to and activates the Gq-DREADD construct. A two-way (virus x test day) RM ANOVA run on ethanol intake data indicated a main effect of viral treatment [$F(1,17)=12.01$, $p=0.003$] but no interaction or effect test day. To determine if the virus had an independent effect, mice received vehicle injections prior to ethanol solution access on the third test day and in this case

there were no significant differences between virus groups. Finally, on the fourth cycle test day, mice were given access to sucrose after CNO administration and results showed no virus group differences in sucrose drinking. Mice were also subjected to an open-field test after CNO administration to determine if astrocyte activation via Gq DREADDs altered locomotor activity or anxiety. T-tests indicated no significant differences between animals with the Gq DREADD and control viruses in total distance traveled, time spent in the center, or distance traveled in the center. Together these data suggest that activation of astrocytes within the BlA specifically reduces binge-like ethanol drinking. The mechanisms by which astrocyte activation modulates ethanol consumption are still elusive. Future studies should determine subsequent signaling cascades following activation of astrocytes that leads to reduced drinking. (Supported by NIH grants AA022048, AA013573, AA015148, AA011605 & NIGMS GM000678).

Title: Pharmacological reinstatement of blood-brain barrier integrity prevents brain inflammation, synaptic dysfunction, and memory impairment in obese mice

Authors: ***S. HAO**[1], A. DEY[1], A. M. STRANAHAN[2];
[1]Med. Col. of Georgia, Georgia Regents Univer, Augusta, GA; [2]Neurosci. and Regenerative Med., Med. Col. of Georgia, Georgia Regents Univ., Augusta, GA

Abstract: Microglia form the predominant immune cell population in the brain and are protected from the systemic milieu by the blood-brain barrier (BBB). However, BBB permeability increases in certain pathologies, including obesity, which reduces expression of tight junction proteins that mediate adhesion between endothelial cells. While several reports have described correlations between BBB breakdown and cognitive impairment in obesity, the question of whether BBB breakdown causes obesity-induced memory deficits has never been addressed. Activation of protein kinase Cβ (PKCβ) causes BBB breakdown in models of infectious disease,

and we used the PKCβ antagonist LY-317615 to prevent BBB leakiness in mice with obesity due to consumption of a high-fat diet (HFD). After validating the reinstatement of BBB integrity in HFD mice treated with LY-317615, we examined hippocampal synaptic plasticity and performance in tests of hippocampus-dependent memory. Vehicle-treated HFD mice had reduced long-term potentiation (LTP) at medial perforant path synapses on dentate granule neurons relative to vehicle-treated mice maintained on a low-fat diet (LFD). Treatment with LY-317615 normalized LTP and prevented obesity-induced reductions in dendritic spine density and synaptic marker expression. Reinstatement of synaptic structure and function in HFD mice treated with LY-317615 was accompanied by normalization of spatial and object recognition memory. These parallel lines of evidence implicate BBB breakdown in microglial activation and deficits in hippocampal plasticity, but do not address whether direct interactions between microglia and neurons contribute to these effects. To address this possibility, we performed immunolabeling for IBA1 and PSD95, which revealed that vehicle-treated HFD mice had significantly greater overlap, even after correcting for increased coverage by IBA1-labeled processes. HFD mice treated with LY-317615 had very little colocalization between IBA1 and PSD95, suggesting that microglial phagocytosis of synapses might increase due to BBB breakdown in obesity. Because obesity is accompanied by peripheral inflammation, additional work will be necessary to determine the peripheral signal(s) that drive microglial activation, and identify the mechanisms that promote microglial internalization of hippocampal synapses.

Title: T lymphocytes promote recovery from inflammation-induced comorbid pain and depression

Authors: *G. O. LAUMET, K. N. KRUKOWSKI, A. K. WALKER, R. DANTZER, C. J. J. HEIJNEN, A. KAVELAARS;
Symptom Res. #1450, Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Chronic pain and depression are two of the most disabling and costly disorders in the USA and they frequently occur together. Increased prevalence of comorbid chronic pain and depression occurs in disease with a chronic inflammatory component such as cancer, diabetes and rheumatoid arthritis. Recent findings indicate that shared neuroimmune pathways underlie comorbid chronic pain and depressive behaviors in the context of peripheral inflammation. The contribution of innate immune cells to the onset of inflammation-induced pain and depressive disorders has been extensively studied, while the adaptive immune system has been under-studied. In addition, little is known about the neuroimmune mechanisms underlying the resolution of these comorbid symptoms. Interestingly, specific T lymphocyte populations may promote resolution of nerve injury-induced pain and a switch in T lymphocyte population profile has been reported in chronic pain patients. Given the high comorbidity of chronic pain and depression, we hypothesized that T lymphocytes are necessary to promote recovery from acute pain and depression induced by peripheral inflammation. Our preliminary data obtained in an animal model show that CD8+ T lymphocytes are necessary for resolution of chemotherapy-induced peripheral neuropathy. To determine the contribution of T lymphocytes in recovery from inflammation-induced pain and depression, we induced mechanical allodynia and depressive-like behavior by injecting 0.83 mg/kg lipopolysaccharide (LPS) i.p. in 9-week old C57Bl/6 (WT) mice and mice deficient in mature T and B lymphocytes (Rag1-/- mice). In Rag1-/- mice LPS-induced mechanical allodynia and depressive-like behaviors measured by increased immobility time in forced swim test were prolonged in comparison to wild-type C57Bl/6 mice. These differences were abrogated by reconstitution of Rag1-/- mice with CD3+ T lymphocytes from wild-type naive mice 7 days before LPS treatment. Interestingly, the involvement of T lymphocytes in recovery from LPS-induced comorbid depression and pain was specific since T lymphocytes did not contribute to recovery from LPS-induced sickness behaviors. These findings indicate that CD3+ T lymphocytes are important for endogenous resolution of acute inflammatory pain and depression and dysregulation of this endogenous recovery mechanism might be responsible for the transition of acute to chronic pain and depression.

Title: The CCL2:CCR2 axis controls infiltration of inflammatory monocytes into the brain during acute picornavirus infection

Authors: *R. G. LAFRANCE-COREY, C. HOWE;
Neurol., Mayo Clin., Rochester, MN

Abstract: Immune control of acute viral infection in the CNS requires a careful balance between efficient clearance of the virus and maintenance of neurologic function. We have observed hippocampal injury that compromises cognitive function and induces seizures following acute infection of C57BL/6 mice with the Theiler's murine encephalomyelitis virus. Injury is independent of direct neuronal infection with the virus and precedes the onset of an adaptive immune response, leading us to hypothesize that an early innate immune response causes the damage. Flow cytometric analysis of brain-infiltrating leukocytes indicated that mice experiencing hippocampal injury mount a robust inflammatory monocyte and neutrophil response in the brain within hours of infection. Microarray analysis, RTPCR, and ELISA revealed a robust pattern of chemokines and cytokines expressed in the brain and present in the serum within 3 hours of infection, including high levels of CCL2, CXCL1, and CXCL2. Genetic deletion of the chemokine receptor CCR2 abrogated infiltration of inflammatory monocytes into the brain, increased neutrophil infiltration, protected the hippocampus, preserved cognitive function, and reduced seizure activity, indicating a central role for the CCL2:CCR2 axis in the recruitment of inflammatory monocytes to the brain. Genetic deletion of CXCR2 blocked neutrophil infiltration but did not protect the brain or prevent seizures. We conclude that hippocampal injury and seizures during acute picornavirus infection are the result of bystander pathology triggered by infiltration of inflammatory monocytes in response to production of CCL2 in the brain.

Title: Effects of neonatal infection on adolescent and adult anxiety in male and female rats and the development of 'anticipatory nausea'

Authors: *J. M. WARD[1], C. TENK[2], M. KAVALIERS[1], K.-P. OSSENKOPP[1];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Brescia Univ. Col., London, ON, Canada

Abstract: Anticipatory nausea (AN) is a common symptom resulting from chemotherapy and other drug treatments. This form of nausea is a conditioned response where the illness resulting from the chemotherapeutic is paired with the environmental context of the hospital. On subsequent exposures to the environmental context, patients will experience nausea despite being in a drug-free state. There is mounting evidence in human populations that anxiety is a strong predictor in the development of anticipatory nausea. Rats are a non-emetic species lacking musculature and brainstem pathways to elicit an emetic response. Investigations of disgust in rats have shown that a behavioural response, known as gaping, is a strong index of anticipatory nausea-related behaviour. The present study is examining the effect of anxiety on AN. Prior research has suggested that this dual neonatal exposure to LPS in the neonatal stage is capable of causing anxiety-like behaviour in adulthood. Neonatal rats were injected with either lipopolysaccharide (LPS; 15 μg/kg or 50 μg/kg) or 0.9% isotonic saline on postnatal days (PND) 3 and 5. Anxiety-like behaviour is being assessed in adolescent rats (PND 42) and adulthood (PND 85) using the light-dark test. Adolescent male rats treated with 15 μg/kg of LPS showed significantly higher anxiety-like behaviour compared to male controls by spending more time in the dark chamber, $p < 0.05$. A significant drug by sex interaction was also found, $p < 0.05$. Female rats showed no significant effect. Anxiety-like behaviour will be reassessed on PND 80. In adulthood (PND90), anticipatory nausea-related behaviour in the rat will be examined by quantifying the gape response to an environmental context in a drug-free state after the context has been paired with the toxicosis resulting from lithium chloride treatment (64 mg/kg). These findings suggest that a neonatal LPS dose of 15 μg/kg is capable of eliciting anxiety-like behaviour in male adolescent rats assessed with the light-dark test and this provides a basis for examining the role of anxiety in the expression of anticipatory nausea.

Title: DREADD activation of hippocampal astrocytes influences contextual fear conditioning

Authors: *M. E. JONES, D. BARRUS, C. L. LEBONVILLE, L. B. COOPER, D. T. LYSLE; Psychology and Neurosci., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Neuroimmune signaling is important in learning and memory processes. For example, our laboratory reported that stress induces a time dependent increase in hippocampal interleukin-1β (IL-1β) and that a central infusion of interleukin-1 receptor antagonist is sufficient to prevent stress-enhanced fear learning. Here, we tested whether activating hippocampal astrocytes altered contextual fear conditioning by employing Gq-coupled Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) under an astrocyte-specific promotor. Rats were infused with rAAV5/GFAP-HA-hm3D-IRES-mCitrine bilaterally into the dorsal hippocampus such that peripheral administration of Clozapine-N-Oxide (CNO) would activate Gq signaling selectively in hippocampal astrocytes. All animals were assigned to a foot shock treatment (foot shock or no foot shock) and a CNO treatment (CNO or vehicle). In Experiment 1, animals received three injections of either CNO (3 mg/kg, i.p.) or saline vehicle at 6, 4, and 2h prior to foot shock fear conditioning. For fear conditioning, animals were subjected to 5 2mA scrambled foot shocks on a 30s variable interval schedule in a distinct context. Control animals received the same treatment with no foot shocks. Twenty-four hours later, animals were placed back into the context and freezing behavior was analyzed. We found that 6h of astrocyte activation significantly enhanced fear learning as rats that received CNO followed by foot shock exhibited more freezing than rats that received vehicle followed by foot shock, $p < 0.02$. In Experiment 2, animals were subjected to the same foot shock fear conditioning paradigm as in Experiment, but received one injection of either CNO (3 mg/kg, i.p.) or saline vehicle immediately following conditioning. Animals were placed back into the conditioning context 24 hours later and freezing behavior was analyzed. Strikingly, astrocyte activation immediately following fear conditioning significantly attenuated fear learning as rats that received foot shock followed by CNO exhibited significantly less freezing than rats that received foot shock followed by vehicle, $p < 0.04$. Collectively, these findings indicate that hippocampal glial cell activation prior to stress induces a hypersensitivity to fear learning, but glial cell activation following stress interrupts fear memory consolidation. Future studies will explore the downstream mechanism through which Gq signaling alters fear learning and test whether Gq signaling directly induces neuroinflammatory signaling through the release of cytokines such as IL-1β.

Title: Consequences of neonatal infection on immune function and spatial learning in juvenile male and female rats

Authors: ***B. OSBORNE**, J. CAULFIELD, J. SCHWARZ;
Dept. of Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Many developmental and psychiatric disorders exhibit strong sex differences with developmental disorders being strongly male biased. Many of these disorders have been linked to early-life immune activation; however, it has never been examined how sex impacts neonatal immune activation and how these factors may contribute to the onset of learning disorders during development. Microglia are the resident immune cells of the brain and respond to infections with rapid increases in cytokine release. Male rats have significantly more microglia in the hippocampus and amygdala compared to female rats on postnatal (P) day 4, thus, this time may represent a period in early development when males are more susceptible to infection than females. To address this hypothesis, we examined proinflammatory cytokine responses to infection at P4 in males and females 8 and 24 hours following a low dose of Escherichia coli (E.coli). Contrary to our predictions, males and females showed similar neuroimmune responses at P4 in the hippocampus, cerebellum, amygdala, and prefrontal cortex with neonatally infected animals showing exaggerated cytokine levels compared to saline controls (p's < .05); however; in the periphery (spleen) males showed significantly greater levels of IL-1ß and TNF-α 8 hours following neonatal infection compared to females (p's < .05). Next, we examined the long-term consequences of neonatal immune activation on subsequent immune activation in juvenile males and females by measuring cytokine responses to a second immune challenge of low-dose

lipopolysaccharide (LPS; 25µg/ml) at P24 either alone or following neonatal infection. We found that neonatally-infected males and females have significantly elevated levels of IL-1ß in the hippocampus and prefrontal cortex (PFC) at baseline and following a second immune challenge (p's < .05). To examine whether neonatal infection would result in developmental delays in learning in juvenile rats alone or in the presence of a second immune challenge, we tested juvenile rats at the onset of spatial learning using the Context Pre-exposure Facilitation Effect (CPFE) paradigm. Contrary to our predictions, we found that in the presence of a second immune challenge males and females that were neonatally infected showed enhanced learning relative to all controls ($p < .05$). These data suggest that neonatal infection enhances learning in the presence of a second immune challenge in male and female juvenile rats (at P24) and that increased IL-1ß levels in the brain may be a mechanism by which enhanced learning is occurring.

Title: A role for the LRRK2 G2019S mutation as a mediator of chronic inflammation in an immunological model of Parkinson's disease

Authors: *Z. DWYER, C. RUDYK, S. BELLEVUE, S. HAYLEY;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disorder after Alzheimer's disease. PD affects approximately 1% of the population over the age of 60 and results from the loss of dopamine producing neurons in the substantia nigra. PD has traditionally been characterized by a set of cardinal motor symptoms including bradykinesia, trembling and altered gait, however, recent work has highlighted several non-motor symptoms and co-morbidities. Importantly many of these have been linked to inflammatory processes and indeed several researchers have demonstrated that neurons in the substantia nigra are predisposed to cell death following inflammation. Leucine-Rich-Repeat Kinase 2 is a gene with unknown function which has been linked to both inflammation and PD. The Gly-2019S-Ser (G2019S) mutation

alone accounts for up to 10% of familian and 1.5% of sporadic PD cases. In our present study we sought to elucidate the role of the LRRK2 G2019S mutation as a potential genetic vulnerability in an immunological model of PD. B6.Cg-Tg(Lrrk2*G2019S)2Yue/J heterozygous mice were bred in house and with wild type (WT) littermates underwent stereotaxic surgery at 12 weeks of age to infuse 2µLs of saline, 1µg/µL Lipopolysaccaride (LPS) or 5µg/µL LPS. Animals were behaviourally assessed at several timepoints for indices of motor and sickness behaviour including home-cage locomotion, rotarod and gait analysis. Animals were perfused 21 days after surgery and both brains and peripheral organs were collected. G2019S mice were found to have significantly altered gait from WT animals regardless of treatment. G2019S animals showed no difference in sickness observed post-surgery, however, they regained lost weight significantly slower than WT LPS treated animals. Analysis of peripheral organs, blood brain barrier permeability, microglial activation, and TH+ cell counts revealed further differences between animals. LRRK2, specifically the G2019S mutation, appears to mediate the transition from acute inflammation to chronic inflammation in response to a central immunological insult (LPS).

Title: Microglial alterations within the postpartum brain

Authors: ***A. HAIM**[1], K. LENZ[2], B. LEUNER[2];
[2]Psychology & Neurosci., [1]The Ohio State Univ., Columbus, OH

Abstract: The postpartum brain is remarkably plastic. In numerous brain regions, motherhood is associated with alterations in the production of new neurons as well as neuronal dendritic and synaptic remodeling. Postpartum modifications are not limited to neurons however, as astrocytic changes have also been documented. Possible postpartum-related alterations in microglia, the primary innate immune cells of the brain, haven't been examined although such a consequence is likely given the well-known peripheral immune changes that occur at this time, the role that microglia play in regulating neuronal plasticity, and the sensitivity of microglia to various hormones that are altered postpartum. To begin investigating this possibility, coronal brain sections from nulliparous female rats, pregnant rats on gestation day 20 and lactating rats on postpartum day 1 (early), postpartum day 8 (mid) and postpartum day 21 (PD21) were stained

for Iba1, a pan-microglial marker. Densitometry of Iba1 staining was performed in the hippocampus, medial prefrontal cortex, nucleus accumbens shell and basolateral amygdala. Our results show that compared to nulliparous females, Iba1 density was reduced during late gestation and early-mid postpartum in all regions examined. Furthermore, Iba1 density returned to nulliparous levels by the late postpartum period. These results are the first to reveal microglial alterations within the maternal brain and will lead to future studies investigating whether reduced Iba1 density reflects a reduction in microglia number and/or a change in microglial phenotype as well the underlying mechanism of these changes and their behavioral significance. While the involvement of microglia in developmental plasticity and pathological conditions is well known, microglial alterations during the postpartum period may provide a unique opportunity to gain a better understanding of how microglia modulate plasticity within the healthy adult brain.

Title: Repeated social defeat stress induces neuroinflammation and impairs hippocampal neurogenesis that differentially regulate mood and cognition

Authors: *A. NIRAULA, D. MCKIM, A. TARR, J. SHERIDAN, J. GODBOUT;
The Ohio State Univ., Columbus, OH

Abstract: Repeated social defeat (RSD) is a murine stressor that models several key physiological, immunological, and behavioral alterations observed in humans exposed to psychosocial stress. RSD induces prolonged anxiety-like behavior associated with myeloid cell trafficking into the brain, including the hippocampus - a key area involved in neuroplasticity, behavior, and cognition. Therefore, the goal of this study was to investigate if the stress-induced

monocyte trafficking affected hippocampal neurogenesis and cognitive function. Here, we show that RSD increased inflammatory mediators (IL1b, TNFa and IL-6) in the hippocampus, and enhanced microglia activation and monocyte trafficking (CD45hi) specifically in the caudal hippocampus. RSD also impaired spatial memory recall in the Barnes maze independent of anxiety-like behavior. RSD did not affect the number of proliferating neural progenitor cells and developing neurons when examined 14 hours post-RSD. However, there was a significant reduction in the number of young neurons and mature neurons when examined 10 days and 28 days post-RSD respectively. Consistent with region-specific neuroinflammation, reduction in the number of mature neurons was greater in the caudal hippocampus of the RSD mice compared to controls. The RSD-induced spatial deficits, which are rostral hippocampus-mediated, were resolved by 28 days. Social avoidance which is caudal hippocampus-mediated still persisted 28 days after stress. Thus, stress-induced neuroinflammation is associated with reduced neuroplasticity, and the stress-induced affective and cognitive deficits are differentially associated with hippocampal neurogenesis.

Title: Prenatal antibiotic exposure alters brain development and behavior: Implications for neurodevelopmental disorders

Authors: *T. B. ARENTSEN, H. RAITH, H. FORSSBERG, R. DIAZ HEIJTZ;
Karolinska Institutet, Stockholm, Sweden

Abstract: A growing number of studies have recently revealed that the indigenous gut microbiota has much wider effects on host physiology and development than originally believed, including the early-life programming of brain circuits involved in the control of emotions, motor activity, and cognitive functions. Therefore, perturbations of the gut microbiota, during key neurodevelopmental stages, may affect early life gut-microbiome brain interactions, altering brain development and behavior. In the present study, we examined the specific contribution of the maternal gut microbiota during pregnancy to brain development and behavior in the offspring. For this purpose, pregnant female C57BL/6N mice were exposed to a broad-spectrum antibiotic treatment in the drinking water during the entire pregnancy. Treatment was stopped immediately after delivery. To determine potential long-term behavioral changes in the offspring, we subjected prenatal-antibiotic treated male and female mice to a battery of tests for motor activity, anxiety-like behavior, sociability and preference for social novelty during the prepubertal period (i.e., P22-25). In the open-field test, we found significant sex-dependent changes in the spontaneous motor activity of juvenile mice exposed to prenatal antibiotic treatment. Prenatal antibiotic-treated males travelled a greater total distance during the initial 15 min of testing (i.e., novelty phase), but not habituation, testing periods than did controls. In contrast, the same treatment in females led to increased levels of both locomotion and rearing activity during the habituation, but not the initial testing, periods, indicating that their hyperactivity was not triggered by novelty. Anxiety-like behavior was not altered by prenatal antibiotic exposure. In the three-cambered social approach test, prenatal-antibiotic treated male mice displayed a significant increase in sociability, as indicated by increased time spent in a chamber containing a stimulus mouse versus the alternative empty chamber. These mice also showed increased preference for social novelty. Adult males exposed to antibiotics during prenatal life showed similar increased levels of social behavior. Interestingly, social behavior was not affected in prenatal-antibiotic treated female mice. Our results indicate that perturbations of the maternal gut microbiota during pregnancy may have life-long lasting effects on brain development and behavior in the offspring, and that these effects are sex-dependent.

Title: Follow the TRAIL: understanding the etiology of persistent fatigue and cognitive impairment following radiation therapy

Authors: L. FENG[1], *K. A. MAGUIRE-ZEISS[2], L. N. SALIGAN[1];
[1]Natl. Inst. of Nursing Res. NIH, Bethesda, MD; [2]Neurosci., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Fatigue is one of the most debilitating side effects of cancer and cancer therapy, and it persists long after treatment completion. In this study, we aimed to investigate changes in immunological markers and cognitive functions in fatigued men receiving external beam radiation therapy for non-metastatic prostate cancer. A sample of 34 men with prostate cancer scheduled to receive radiation therapy were followed at baseline (prior to treatment initiation) and one year after treatment completion. Demographic and clinical data were obtained by chart review. The Functional Assessment of Cancer Therapy-Fatigue (FACT-F) was administered to measure fatigue levels. The Computer Assessment of Mild Cognitive Impairment (CAMCI®), a computerized screening tool was administered at each time point to evaluate cognitive decline. Blood was drawn at baseline and one year after completion of radiation therapy; plasma cytokine levels were determined using the Bio-Rad Bio-Plex Cytokine Assay Kits. Gene expression profiles were determined using microarray analysis and analyzed using Partek Genomics Suite 6.6 as well as Ingenuity Pathway Analysis. At one year after EBRT completion, 34% of subjects continued to experience persistent fatigue, defined as a decline in FACT-F scores of 3 points or greater. Fatigued subjects also exhibited signs of mild cognitive impairment as measured by CAMCI. Microarray analysis of blood samples collected one year following radiation therapy revealed 44 genes that were differentially expressed between fatigued and non-fatigued subjects. The main disease networks identified by pathway analysis are related to cancer pathophysiology. Compared to non-fatigued subjects, there was an increase in expression levels of the decoy receptor TRAIL-R3 in the fatigued group. Interestingly, the ligand of this receptor, TRAIL, is also significantly upregulated in fatigued subjects. Evidence of the involvement of cancer disease networks as well as the concomitant upregulation of TRAIL and its decoy receptor suggest that fatigue and cognitive impairment may be more than distressing side effects of cancer treatment. Instead, these symptoms may serve as behavioral indicators of the underlying disease status in cancer patients.

Title: A clinically relevant model of prenatal inflammation (intrauterine lipopolysaccharide) results in offspring hyperactivity

Authors: N. GRISSOM[1], S. MCKEE[1], *T. M. REYES[2];
[1]UNIV OF PENNSYLVANIA, PHILADELPHIA, PA; [2]Pharmacol., Univ. Pennsylvania, Sch. of Med., Philadelphia, PA

Abstract: Maternal infection during pregnancy is common and can cause adverse neurodevelopmental outcomes. While systemic administration of bacterial or viral mimetics are widely used models of prenatal inflammation, an alternative approach is local inflammation of the uterus, which models chorioamnionitis (inflammation of the fetal membranes). Importantly, this mimics the most common human clinical scenario by which a fetus is exposed to prenatal inflammation. Using CD-1 mice, local inflammation was induced via intrauterine lipopolysaccharide (LPS) infusion at E15 (term = E19). Behavioral, molecular and immune endpoints were evaluated in adult offspring. Males and females demonstrated hyperactivity, as well as an overall decrease in anxiety-like behavior (open field, elevated zero, light-dark box). Operant testing was initiated to examine executive function, however all mice (regardless of prenatal condition) failed to reach criterion performance, which may be due to reduced visual acuity in the albino CD1 strain. Prenatal LPS exposure increased the number of microglia, quantified by flow cytometric analysis of the whole brain. Expression of 30 genes related to immune, epigenetic and neurotransmitter function was measured, both at baseline and in response to an acute immune challenge, and these analyses are ongoing. These data indicate that local inflammation of the uterus, in the absence of a maternal plasma cytokine response, affects offspring brain development, and support additional work in this translationally relevant model of prenatal inflammation.

Title: Fit but Frazzled? Comparing the effects of chronic stress and fitness on college freshmen

Authors: M. KIM[1], R. R. CLOUSE[1], L. A. MUASAU[1], K. G. BAILEY[2], *P. S. LITVAK[1]; [1]Biol., [2]Psychology, Andrews Univ., Berrien Springs, MI

Abstract: College freshmen face several unique stressors, including adjusting to a new living and academic environment, and dealing with mounting financial obligations. Chronic stress leads to structural changes in the prefrontal cortex and hippocampus that cause cognitive impairment. But interestingly, exercise is a physical stressor that facilitates function in these brain areas. The goals of the current study were to: 1) compare the effects of physical fitness vs. stress on memory performance in college freshmen (n=22), and 2) compare the effects of fitness vs. stress on the students' acute stress response. Preliminary data indicated that higher fitness levels may have been associated with improved hippocampus-dependent memory scores ($p = 0.08$, Cohen's $d=0.7$) , but not prefrontal cortex memory. Higher fit students had an increased salivary cortisol response but decreased blood pressure response to a mild, cognitive stressor ($p < 0.05$). Students with higher self-reports of stress performed significantly worse on the prefrontal cortex-based task ($p < 0.05$) and showed a statistical trend for impairment on the hippocampus-based task ($p = 0.06$). Higher stress levels resulted in a significant decrease in salivary cortisol and increase in blood pressure to a mild, cognitive stressor ($p < 0.05$).

Title: Reactivation of a fear memory prior to learning sex-dependently influences long-term memory

Authors: *A. M. DAILEY[1], C. E. CADLE[1], D. M. PETERS[1], A. E. KALCHIK[1], R. L. AUFDENKAMPE[1], C. M. BROWN[1], A. R. SCHARF[1], M. B. EARLEY[1], C. L. KNIPPEN[1], H. E. NAGLE[1], B. R. RORABAUGH[2], P. R. ZOLADZ[1];
[1]Psychology, Sociology, & Criminal Justice, [2]Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: Despite having powerful memories of their trauma, individuals with post-traumatic stress disorder (PTSD) display a paradoxical deficit for learning new information. Investigators have speculated that this impairment results from intrusive memories transiently interfering with the ability of PTSD patients to process new information. However, due to the ethical problem of provoking traumatic memories in PTSD patients, this hypothesis has gone unstudied in humans. Thus, the purpose of the present study was to examine the effects of fear memory reactivation on subsequent learning in humans, thereby providing a basic model of intrusive memory effects on cognitive processing. On Day 1, participants sat in a dark room and viewed a fear-inducing or control video in the presence of a non-related, but constant, background auditory stimulus (tone). The next day, participants returned to the laboratory and sat quietly in a dark room with the same background auditory stimulus for 3 min to reactivate the memory of the video from the previous day. Immediately following reactivation, participants viewed 30 images varying in emotional valence. Participants underwent free recall testing immediately after learning. Twenty-four hours later, participants returned to the laboratory and completed free recall and recognition assessments. Results revealed that reactivation of the fear video memory led to impaired 24-hr recall in males, but not females. Independent of sex, there was a significant negative correlation between systolic blood pressure response to fear memory reactivation and emotional picture recall. Interestingly, in females, systolic blood pressure response to fear memory reactivation was positively correlated with negative picture recall. These findings reveal sex-dependent effects of fear memory reactivation on emotional memory and may provide insight into the mechanisms underlying intrusive memory-induced modulation of cognitive processing in people with PTSD.

[3]Psychology, Sociology & Criminal Justice, Ohio Northern Univ., Ada, OH

Abstract: One of the hallmarks of post-traumatic stress disorder (PTSD) is the occurrence of recurrent, intrusive memories of the traumatic event. A consequence of repeated intrusive memory reactivation is that new memory processing can be impaired. Zoladz and Diamond (Neurosci. Biobehav Rev 2013) addressed this issue, suggesting that reactivation of trauma memories produces heightened anxiety, which interferes with hippocampal functioning during cognitive testing. We studied an analogous phenomenon in rats in which activation of a fear-provoking memory, up to one year after the original traumatic event, interfered with retrieval of a newly acquired spatial memory (Zoladz et al. Stress, 2010). That work showed that retrieval of the memory for shock inhibitory avoidance (IA) impaired the retrieval of the memory for the hidden platform location in a radial-arm water maze task (RAWM). In the current work we have extended this investigation to include two different fear-provoking tasks, classical fear conditioning (FC) and predator-based fear conditioning (PBFC), as the memory reactivation stimuli. We hypothesized that training or memory reactivation for FC and PBFC would impair retrieval of water maze spatial memory. Adult male rats were trained on IA, FC or PBFC tasks. One day later they were trained on a spatial memory task to locate a hidden escape platform in a radial-arm water maze. Memory for the platform location was tested 30 min later. Immediately before the spatial memory retrieval trial, the rats were re-exposed to the fear-provoking apparatus where they had been trained 24 hr previously. Other groups of rats were administered IA, FC or PBFC during the 30 min period between water maze learning and memory testing. Neither training nor retrieval of fear conditioning interfered with short-term (30 min) spatial memory. Re-exposure to the context associated with predator stress (PBFC) also did not interfere with spatial memory. Though all three tasks used an aversive stimulus to generate a fear-provoking memory, only IA training and memory testing impaired spatial memory. This finding suggests that differences in processing of the IA vs FC contingency, perhaps in terms of differences in cognitive resource allocation and the differential involvement of the prefrontal cortex in the two tasks, may explain why IA training is so intrusive. The intrusiveness of IA memory processing may provide a better model than FC for traumatic memory processing in PTSD.

Title: Effects of chronic unpredictable stress and chronic intermittent cold stress on cognitive flexibility in female rats

Authors: *D. PAREDES, J. D. SILVA, D. A. MORILAK;
Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX

Abstract: Susceptibility to stress-related neuropsychiatric disorders, such as depression, post-traumatic stress disorder and other anxiety disorders, is higher in women than in men. However, there is limited research on the mechanisms underlying these gender differences in animal models of such disorders. Chronic stress is a known risk factor for many of these neuropsychiatric disorders. They are often characterized by cognitive and emotional biases, such as perseverative thought and cognitive inflexibility, which can be promoted by stress. Our research in male rats has shown chronic stress to induce prefrontal cortical dysfunction and associated impairments in cognitive flexibility, including deficits in reversal learning and cognitive set-shifting. Specifically, chronic unpredictable stress (CUS) induced deficits in set-shifting, mediated in the ventral medial prefrontal cortex, whereas chronic intermittent cold (CIC) stress produced a selective deficit in reversal learning, mediated in the orbitofrontal cortex. However, these studies have all been conducted using male rats. It is unknown if chronic stress induces similar cognitive deficits and prefrontal cortical dysfunction in female rats. Thus, the purpose of this study was to examine the effects of CIC stress and CUS on cognitive flexibility in female rats using the attentional set-shifting test (AST). We hypothesized that female rats would exhibit deficits in cognitive flexibility after chronic stress similar to those seen in males. Adult female Sprague Dawley rats underwent 14 days of CIC (4°C, 6hr/day) or no stress, and were subsequently tested for reversal learning on the AST. Control rats were handled daily prior to testing. Another cohort of females received 14 days of CUS or control treatment and were tested on Day 15 for reversal learning and set-shifting on the AST. As predicted, CIC rats showed a deficit in reversal learning compared to controls ($p<0.01$). By contrast, no differences were observed in reversal learning or set-shifting between CUS and control female rats, contrary to previous results in males. However, because we had to modify several components of the CUS procedure to accommodate female subjects (for example, we had to eliminate the social defeat

stimulus, and replaced it instead with footshock), we cannot determine if the lack of effect was truly due to a gender difference in susceptibility to CUS, or if these modifications to the CUS procedure rendered it less stressful in females. In subsequent experiments, we will test the effect of antidepressant drugs, including SSRIs, on the deficit in reversal learning induced by CIC stress in females.

Title: Permanent effects of environmental noise on working memory and astrocyte proliferation in the medial preforntal cortex

Authors: *Y. RUVALCABA DELGADILLO[1], T. MORALES-SALCEDO[2], G. YAÑEZ-DELGADILLO[2], P. HERNÁNDEZ[2], G. CHIPRÉS-TINAJERO[2], R. RAMOS-ZÚÑIGA[2], A. FERIA-VELASCO[2], J. GARCÍA-ESTRADA[3], F. JAUREGUI-HUERTA[2], M. LUQUÍN[2]; [1]Neurosci., Univ. De Guadalajara, Guadalajara, Mexico; [2]Univ. de Guadalajara, Guadalajara, Mexico; [3]Inst. Mexicano del Seguro Social, Guadalajara, Mexico

Abstract: Aversive experiences during development can influences maturity process of the nervious and endocrine systems. Environmental exposure to aversive estimuli activate the stress response and thus the release of glucocorticoids (GLCs). GLCs are involved in multiple functions through their receptors distributed in Central Nervous Sistem (CNS) structures, including the medial prefrontal cortex (mPFC). mPFC regulates the activity of the stress response and is involved in cognitive functions such as working memory. Also this structure is vulnerable to early experiences because of its intense maturational activity in postnatal life.

Much of the cells in the CNS have receptors for GLCs and these hormons can be deletereous effects if they released in excess. These cells include astrocytes, which have a lot important fuctions, regulate neuronal micro environmental, possess transport systems for the neuro trans mitters and their precursors, regulate synapsis circuits and exert crucial neuro endocrine functions. Astrocytes also play a central rol in the defense against damage by modifying their pro liferative activity and morphology. We evaluated the long-term effects of noise by assessing both, astrocyte changes in medial prefrontal cortex (mPFC) and mPFC related alternation/discrimination tasks. METHODS: 21-day-old male Wistar rats were exposed to environmental noise (EN) in a 24-h fashion. We used for this purpose a standardized rats' audiogram-fitted adaptation of a human noisy environment. We measured corticosterone (CORT) serum levels at the end of the exposure and registered body weight gain during the first 2 weeks of the experiment. In order to assess non-auditory long-term effects of the early EN exposure, we assessed the rats' performance on T-Maze related PFC tasks and measuring the astrocyte numbers in the mPFC 10 months after the end of the exposure to EN. RESULTS: EN increased the levels of CORT of the rats exposed even after fifteen days of exposure and negatively affected the body weight gain. Accordingly, enduring effects of noise were also demonstrated on mPFC structure and function. The ability to solve alternation/discrimination tasks were reduced as well as the numbers of astroglial cells in the mPFC. CONCLUSION: Chronic EN produced stressing effects evidenced by the increased circulating levels of CORT. The exposure to this developmental stress model may have enduring effects as suggested by the decrease of the performance on T-Maze related mPFC tasks in the mPFC astrocityc population.

Title: Chronic stress, cognitive dysfunction and serotonin innervation to the medial prefrontal cortex from the dorsal raphe

Authors: *R. NATARAJAN, N. L. CHIAIA, N. A. NORTHROP, B. YAMAMOTO;
Dept. of Neurosciences, Univ. of Toledo, Toledo, OH

Abstract: Stress differentially activates specific subregions of the dorsal raphe (DRN) serotonergic (5HTergic) cells to affect 5HT release in forebrain targets such as the medial prefrontal cortex (mPFC). The mPFC mediates cognition and chronic exposure to stress is known to affect mPFC function. However, the mechanism underlying stress induced dysfunction of the mPFC is unknown. We tested the hypothesis that exposure to chronic unpredictable stress (CUS) decreases 5HT cells in the DRN leading to fewer 5HTergic innervation of the mPFC and resulting in persistent cognitive deficits. Adult male Sprague-Dawley rats underwent 21 days of CUS or daily handling (NoCUS). One week after the end of CUS, 5HT cells were counted in the ventromedial, dorsomedial, ventrolateral, and interfascicular (DRI) subregions of the DRN. Results show that CUS caused a 43.2 ± 8.9 % decrease in 5HT cells that is specific to the DRI subregion. Additionally, experiments were conducted to determine if corticosterone (CORT) played a role in CUS induced 5HT cell decreases in the DRI. Rats received 50 mg/kg metyrapone (Mety), a CORT synthesis inhibitor, or 10% EtOH vehicle (Veh), i.p., 15 min prior to each stressor. After CUS, a retrograde tracer TrueBlue was injected bilaterally into the mPFC to ascertain that CUS decreased DRI cells that innervate mPFC. Tracer positive soma were counted in the DRI one week after termination of CUS and results show that CUS caused a (CUS+Veh = 42.6 ± 7.6 %) loss of cells in the DRI that project to the mPFC and Mety pretreatment during CUS significantly blocked this effect (CUS+Mety = 80.9 ± 7.1 %). To assess CUS dependent deficits in cognitive function, 4 weeks after CUS, rats pretreated with Veh or Mety during CUS underwent Barnes maze testing. Results show no difference in the latency to acquire the task between CUS and NoCUS. However, the latency to recall the location of the goal box after a 2 day break from the maze was increased in the CUS+Veh group (NoCUS+Veh = 17.8 ± 2.6 s, CUS+Veh = 34.7 ± 3.9 s, $p < 0.05$). Additionally, the latency to find the goal box in a new location was significantly increased in the CUS+Veh group compared to NoCUS+Veh, and Mety pretreatment during CUS blocked this deficit in reversal learning (NoCUS+Veh = 22.5 ± 4.1s, CUS+Veh = 67.8 ± 14.7 s, CUS+Mety = 22.0 ± 4.2 s, $p < 0.05$), indicating that CUS causes long-term deficits in memory recall and perseveration, and that CORT mediates CUS induced deficits in behavioral flexibility. These results suggest that CUS induced loss of 5HT neurons of the DRI decreases 5HTergic innervation of the mPFC to cause lasting cognitive dysfunction. Future experiments will focus on the mechanism mediating these cognitive deficits.

Title: A novel behavior of unconditioned fear: characterization and quantification of the K-turn

Authors: K. J. KUJAWA[1], *M. BABCOCK[2];
[1]Psychology, [2]Montana State Univ., Bozeman, MT

Abstract: A detailed behavioral analysis was conducted on mice tested in a traditional unconditioned olfactory fear paradigm. Previous studies have relied on proximity, freezing, or time spent exploring the fear scent. In the present series of studies, we documented several novel behaviors that may represent important responses to odors that are fearful to rodents. Mice in the present study were exposed to a cloth without predator odor for 5 min on four consecutive testing days. On the fifth day, mice were exposed to a cloth containing cat odor for 5 min. When exposed to the predator odor, mice displayed a behavior pattern that has not been previously reported in the literature. Specifically, mice responded by displaying a stretch-attend behavior and, upon returning to the original position, retreated from the odorant to the far side of the apparatus. The frequency of this behavior pattern was significantly higher relative to the previous trial when the predator odor was not present. For the purposes of distinguishing this behavior from the stretch-attend behavior, we term this behavioral sequence a K-turn. Our study characterizes the K-turn and its relationship with other behaviors traditionally measured in unconditioned fear paradigms. We have evaluated K-turns in animals tested during different periods of the light-dark cycle. The results of the present study offer additional behavioral measurements that may provide greater sensitivity in detecting fear-related responses. The addition of the K-turn behavioral sequence many represent a sensitive and valid marker of a fear response.

Title: Long-term effects caused by the exposure to unpredictable chronic stress

Authors: *H. SANCHEZ-CASTILLO[1,2], P. TORRES-CARRILLO[1], B. ROJAS-LITA[1], C. MENDOZA-ROSALES[1], M. MIGLIARO[1], D. B. PAZ-TREJO[1,2], V. M. SOLIS[1], E. HONG[3]; [1]Univ. Nacional Autonoma De Mexico. Fac Psicologia, Mexico City, Mexico; [2]Sociedad Iberoamericana de Neurociencia Aplicada, Mexico City, Mexico; [3]Farmacologia, CINVESTAV, Mexico City, Mexico

Abstract: There is a current research interest that is focused on elucidating the effects of chronic stress on brain structures involved in the modulation of behavioral patterns, such as the prefrontal cortex (PFC). The functional impairment of the PFC that occurs during high levels of stress is significant for understanding the condition of mental health of patients with stress-related disorders. In addition, loss of self-control during exposure to stress can bring a large number of maladaptive behaviors, such as substance abuse. On the other hand, it has been described that intense stressful events (such as natural disasters, military combat, sexual abuse or domestic violence) can lead to Post-traumatic Stress Disorder (PTSD). However, not sufficient attention has been given to the long-term effect that exposure to chronic stress has on cognition after an interval of recovery. The objective of this research project was to evaluate the effect of chronic unpredictable stress in a Y-maze task, which served as a measuring tool for behavioral flexibility. Performance was compared among different rat strains: Wistar, Wistar Kyoto, and SHR. All experimental subjects were male and had an approximate age of four months at the beginning of the experiment. Animals were exposed to a Chronic Unpredictable Stress Battery (CUSB) for ten days. The behavioral assessments were performed before, immediately after (acute effects), and after a temporary recovery window of three months (persistent effects) after the CUSB exposure. Differential results were observed dependent to the rat strains. The rats belonging to the Wistar strain had an increase in the number of sessions required to satisfy the learning criteria, on the second evaluation that assessed acute effects compared to the first evaluation, meanwhile on the first evaluation and on the third evaluation we observed similar values for the number of errors and latency (both lower than those of the second evaluation). With the SHR strain, no distinguishable effects caused by the stress exposure were observed on all three evaluations. The rats belonging to the Wistar Kyoto strain showed a considerable increase in the number of errors and latency on the third evaluation, which suggests that this strain is susceptible to the long-term effects of stress even after the window of recovery. It is notable to mention that not all subjects from the SHR and Wistar Kyoto strains achieved the learning criteria in the first evaluation.

Title: Acute restraint stress alters adult zebra finch song performance and neuronal morphology: Potential model for evaluation of neurobiological effects of developmental stress

Authors: *T. L. HOLLAND, K. SODERSTROM;
East Carolina Univ., Greenville, NC

Abstract: During a sensitive period of development, male zebra finches learn a complex song that is important to courtship. During early stages of vocal development they listen to and memorize an adult's song, forming a template. Later in development they gradually improve the song by practicing and using auditory feedback. In adulthood, the song has low variability and is stable over time. This process parallels language acquisition in humans. We are interested in the effect of psychological stress on vocal development in zebra finches. Currently, we have evaluated the effect of acute restraint stress on song performance and corresponding neuronal morphology in adult zebra finches. We hypothesized that stress would alter spectral and temporal features of the adult's song. Zebra finches (n = 4-5) were administered 30 minutes of restraint stress or 30 minutes of no stress, immediately followed by two hours of audio recording. A female audience bird was presented as a social stimulus to promote singing. Songs were compared to previously obtained baseline recordings in a paired design. Sound Analysis Pro software was used to analyze songs and export spectral and temporal data for each song syllable. Song syllables of the stress group had significantly higher pitch and longer duration when compared to baseline recordings (Wilcoxon signed-rank test, $p < 0.05$). The no stress group had no significant differences from baseline recordings. In a complimentary experiment, adults were administered acute restraint stress (n = 5), and following cessation of the stressor, brains were collected for Golgi-Cox staining in order to evaluate changes in dendritic spine density as a morphological measure of neuronal activity. In a premotor brain region for song production (HVC), no changes were observed. In NCM, a secondary auditory region, dendritic spine densities increased. Since no clear alteration within the motor circuit was observed, altered spectral and temporal features following restraint stress may be related to altered synaptic activity within the auditory system. The stress-altered song may be an adaptive response, possibly relevant to communicating anxiety. In the future, we will evaluate the effects of concurrent developmental stress and cannabinoid CB1 receptor agonist treatment on vocal

learning in order to learn more about the neurobiological consequences, and potential interaction of stress and drug abuse on developmental-dependent learning.

Title: Anti-stress effects and memory enhancer properties of n-3 PUFA in stressed rats

Authors: *A. DAGNINO-SUBIABRE[1], M. A. PÉREZ[2], V. PEÑALOZA-SANCHO[2], J. AHUMADA[3], M. FUENZALIDA[3];
[1]Physiol., Univ. of Valparaiso, Valparaiso, Chile; [2]Lab. of Behavioral Neurobiology, Inst. of Physiol., [3]Lab. of Neural Plasticity, Inst. of Physiol., Univ. de Valparaíso, Valparaíso, Chile

Abstract: While chronic stress induces dendritic atrophy in the hippocampus and impairs learning and memory, supplementation with n-3 Polyunsaturated fatty acid (PUFA) is known to improves learning and memory of unstressed rats. Whether n-3 PUFA supplementation could improve dendritic morphology and memory of stressed rats, as well as decrease the major stress markers, remain unknown. Male Sprague-Dawley rats were randomly assigned to unstressed and stressed (chronic restraint stress) experimental groups. Afterward, animals were supplemented with n-3 PUFA (DHA and EPA mix) or vehicle. Dendritic morphology and synaptic transmission in the hippocampus were evaluated by Golgi stain and patch-clamp tools, respectively. The Morris water maze were used to analyze the effects of chronic stress on memory. ELISA and the plus-maze test were used to evaluate plasma corticosterone levels and anxiety as stress markers. Supplementation with n-3 improved dendritic architecture and restored the frequency of inhibitory postsynaptic currents of hippocampal pyramidal neurons of stressed rats. In addition, n-3 supplementation improved spatial memory and decreased corticosterone levels and anxiety of stressed rats. Our results demonstrate that n-3 supplementation had four beneficial effects on stressed rats: prevents dendritic atrophy in CA3, restores the GABA release probability in CA1, improves spatial memory, and a strong anti-stress property. We speculate

that ω-3 supplementation could be used in the treatment of stress-related psychiatric disorders such as depressive and anxiety disorders.

Title: The effects of wheel-running and monthly 6-hour advance on the progression of type-2 diabetes in C57Bl/6J and TallyHo/JngJ mice

Authors: *J. A. SEGGIO, J. A. HICKS, A. HATZIDIS, N. F. NASCIMENTO, K. N. CARLSON, N. L. ARRUDA, R. R. GELINEAU, I. K. MONTEIRO DE PINA, J. H. WEST; Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: Type-2 Diabetes is the most common form of human diabetes, accounting for about 90% of cases and affecting about 23 million Americans. It is often accompanied by hyperglycemia and obesity. Diabetes has been linked to disruptions in the circadian rhythms of both the organism and specific organs as it can affect critical clock genes and can lead to an increased possibility of developing the disorder or exacerbating it. This study looked at the effects of voluntary exercise on parameters associated with diabetes and obesity, including blood glucose and insulin, in C57BL6/J (B6) and TallyHo/JngJ (TH) mice when experiencing an acute 6-hour advance shift. Two groups of each genotype of mice were kept in either a 12:12 LD cycle or a 6-hour advance simulated jet-lag; half of each strain received access to a running wheel while the other half were placed into a home cage, which can monitor locomotor activity without a wheel. 12-hour fasting glucose tolerance tests were conducted every four weeks starting at age-week eight until age-week 24. Additionally, insulin and lipid (i.e., cholesterols and triglycerides) levels were tested during the final shift. In LD conditions, early access to a running-wheel had no effect on the behavior or physiology of each mouse genotype; however, after prolonged exposure, TH mice exhibited reductions in blood lipids and insulin levels, and better glucose tolerance. Interestingly, TH mice undergoing the 6-hour advance, showed overall reduced insulin and blood lipid levels and lower glucose compared to TH mice in LD. Additionally, the running-wheel did not produce further improvements on insulin or glucose tolerance, as it did during LD. In addition, TH mice appeared to shift much more quickly to the new light phase compared to

B6. One possibility for the alteration in diabetic symptoms in TH mice is that the 6-hour shift leads to an alteration in the insulin secreting rhythm, which may promote circadian desynchrony between central and peripheral oscillators, when being subjected to jet-lag.

Nacional Autónoma de México, Inst. de Neurobioloía, Querétaro, Mexico; [4]Dept. de Farmacología, Facultad de Medicicna, UANL, Monterrey, Mexico

Abstract: Obesity is becoming an increasing problem in industrialized countries. Recent studies have linked obesity to changes in the circadian regulation. Circadian cycling disturbances such as reductions in nocturnal activity, an increase in the variability of the free-running period as well as alterations in photic resetting are associated with obesity. The aim of the present work was to elucidate whether obesity affects the glutamatergic system in the suprachiasmatic nucleus (SCN). We initially evaluated circadian locomotor activity and the phase response curve to light. Secondly, we measured expression levels of the glutamate receptor and neuronal activity. Male Wistar rats fed with regular diet and water (control) or sucrose 30% (obese model) for 7 months.

In our obese model, we found an increase in adipose tissue reflected in body mass gain, a wide range of metabolic disorders, such as hyperleptinaemia, and an increase in insulin levels. Moreover obese animals have a diminished response to light pulses at CT22. The loss of response to light pulses appears to indicate an alteration on the glutamatergic system or photo-induction of clock genes. Because an alteration in the glutamatergic systems impacts clock gene expression we next sought to investigate the first option. As a first approximation we quantified the levels of synaptic NMDA receptors (NR) on isolated synaptosomes of obese and control rats. Our results show a reduction in NR-2b expression after the light pulse in obese rats, which could explain the alteration in behavior. To our knowledge this is the first study to link metabolic disorders to alterations in glutamate receptors on the SCN.

Title: Effect of light therapy for type 2 diabetics with poorly controlled glycemia during the winter season

Authors: *H. HIRANO[1], H. NISHIKAWA[2], M. MATSUDA[2];
[1]Yamaguchi Univ. Org Univ. Edu, Yamaguchi, Japan; [2]Dept of Lab. Sciences, Grad. Sch. of Med., Yamaguchi Univ., Ube, Japan

Abstract: Background and aims: Light therapy (LT) has been used as a beneficial treatment for several diseases, including seasonal affective disorder (SAD) and circadian rhythm sleep disorders. SAD is a mood disorder characterized by recurring symptoms in autumn and winter with atypical features such as hypersomnia, increased appetite, and weight gain. Unless the amount of antihyperglycemic agent is increased, some diabetic patients experience great difficulty controlling their glycemia during days of short photoperiod. To evaluate the effects of LT on diabetes, a clinical investigation was conducted over six years. Materials and methods:

Three male subjects aged 45 to 58 and nine female subjects aged 59 to 78 were enrolled in this investigation. They had all been treated for type 2 diabetes for a period ranging 8 years to more than 40 years. LT was randomly started between November and January, and terminated in April or May. One subject received bright-light therapy (BLT). Another subject first received BLT, and then treatment was changed to dawn simulation (DS). The rest received DS. All subjects completed the Seasonal Pattern Assessment Questionnaire (SPAQ), and underwent a structured diagnostic interview for DSM-IV axis 1 disorders (SCID-1) at the beginning and end of LT, respectively. In addition to measurement of HbA1c every 4 weeks, they were asked about their satisfaction on the following quality of life (QOL)-related items: sleep, extreme cold, food restriction, mood, and activity. Results: Though no one had a history of psychiatric consultation or met diagnostic criteria for any type of mood disorders, results of SPAQ revealed that each of them showed seasonal variations in sleep length, social activity, mood, weight, appetite and energy level. Their Global Seasonality Score ranged from 2 to 15, and its mean and SEM were 7.08 ± 1.89. For eleven subjects, LT improved satisfaction with all types of QOL-related items. Furthermore, four subjects lost weight, and HbA1c values of seven subjects significantly decreased. Discussion & Conclusions: LT appears effective in improving both QOL and glycemic control of the patients. The precise mechanism causing the beneficial effects of LT for type 2 diabetics remains unexplained. Our current understanding is as follows: LT advances phase-delayed circadian rhythms of the enrolled subjects. LT-induced phase advance alters the functions of the autonomic nervous system towards a sympathetic predominance. Consequently, the basal metabolic rate of the diabetics is increased, resulting in an improvement of QOL, weight loss and decreases in HbA1c values. This is all likely to lead to increases in daily activity.

Title: Measuring the physiological cost of circadian desynchrony in mammals

Authors: A. C. WEST[1], *D. A. BECHTOLD[2];
[1]Fac. of Life Sci., The Univ. of Manchester, Manchester, United Kingdom; [2]Univ. Manchester, Manchester, United Kingdom

Abstract: Almost all organisms on the planet rely on intrinsic timekeeping mechanisms to anticipate fluctuations within the environment and adapt their physiology accordingly. Mammals are certainly no exception, and coordinated daily rhythms are evident in most aspects of our behaviour and physiology (e.g. from sleep/wake and feeding cycles to hormone rhythms and metabolism), all driven by a circadian clock network. The circadian clockwork is responsive to environmental signals (such as light/dark and food availability), which not only reinforces our synchronisation with the external environment, but also facilitates internal synchrony between brain and tissue clocks located across the body. Unfortunately, within our modern society the natural framework of perpetual and predictable environmental rhythmicity has been undermined. Indeed epidemiological evidence clearly associates shift-working patterns with cancer, immune dysfunction and numerous metabolic problems. The adaptive and fitness value of the circadian timing has been clearly demonstrated in lower organisms. However, the intrinsic value of the circadian system in mammals is less clear, and little is known of the underpinning biology that associates clock disruption with disease states. We therefore set out to define the impact of circadian misalignment in mice by imposing stable, but non-resonant (i.e. non-24hr) cycles of light and/or food. As expected, mice exhibited robust entrainment to environments that were within the limits of the circadian clock (e.g. 22.5hr to 27hr cycles). However, despite achieving stable entrainment, chronic exposure (>16 weeks) to non-resonant light/dark cycles resulted in widespread and tissue specific disruption of the molecular clockwork and downstream clock regulated transcriptional rhythms. Moreover, mice maintained in non-resonant light/dark cycles also exhibited a number of physiological consequences, including altered metabolic rate, reduced insulin sensitivity, and cardiac dysfunction. Together these studies highlight the profound impact of circadian misalignment on mammalian physiology, and provide mechanistic insight into the clock disruption-associated pathophysiology associated with circadian disruption in human populations (such as shift work and forced desynchrony).

Title: Prenatal exposure to dim light at night impairs offspring delayed-type hypersensitivity reaction

Authors: *Y. M. CISSE, R. NELSON;
Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Light is one of the most potent signals to the circadian system. Adoption of electrical lighting has occurred without consideration or understanding of the wide ranging physiological and psychological effects of light at night. Disruption of natural light/dark cycles by light at night (LAN) dampens endogenous biological rhythms to maintain optimal functioning of various organ systems and other bodily functions. The immune system, especially T cell proliferation and NK-cell activity, exhibits circadian rhythms in function. Dim LAN (dLAN) exposure impairs response to delayed type hypersensitivity (DTH), an antigen specific T-cell mediated immune response, in Siberian hamsters (*Phodopus sungorus*). Studies of the effects of LAN on immune function have thus far focused on adult immune function, but impaired maternal immune function has downstream effects on offspring immune phenotype. Thus, we hypothesized that parental exposure to dLAN impairs offspring immune function and decreases DTH responses in adult offspring. Adult (8 week) male and female Siberian hamsters were exposed to either dark or dimly lit nights (dLAN) for 9 weeks, at which point they were paired and mated in dark nights. Pairings resulted in four groups: Dark/Dark (M/F), Dark/Dim (M/F), Dim/Dark (M/F), and Dim/Dim (M/F). At 8 weeks of age, offspring underwent sensitization to 2-4-dinitro-1-fluorobenzene (DNFB) on the dorsum followed a week later by a secondary DNFB challenge on the pinna in order to assess DTH. Male offspring of mothers exposed to dLAN suppressed DTH mediated inflammation, suggesting impaired T cell function. Female offspring required both maternal and paternal exposure to dLAN to affect swelling 2 days after challenge. Decreased T-cell function in offspring that have only experienced dLAN in their germline suggests that seemingly innocuous, but pervasive, nighttime lighting may have long ranging effects on offspring fitness. Future studies will investigate circulating and splenic immune cell phenotype via flow cytometry.

Title: Impact of shift work on attention, female estrous cycling, and cholinergic signalling in a rat model

Authors: *M. B. LEVENTHAL, R. BALACHANDRAN, A. ROBERTSON, P. EUBIG, M. MAHONEY;
Univ. of Illinois Col. of Vet. Medic, Urbana, IL

Abstract: There has been a sharp rise in the number of shift workers- those who work outside of the normal "9 to 5" schedule. Because they work when they would normally be inactive, shift workers are faced with perturbed biological rhythms and increased risk for health conditions including cancer, diabetes, cardiovascular issues, obesity, and mood disorders. Furthermore, female shift workers face additional risks such as infertility and irregular reproductive cycles. There has been a strong focus on identifying how shift work affects physiological systems, however, relatively few studies have examined cognitive deficits caused by shift work and altered biological rhythms. Here we investigate how shift work-like schedules impact attention and whether there are sex differences in the response to shift work, attentional processes, and the interaction of these variables. We tested male and female Long Evans rats on a well-established behavioral measure of attention, the 5-choice serial reaction time task (5CSRTT). Animals were tested during their light phase (4 hours after lights-on) or during their dark phase (4 hours after lights-off) when they would be inactive or active, respectively. We analyzed daily wheel running activity patterns and female reproductive cycles. After test completion, brains were collected and stained for choline acetyltransferase (ChAT) in the nucleus basalis magnocellularis (nbm) and protein quantification of nicotinic acetylcholine receptors and ChAT in the medial prefrontal cortex (mPFC). These areas were selected because cholinergic projections from the nbm to the cortex have been shown to be important for 5CSRTT performance and involved in learning, memory, and arousal. Contrary to our hypothesis, animals that performed the 5CSRTT during the day, outside of their normal active phase made fewer incorrect responses, suggesting that they are more attentive. However, within day-tested animals, those that shifted to a diurnal activity pattern performed better than those that remained nocturnal. Furthermore, females tested during the day made fewer incorrect responses than male counterparts, indicating there is a sex difference in the impact of time of day on attention. Light-phase tested females had lengthened and irregular estrus cycles. The majority of experimental (9/12) and control animals (8/14) tested in the day became predominantly active during the light phase, demonstrating that 5CSRTT performance, as well as food cues alone, are capable of entraining activity. Finally, animals who were active during the light phase had increased numbers of ChAT-positive cells in the nbm compared to animals who were active during the dark phase.

Title: Characterizing cerebellin-short, a novel circadian peptide, in the rat suprachiasmatic nucleus

Authors: *J. L. CHU[1], J. W. MITCHELL[1], M. U. GILLETTE[2];
[1]Cell. & Developmental Biol., [2]Neurosci. Program, Univ. Illinois Urbana-Champaign, Urbana, IL

Abstract: The suprachiasmatic nucleus (SCN), the central circadian clock in mammals, contains a number of peptides important for synchronizing the intrinsic rhythm and conveying it to other parts of the brain. Cerebellin-short (SGSAKVAFSAIRSTN) is a small peptide consisting of 15 amino acids identified in mass spectrometry proteomics to be secreted from the SCN in circadian fashion (Hatcher et al., PNAS, 2008). Cerebellin-short is the C-terminus histidine-truncated form of 16 amino acid full-length cerebellin, a peptide enriched in cerebellum (Slemmon et al., PNAS, 1984). The distribution and function of cerebellin-short in the SCN, however, are unknown. Here we show that Cbln1, the precursor for cerebellin, is expressed in the SCN with daily oscillations in mRNA and protein levels. Exogenous cerebellin-short applied at midday and early night phase advance the spontaneous firing rhythm of SCN neurons, suggesting that endogenous cerebellin-short contributes a circadian regulatory function. These findings present the possibility for the involvement of cerebellin-short in the intrinsic circadian timekeeping of SCN.

Title: Intrinsically photosensitive retinal ganglion cells (ipRGCS) mediate light entrainment of peripheral clocks

Authors: *P. KOFUJI, N. PURRIER, S. MISHRA, W. C. ENGELAND;
Dept Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: The suprachiasmatic nucleus (SCN) in the hypothalamus houses the central circadian pacemaker and synchronizes autonomous circadian clocks in peripheral tissues to generate rhythms of metabolism and physiology. While the SCN biological clock follows an intrinsic period of ~24 hours, neurochemical signals from the retina provide photic information for the precise alignment of the SCN to environmental light-dark cycles. This photic information is conveyed by a subpopulation of retinal ganglion cells, intrinsically photosensitive retinal ganglion cells (ipRGCs), that express the photopigment melanopsin (Opn4) and therefore respond to light even in the absence of rod and cone photoreceptor input. It is still unclear whether ipRGCs are the sole pathway for photic entrainment of the peripheral clocks present in tissues throughout the body. In this study we have assessed the role of ipRGCs in synchronizing peripheral clocks to environmental light-dark cycles in mice. ipRGC neurotransmission was silenced by expression of tetanus toxin light chain fragment (TeNT) in melanopsin-expressing ganglion cells by crossing the $Opn4^{Cre/+}$ with $R26R^{TeNT/+}$ mouse line that has Cre recombinase-controlled expression of TeNT. As expected, non-image-forming visual behaviors such as the pupillary light reflex and photoentrainment of circadian locomotor activity were effectively abolished in $Opn4^{Cre/+}$, $R26R^{TeNT/+}$ mice; loss of photoentrainment resulted in "free-running" rhythms in locomotor activity. Moreover, light pulse-induced c-fos expression in the SCN was largely reduced in the mutant mice in comparison to littermate controls. The rhythmicity of peripheral clocks was monitored by intercrossing $Opn4^{Cre/+}$, $R26R^{TeNT/+}$ with $mPer2^{Luciferase}$ ($mPer2^{Luc}$) knockin mice. Both SCN and peripheral tissues from $Opn4^{Cre/+}$, $R26R^{TeNT/+}$, $Per2^{Luc/+}$mice showed robust and self-sustained circadian rhythms for several days in explant cultures; importantly, peak phase of PER2Luc rhythms was aligned with circadian locomotor activity, not environmental light-dark cycles. Likewise, using subcutaneous microdialysis probes to collect samples for corticosterone over several days, circadian glucocorticoid rhythms were observed to be “free running” in mutant mice. Overall these results indicate that ipRGCs are required for the synchronization of circadian clocks in peripheral tissues to environmental light-dark cycles.

Title: The adrenal clock acts as a buffer that prevents disruption of glucocorticoid rhythms by aberrant light exposure

Authors: *W. C. ENGELAND[1], S. MISHRA[1], P. KOFUJI[1], D. BREAULT[2];
[1]Neurosci, Univ. Minnesota, Minneapolis, MN; [2]Harvard Med. Sch., Boston, MA

Abstract: The circadian rhythm in adrenal glucocorticoid (GC) secretion provides the brain with a hormonal milieu that is critical for cognitive resiliency in the face of distress. The GC rhythm is entrained to light-dark (LD) cycles via a molecular clock in the suprachiasmatic nucleus (SCN) that is reset daily by photic signals and is maintained by an adrenal clock that is synchronized by SCN-dependent signals. Aberrant light exposure (e.g. light at night) observed during shift work or jet lag can disrupt the GC rhythm. To determine the requirement of the adrenal clock in stabilizing the circadian GC rhythm during exposure to an aberrant LD cycle, experiments were done using a novel adrenal clock KO mouse and microdialysis sampling to monitor corticosterone rhythmicity. We generated $AS^{Cre/+}$ :: $Bmal1^{fl/fl}$ :: $R26R^{mTom/mGFP/+}$ mice (adrenal clock KO) by intercrossing $AS^{Cre/+}$ mice (Cre recombinase inserted in the aldosterone synthase (AS) genetic locus) with the mT/mG Cre reporter and the floxed Bmal1 strains. In adult male and female wild-type (WT) mice, membrane bound green fluorescent protein (mGFP) expressed in adrenal cortex, but not medulla, was co-localized with nuclear BMAL1 labeling. In adult male and female KO mice, expression of mGFP was associated with loss of BMAL1 labeling. Mice implanted with subcutaneous microdialysis probes were sampled continuously at 30-60 min intervals for up to 3 days under both 12:12h (tau (T) 24) LD and 3.5:3.5h (T7) LD cycles, aberrant light exposure that produces a depressive-like phenotype in mice. Dialysate corticosterone was assayed by radioimmunoassay; rhythmicity was assessed using Pulsar analysis. Corticosterone rhythms remain entrained to a T24 LD cycle in WT and adrenal clock KO mice. Under a T7 LD cycle, a circadian rhythm in corticosterone persists in WT mice that is disrupted by intermittent corticosterone pulses. In contrast, circadian rhythms are abolished in adrenal clock KO mice under a T7 LD cycle due to corticosterone pulses that are magnified in

frequency and in amplitude. These data suggest that circadian GC rhythmicity under a T24 LD cycle is resistant to loss of the adrenal clock. In contrast, under a T7 LD cycle the adrenal clock is required to stabilize the circadian GC rhythm, buffering GC responses to aberrant light. Title: Ovariectomy shortens the period and increases photic phase shift of circadian locomotor activity rhythm in the mouse Neotomodon alstoni

Authors: C. R. JUÁREZ TAPIA, *M. MIRANDA-ANAYA, A. CARMONA-CASTRO, G. MARTÍNEZ-MORALES;
Facultad De Ciencias, UNAM, Juriquilla Querétaro, Mexico

Abstract: The Suprachiasmatic nucleus (SCN) is considered the master circadian pacemaker in mammals; it receives photic information mainly through the retino-hypothalamic tract and its effect on the oscillator depends on the phase of the cycle. A circadian oscillator exists in diverse tissues different than SCN, known as peripheral oscillators that are coordinated and feeds back to the SCN. The ovary is a peripheral oscillator in rodents and it produces hormones that influence the hypothalamus, including the regulation of the circadian rhythms. However, the mechanisms through which ovarian hormones impact such regulation have not been thoroughly studied. The effects of ovariectomy over circadian rhythms and its response to light seems to be different according to the species tested; in the present study we studied its effect on the circadian locomotor activity rhythm in the Mexican volcano mouse *Neotomodon alstoni.* Effects upon free running period, entrainment and photic phase shifting were tested. Adult females were used intact, sham surgery or ovariectomized. The circadian rhythm of locomotor activity was automatically registered in individual mice by means of infrared light beams and observed in constant darkness. Phase changes were induced by a 1 hour light (300 lx) pulse at Circadian Time (CT) 14 and CT22. The results show that ovariectomized females display shorter circadian period value and amplitude of the circadian rhythm of locomotor activity in free running than

sham or intact; circadian activity profile changes includes decreasing in amplitude and a biphasic pattern. The effect of a light pulse at CT14 shows greater phase shift delays in ovariectomized than the sham or intact but no differences were noted at CT22. The latter indicates that the ovaries, possibly through their hormones, influence period regulation and light sensitivity of the SCN in this species where estrogen profile along the estrous cycle is similar to traditional laboratory rodents.

Title: Simulating temperature cycles in the colony uncover chronotypes in honey bee foragers

Authors: *M. A. GIANNONI GUZMAN, J. ALEMAN-RIOS, T. GIRAY, J. L. AGOSTO-RIVERA;
Dept. of Biol., Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR

Abstract: Individual variation in diurnal preference in humans (chronotypes), have been correlated with differences in period length, circadian phase and other physiological measures. Furthermore, chronotypes have been associated with individual variation in different physiological and neurological processes as well as in the susceptibility to various diseases. We have previously shown large individual variation in the endogenous period length of honey bee foragers from the same colony. In this study we investigated the temporal pattern of light and temperature within honey bee colonies in the filed, simulated in the laboratory and determined its effectiveness as a as a potential Zeitgeber in the hive and whether individuals present differences in the circadian phase with respect to this time giver. To determine if temperature oscillates in a circadian manner within the colony, we placed data loggers throughout the colony to measure light and temperature. Our results show temperature oscillations that increase in amplitude as you move away from the core of the colony. To determine if these cycles are sufficient to entrain the circadian clock of honey bees, we simulated these cycles in our biological incubators in the laboratory. Our results show that these temperature cycles are indeed capable of entraining the

circadian clock. Surprisingly, we also found that there is individual variation in the circadian phase of individuals with respect to temperature and ranges from -6 hours to 2 hours, with more than 60% of the individuals having a phase between -2 and 0. Moreover, we found that advancing the temperature cycle by six hours, resulted in individual differences in the response to the environmental manipulation, such that some individuals adjusted to the new temperature regiment, while others didn't. Taken together our describe for the first time circadian chronotypes in honey bee foragers. In addition, we find that temperature is a potential Zeitgeber for honey bee foragers, but its relative contribution compared with light entrainment requires further examination. Studying the observed phase differences between the endogenous clock and temperature cycles could provide critical insight into how honey bee colonies manage and efficiently exploit resources available at specific times of the day.

Title: Role of tissue-type plasminogen activator (tPA) in food anticipatory activity in mice fed one or two meals a day

Authors: *A. RASTOGI, E. M. MINTZ;
Department Of Biological Sciences, Kent State University, Kent, OH

Abstract: In rodents, the presence of food for only a few hours a day (one meal) results in the appearance of food anticipatory activity (FAA). They can also anticipate two meals per day, with FAA split between these meals. The underlying neural mechanism of FAA and its behavioral splitting in the case of two meals may differ from that of one meal, with the possible involvement of two different neuronal populations. To study this, two experiments were performed using memory deficient tissue-type plasminogen activator knock out (tPA-/-) male mice and wild type (tPA+/+, C57BL/6J) males. tPA-/- mice are severely deficient in long-term potentiation, long-term depression, and hippocampal-based learning and memory tasks. We have previously shown that these mice show increased FAA when presented a single period of food

availability per day. Mice were individually maintained in 12L:12D photoperiod with ad libitum food. After entraining to LD conditions, in the first experiment, mice (n=6) received either one meal of four hours at ZT6 (ZT0: lights onset) or continued in ad libitum, and perfused after 1 week at ZT5. In the second experiment, the LD cycle was changed to 18L:6D, and after two weeks in this condition, mice (n=12) received two meals (separating from 5 hours) of two hours each, at ZT5 and ZT12. After a week, mice were perfused (n=6 each time) either at ZT4 or at ZT11. Behavioral results suggest that with one meal mice lose 12-18% weight, although with two meals they lose 8-10% weight, which showed a better adaptation of mice with two meal timings. With one meal, FAA developed in all the mice with higher activity amplitude in tPA-/- than tPA+/+. Contrary to this, with two meals, tPA+/+ mice showed higher activity amplitude than tPA-/- with individual variations in FAA appearance between genotypes. With the 1st meal at ZT5, all mice developed FAA, though with the 2nd meal at ZT12, 58% tPA+/+ and 75% tPA-/- mice developed FAA. Our Fos-immunohistochemistry data suggests that in response to one meal, Fos expression in dorsomedial hypothalamus (DMH) and arcuate nucleus (ARC) increases several folds relative to ad libitum food condition. Contrary to this, under two meals, Fos expression dampens compared to one meal in DMH and ARC. Interestingly, Fos was equally expressed in DMH between genotypes, although in ARC expression was higher in tPA-/- than tPA+/+ between both meal timings. These data suggest that the mechanisms underlying FAA differ between the one and two-meal situations, and that the loss of tPA may limit adaptation to multiple periods of food availability per day.

Title: Investigating the role of ghrelin in food anticipatory activity of a scheduled treat

Authors: ***R. KHAZALL**, H. MACKAY, A. ABIZAID;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Food availability constitutes an environmental variable that can influence circadian rhythms. For instance, laboratory rodents exposed to restricted feeding schedules (i.e.schedules

where food is available only a few hours during the day) results in changes in locomotor activity that include an increase in locomotor activity in anticipation of the oncoming meal. Interestingly, these behaviours are not only expressed under negative energy balance. Exposure to palatable foods is also associated with increases in food anticipatory behavior in rats and mice. Ghrelin, a hormone associated with feeding and metabolism, has also been implicated in the expression of food anticipatory behavior in mice and rats, but it's not known if ghrelin is also associated with increased anticipatory behaviors to scheduled snacks. To determine if this is the case, we conducted experiments where male CD-1 mice were housed in locomotor activity boxes. After a 7 day baseline period of ad lib access to a standard laboratory chow, experimental mice were given daily 2hr access to commercial chocolate chip cookie dough in the middle of their light cycle (ZT6-ZT8) for 15 days. Results showed that experimental mice exhibited a significant increase in locomotor activity in anticipation of the cookie dough. This increase in anticipatory activity was maintained several days after access to the treat was terminated. The experimental mice also consumed more calories than controls, but did not gain more weight than controls, nor did they differ from the controls in plasma levels of glucose, corticosterone,or ghrelin. In a second experiment the experimental period was extended to 21 days and a 6 day re-exposure period was added, in which the animals were reintroduced to the cookie dough following the recovery period. As previously observed, mice that had limited access to cookie dough demonstrated a significant increase in anticipatory locomotor activity throughout the experimental period, which was maintained throughout recovery and was re-established during the re-exposure period. Body weight, food intake and plasma levels of ghrelin and glucose did not differ between the groups. These results suggest that CD-1 mice display robust locomotor activity in anticipation of a scheduled snack, and that behaviour continues for days following the last day of cookie dough exposure. The maintenance of treat anticipation after the cookie dough is no longer presented, however, is not associated with plasma ghrelin concentrations.

Title: Circadian restricted feeding: effects of amphetamine sensitization and cross-sensitization

Authors: *H. N. OPIOL, S. RUTHERFORD, N. DE ZAVALIA, S. AMIR;
Psychology, Ctr. For Studies In Behavioral Neurobiology, Con, Montreal, QC, Canada

Abstract: Circadian restricted feeding (RF) is the application of daily timed feeding schedules that occur at the same time each day. RF shifts our internal 24h biological rhythms and behaviour. Dopamine is believed to be a key component in circadian RF. To test whether enhancing dopamine would also enhance behavioural properties of circadian feeding, rats underwent different amphetamine sensitization protocols and food anticipatory activity (FAA) was observed (between and within design). FAA is the behavioural hallmark of circadian RF that is defined as increased activity (e.g. running wheel) prior to feeding time once internal synchrony to feeding is achieved. Our study found no evidence for amphetamine sensitization on FAA. Further investigation suggested a ceiling effect between controls and amphetamine sensitized rats, such that RF itself could be causing behavioural sensitization. We hypothesized that behavioural sensitization was occurring during RF and perhaps continued after body weight had been restored. Studies by other labs have shown that caloric restriction results in dopamine-related enhancement, especially by increasing behavioural response to rewarding drugs. Though, these studies report the effects subside when free access to food and body weight are returned. Preliminary evidence from our lab indicated that cross-sensitization was present after body weight was restored. To test whether circadian RF could lead to cross-sensitization after body weight had been restored we placed rats on RF for 2 weeks then waited 10-14 days before giving an acute injection of amphetamine. Behaviour was measured using an open-field box. Results indicated that rats subjected to RF had a higher response to amphetamine than ad lib and saline controls. We then tested if behavioural cross-sensitization was specific to circadian RF or simply caloric restriction itself. Rats were divided into 2 groups: RF or variable RF that provided food at the same time or unpredictable time each day, respectively. Results indicated that cross-sensitization is not the result of caloric restriction itself; circadian scheduled feeding produced a significantly higher behavioural response than unpredictable RF, compared to controls. Finally, we tested whether daily scheduled access to a treat (no caloric restriction) would yield similar cross-sensitization to amphetamine, both under circadian and variable schedules- it did not. Our data indicate that circadian RF appears to be a unique feeding paradigm, requiring caloric restriction and the induction of circadian controlled oscillators that result in the maintenance of post-feeding behavioural cross-sensitization.

Title: GIRK channels mediate the nonphotic effects of exogenous melatonin

Authors: *L. M. HABLITZ[1], H. E. MOLZOF[2], K. L. GAMBLE[2];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Psychiatry- Behavioral Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Melatonin supplementation has been used as a therapeutic agent for several diseases, yet little is known about the underlying molecular mechanisms by which melatonin acts within the brain to synchronize circadian rhythms. G protein signaling plays a large role in melatonin-induced phase shifts of locomotor behavior. Melatonin receptors have been shown to activate G protein-coupled inwardly-rectifying potassium (GIRK) channels in Xenopus oocytes. The present study tested the hypothesis that melatonin influences circadian phase and electrical activity within the clock center of the brain, the suprachiasmatic nucleus (SCN), through GIRK channel activation. The results showed that, unlike wild-type littermates, GIRK2 knockout mice failed to phase advance wheel-running behavior in response to 3-day subcutaneous injections of melatonin in the late day. Loose patch electrophysiological recordings of SCN neurons revealed a significant reduction in the average intrinsic action potential rate in response to melatonin. This effect was lost in the presence of a GIRK antagonist, tertiapin-q (TPQ), and in SCN neurons from GIRK2 knockout mice. The melatonin-induced suppression of firing rate corresponded with an increased inward current that was blocked by TPQ. Finally, application of ramelteon, a potent melatonin receptor agonist, also significantly decreased firing rate and increased inward current within SCN neurons in a GIRK-dependent manner. These results are the first to show that GIRK channels are necessary for the effects of melatonin and ramelteon within the SCN. This study suggests that GIRK channels may be an alternative therapeutic target for diseases with evidence of circadian disruption, including aberrant melatonin signaling.

Title: Using optogenetics to shift the circadian clock

Authors: *M. TACKENBERG[1], J. R. JONES[1], D. G. MCMAHON[2];
[1]Neurosci., [2]Biol. Sci., Vanderbilt Univ., Nashville, TN

Abstract: The mammalian biological clock, the suprachiasmatic nucleus (SCN), is composed of individual oscillators that maintain 24-hour rhythms in gene expression, firing rate, and peptide release. In the past, electrophysiological measurements and actigraphy, in combination with gene knockouts or modifications, have been used to determine the role of the each rhythmic "layer" of the SCN. These unidirectional techniques have given us a partial understanding of the interaction between gene, firing rate, and peptide release oscillations, but fall short of providing a complete picture of this system. To address this lack, we have developed an optogenetic system capable of initiating action potentials within the SCN with great temporal and spatial resolution, both *in vivo* and *in vitro*. By doing so in combination with real-time clock gene luminescence reporters *in vitro* and actigraphy *in vivo*, we have been able to measure the sufficiency of action potential generation throughout the SCN in shifting the circadian clock. We have found that, both *in vivo* and *in vitro*, action potential generation within the SCN is capable of producing circadian changes in locomotor behavior and gene expression, respectively. Interestingly, we have found that these changes are VIP-dependent and do not occur in the presence of TTX. Taken together, these results indicate that action potentials are both sufficient and necessary to produce phase shifts within the SCN. This information will provide us with a better approach for the future in determining the functional significance of SCN heterogeneity, that is, the differing role of action potentials within segregated populations of SCN neurons.

Title: Redox state of the suprachiasmatic nucleus affects photic resetting in early night

Authors: ***M. YU**[1], Y. YU[2], J. W. MITCHELL[3], M. X. LU[4], M. U. GILLETTE[3];
[1]Mol. and Integrative Physiol., [2]Neurosci. Program, [3]Cell and Developmental Biol., Univ. of Illinois At Urbana Champaign, Urbana, IL; [4]Univ. of Illinois Lab. High Sch., Urbana, IL

Abstract: The main driver of circadian behavior is a transcriptional-translational feedback loop of core circadian genes. Emerging evidence suggests that metabolic oscillators also play a crucial role in circadian rhythm generation. The discovery of a near-24h oscillation of redox state in the suprachiasmatic nucleus (SCN) has put metabolism in the center of circadian biology (Wang et al. Science 2012), yet little is known about what drives the redox rhythm or the extent of its influence in the SCN. The mammalian circadian clock is especially sensitive to photic signals and can adjust its phasing in response to retinal light exposure during the night. This response to light is biphasic: exposure to light during the early night results in a phase delay in behavioral rhythms, whereas exposure to light during the late night results in a phase advance in the rhythms. In this study, we examined the relative redox states of the rat SCN in early and late night by western blot analysis for glutathiolation and found a more oxidized state in early night and a more reduced state in late night. Using single-unit recording techniques to assess phasing of the neuronal activity rhythm in SCN brain slices, we found that changing the redox environment in early night altered the directionality of phase shifting in response to glutamate, the messenger of the light signal from the retina to the SCN. To determine the effect of redox state on photic resetting in early night in intact animals, we performed intra-SCN cannulation surgery on male C57Bl/6 mice and injected glutathione (GSH), a natural reducing agent, directly into the SCN at circadian time (CT) 14 followed immediately by a light pulse. The onset of wheel running activity in constant dark conditions was used to evaluate effects on phasing of behavioral rhythms. We found that GSH blocked the usual light-induced phase delay in the early night, while the vehicle had no effect. These results suggest that flipping the SCN redox state from oxidized to reduced can block the photic resetting response in early night, providing further evidence that the redox rhythm may play a regulatory role in circadian physiology.

Title: Glycogen synthase kinase 3 (GSK3) regulates light signaling in the suprachiasmatic nucleus

Authors: *J. R. PAUL, S. K. TOTSCH, R. M. COWELL, K. L. GAMBLE;
Dept. of Psychiatry and Behavioral Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Glycogen synthase kinase 3 (GSK3) regulates light signaling in the suprachiasmatic nucleus Paul, J.R., Totsch, S.K., Cowell, R.M., and Gamble, K.L. Glycogen synthase kinase 3 (GSK3) is a serine-threonine kinase that is an emerging regulator of mammalian circadian rhythms at the behavioral, molecular and neurophysiological levels. In the central circadian pacemaker, the suprachiasmatic nucleus (SCN), GSK3 exhibits a rhythm in inhibitory phosphorylation across the 24h day. We have recently shown that GSK3 is capable of influencing both the molecular clock and SCN neuronal activity rhythms. However, whether GSK3 regulates the response to environmental cues such as light is not yet known. The goal of this project was to test the hypothesis that GSK3 activation mediates light-induced SCN excitability and photic entrainment. Immunofluorescence staining in the SCN showed that late-night light exposure significantly increased GSK3 activity (i.e., decreased p-GSK3β levels) 30-60 minutes after the light-pulse. Additionally, pharmacological inhibition of GSK3 blocked the typical light-induced excitability in *Per1*::GFP expressing SCN neurons; however, this effect was not associated with changes in resting membrane potential or input resistance. Behaviorally, mice with constitutively active GSK3 (GSK3-KI) re-entrained significantly more rapidly to a 6-hour phase-advance than WT control animals. Furthermore, GSK3-KI mice had a significantly advanced phase-angle of entrainment when released into constant darkness, which mimicked the effect of a 1-hour light pulse in WT mice. Finally, GSK3-KI mice exhibited normal negative-masking behavior, suggesting that the enhanced photic entrainment is not due to an overall increased sensitivity to light in these animals. Taken together, these results provide strong evidence that GSK3 activation contributes to light-induced phase-resetting at both the neurophysiological and behavioral levels. Given that GSK3 dysregulation has been implicated in multiple disorders that have also been associated with chronic light at night, such as depression,

obesity, and cancer, a better understanding the effects of light on GSK3, and its role in regulating SCN neurophysiology could provide new treatment strategies for these disorders in the future. This work was supported by NIH 1R01NS082413 to KLG and F31NS086282 to JRP.

Title: Activation of the stress axis is associated with novel wheel-induced blockade of the luteinizing hormone (LH) surge in Syrian hamsters

Authors: *S. J. LEGAN[1], X. PENG[2], M. J. DUNCAN[3];
[1]Dept Physiol, [2]Dept Physiol., [3]Dept Anat. and Neurobio., Univ. of Kentucky, Lexington, KY

Abstract: Circadian rhythm desynchrony, which is common in shift workers, is associated with decreased fertility in women. In proestrous hamsters, arousal induced by a novel wheel (NW) and transfer to constant darkness (DD) in the mid-day usually blocks the preovulatory LH surge that day and phase-advances its occurrence the next day (Legan et al., 2010). A locked NW also blocks the LH surge, suggesting that intense running is not required for this phenomenon. Exposure to a NW (either locked or freely turning) also activates orexin neurons, and antagonism of orexin receptors prevents NW blockade of the LH surge (Duncan et al., 2014). These results suggest that arousal/wakefulness plays a major role in the mechanism whereby non-photic stimuli suppress LH surges. This is supported by the finding that exposing estradiol benzoate (EB)-treated ovariectomized (ovx) hamsters to arousal using toys also suppresses and delays LH surges, similar to the effect of a NW (Legan et al., 2015). Therefore we tested the hypotheses that: (1) presenting a NW in the middle of the day transiently activates the stress axis, and (2) that blockade of the LH surge is associated with the magnitude of the resultant increase in corticosterone (CORT) levels. Diestrous hamsters and ovx hamsters treated s.c. with EB were surgically fitted with jugular cannulae. The next day at zeitgeber time (ZT) 5 (ZT 12=lights off), after obtaining a baseline blood sample, each hamster was exposed to DD and either returned to her home cage (HC) or transferred to a new cage with a NW. Serial blood samples were taken hourly until ZT 11 in red light. Activity was monitored in DD for 1-2 weeks. Plasma LH and

CORT concentrations were assessed by RIA. Phase advances in the activity rhythm did not differ among the groups (HC, 4.5 ± 0.4 h; NW proestrous, 3.3 ± 0.3 h; NW ovx+EB, 3.1 ± 0. 6 h; P=0.06). LH surges were blocked in 6 of 12 HC hamsters. In contrast, a NW blocked the LH surge in 10 of 12 proestrous hamsters and greatly attenuated it in all 7 ovx+EB hamsters. In HC hamsters, plasma CORT concentrations remained low regardless of whether an LH surge occurred. In contrast, CORT levels rose about 2-fold above baseline for ~2 h only in the 10 NW-exposed hamsters in which the LH surge was blocked, and remained unchanged in the 2 hamsters whose LH surge was not blocked. Interestingly, the suppression of the LH surge in the ovx+EB hamsters was associated with a 1-h elevation in plasma CORT. Thus the effectiveness of the NW in blocking or suppressing the LH surge is associated with the duration of its stimulation of plasma CORT levels. These results suggest that activation of the stress axis is part of the mechanism by which acute arousal blocks the LH surge.

Title: Role of the CREB-CRE signalling pathway on the crayfish Procambarus clarkii's locomotor activity rhythm entrainment

Authors: *C. M. AMBRÍZ, J. PRIETO SAGREDO;
Ecologia y recursos naturales, Univ. Nacional Autónoma De México, ciudad de mexico, Mexico

Abstract: Recent findings in vertebrates show that an increase in the intracellular cAMP may play a role in the light entrainment pathway in the suprachiasmatic nucleus of the rat brain. The cAMP activation of the CREB-CRE signalling pathway, promotes changes in the clock genes per1 and tim expression that ultimately produces a phase shift of the locomotor activity rhythm in the animal. Little is known about the signal transduction pathways in entrainment by light of the circadian system of invertebrates like the crayfish Procambarus clarkii. To address this question, we recorded the crayfish locomotor activity rhythm before and after the stimulation by light (300 lx) or the injection of a cAMP analog (db-cAMP) or a PKA antagonist (H89) at 3 different circadian times (CT13, CT10 and CT23). Results show that the light stimulus (control) induces phase delays of about 4 h at CT13 and phase advances of 4 h at CT23 and no significant changes at CT10. The db-cAMP injections induces similar changes as the light pulses. The

protocol for the PKA inhibitor, includes the injection of H89 1 h before the light pulse for each of the CT explored. In this way, PKA was inhibited before the light activated the cAMP signalling pathway. The results showed that the locomotor rhythm is disrupted by the H89 but in some cases there was phase shifts with magnitude and direction different of those produced by light and the cAMP analog. We conclude that the light may be signalling the molecular clock of the crayfish by activating the cAMP pathway and probably inducing changes in per and tim clock genes that control the period and phase of the clock in the animal's brain.

Title: Biological rhythms in an invertebrate model marine organism, the Starlet Sea Anemone

Authors: *E. L. MEYER-BERNSTEIN[1,2], W. D. HENDRICKS[2], C. C. JAMES[2], E. E. MCPHERSON[2,1], M. R. JAMES[2,1];

Abstract: Animals display rhythms in physiology and behavior that are governed by a self-sustaining biological clock. Environmental stimuli serve to synchronize an animal’s clock at the molecular level, which leads to correlated changes in behavior. Rhythmic behavior is primarily driven by daily photic signals in most organisms, but can also be influenced by other non-photic environmental stimuli such as temperature and food availability. A concerted effort has led to significant progress in elucidating biological clocks at the behavioral, cellular and molecular level in terrestrial organisms. However, marine organisms, particularly invertebrates, are not well-studied and, consequently, our understanding of the rhythms in such species is comparatively underdeveloped. Considerable attention has also been placed on understanding the molecular clockwork underlying circadian rhythmicity; However, the regulation of non-circadian rhythms (i.e. tidal, lunar) remains unclear. Moreover, signals that drive these rhythms and their integration with the circadian clock have not been thoroughly investigated. Intertidal organisms

may provide a means to develop our understanding of biological rhythms in marine organisms as well as an opportunity to advance our knowledge of rhythms with a diversity of frequencies. Intertidal organisms are particularly interesting as their behavior can be synchronized to a variety of stimuli (light, temperature, hydrostatic pressure, salinity, etc), some of which cycle with periods other than 24 hours. Our laboratory is developing the starlet sea anemone, Nematostella vectensis, as a model organism for the study of biological rhythms. We previously established a circadian rhythm in body column elongation in this species. We have continued our efforts on the localization of circadian gene expression and cellular identification as well as the behavioral and molecular synchronization by photic, temperature and tidal stimuli. Our anatomical data indicate a localization of canonical circadian gene expression in the oral disk and tentacles that is closely associated with GABAergic cells. Behavioral synchronization to non-photic stimuli was observed with accompanying changes in critical molecular components. Outcomes of these experiments will allow us to better understand the potential interactions between multiple sensory stimuli that impact rhythmic behavior and the underlying molecular components in this evolutionarily informative species.

Medicine, Gachon Univ., Incheon, Korea, Republic of; [7]Psychiatry, Korea Univ. Anam Hosp., Seoul, Korea, Republic of

Abstract: ***Objective:*** Bipolar disorder (BD) is a common mental disorder that causes pathological shifts in mood, activity, and energy levels. We observed behavioral and molecular circadian rhythms in severe manic states and in recovery states in hospitalized patients with BD, and compared them with those of healthy participants. ***Methods:*** Included in the study were 24 manic episodes of 21 type I BD patients (12 male and 9 female) who were hospitalized in from May 2012 to June 2014, and 18 healthy subjects (11 male and 7 female). The age of the subjects [mean ± SEM] was 30.0 ± 2.3 years for patients in mania, 23.0 ± 0.8 years for the control group. To assess the circadian rhythms of activity, actigraphy data were obtained by actiwatch from all participants. From healthy participants, sample collections of salivary and buccal epithelial cells were performed at 8:00, 11:00, 15:00, 19:00, and 23:00 for two consecutive days. From BP patients, sample collections were performed in the same schedule with healthy participants and repeated with 2 weeks intervals during hospitalization and right before discharge. Collected salivary samples were used for cortisol assay and each participant's cortisol circadian rhythm were determined. mRNA was isolated from collected buccal epithelial cells, and the rhythms of circadian genes were determined as a ratio of *Per1*/*Bmal1* expression. Paired t-test were used as appropriate to assess the significance of differences between groups. ***Results:*** Mean treatment duration of the BP patients was 24.6 ± 2.6 (SEM) days. For cortisol circadian rhythms, the average acrophase of each BD patients in the severe manic states were significantly advanced compared to the healthy controls (p = 5.43E-07) by the amount of 8h 40m. In contrast, the acrophases in recovered euthymic states were not significantly different from those of healthy controls (P>0.05). For the ratio of *Per1*/*Bmal1* circadian rhythm, the average acrophase of each BD patients in the severe manic states was significantly advanced compared to the healthy controls (p = 1.35E-08) by the amount of 11h 13m. Whereas, the acrophases in recovered euthymic states were not significantly different from those of healthy controls (P>0.05). Actigraphy data indicated no significant difference in circadian rhythm of activity between manic and euthymic states. ***Conclusions:*** Molecular circadian rhythm in severe manic episodes of BD patients was significantly advanced compared to healthy controls. After the treatment, the advanced rhythm was changed to normal. This finding provides a means for our understanding of the mechanisms of the circadian rhythm of the BD.

Title: Assessment of molecules involved in circadian rhythms and memory in the hippocampi of circadian rhythm disrupted rats

Authors: *S. H. DEIBEL[1], D. KOCHAN[2], J. Q. LEE[1], R. J. KEELEY[1], K. M. NIEDERMEIER[1], I. BARKLEY[1], N. S. HONG[1], O. KOVALCHUK[2], R. J. MCDONALD[1]; [1]Canadian Ctr. for Behavioural Neuroscience, Neurosci., [2]Dept. of Biol. Sci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: There is a large body of evidence in rodents suggesting that circadian rhythm dysfunction (disruption) impairs memory. In rats, we have demonstrated that circadian rhythm disruption induced by acute or chronic photoperiod shifting elicits memory impairments in hippocampal-dependent memory tasks. It appears that these impairments are due to disrupted memory consolidation, however, the mechanisms mediating this effect are largely unknown. Clock genes, and molecules involved in synaptic plasticity and epigenetics oscillate in the hippocampus. While unknown, it is likely that the oscillations of these molecules are disrupted in the hippocampi of circadian rhythm-disrupted animals. The present study assessed clock gene expression, clock protein expression, and sirtuin1 - a histone deacteylase enzyme involved in circadian rhythms and memory - in the hippocampi of photoperiod shifted rats. We anticipate that the phase of the oscillations of these rhythmically expressed molecules will be shifted in the circadian rhythm-disrupted animals, but it is possible that this effect will be dependent on the length of the photoperiod shifting paradigm. Preliminary data suggests that the phase of CLOCK protein expression in the hippocampus is unaffected by a brief amount of photoperiod shifting. These data will contribute to the elucidation of the mechanisms underlying the memory impairment induced by circadian rhythm disruption.

Title: Time-dependent changes of deta power across NREM sleep episodes in mice

Authors: *A. SUZUKI[1], R. W. GREENE[1,2];
[1]UT Southwestern Med. Ctr., Dallas, TX; [2]Intl. Inst. for Integrative Sleep Med., Tsukuba, Japan

Abstract: Sleep is homeostatically regulated. Delta power increases and promotes the drive to sleep after sleep debt, and decreases following sleep duration. Generally, delta power is averaged over a NREM sleep episode and indicates the need for sleep. In this study, we investigated details of the time-dependent changes of delta power across NREM sleep episodes after sleep deprivation. C57/bl6 mice were implanted with EEG/EMG electrodes, allowed to recover for 10 days, habituated to the recording environment for 21 days, and then used for sleep experiments. All sleep deprivation was employed from ZT0-6. Each of the sleep deprivation experiments was separated by at least 21 days. Baseline EEG/EMG activities were monitored on the day before each sleep deprivation experiment. Sleep state were scored in 10-second epochs. For all conditions, delta power in NREM sleep episodes between 0-12 min in ZT6-8 were collected for each mouse and averaged in 10-second bins. These data were then averaged across mice. In the baseline condition, delta power was constant between 0-10 min in an average NREM sleep episode. Furthermore, this constant delta power was observed in any average NREM sleep episode during light or dark phases, or 24-h durations in the baseline condition. After 6-h acute sleep deprivation using a treadmill, significant increase of delta power was observed mainly in the onset of an average NREM sleep episode (< 4 min). This delta power elevation in an average NREM sleep episode was similarly observed in mice following 6-h spontaneous wakefulness induced by approaching novel objects. Consecutive 5-day chronic sleep restriction (sleep deprivation during ZT0-6 using a treadmill) evoked a greater delta power increase in an average NREM sleep episode (< 8 min) compared with the baseline condition. These observations suggest that (1) the delta power level in a NREM sleep episode is constant in normal sleep conditions, and (2) sleep pressure accumulation prolongs delta power elevation within a NREM sleep episode.

Abstract: In mammals, breathing and sleep are vital behaviors necessary for survival. Breathing is a continuous process to maintaining gas homeostasis whereas sleep is necessary to restore the homeostasis of the central nervous system. These behaviors are controlled by neurons in specific areas of the brainstem. Here, by using c-Fos immunoreactivity as a marker of neuronal activity, we examined the effect of selective REM sleep deprivation on activity of neurons from brainstem areas related to breathing such as the ventral respiratory column (VRC) and the parafacial respiratory group (pFRG/RTN). Male Wistar rats were divided in two groups: control (n=6) and selectively-deprived of REM sleep using the flowerpot technique (n=11). Respiratory rate, heart rate, temperature and oxygen saturation (SpO2) were measured before and during deprivation. No differences were found in the number of c-Fos positive neurons in the VRC and pFRG/RTN in the selectively REM sleep deprived group compared to control. In conclusion we suggest that activity of VRC and pFRG/RTN neurons is highly regulated during sleep to ensuring a stable breathing rate and gas homeostasis.

Abstract: Although sleep is a ubiquitous animal behavior, the molecular mechanism of sleep homeostasis remains unknown. We performed high-throughput screening of ENU-mutagenized mice in order to identify genes regulating sleep/wake behavior. We have so far analyzed EEG/EMG data of more than 7,000 mutagenized male mice. We established several pedigrees showing heritable sleep/wakefulness abnormalities. Among them, the Dreamless mutant pedigree shows about 50% reduction in 24-h REM sleep time. To map a chromosomal region responsible for the sleep phenotype of Dreamless mutant mice, we performed a linkage analysis in N2 mice, obtained by backcrossing the mutagenized founder C57BL/6J male to C57BL/6N female mice for two generations. The analysis revealed a single peak with a LOD score of more than 11. Whole exome sequencing of mutants and wild-type littermates from the Dreamless pedigree identified a nucleotide change specific to Dreamless mutant mice within the mapped chromosomal region. The single nucleotide substitution leads a single amino acid substitution of the gene product that we termed Dreamless. We adopted CRISPR/Cas system for reproduction of Dreamless phenotype and confirmed that the one base substitution was responsible for REM sleep abnormality. Functional analyses of the Dreamless gene are now underway.

Table 1. Sleep/wakefulness parameters of CRISPR-*Dreamless* mice (at 2~3 months age)

Title: Thalamic modulation of the cortical slow oscillation

Authors: *A. OZUR, S. CHAUVETTE, I. TIMOFEEV;
Faculté de médecine, Dept. de psychiatrie et neurosciences, Univ. Laval, Quebec, QC, Canada

Abstract: Despite recent progress, the role and mechanisms of sleep and the origin of the synchronous sleep slow oscillation remain a controversial topic. The slow/delta power is one of the main quantifiable parameters characterizing the quality of sleep. The thalamus is involved in slow-wave activity. However, the role played by the various thalamic nuclei in the generation of the slow oscillation and its synchronization is not known. We hypothesized that the first-order (specific) thalamic nuclei provide a control of slow waves in primary cortical areas, while high-order (non-specific) thalamic nuclei may synchronize the slow-wave activities across wide cortical regions. We analyzed local field potentials (LFP) and spiking activities from different cortical and thalamic areas of anesthetized mice while a thalamic nucleus was inactivated by either the sodium channel blocker QX-314 or the GABA-agonist muscimol. Extracellular multiunit recordings in specific (VPM, VL) and non-specific (PO, CL) thalamic nuclei show a dramatically decreased overall spiking activity and a strongly reduced burst firing after muscimol or QX-314 inactivation. We conclude that the injection of muscimol strongly reduced the spiking activity and does not potentiate the generation of low-threshold spike mediated bursts. Inactivation of specific thalamic nuclei (VL, VPM) with muscimol decreased the power of the slow/delta band in the corresponding primary cortical area while the injection of QX-314 reduced the slow/delta power in larger territories. The inactivation of a non-specific nucleus (CL/CM) with muscimol significantly reduced the delta power in all investigated cortical areas

and the effect was even stronger after the injection of QX-314. Our experiments demonstrate that the thalamus is required for the fine tuning of the cortical slow oscillation. Generally, the use of QX-314 affected larger cortical territories as compared to muscimol, likely because it affected not only local neurons but also passing fibers. We conclude that the non-specific thalamic nuclei play a major role in the regulation of the global cortical slow-wave activity.

Title: Programming of sleep disturbances by peripubertal diet-induced obesity - Implication of altered serotonergic actions in the brain

Authors: M. GAZEA, A. V. PATCHEV, E. ANDERZHANOVA, E. LEIDMAA, A. PISSIOTI, C. FLACHSKAMM, O. F. X. ALMEIDA, *M. KIMURA;
Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: Overconsumption of palatable foods is the main driver of obesity, a condition affecting a large number of adolescents. Recent work shows that early-life obesity may amplify health risks in later life. Obesity and sleep disorders often accompany each other in a variety of medical conditions. While the causal link between obesity and sleep disturbances is unknown, it plausibly involves altered setpoints in the hedonic mechanism regulating eating behavior and the homoeostatic control in both feeding and sleep-wake behaviors. This hypothesis was here examined in the context of obesity during peripubertal development. Our mouse model of peripubertal diet-induced obesity (ppDIO) was generated by feeding male C57BL/6N mice a high-fat diet (HFD) between postnatal weeks 4 and 10. Cessation of HFD was followed by a standard diet (SD). EEG/EMG recordings were performed at different ages (10, 12, 24 and 52 weeks). In addition, neurotransmitter and neuropeptide levels in areas related to reward, feeding and sleep-wake regulation were evaluated. Mice that were maintained on SD served as controls. Chronic HFD exposure led to a hypo-dopaminergic and hypo-serotonergic state in ppDIO mice as compared to controls. These changes were accompanied by sleep fragmentation during the resting phase and increased sleep time during the active period. Cessation of HFD and re-

exposure to SD resulted in bodyweight loss and a dramatic reduction in sleep time during the active phase below those observed in control mice. Concomitant with HFD withdrawal, dopamine levels in reward-related areas were reduced, while serotonin levels in the lateral hypothalamus were increased; the latter area is an important integrator of sleep-wake and feeding behaviors. Interestingly, aged ppDIO mice (52 weeks) showed increased nocturnal sleep time in parallel with a hypo-serotonergic tone in the lateral hypothalamus. Sleep disturbances observed in both young and aged mice were rescued by i.p. injection of PYY3-36, a peripheral satiety hormone. In conclusion, ppDIO has marked effects on the long-term regulation of sleep-wake behaviors. Our results suggest that reduced serotonergic tone underlies sleep disturbances associated with obesity. During weight loss following HFD withdrawal, serotonergic tone increases, which may produce increased vigilance. Lastly, PYY3-36 has the potential to ameliorate sleep disturbances triggered by ppDIO.

Title: Wakefulness is governed by GABA and histamine co-transmission

Authors: *X. YU[1], Z. YE[1], C. M. HOUSTON[1], A. Y. ZECHARIA[1], Y. MA[1], Z. ZHANG[1], D. S. UYGUN[1], S. PARKER[1], A. L. VYSSOTSKI[2], R. YUSTOS[1], N. P. FRANKS[1], S. G. BRICKLEY[1], W. WISDEN[1];

Abstract: Histaminergic neurons in the tuberomammilary nucleus (TMN) of the hypothalamus form a widely projecting, wake-active network that sustains arousal. Yet most histaminergic neurons contain GABA. Selective siRNA knockdown of the vesicular GABA transporter (vgat, SLC32A1) in histaminergic neurons produced hyperactive mice with an exceptional amount of sustained wakefulness. Ablation of the vgat gene throughout the TMN further sharpened this phenotype. Optogenetic stimulation in the caudate-putamen and neocortex of "histaminergic" axonal projections from the TMN evoked tonic (extrasynaptic) GABAA receptor Cl- currents onto medium spiny neurons and pyramidal neurons. These currents were abolished following vgat gene removal from the TMN area. Thus wake-active histaminergic neurons generate a paracrine GABAergic signal that serves to provide a brake on over-activation from histamine, but could also increase the precision of neocortical processing. The long-range of histamine-GABA axonal projections suggests that extrasynaptic inhibition will be coordinated over large neocortical and striatal areas.

Title: Ontogeny of activation in sleep and waking regulatory systems in the chick

Authors: ***M. POMPEIANO**[1], A. CHAN[1], S. LI[1], N. RATTENBORG[2], E. BALABAN[1], D. MARTINEZ-GONZALEZ[2];
[1]Psychology, McGill Univ., Montreal, QC, Canada; [2]Avian Sleep Group, Max Planck Inst. for Ornithology, Seewiesen, Germany

Abstract: In adult rodents, wakefulness is sustained by activity in an interconnected set of neuronal populations (the "arousal systems"), which includes hypocretin/orexin (H/O), noradrenergic Locus Coeruleus (NA-LC), serotonergic Dorsal Raphe (5HT-DR) and pontine cholinergic (Ch-P) neurons. Sleep is supported by activity in various GABAergic neuronal populations, and a lack of activity in the arousal systems. Rapid eye movement (REM) sleep is

supported by activation of Ch-P and melanin-concentrating hormone (MCH) neurons. Birds and mammals show similar sleep and waking states (Lesku and Rattenborg 2014). Chickens are precocial; they develop sleep-like electroencephalographic (EEG) patterns before hatching, and a stable waking state within a few hours after hatching (Mellor and Diesch 2007; Martinez-Gonzalez et al 2012). In order to understand when activity in neuronal populations that regulate sleep and waking becomes coordinated and able to support stable states, we investigated activity in the H/O, NA/LC, 5HT/DR, Ch-P and MCH systems of undisturbed chick embryos, and in neonatal (P1) chicks that were spontaneously sleeping or kept awake by gentle handling. cFos was used as a marker of neuronal activation. Fertilized eggs were incubated at 37.5° C, 55-60% relative humidity. Embryos (in ovo) and hatchlings were anesthetized (isoflurane) and intracardially perfused with fixative. Cryostat-cut sections were processed using standard fluorescent double labelling techniques. Stereological techniques were used to calculate the percentage of cFos-expressing cells in the 5 groups of neuronal populations. In general, activation of the arousal systems was low at embryonic day (E) 12, slowly increased at E16 and E20 and reached its highest values in the awake P1 chicks. Very low values were seen in sleeping P1 chicks. Activation of MCH neurons also progressively increased in embryos, reached its highest values at E20, but was low in both awake and sleeping P1 chicks. Among neuronal populations, significantly correlated activity was seen only between NA-LC and 5HT-DR cFos expression in embryos, and among most arousal systems at P1. We conclude that the arousal systems become progressively recruited in embryos and become coordinated only after hatching. MCH neurons may be involved in the emergence of REM sleep-like in chick embryos. Absence of activation of the Ch-P and MCH systems in the sleeping postnatal chicks may be due to the relatively short duration of the sleep episodes studied here.

Title: Sleep history modulates excitatory transmission to orexin and melanin concentrating hormone neurons via glial glutamate transporter 1

Authors: *C. L. BRIGGS[1,2], K. SEMBA[1], M. HIRASAWA[2];
[1]Dept. of Med. Neurosci., Dalhousie Univ., Halifax, NS, Canada; [2]Div. of BioMedical Sci., Mem. Univ., St John's, NL, Canada

Abstract: Orexin (ORX) and melanin concentrating hormone (MCH) neurons of the lateral hypothalamus play important roles in sleep/wake behaviour. These neurons have opposite activity patterns, where ORX neurons are wake-active and MCH neurons sleep-active, suggesting that their regulatory mechanisms are also reciprocally active. We previously determined that the amount of astrocytic glutamate transporter 1 (GLT1) surrounding these neurons is altered by prior sleep history; acute 6h sleep deprivation (SD) decreased GLT1 surrounding ORX neurons and increased it surrounding MCH neurons. Glutamatergic transmission is shaped by glutamate transporters. We therefore asked whether sleep history affects GLT1 modulation of excitatory transmission to these neurons, using whole-cell recording in acute brain slices obtained from 6h SD or time-matched rested rats. In the rested condition, the GLT1 inhibitor DHK significantly reduced the amplitude of evoked excitatory postsynaptic currents (eEPSCs) in ORX neurons while increasing paired-pulse ratio (PPR), suggesting presynaptic inhibition. These effects were blocked by the group III metabotropic glutamate receptor (mGluR) antagonist CPPG while mimicked by the agonist L-AP4. CPPG alone did not alter eEPSC amplitude or PPR, indicating no tonic presynaptic inhibition. Following SD, the effects of DHK on eEPSC amplitude and PPR were largely eliminated. This appears to be an occlusion by endogenous glutamate tonically activating group III mGluRs, since application of CPPG alone decreased PPR. These results indicate that GLT1 facilitates excitatory transmission to ORX neurons specifically in rested conditions by preventing activation of presynaptic mGluRs. In contrast, we found no effect of DHK on eEPSC amplitude or PPR in MCH neurons from rested rats. However, following SD, DHK significantly reduced eEPSC amplitude (mechanism under investigation). These results indicate that GLT1 has no role in modulating fast excitatory transmission to MCH neurons in rested conditions, but facilitates excitatory transmission specifically in SD conditions. In conclusion, within a single hypothalamic area, astrocytes can differentially modulate two neuronal populations through GLT1. This regulation is opposite for ORX and MCH neurons in accordance with their roles in sleep/wake behaviour, dependent on sleep history, and in line with our anatomical results. GLT1 facilitates excitatory transmission specifically when GLT1 coverage is high, by limiting glutamate spillover and presynaptic activation of inhibitory autoreceptors. This may be a novel homeostatic mechanism for the control of sleep/wake behaviour.

Title: Conditional knockdown of tyrosine hydroxylase in LC neurons increases REM sleep by withdrawal of inhibition from PPT neurons and prevents REM sleep-loss associated expression in rats

Authors: *M. A. KHANDAY, B. SOMARAJAN, R. MEHTA, B. N. MALLICK;
Sch. of Life Sci., Jawaharlal Nehru Univ., New Delhi, India

Abstract: Sleep, an instinct behavior, has been divided into rapid eye movement sleep (REMS) and non-REMS. The REMS has been preserved through evolution and species; however, its detailed mechanism of regulation and function(s) are yet unknown. Notwithstanding, it is known that there are REM-ON neurons (active during REMS) in pedunculopontine tegmental (PPT) and REM-OFF neurons (cease firing during REMS) in the locus coeruleus (LC); cessation of the REM-OFF neurons is a necessity for REMS generation. The noradrenalin (NA)-ergic REM-OFF neurons in the LC inhibit the PPT REM-ON neurons and prevent appearance of REMS. It has been reported that the REM-OFF neurons continue activity during REMS deprivation (REMSD) and if those neurons are kept active, REMS does not appear. Further, continuous activity of REM-OFF neurons would elevate NA level in the brain. Although isolated independent studies showed that elevated NA indeed reduced REMS and induced many of the REMSD associated symptoms, the detailed mechanism and direct evidence thereof were lacking. Therefore, in this study, NA synthesis was inhibited by conditionally down regulating tyrosine hydroxylase (TH) gene expression in the NA-ergic LC neurons using TH-siRNA/TH-shRNA and the effects on REMS and REMSD associated expressions were evaluated. Materials and Methods: Male Wistar rats (250-350g) were surgically prepared for chronic electrophysiological sleep-waking recording with simultaneous bilateral microinjection into either or both, LC and PPT. TH was knocked down in the LC neurons to reduce NA synthesis and REMS was estimated with or without infusion of NA bilaterally into the PPT. In other groups TH knock down rats were REMS deprived for 4 days. TH knock down in LC neurons was confirmed by counting TH immunostained neurons, quantitative PCR and Western blotting of LC. Results: Microinjection of TH-shRNA into LC significantly decreased TH-mRNA and TH protein in LC. TH-shRNA/TH-siRNA microinjection into LC significantly increased the total time spent in REMS

and the effect was prevented if NA was simultaneously injected into the PPT. Further, if such conditional NA-depleted rats were REMS deprived, Na-K ATPase activity was not increased, which was increased in otherwise REMSD rat brain. Conclusion: The results provide direct evidence that NA from LC neurons inhibits the REM-ON neurons and prevents REMS. Further, the NA released from the LC neurons is responsible for inducing REMSD associated expression. These findings confirm our hypothesis and are proof of principle for ameliorating REMS loss associated symptoms.

Title: Cortical nNOS/NK1 neurons are regulated by adenosinergic tone

Authors: *R. H. WILLIAMS, J. VAZQUEZ-DEROSE, A. NGUYEN, T. S. KILDUFF; SRI Intl., Menlo Park, CA

Abstract: Cortical neuronal nitric oxide synthase (nNOS) neurons that express the neurokinin-1 (NK1) receptor may play a role in sleep homeostasis (Kilduff et al. 2011 *TiNS*; Morairty et al 2013; *PNAS*). As nNOS/NK1 neurons appear to sense sleep need (Dittrich et al 2015; *Neuropsychopharmacol*) and as adenosine (ADO) is an indicator for sleep pressure, we investigated whether ADO affects nNOS/NK1 cells *in vitro* and examined the role for ADO receptors on recovery from sleep deprivation (SD). We prepared mouse brain slices (250μm) for whole-cell patch clamp recording and identified cortical nNOS/NK1 cells with substance P-tetramethylrhodamine (SP-TMR), a fluorescent agonist for NK1 receptors. Bath applied ADO (50μM) evoked either an outward (n=5) or inward current (n=8) in most cells. Both responses were retained in the presence of TTX (n=13 and n=14, respectively), indicating direct postsynaptic action. Changes in the resting membrane potential (RMP) of nNOS/NK1 cells induced by ADO were inhibitory (n=12) or excitatory (n=20); some neurons (n=8) lacked a response to ADO. The A1R antagonist DPCPX (3μM) blocked the inhibitory effects on RMP (n=5) and outward current (n=4). However, application of the A2R antagonist DMPX (10μM)

only blocked excitatory responses on RMP (n= 4 of 7) or current (n=2 of 5) in some cells. The $A2_AR$ agonist CGS21680 (30nm) evoked RMP depolarization (n=6) and inward current (n=6). ADO also affected both sEPSCs (n=10) and mEPSCs (n=14) onto nNOS/NK1 neurons, indicating presynaptic A1 and A2 receptors. When ADO was applied in the presence of the adenosine deaminase inhibitor EHNA, RMP inhibition (n=5) and excitation (n=2) occurred with concomitant outward or inward currents. The response to ADO receptor blockade changed if mice were given 4h SD prior to sacrifice. The magnitude of response to A1R blockade with DPCPX resulted in an inward current (n=5) and increased RMP (n=3) which were >100% greater than in mice without prior SD; responses to A2R blockade with DMPX was largely unchanged. These observations suggest that different subsets of nNOS/NK1 cells may be preferentially controlled by ADO. We tested the *in vivo* response of $A2_AR$ KO mice to 4h SD followed by a 4h recovery sleep (RS) "opportunity" on EEG parameters. The A1R antagonist CPT (9mg/kg, ip) administered before SD did not affect the percent of, or latency to, NREM sleep during RS in WT or $A2_AR$ KO mice (n=3). In contrast, the selective $A2_BR$ antagonist MRS1754 (0.5mg/kg) increased NREM latency during RS in $A2_AR$ KOs compared to WTs but increased % NREM during RS in WTs. These data support a role for A2Rs in sleep control and suggest ADO may act to fine-tune cortical activation and slow wave activity via nNOS/NK1 cells.

Title: Identification of discrete, intermingled hypocretin neuronal populations

Authors: M. IYER, *M. CARTER;
Williams Col., Williamstown, MA

Abstract: Neurons in the lateral hypothalamus that express hypocretin (Hcrt) neuropeptides are known to play roles in wakefulness and reward-seeking behaviors. To address these two potentially dichotomous functions, it has been proposed that Hcrt neurons can be functionally subdivided into at least two populations: one population forms a “medial group,” which regulates wakefulness by projecting to wake-promoting populations such as the noradrenergic locus

coeruleus (LC) and histaminergic tuberomammilary nucleus (TMN); the other population forms a "lateral group," which regulates reward-seeking by projecting to the dopaminergic ventral tegmental area (VTA) or nucleus accumbens (NAc). This hypothesis was initially supported by the finding that hypocretin neurons can be functionally subdivided into at least two populations based on their electrophysiological properties. However, retrograde tracers injected into either the LC or VTA do not seem to preferentially label either electrically active subclass of Hcrt neurons, nor do they preferentially label a medial or lateral population. To resolve whether Hcrt neurons can be anatomically subdivided into medial and lateral subpopulations, we injected fluorescent retrograde tracers into two downstream populations of Hcrt neurons in the same animal. A red tracer was injected into either the LC or TMN while a green tracer was injected into either the VTA or NAc. We found that red retrograde signal in Hcrt neurons from the LC or TMN rarely overlapped with green retrograde signal from the VTA or NAc, indicating that Hcrt neurons that project to wake-promoting or reward-promoting areas are anatomically distinct. Interestingly, we found no side preference for Hcrt neurons based on their downstream targets. These results suggest there are intermingled populations of Hcrt neurons that can be anatomically subdivided based on their downstream projections.

Title: Instantaneous and persistent arousal induced by bilateral optogenetic and pharmacogenetic excitation of HCRT neurons

Authors: *J. E. HEISS[1,2], T. S. KILDUFF[1], A. YAMANAKA[2];
[1]Ctr. for Neuroscience, Biosci. division, SRI Intl., Menlo Park, CA; [2]Dept. of Neurosci. II, Res. Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan

Abstract: HCRT (Orexin) neurons located in the lateral hypothalamus are a key regulator of arousal; loss of this neuronal group leads to the sleep disorder narcolepsy. HCRT cells provide

excitatory input to noradrenergic, histaminergic and serotonergic neurons, thereby regulating their activity and influencing the global state of the brain. In addition to the Hcrt1 and Hcrt2 peptides, HCRT neurons can release glutamate and dynorphin and perhaps other unknown neurotransmitters. *In vitro* studies have shown that HCRT neurons can induce brief glutamate-mediated excitation and persistent HCRT-mediated depolarization of histaminergic neurons. *In vivo* optogenetic studies have shown that unilateral stimulation of HCRT neurons during REM and NREM sleep induces an increase in the probability of awakening that is mediated by HCRT peptide release. To test whether brief stimulation of a larger population of HCRT neurons has a more robust effect on arousal than previously reported, we performed single pulse, bilateral optogenetic excitation of HCRT neurons in Orexin/tTA;TetO Chr2 (C128S) mice which constitutively express a "step function" opsin in HCRT neurons that is activated by a single pulse of blue light (475 nm) and inactivated by yellow light (575 nm). All manipulations described below were performed in the middle of the day (around ZT 6). In a pilot study (N=4 mice), a single 50 ms pulse of blue light flanked by a 200 ms yellow light pulse 50 ms before and 30 s later was delivered 1 mm above both HCRT fields. Blue light flanked by yellow pulses was alternated with yellow light flanked by yellow pulses (control) every 2 min for 30 min. Blue light stimulation induced awakening within 4 s after stimulation in over 75% of the trials. In contrast, the probability of a NREM-Wake transition was 20% for control trials. To determine whether prolonged stimulation of larger populations of HCRT neurons affects arousal, we injected Orexin/tTA mice with AAV-TetO-hM3Dq-mCherry bilaterally. Persistent pharmacogenetic stimulation of HCRT neurons by CNO injection (0.5-3 mg/Kg, IP) induced prolonged wakefulness that lasted 2-4 h (N=4). In the presence of the dual orexin receptor antagonist almorexant (200 mg/Kg, IP), preliminary data shows that the effect of optogenetic excitation of HCRT cells was unaffected (N=3) whereas the effects of persistent excitation mediated by hM3Dq DREADD was attenuated (N=3). Our results suggest that direct excitation of large populations of HCRT neurons is sufficient to induce wakefulness with a very short latency and that persistent, but not brief, arousal is mediated at least partially by HCRT peptides.

Title: Orexin neurons suppress narcolepsy via 2 distinct efferent pathways

Authors: *E. HASEGAWA[1], M. YANAGISAWA[2], T. SAKURAI[1], M. MIEDA[1];
[1]Kanazawa Univ., Ishikawa, Japan; [2]IIIS, Tukuba Univ., Ibaraki, Japan

Abstract: The loss of orexin neurons in humans is associated with the sleep disorder narcolepsy, which is characterized by excessive daytime sleepiness and cataplexy. Mice lacking orexin peptides, orexin neurons, or orexin receptors recapitulate human narcolepsy phenotypes, further highlighting a critical role for orexin signaling in the maintenance of wakefulness. Despite the known role of orexin neurons in narcolepsy, the precise neural mechanisms downstream of these neurons remain unknown. We found that targeted restoration of orexin receptor expression in the dorsal raphe (DR) and in the locus coeruleus (LC) of mice lacking orexin receptors inhibited cataplexy-like episodes and pathological fragmentation of wakefulness (i.e., sleepiness), respectively. The suppression of cataplexy-like episodes correlated with the number of serotonergic neurons restored with orexin receptor expression in the DR, while the consolidation of fragmented wakefulness correlated with the number of noradrenergic neurons restored in the LC. Furthermore, pharmacogenetic activation of these neurons using designer receptor exclusively activated by designer drug (DREADD) technology ameliorated narcolepsy in mice lacking orexin neurons (orexin/ataxin-3 mice). These results suggest that DR serotonergic and LC noradrenergic neurons play differential roles in orexin neuron-dependent regulation of sleep/wakefulness. As a next step, we are aiming to identify the target area that mediates anti-cataplectic effects of activating DR serotonergic neurons. For this purpose, channelrhodopsin 2 was expressed specifically in DR serotonergic neurons by focal injection of a Cre-dependent AAV expression vector in the DR of SERT-Cre;orexin/ataxin-3 mice. Acute optogenetic activation of DR serotonergic neurons suppressed cataplexy-like episodes. Currently, we are searching serotonergic terminals that suppress cataplexy-like episodes upon their optogenetic activation.

Title: Role of cholinergic and GABAergic pontomesencephalic neurons in theta generation studied by optogenetic manipulation in naturally waking/sleeping head-fixed mice

Authors: Y. CISSÉ[1], H. TOOSSI[1], M. ISHIBASHI[2], L. MAINVILLE[1], A. ADAMANTIDIS[3], C. LEONARD[2], *B. E. JONES[1];
[1]Neurol. & Neurosurg., McGill Univ., Montreal, QC, Canada; [2]Physiol., New York Med. Col., Valhalla, NY; [3]Neurol., Univ. of Bern, Bern, Switzerland

Abstract: Cholinergic neurons in the pontomesencephalic tegmentum are thought to play an important role in modulating cortical activity across the sleep-waking cycle. Distributed in the laterodorsal and sublaterodorsal tegmental nuclei (LDT and SubLDT), cholinergic neurons lie intermingled with GABAergic neurons which could also modulate cortical activity. Through application of optogenetics, we sought to determine if tonic or phasic excitation of these cholinergic or GABAergic neurons could elicit theta activity in limbic cortex. Using ChAT-ChR-EYFP or VGAT-ChR-EYFP expressing transgenic mice, we confirmed in brain slices by whole-cell recordings that light pulses evoked photocurrents sufficient to drive repetitive firing selectively in cholinergic and GABAergic neurons respectively. In urethane-anesthetized transgenic mice, photostimulation allowed the *in vivo* identification of cholinergic or GABAergic neurons by short latency spike elicitation and thereby recording along with excitation of these specific cells in association with EEG activity. As previously reported (Cisse et al., SfN, 2013), light-evoked firing by the cholinergic neurons and also GABAergic neurons was associated with a shift from irregular slow to rhythmic slow (theta-like) activity under urethane. Here, using the same optogenetic approach, we sought to record from and modulate identified cholinergic and GABAergic LDT/SubLDT neurons in naturally waking/sleeping, head-fixed transgenic mice. Photo-identified during recording, neurons were also labeled with Neurobiotin using the juxtacellular technique and their location and identity confirmed using immunofluorescent staining for ChAT or GABA. Identified cholinergic neurons discharged spontaneously in a slow tonic manner in association with cortical activation and when photo-excited from relative silence during EEG slow wave activity and sleep to their maximal rate, elicited cortical activation characterized by theta activity along with increased gamma activity. GABAergic neurons discharged spontaneously in a fast phasic manner in association with cortical activation and when photo-excited from minimal discharge during slow wave sleep with phasic theta pulsed stimulation, elicited theta activity with increased gamma. Our findings suggest that cholinergic and GABAergic LDT/SubLDT neurons can serve collectively to promote theta activity along with increased gamma and transition from slow wave sleep to wakefulness or paradoxical sleep (PS or REM sleep).

Title: Chronic inflammation of the preoptic-hypothalamic sleep-regulatory systems induces aging-like changes in sleep-wake organization in young rats

Authors: A. KOSTIN[1], M. ALAM[1], R. SZYMUSIAK[1,2], D. MCGINTY[1,3], *N. ALAM[1,2]; [1]Res. Service (151A3), VAGLAHS, Sepulveda, CA; [2]Dept. of Med., University of California, Los Angeles, CA; [3]Dept. of Psychology, University of California, Los Angeles, CA

Abstract: INTRODUCTION: Sleep disturbance is a significant problem of advancing age and includes more frequent awakenings, decreases in nonREM and REM sleep amounts and nonREM slow wave activity and increases in daytime sleepiness. Both animal and human studies indicate that the brains in older subjects are in a native heightened inflammatory state, even in the absence of overt disease. Evidence also suggests that chronic inflammatory processes play a role in cellular aging including neuronal aging. We examined effects of chronic inflammation of sleep-regulatory preoptic-hypothalamic median preoptic nucleus (MnPN) and ventrolateral preoptic area (VLPO) on sleep-wake organization in young rats. METHOD: Three months old Fisher 344 male rats were implanted with EEG and EMG electrodes for chronic recording of sleep-wake states and with a guide cannula targeting at MnPN or VLPO for the delivery of artificial cerebrospinal fluid (aCSF) or lipopolysaccharides (LPS) using an alzet mini-osmotic pump. The sleep-wake profiles of rats were recorded during baseline (without any treatment) and during chronic infusion of aCSF (n=1, MnPN) or LPS (0.11µg/h) for 2 weeks into the MnPN (n=2) or VLPO (n=2). At the end, the sites of drug delivery were histologically confirmed. RESULTS: The data analyzed after 4 days of treatment shows that during the lights-on phase (inactive period), as compared to the baseline/aCSF control, chronic LPS infusion into the MnPN of young rats decreased both nonREM (54 ± 3% vs. 40 ± 4%) and REM sleep (11 ± 2% vs. 5 ± 1%) and increased sleep fragmentation as marked by increases in number of sleep episodes (28 ± 2 vs. 34 ± 6) and frequent awakenings (11 ± 2 vs. 16 ± 6). On the other hand, during the dark-phase (active period) waking was decreased (77 ± 1% vs. 62 ± 8%) and marked by increased sleep intrusions (15 ± 2 vs. 22 ± 1). An initial review of the sleep-wake records indicates that these effects persisted during the last days of treatment. Chronic LPS infusion into the VLPO produced similar changes in sleep-wake organization. CONCLUSION: LPS-induced chronic

inflammation of the MnPN and VLPO in young rats produces sleep-wake features that are similar to those observed in aging. Although the underlying mechanisms remain unknown, these preliminary findings suggest that chronic inflammation of sleep-regulatory MnPN and VLPO may play a role in sleep disturbance that accompany aging.

Title: Shared striatal subnetworks relevant for stress, sleep, and Huntington's disease implicate TGFβ-FOXO3 signaling

Authors: *J. R. SCARPA[1], P. JIANG[2], K. FITZPATRICK[2], B. LOSIC[1], V. D. GAO[2], K. HAO[1], K. C. SUMMA[2], B. ZHANG[1], R. ALLADA[2], M. H. VITATERNA[2], F. W. TUREK[2], A. KASARSKIS[1];
[1]Genomics, Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Northwestern Univ., Evanston, IL

Abstract: Recent systems-based analyses have demonstrated that sleep and stress traits emerge from shared genetic and transcriptional networks(Jiang et al., 2015), and clinical and experimental work have elucidated the emergence of sleep dysfunction and stress susceptibility in neurodegenerative disease. In the present work, we specifically examine the relationship between these psychiatric traits and Huntington's disease (HD) by identifying striatal transcriptional networks shared by HD, stress, and sleep phenotypes. Using a public microarray dataset (GSE3790), we identified a caudate network that is differentially connected in HD

compared to controls and is enriched for previously identified sets of differentially expressed HD genes (Durrenberger et al., 2014; Hodges et al., 2006). Further analysis revealed that this HD-relevant network is enriched specifically for astrocyte gene signatures (Cahoy et al., 2008; Lein et al., 2007). We used multiple public experimental datasets (GSE60137, GSE13347, GSE18326) to demonstrate that this astrocyte HD network is downstream of a signaling pathway important in adult neurogenesis (TGFβ-FOXO3). We then mapped this HD-relevant caudate subnetwork to striatal transcriptional networks in a large (n=100) chronically stressed (B6xA/J)F2 mouse population that has been extensively phenotyped (328 stress- and sleep-related measurements). We identified the causal regulators of this mouse subnetwork through Bayesian network analysis, and we verified their relevance to HD, sleep, and stress through multiple in silico approaches, including an examination of their protein interaction network. Lastly, we suggest that these causal regulators may be therapeutically viable for HD because their downstream network is partially modulated by deep brain stimulation, a medical intervention thought to confer some therapeutic benefit to HD patients(Gruber et al., 2014; Zielonka et al., 2014). By analyzing and integrating multiple independent datasets, we identify a point of molecular convergence between sleep, stress, and HD that reflects their phenotypic comorbidity and supports a fundamental mechanism of neuropathogenesis.

and Multiscale Biology, Dept. of Genet. and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: An accumulating body of literature has documented comorbidities of sleep dysfunction, stress susceptibility and a range of neuropsychiatric and neurodegenerative disorders. However, molecular pathways and networks underlying such connections remain largely unknown. Our previous work screened a large number of complex phenotypes (N = 328) relevant for sleep and stress in a large population of chronically stressed (C57BL/6J x A/J) F2 mice. We utilized multi-scale approaches integrating phenotypic, genotypic and gene expression data in the striatum, and identified gene regulatory networks underlying sleep, stress and their interactions. This provides a rich resource for further exploration of the links between sleep, stress, health and disease. Here, by integrating genetic and gene expression signatures of neuropsychiatric and neurodegeneration disorders, we show that a number of striatal networks associated with multiple sleep and stress phenotypes are also enriched with or even causally driven by genes important for neuropsychiatric and neurodegenerative disorders. For example, we show that a cellular stress response network associated with sleep after acute restraint stress is driven by a GWAS candidate gene for attention-deficit/hyperactivity disorder. Similar overlapping between causal regulators of sleep/stress networks and GWAS candidate genes for neuropsychiatric disorders is prevalent, and thus it may suggest a common feature for gene networks underlying sleep and stress. We also show that a microglia/immune network enriched with GWAS and gene expression signatures of Parkinson's disease is strongly associated with EEG activities during sleep, highlighting the links between inflammatory signaling, sleep and neurodegeneration. In summary, our findings recapitulated phenotypic comorbidities between stress, sleep and central nervous system disorders, and suggest the interplay between sleep, stress, and neuropathology emerge from genetic influences on gene expression and their collective organization through complex molecular networks.

Title: Optogenetic regulation of parvalbumin (PV) GABAergic neurons in thalamic reticular nucleus (TRN) in control of cortical spindle generation and its implications in schizophrenia

Authors: *S. THANKACHAN, J. M. MCNALLY, J. T. MCKENNA, F. KATSUKI, R. E. STRECKER, R. E. BROWN, R. W. MCCARLEY;
Psychiatry, VA Boston Healthcare Syst & Harvard Med. Sch., Brockton, MA

Abstract: Sleep spindles (8-15Hz) are waxing and waning EEG patterns observed during light non-REM sleep. Recent studies in schizophrenia (Sz) patients have provided consistent evidence for abnormalities in the number and intrinsic frequency of sleep spindles, together with associated cognitive problems. Sleep spindles originate in the thalamic reticular nucleus (TRN) that contains GABAergic neurons, most of which are parvalbumin (PV) positive. A plausible but untested hypothesis is that sleep spindle abnormalities are due to down regulation of the activity of TRN PV neurons, either due to intrinsic deficits or due to changes in afferent inputs. One major, likely inhibitory, input comes from wake-promoting basal forebrain (BF) PV neurons. Thus, here we test the effect on spindles by optogenetic manipulation of both TRN PV neurons and afferent inputs from BF PV neurons. Experiments were performed in mice that express Cre recombinase in PV neurons (PV-Cre). The selective activation or inhibition of TRN PV neurons was performed using channelrhodopsin2 (ChR2) or archaeorhodopsin (ArchT), respectively. Adeno-associated virus (AAV)-ChR2-EYFP or AAV-ArchT-GFP were bilaterally injected into TRN in PV-Cre mice, implanted with optical fibers targeting TRN, and instrumented to record sleep. ChR2 excitation of PV TRN neurons at 10Hz (n=5) elicited both a significant increase of cortical EEG power at the stimulation frequency, and consistently produced cortical EEG spindles when the mouse was in NREM sleep. Concomitantly, there was an increase (~30%) in NREM sleep (n=2) while wake decreased. ArchT inhibition of TRN PV neurons blocked the ongoing spontaneous trains of spindles for 4s ($p<0.0001$; vs. no laser); and increased wake time (28%) (n=4). ArchT inhibition of TRN PV neurons also enhanced the cortical response to 40 Hz auditory stimulation, suggesting an enhancement of sensory transmission. To test if the BF-to-TRN pathway modulates spindles, we stimulated the BF PV terminals in the TRN with laser light after injecting AAV-ChR2-EYFP into BF and studied spindle modulation. ChR2 BF PV terminal stimulation (n=1 thus far) in TRN blocked 90% of ongoing spontaneous spindles for >15 sec (vs. no laser). An increase in wake (22%), compared to no stimulation was also observed in this mouse. Based on the results, we conclude TRN PV neurons generate cortical spindles and influence NREM sleep. The BF-to-TRN pathway modulates spindles with the consequence that spindles are inhibited when during BF PV neurons are active. These mechanistic insights are

ultimately important for pharmacological target development for spindle deficits in Sz that are based on TRN or BF PV neuronal abnormalities.

Title: Phenotype associations in a battery of psychiatric assays, stress measurements, and sleep traits in an F2 mouse population

Authors: *V. GAO[1], P. JIANG[1], J. SCARPA[2], K. FITZPATRICK[1], K. HAO[2], B. LOSIC[2], K. SUMMA[1], B. ZHANG[2], R. ALLADA[1], M. VITATERNA[1], A. KASARSKIS[2], F. TUREK[1]; [1]Neurobio., Northwestern Univ., Evanston, IL; [2]Icahn Inst. for Genomics and Multiscale Biol., Mt. Sinai Sch. of Med., New York, NY

Abstract: >Psychiatric disorders in humans are known to be associated with stress susceptibility and sleep disturbances, though the nature of these connections are not clear. We wished to see how these traits are related in mice, both phenotypically and genetically. (C57BL/6 x A/J) F2 mice (N=338) were tested in a multi-week battery of behavioral and physiological assays, including but not limited to elevated plus maze, open field arena, forced swim test, fear conditioning, glucose tolerance test, restraint stress, corticosterone measurements, immunological measurements, and telomerase activity. We then implanted the mice with head electrodes and recorded electroencephalogram signals in order to quantify their sleep during baseline conditions as well as during recovery from sleep deprivation and restraint stress. Although correlations between phenotypes were sparser than expected, many interesting associations were discovered. We used factor analysis and clustering to categorize similar phenotypes into groups and discover hidden structure in the data. Predictable associations were seen, such as between body weight and glucose, between various anxiety tests, and between REM sleep traits and retention of fear conditioning. Many more unexpected associations were also observed, such as between circadian timing of sleep and glucose tolerance, elevated plus maze performance and REM sleep after restraint, and corticosterone and sleep fragmentation.

The relationships found in this phenotypic dataset will generate many interesting hypotheses that spur further investigation. Title: Complex sleep architecture is common to parrots, songbirds, and mammals

Authors: *S. CANAVAN, D. MARGOLIASH;
Univ. of Chicago, Chicago, IL

Abstract: Avian sleep reportedly lacks several traits of mammalian sleep, including significant amounts of rapid eye movement sleep (REM) and slow wave sleep (SWS), and an ultradian pattern that governs sleep stage proportions across the sleep period. Although such traits have recently been identified in multiple songbird (oscine passerine) species, reptilian sleep possesses none of these traits, suggesting convergent evolution in mammals and songbirds. To determine whether these sleep traits also appear in non-songbird lineages of birds, we investigated sleep architecture in the budgerigar (Melopscittacus undulatus). Five adult budgerigars (3 female, 2 male) were implanted with electrodes to measure the electroencephalogram (EEG) and electrooculogram (EOG). Behavioral signs of sleep were monitored via continuous infrared video recording. Sleep data were analyzed by expert manual scoring and by a k-means clustering algorithm previously used to classify sleep stages in zebra finches and starlings. Sleep was classified into 3 states: a REM-like state, a SWS-like state, and a non-REM intermediate sleep state. Surprisingly, we found that budgerigars spent significant time in REM-like sleep. They also exhibited an ultradian pattern of decreasing SWS and increasing REM. Like other birds, budgerigars lacked both sleep spindles during non-REM and consistent muscle atonia during REM. We confirmed that the pattern of sleep structure in budgerigars is disrupted when birds are

maintained in constant light conditions, as reported in the only prior study of budgerigar sleep. Our results motivate a reinterpretation of the evolution of avian sleep. Recent molecular phylogenetic analysis reveals that parrots and songbirds are sister taxa sharing a single common ancestor. It remains to be determined if other avian taxa exhibit more complex sleep architecture than previously recognized. Such investigations may open a window into what are the mechanisms giving rise to complex sleep architecture, and what attributes were shared through reptiles or arose independently in birds and mammals.

Title: High glycine prolongs recovery time from anesthesia

Authors: *J. E. DALLMAN[1], M. VENINCASA[2], M. STARK[2], Q. YAN[1], L. CHIYUAN[3], R. BINDERNAGAL[1], S. SLOAN[4,5], C. HIBBS[6], S. SYED[3];

Abstract: Of the estimated sixty thousand individuals who undergo general anesthesia daily, thousands experience significant delays as they emerge from the anesthetized state (Aldrete and Kroulik, 1970; Philip et al., 1996). Such delayed emergence from anesthesia was recently linked elevated nervous system glycine by a case study of a three-year-old girl with an inherited disorder, Glycine Encephalopathy (GE) (Liu and Fan, 2006). The anesthesiologists hypothesized that delayed emergence in their patient was caused by elevated glycine. To test this idea, we used zebrafish glial glycine transporter (GlyT1) mutants as a model. Like individuals with GE, GlyT1 mutants have elevated nervous system glycine, and, like the anesthetized GE patient, we found that GlyT1 mutants show delayed emergence from anesthesia. Despite this delayed emergence, GlyT1 mutants exhibit a normal dose/response curve for anesthesia-induced sedation, indicating elevated glycine specifically impacts emergence. We hypothesized that high nervous system glycine in GE and GlyT1 mutants might disrupt arousal pathways known to be required

specifically for timely emergence from anesthesia. Consistent with this idea, we were able to overcome delayed emergence from anesthesia in GlyT1 mutants either by reducing glycine, blocking $GABA_A$ receptors or by stimulating dopaminergic arousal pathways. Moreover, we show that in addition to delaying emergence from anesthesia, high glycine disrupts state transitions more generally, indicating that measurements of arousal state prior to anesthesia might be able to predict complications during emergence from anesthesia. Our results support a mechanism whereby elevated glycine inhibits brain arousal pathway to delay emergence from anesthesia.

Title: Improved Sleep related Gene Ontologies through analysis of KOMP2 sleep phenotyping data and gene expression studies

Authors: *S. JOSHI[1], M. SETHI[1], M. STRIZ[1], N. COLE[4], J. RYAN[4], M. E. LHAMON[5], A. AGARWAL[5], S. J. SUKOFF RIZZO[4], J. M. DENEGRE[4], R. E. BRAUN[4], D. W. FARDO[2], K. D. DONOHUE[3], E. J. CHESLER[4], K. L. SVENSON[4], B. F. O'HARA[1];
[1]Biol., [2]Statistics, [3]Engin., Univ. of Kentucky, Lexington, KY; [4]The Jackson Lab., Bar Harbor, ME; [5]Signal Solutions LLC, Lexington, KY

Abstract: A nearly random gene ontology (GO) for sleep-related genes and lack of a dedicated database containing a comprehensive list of these genes and their function presents a hurdle for sleep researchers. Increased data from sleep phenotyping studies in mouse and other species, genetic crosses, and gene expression databases can all help improve this situation. Here, we present our own sleep data from the large scale phenotyping program at The Jackson Laboratory (JAX), and then utilize publically available gene expression data to potentially strengthen and

help understand the best gene candidates for influencing sleep traits. The original knockout mouse project (KOMP) was a worldwide collaborative effort to produce embryonic stem (ES) cell lines with one of mouse's 21,000 protein coding genes knocked out. The objective of KOMP2 is to phenotype as many as of these lines as feasible, with each mouse studied over a ten week period (www.mousephenotype.org). The phenotyping for sleep behavior is done using our non-invasive Piezo system for mouse activity monitoring. Thus far, we have recorded sleep behavior in more than 1500 mice representing 150 knockout lines and over 1000 control mice. We have compared control and KO mice using multivariate statistical approaches to identify genes that exhibit significant effects on sleep variables from Piezo data. Using these statistical approaches, we have been able to identify significant genes affecting sleep specifically during daytime and/or night. Sleep is governed by both circadian and homeostatic processes. While the circadian process is dependent on time of day, the homeostatic process is affected by previous sleep. To study if the genes identified from KOMP2 data are associated with circadian or homeostatic sleep processes, we are using gene expression data from NCBI GEO (National Center for Biotechnology Information - Gene Expression Omnibus) database. Using a pattern matching approach, gene expression patterns of previously identified circadian and sleep related genes are matched with those of candidate genes from KOMP2. While important sleep-related genes will not necessarily change mRNA levels AND sleep phenotypes, those that do may be especially good candidates to pursue further. The use of gene expression and KOMP2 data for improved lists of sleep related genes should represent a substantial improvement over the existing list of genes returned using the query "sleep" or other similar terms in gene ontology database, and should be useful to help identify key players and key pathways in sleep regulation, sleep function, and both direct and indirect influences on sleep behavior.

Title: Slow wave activity increase after acute sleep deprivation and after chronic sleep restriction

Authors: *A. MARIC[1,2], C. LUSTENBERGER[1,4,5], E. WERTH[1], J. LEEMANN[1,2], R. HUBER[2,3,4], C. R. BAUMANN[1,2], R. PORYAZOVA[1];

Zurich, Zurich, Switzerland; [5]Dept. of Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: **Introduction** Increased slow wave activity (SWA), i.e. spectral power in the 1-4.5 Hz range in the sleep electroencephalography (EEG), is a well-established marker of sleep pressure. The impact of sleep loss on neurobehavioral functioning differs between individuals, with some showing more impairments than others. This individual vulnerability is preserved across different paradigms of sleep loss, e.g. when comparing acute sleep deprivation (aSD) and chronic sleep restriction (cSR). Up to date, it is not known if increased SWA reflects an individual vulnerability to sleep loss too. Thus, we aimed at directly comparing the amount of SWA increase after aSD and cSR in the same subjects. **Methods** Nine male subjects underwent 40 hours of aSD and 7 nights of cSR (5h instead of 8h sleep/night) in a counterbalanced way. Sleep was recorded during a baseline night prior to any sleep loss, after aSD, and after 7 nights of cSR, using high-density EEG (128 electrodes). We compared the increase in SWA (power density in the 1.25-4.5 Hz range) during the first sleep cycle of the recovery nights after aSD and cSR relative to the baseline night. The relative increase of SWA in individual electrodes was averaged over clusters of electrodes corresponding either to the frontal, parietal, occipital or temporal lobe. Comparisons were performed by paired t-test. To investigate the relationship between the relative increase in SWA over different brain areas after aSD and cSR, we calculated partial correlations controlling for baseline levels of SWA. **Results** The increase of SWA observed after aSD was higher in all areas compared to cSR (smallest difference in the parietal cluster +32.4 ± 12.5% [mean ± SD], $p<0.001$, largest difference in the occipital cluster +43.2 ± 14.2%, $p<0.001$). The increase in SWA after aSD and after cSR was significantly correlated in all areas. The correlation coefficient ranged from $r = 0.78$ ($p<0.05$) for the frontal lobe to $r = 0.90$ ($p<0.01$) for the temporal lobe. **Conclusions** Despite large differences in the increase of SWA after aSD compared to cSR, the relative SWA increase over different brain regions after the two kinds of sleep loss is highly correlated in the same subjects. These results imply that the SWA increase after sleep loss might reflect an individual's vulnerability to sleep loss. Notably, this relationship is not merely a result of differences in baseline levels. Further

analysis looking into potential regional differences more closely and relating the vulnerability to sleep loss as measured by SWA to neurobehavioral impairments, might contribute to the understanding of the similarities and dissimilarities between the consequences of acute and chronic sleep loss.

Title: Circadian regulation of perineuronal net composition

Authors: *H. PANTAZOPOULOS[1], E. YILDIZ[1], L. TURIAK[2], J. ZAIA[2], S. BERRETTA[1], M. ARDELT[1];
[1]Psychiatry, Harvard Med. School, McLean Hosp., Belmont, MA; [2]Ctr. for Biomed. Mass Spectrometry, Boston Univ. Sch. of Med., Boston, MA

Abstract: Background: Perineuronal Nets (PNNs), extracellular matrix structures that envelop subpopulations of neurons and restrict synaptic plasticity, were long thought to be stable, cartilage-like structures. Recent studies however suggest that PNN composition is modified during learning tasks, possibly allowing for formation of new synapses in response to environmental stimuli. New synapses are believed to undergo strengthening during sleep, a process termed ‘memory consolidation’. We tested the hypothesis that PNNs are regulated in a circadian manner, possibly allowing for increased plasticity during active periods and contributing to strengthening of new synapses during sleep. Methods: Total numbers and numerical densities of PNNs labeled with wisteria floribunda agglutinin lectin (WFA), or with the antibody cat-301 directed against the aggrecan core protein, were quantified in the amygdala and reticular nucleus of the thalamus (RTN) in a cohort of postmortem brain samples from normal human subjects (12-15 subjects) and plotted by time of death for each subject. Glycomics analysis was carried out using mass spectrometry on free-floating sections from the human amygdala and RTN to quantify specific sulfated chondroitin sulfate (CS) disaccharides. In addition, WFA and cat-301 were used to quantify PNNs in a cohort of wild type male 129sv mice sacrificed every 4 hours across the 24 hour cycle in the amygdala, thalamus, hippocampus, and prefrontal cortex. Results: We observed a ‘rhythmic-like’ relationship of WFA labeled PNNs

in the human amygdala and RTN. In addition, mass spectrometry analysis of CS disaccharides in the RTN revealed a rhythmic-like relationship of non-sulfated CS, as well as the 4S to 6S sulfation ratio, with time of death. In comparison, aggrecan immunoreactive (IR) PNNs in the human amygdala did not show a 'rhythmic-like' relationship with time of death. In mice, we observed a similar rhythmic distribution of WFA labeled PNNs in the RTN and in the lateral and basolateral amygdala nuclei. Quantification of WFA labeled PNNs in the hippocampus and prefrontal cortex, and of aggrecan-IR PNNs in mice, is in progress. Conclusion: Our data suggest that PNN CS composition varies in a circadian manner while the core protein levels do not change. Rhythmic modification of PNNs may contribute to circadian regulation of neuronal firing properties, increased plasticity during active periods, and memory consolidation during sleep.

Title: Is schizophrenia associated with a general impairment in sleep-dependent memory consolidation?

Authors: *B. BARAN[1,2,3], C. DEMANUELE[1,2,3], D. CORRELL[2,3], T. C. VUPER[2,3], B. SEICOL[4], R. A. FOWLER[2,3], C. CALLAHAN[4], E. PARR[4], S. DURRANT[5], R. STICKGOLD[1,4], D. S. MANOACH[1,2,3];

Abstract: Learning and memory impairments are a core feature of schizophrenia (SZ). While sleep promotes memory consolidation in healthy adults, patients with SZ have deficits in sleep-

dependent consolidation of motor procedural memory that are associated with reduced sleep spindle activity. Here we investigate whether this deficit generalizes to other types of memory. We predicted that patients would be impaired in sleep-dependent consolidation of memories that are mediated by spindles. Schizophrenia patients (n=17) and demographically-matched healthy controls (HC, n=14) were trained on three tasks: a declarative word-pair learning task, a statistical learning paradigm that tests recognition of regularities in tone sequences, and a visual discrimination task that involves procedural learning. Performance was tested 24 hrs later after a night of sleep. Relative to controls, SZ patients showed a non-significantly greater decrement in word-pair recall (13.5% decrease from training in SZ; 4.7% in HC; $t(30) = 1.4$, $p = .16$). For the statistical learning task, HC showed a 5.9% post-sleep improvement in correctly identified tone sequences while patients showed, a 1% decrement ($t(25) = 1.5$, $p = .14$). In contrast, patients showed greater performance improvement on the visual discrimination task than HC (SZ: 19%, HC: 9%; $t(23) = 1.4$, $p = .18$). Results provide preliminary support for the hypothesis that types of memory mediated by spindles (i.e. declarative memory and abstraction of statistical regularities) are impaired in schizophrenia. Future plans include increasing the sample size to determine whether SZ is associated with a reliable pattern of sleep-dependent consolidation deficits that correspond to spindles, and determining whether memory deficits are related to the functional and structural integrity of thalamocortical circuits that mediate spindles using diffusion tensor imaging and resting-state functional connectivity MRI.

Title: Sleep leads to enhanced amygdala connectivity during retrieval of emotional items and the neutral contexts with which they were previously studied

Authors: *K. A. BENNION[1], J. D. PAYNE[2], E. A. KENSINGER[1];
[1]Psychology, Boston Col., Chestnut Hill, MA; [2]The Univ. of Notre Dame, Notre Dame, IN

Abstract: INTRODUCTION: Although prior research has shown that sleep selectively consolidates emotional memory, as well as enhances connectivity among limbic regions during emotional memory retrieval (Payne & Kensinger, 2011), this work has typically utilized emotional cues. What is unknown is whether sleep affects retrieval processes when the retrieval cue is void of the emotionally salient component of a stimulus (i.e., the retrieval of a neutral background previously studied with emotional content), and also how sleep during consolidation affects these processes. The present study investigates amygdala connectivity following sleep versus wake during retrieval of 1) emotional items and 2) the neutral backgrounds they were studied with, the latter determining if residual effects of emotion on limbic connectivity persist even once the emotional cue is no longer present. METHOD: Participants encoded scenes composed of a negative or neutral item on a neutral background either in the morning (preceding 12 hours awake; Wake group) or evening (preceding 12 hours including a night of sleep; Sleep group). At retrieval, during fMRI, participants viewed the items and backgrounds separately, distinguishing new items and backgrounds from those previously studied. RESULTS AND DISCUSSION: Following Sleep (relative to Wake), there was enhanced connectivity between an amygdala seed region (-24 -6 -22) and several regions, including the insula, parahippocampal gyrus, precuneus, posterior cingulate, middle frontal gyrus, and superior and middle temporal gyrus, during the retrieval of negative versus neutral items. There was also some evidence of sleep enhancing amygdala connectivity during retrieval of neutral backgrounds studied with emotional content, particularly with the medial prefrontal gyrus and three clusters within the precentral gyrus. Conversely, there were no regions that exhibited greater connectivity with the amygdala following Wake greater than Sleep, either for emotional items or their neutral backgrounds. This provides further evidence for sleep leading to profound changes within the emotional memory retrieval network, and demonstrates for the first time that residual emotion effects may be reflected in amygdala-frontal lobe connectivity, following sleep but not wake.

Title: Identification of sleep patterns in dominant and submissive crayfish

Authors: M. OSORIO-PALACIOS[1], *K. MENDOZA-ANGELES[2], G. ROLDAN[1], J. HERNÁNDEZ-FALCÓN[1];
[1]Univ. Nacional Autónoma de México, México, Mexico; [2]Univ. Nacional Autónoma De México, México, Mexico

Abstract: Different biological models used until now show that sleep is essential not only to have a good quality of life, but for the maintenance of life itself. The crayfish is an invertebrate with a 'simple' brain in which many functions have been studied. Previously it has been demonstrated that crayfish sleep fulfills behavioral and electrophysiological criteria defined for vertebrates. When crayfish are in social interaction, they establish a hierarchical order of dominance-submission. Preliminary results, obtained from behavioral observations, indicate that dominant and submissive animals have different sleep patterns. It has not been determined whether sleep patterns determine the role that a given crayfish will play in the hierarchical order, or if hierarchical scale determines the sleep pattern of crayfish of a given triad. The aim of this work was to study the behavioral and electrophysiological sleep patterns of adult isolated crayfish Procambarus clarkii and the effects induced by the establishment of a dominance-submission social relationship. We used triads of male crayfish in intermolt, synchronized to light-dark cycles 12:12. Animal's weight and size differ in less than 10%. We performed behavioral recordings of crayfish triads placed in individual aquaria during 24 continuous hours. Then, we placed the animals in a common aquarium during 48 hours. To analyze the recordings we quantify the following variables: a) total sleep time, b) number of position transitions, and c) length of sleep interval. Each crayfish showed a different sleep pattern during the isolation period. The would-be dominant animal had the greater total sleep time, fewer position transitions, and the longest duration of sleep intervals. The submissive crayfish 1 showed shorter sleep duration periods and a high number of transition position. In comparison, the submissive crayfish 2 had the shorter total sleep time. When animals were in social interaction, the dominant crayfish decreased its total sleep time and displayed fewer transitions in position. Submissive animals further reduced their total sleep time; nonetheless, submissive crayfish 1 increased significantly the number of transitions in position. These findings suggest that dominance is associated with a great ability to adapt even in complex functions as sleep.

Title: Sleep benefits memory to complete goal-relevant behavior

Authors: *T. CUNNINGHAM[1], A. M. CHAMBERS[1], J. D. PAYNE[2];
[2]Psychology, [1]Univ. of Notre Dame, Notre Dame, IN

Abstract: Prospective memory (PM), or the ability to plan and spontaneously remember to execute activities in the future, is a vital skill that healthy individuals utilize every day without even knowing it. Recent evidence demonstrates that sleep enhances PM abilities in the context of a semantic categorization task (Scullin and McDaniel, 2010). The goal of the present study was to determine if sleep's benefit to prospective memory would be generalized across a variety of tasks. Participants were divided into 4 groups: morning short-delay (n=16), evening short-delay (n=16), morning long-delay (wake group, n=30), and evening long-delay (sleep group, n=30). Each group completed two sessions. Morning participants arrived to the lab for session one at 9am and evening participants at 9pm. Session one began with a battery of cognitive tests including three ongoing tasks: living/nonliving decision, lexical decision, and semantic categorization. After completion of the final ongoing task, a PM instruction to be carried out during the second session was given (i.e., hit "q" whenever "table" or "horse" appears), followed by a 20 min distracter task. Following this task, short-delay groups immediately completed the second session, while the wake and sleep groups were dismissed for a 12-hour period spanning daytime wakefulness or nocturnal sleep, respectively, before returning for the second session. The second session included another round of the ongoing tasks and a test of prospective memory for the critical words. Results showed that there was no main effect of task type, indicating that performance was similar across all three tasks. Because the morning and evening short-delay groups did not differ in performance [$t(30) = 1.3$, $p=0.2$], these groups were collapsed into a single short-delay group. Critically, the wake group showed significant PM deterioration compared to the short-delay group [$t(60)=3.94$, $p < 0.0001$], while the sleep group did not significantly differ from the short-delay groups. These results suggest that sleep protects the ability to successfully perform future actions, while wakefulness degrades this ability . This study not only replicates a previous report indicating that sleep benefits prospective memory performance, but also extends it by suggesting that this effect is not limited to a certain test context, and can be generalized across different testing modalities. During sleep, our daily goals may be reactivated and rehearsed leading to a better chance of remembering to execute them at the appropriate time.

Title: Generation of spontaneous EEG rhythms across cortical layers in humans

Authors: *M. HALGREN[1], I. ULBERT[3], J. MADSEN[4], W. K. DOYLE[5], E. HALGREN[2], S. S. CASH[6];
[2]Radiology and Neurosciences, [1]UCSD, La Jolla, CA; [3]Inst. of Cognitive Neurosci. and Psychology, Res. Ctr. for Natural Sciences, Hungarian Acad. of Sci., Budapest, Hungary; [4]Dept. of Neurosurg., Boston Children's Hosp., Boston, MA; [5]Dept. of Neurol., Comprehensive Epilepsy Center, New York Univ. Sch. of Med., New York City, NY; [6]Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Cortical rhythms are a central aspect of brain activity and have been implicated in information transfer, network dynamics and synaptic plasticity. Though various recording modalities have been used in humans and animal models to correlate rhythms with cortical areas and states, little has been done to shed light on which cortical layers generate which frequency bands. To investigate this, we used laminar electrodes with 40 micron diameters and 150 microns between contact centers implanted in the grey matter of patients with medically intractable epilepsy to examine how the power spectrum of the spontaneous LFP changes across cortical layers. Superficial layers were responsible for almost all of the power between 1-6 hz. After this, the dominant frequency band gradually increased with cortical depth. From about 1-20 hz, a positive relationship between cortical depth and frequency was found across patient, state (wakefulness or non-REM sleep) and cortical area. This general principle might reflect the longer timescales needed to integrate inputs from distant cortical areas, suggesting that a given column’s information processing becomes increasingly local with depth. This is consonant with the prevalence of cortico-cortical connectivity in superficial layers. Complementing these findings, Shannon’s entropy was found to decrease with cortical depth, perhaps indicative of a

higher degree of informational complexity associated with cortico-cortical processing. Coherence and mutual information were also used to assess functional connectivity between layers. Although significant connectivity was found between and within supragranular and infragranular cortical layers, a putative layer IV exhibited little coherence/mutual information with other layers. This suggests that layer IV participates in a different kind of informational processing than other cortical layers, possibly reflecting its role as a recipient of topographic feed-forward input whereas superficial and deep cortex might be co-modulated by coherent afferents. These differences may also be explained by thalamocortical matrix/core afferents, the former synapsing diffusely on superficial and deep cortex driving coherent activity, and the latter topographically in granular cortex. Although these results are significant for understanding network processing, they also have important implications for the interpretation of ECOG, EEG and MEG. Superficial LFP was found to have large broadband power, suggesting that the oscillatory activity measured on the scalp/cortical surface is dominated by supragranular activity, and by extension cortico-cortical, cognitive processing.

Title: Phase-amplitude coupling of sleep spindles and slow oscillations improves verbal memory

Authors: ***M. NIKNAZAR**[1,2], G. PRASHANTH[1], M. BAZHENOV[1], S. C. MEDNICK[2]; [1]Cell Biol. & Neurosci., [2]Psychology, Univ. of California, Riverside, Riverside, CA

Abstract: Prior studies have shown that boosting non-rapid eye movement (NREM) sleep spindles (12-15Hz) (Mednick et al. 2013) and slow oscillations (SOs, 0.5-1Hz) (Marshall et al. 2006) in a targeted manner selectively enhances declarative memory, suggesting a causal role for each oscillatory band independently. However, the functional consequence for memory of coupling between spindles and SOs, when they co-occur, is not known. Here, we use signal

processing techniques to address this question. Thirty subjects were tested in two drug conditions (zolpidem and placebo) on a verbal memory task. Recorded EEG during stage 2 sleep was first filtered (0.5-1Hz). Spindle windows were set to 1-sec before and 1-sec after spindle markers. Spindle/SO complex were identified when the maximum amplitude envelope of the signal crossed a threshold 2-sec before a spindle. The phase of SOs at the peak of the spindle amplitude envelope was calculated within the spindle window. We also calculated the unwrapped phase change of SOs in the interval between the peaks of SO and spindle amplitude envelopes in order to consider phase across cycles, as well as the normalized modulation index. We found that correlation of the mean of the actual phase of SO at the peak of the spindle amplitude envelope with performance improvement in the zolpidem condition was higher ($r=-.446$; $p=.017$) than that in the placebo condition ($r=-.369$; $p=.057$). These findings indicate that tighter coupling between SO and spindles increased memory consolidation in both groups, but that zolpidem intensified this effect. These data also suggest a preferred SO phase for the occurrence of spindles events that resulted in better memory consolidation. The unwrapped phase change of the SOs was significantly correlated with performance improvement in zolpidem condition ($r=.597$; $p<.001$) but not in placebo condition ($r=.111$; $p=.579$). Moreover, the normalized modulation index for spindle/SO complexes was significantly higher in the zolpidem condition compared to the placebo condition ($p=.004$) indicating stronger coupling between SOs and spindles in zolpidem condition. Our study revealed that memory consolidation critically depends on the tight temporal coupling of spindle and SO events. Occurrence of the maximum spindle amplitude at a certain phase of SO predicted performance improvement across all subjects in both groups. Pharmacological intervention with zolpidem may have increased the magnitude of this effect by increasing the modulation index. These findings suggest the existence of a preferred phase of SO, in which the spindle maximum should occur for optimized consolidation.

Title: Cortical layer 6. modulates spindle generation in thalamus

Authors: *P. BARTHO, F. MATYAS, M. CSERNAI;
MTA-TTK NAP-B Sleep Oscillations Res. Group, Res. Ctr. For Natural Sciences, Hungarian Ac, Budapest, Hungary

Abstract: Sleep spindles are generated by the interplay of excitatory thalamocortical (TC) and inhibitory thalamic reticular (nRT) neurons. Stimulation of nRT cells or axon terminals can elicit spindles in a state dependent fashion. The third component of the network, layer 6. of the cortex (L6) provides excitatory feedback to both cell types, however its role in spindle generation is unclear. We recorded thalamic multiunit activity in urethane anaesthetized NTSR1-ChR mice, a strain expressing channelrhodospin in L6 corticothalamic cells selectively. Brief, pulse-like light stimuli to L6 terminals elicited spindles in a fashion similar to direct nRT activation. Namely, no spindles could be evoked during deeply synchronized and desynchronized network states, only during light synchronization, a state analogous to stage 2. sleep, in which spontaneous spindles also appear. Tonic L6 stimulation, on the other hand, elicited a progressively increasing thalamic multiunit activity, which ended in a complete cessation of firing for several seconds, possibly through a depolarization block. We assume that the former effect is mediated by direct L6 activation of nRT, while the latter through TC cells.

Title: Infra-slow neural and cardiac fluctuations predict behavioral arousability during mouse NREM sleep

Authors: S. LECCI[1], L. M. J. FERNANDEZ[1], R. D. WIMMER[2], J.-Y. CHATTON[1], *A. LUTHI[1];
[1]Univ. of Lausanne, Lausanne, Switzerland; [2]Neurosci. and Physiol., NYU Sch. of Med., New York, NY

Abstract: Environmental noise at night disrupts sleep and adversely affects general health by causing daytime sleepiness and increasing cardiovascular risk factors. This calls for a profiling of sleep in terms of fragility to acoustic disturbance and in association with cardiovascular activity. Electrophysiological and imaging studies in humans and animals show that thalamocortical sleep rhythms cause substantial sensory response variability. Nevertheless, the tell-tale signs that determine whether or not noise causes behavioral arousal remain incompletely understood. Here we show that noise-induced arousal is specifically predicted during mouse non-rapid-eye-movement sleep by an infra-slow fluctuation (periodicity ~45 s) in the power of sleep spindles, a 10-15 Hz electroencephalographic rhythm implied in sleep's beneficial actions on memory formation, which is phase-locked to slow components of heart rate variability. By choosing an acoustic stimulus such that mice wake up or sleep through noise at comparable rates, we discovered that, prior to noise onset, sleep spindle power peaked when an arousal followed. Conversely, sleep-through was preceded by a trough in spindle power, concurrent with augmented heart rate fluctuations. Varying arousability hence arises from joint central autonomous and sleep-wake control mechanisms, going beyond traditional views of thalamocortical sensory gating. Infra-slow fluctuations occurred in sensory and associational cortical areas and were suppressed by zolpidem, a widely used hypnotic drug, substantiating their role as sleep fragility markers. Together, we show for the first time that arousability during mammalian sleep fluctuates constantly due to a specific brain-heart crosstalk. The coordination between a salient sleep rhythm and an index for cardiac health bears the potential for assessing the pathophysiological links between sleep disorders, cognitive deficits, and cardiovascular disturbance.

Abstract: Cortical network models based on ionic mechanisms have many parameters that must be chosen to match cortical recordings. One measure is comparison of the local field potentials generated by simulations of the model with electrocephalogram (EEG). Here, we use delay differential analysis (DDA), which is a time domain classification framework based on embedding theory in nonlinear dynamics to make the comparison. An embedding reveals the nonlinear invariant properties of an unknown dynamical system (here the brain) from a single time series (here EEG data). The embedding in DDA serves then as a low-dimensional nonlinear functional basis onto which the data are mapped. Since the basis is built on the dynamical structure of the data, preprocessing of the data (such as filtering) is not necessary. DDA yields a low number of features (around 4), far fewer than traditional spectral techniques. This greatly reduces the risk of overfitting. A model that was trained on a single EEG channel from one subject can be applied to a wide range of data from different subjects, channels, and recording systems. In this project, we varied the network's thalamocortical fan-out to simulate networks with different levels of connectivities. Then, we apply DDA to construct a set of non-linear features for the real human sleep EEG data and each network simulation. Finally, the cross correlation between each network simulation and the real sleep data is computed. Our results show that within the connection range we simulated, networks with medium levels of fan-out rate have the highest correlation with real sleep data. This implies that there is an optimum level of connection between the thalamus and the cortex. A too narrow or too broad fanout will disrupt the simulation dynamic from that of real sleep. Title: Using Acoustic stimulation to increase slow-wave activity and improve memory in older adults

Authors: *P. A. PAPALAMBROS[1], G. SANTOSTASI[1], R. G. MALKANI[1], S. WEINTRAUB[2], K. A. PALLER[3], P. C. ZEE[1];
[1]Neurol., [2]Cognitive Neurol. and Alzheimer's Dis. Ctr. and Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL; [3]Psychology, Northwestern Univ., Evanston, IL

Abstract: Age-related decrease in the amount of slow-wave sleep has been postulated to play a role in impaired cognitive and metabolic function. Acoustic stimulation during sleep has been shown to increase slow-wave activity (SWA) in young adults but has not been examined in older adults. The aim of this study is to examine the ability of acoustic stimulation to increase SWA in adults ≥50 years old. Twelve cognitively healthy adults (age 68.9 ±9 years, 2 male) completed one night of acoustic stimulation and one night of sham stimulation. During sleep, an adaptive phase-locked loop (PLL) algorithm was used to lock on to endogenous slow waves measured in midline frontopolar electroencephalographic recordings in real time. Acoustic stimuli were delivered when the PLL system predicted the positive upstate of the slow wave. Stimuli consisted of pulses of pink (1/f) noise lasting 50 ms with an inter-tone interval of approximately 1 s, depending on the individual's slow oscillations. Tones occurred in blocks of 5 pulses ("ON blocks") followed by a refractory period of equal length ("OFF blocks"). Participants completed a declarative memory 88-word pair test before and after sleep. Power spectral analysis was used to identify power in the slow oscillation delta frequency band (slow delta: 0.8Hz-2.1Hz). Wilcoxon signed-rank test was used to evaluate differences in power within and between stimulation and sham nights. Memory scores are a subtraction of the raw evening score from the raw morning score to give a change in memory. During the stimulation night, there was a 58.7% increase in slow delta during the ON blocks compared to OFF blocks ($p=0.015$). Slow delta during ON blocks during the stimulation night was 61.1% higher when compared to ON blocks in the sham night ($p=0.018$). On average, participants recalled 5 more words when tested the morning following a sham night, and 8.8 words the morning following a stimulation night. This reflects a relative improvement of 3.8 additional words with auditory stimulation. Acoustic stimulation during sleep can enhance SWA and has the potential to improve sleep quality and

memory in middle age and older adults. Acoustic stimulation may be a drug free alternative to improving memory in those with cognitive decline.

Title: Weighing in on sleep: Exploring the relation between maternal sleep patterns during pregnancy and subsequent weight gain of the child

Authors: K. VIJAYAKUMAR[1], B. LOW[1], J. J. GOOLEY[2], Y. S. LEE[3], F. YAP[4], M. F. F. CHONG[5], B. BROEKMAN[5], A. RIFKIN-GRABOI[5], M. MEANEY[5], P. GLUCKMAN[5], K. KWEK[4], Y. S. CHONG[3], *J. C. LIU[6];

Abstract: A large body of epidemiological studies suggests that sleep deprivation is a risk factor for illness and for all-cause mortality. While within-person effects have been catalogued extensively, there has been recent interest in possible transgenerational effects of sleep deprivation. Results from rodent studies suggest that maternal sleep deprivation during pregnancy may have profound effects on the weight and food preferences of the offspring. In humans, a cohort study likewise found that maternal sleep deprivation was a risk factor for low birth weight. In this study, we sought to extend these findings by exploring how maternal sleep patterns would relate to the weight status of a child over a longer period of observation. 545 female participants were recruited during their pregnancy as part of the "Growing Up in Singapore Towards healthy Outcomes" study (GUSTO), an ongoing longitudinal study where both mothers and their children are observed from gestation until the child is seven years of age. As a measure of maternal sleep, mothers completed the Pittsburgh Sleep Quality Index (PSQI) between the 26th and 28th week of pregnancy. This is a standardised self-reported measure assessing sleep duration and quality during the past month. For our analyses, we focused on a

single question requiring participants to estimate the hours of sleep they obtain in an average night. This was correlated with the child's body mass index (BMI) at three years of age. We found a significant negative correlation between maternal sleep duration and the child's BMI. Namely, decreased habitual sleep during pregnancy was associated with an increased risk for offspring weight gain at three years of age. This is consistent with prior rodent studies suggesting transgenerational effects of sleep deprivation. However, we note also that our observed correlation was weak, raising the possibility of mediating variables underlying this relationship.

Title: Spectral analysis of sleep EEG reveals new deep sleep stage with dominant frequencies below 1 Hz

Authors: *J. A. ONTON[1,2], V. VIJAYAN[3], C. PARK[4], S. KIM[5], T. P. COLEMAN[5]; [1]Warfighter Performance Dept 162, Warfighter Performance, San Diego, CA; [2]Inst. for Neural Computation, Univ. of CA San Diego, La Jolla, CA; [3]Natera, Inc, San Carlos, CA; [4]Dept. of Computer Engin., Kwangwoon Univ., Seoul, Korea, Republic of; [5]Dept. of Bioengineering, Univ. CA San Diego, La Jolla, CA

Abstract: Traditionally, sleep EEG is interpreted by the trained eye of a sleep technician who can evaluate the EEG and other available measures to determine the sleep stage during each 30 second stretch of time. While this approach can produce reliable estimates of sleep architecture, it is extremely time-consuming and subjective and lacks the possibility of appreciating the spectral complexity of the sleep signal and how this complexity is embedded in the full sleep record. In this study, 40 un-medicated, self-reported normal sleepers, with no problems falling or staying asleep, wore a 2-channel EEG recording device that captured forehead EEG with

reference to the right mastoid. Subjects were instructed on proper self-application of EEG electrodes so that recordings could occur in subject homes without investigator presence. EEG data were decomposed to reveal spectral power fluctuations over the course of the entire night from 0.1 Hz to 145 Hz for each channel individually and for the forehead-forehead difference channel. Spectral band power was submitted to a customized Hidden Markov Model and Expectation-Maximization algorithm for automatic scoring based on priors derived from the literature and observed spectral qualities of the data. This approach provides a rapid and accurate display of sleep architecture, and a means for quantification of sleep stage durations. Using this technique, we were able to detect distinct stages of deep sleep that are characterized by 1-3 Hz power dominance ('hi deep') and 0.1-1 Hz dominance ('lo deep'), respectively. Presence of lo deep sleep is almost always present in one or more cycles in normal sleepers, while hi deep sleep is less consistently present, but is most common in the first sleep cycle. Preliminary, investigations indicate that the electrodermal response (EDA) is correlated specifically with the lo deep sleep stage and may therefore represent a physiologically distinct and important sleep stage.

Title: Distribution, amplitude, incidence, co-occurrence, and propagation of human K-Complexes in focal transcortical recordings

Authors: *R. A. MAK-MCCULLY[1], B. Q. ROSEN[2], M. ROLLAND[2], J. REGIS[3], F. BARTOLOMEI[3], P. CHAUVEL[3], S. S. CASH[4], E. HALGREN[2];

Abstract: K-complexes are thought to play a key role in sleep homeostasis and memory consolidation. The commonly held view from scalp EEG is that KCs are primarily generated in insular or medial frontal cortex and propagate parietally, whereas ECOG suggests dorsolateral prefrontal generators and an absence of KCs in many areas. We investigated the spatiotemporal relationships of KCs using unambiguously focal bipolar depth electrode recordings in patients with intractable epilepsy. KCs were marked manually on each channel and local generation was confirmed with decreased gamma power. In most cases (76%), KCs occurred in a single location, and rarely (1%) in all locations. However, if automatically-detected KC-like phenomena were included, only 15% occurred in a single location and 27% in all locations. Locally-generated KCs were found in all recorded areas, including cingulate, ventral temporal, and occipital cortices. Surprisingly, KCs vary by >50% in amplitude and incidence across locations, being largest and most frequent in subcallosal and posterior prefrontal areas. When KCs occur on two channels, the order of their peaks is random in 87% of cases. For significant pairs, the only systematic anatomical pattern was a tendency for lateral temporal channels to follow prefrontal. Overall, the anterior-posterior separation of electrode-pairs explained only 2% of the variance in their latencies. These results open a novel view where KCs overall are universal cortical phenomena, but each KC may variably involve small or large cortical regions, and spread in variable directions, allowing flexible and heterogeneous contributions to sleep homeostasis and memory consolidation.

Title: Spatiotemporal evolution of the sleep spindle in human neocortex

Authors: *G. PIANTONI[1,2], E. HALGREN[3], S. S. CASH[1,2];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]UCSD, La Jolla, CA

Abstract: Brain activity is the result of a dynamic interplay between cortical and thalamic neuronal populations and this often takes the shape of an oscillation. A characteristic phenomenon that is generated by the thalamocortical network during sleep is the spindle, a 0.5-2 s long burst of oscillations between 11 and 16 Hz. While animal and computational studies have highlighted the importance of the reciprocal connections between cortex and thalamus, the spatio-temporal properties of the spindle on the cortex remain largely unexplored. We here investigated the evolution of the spindle oscillations over large cortical areas, measured on the human neocortex. Spindles were described by their instantaneous amplitude and phase over neighboring electrodes. We collected recordings from NREM sleep stage 2, using electrocorticography in eight patients undergoing evaluation for intractable epilepsy. Electrodes covered large parts of one hemisphere and were spaced 1 cm apart. The research was approved by the local institutional review board and electrode placement was determined solely by clinical criteria. Based on the instantaneous amplitude in the spindle frequency band for each electrode, we computed the covariance on overlapping 1s long intervals of these time-series. We observed recurring patterns of spatio-temporal organization, which include focal, widespread and global spindling activities. Spindles were more likely to synchronize over multiple cortical areas if they included the lateral prefrontal cortex, a putative pivot of spindle activity. In addition, we observed a drastic phase reset at the beginning of the sleep spindle. We interpret this phase reset as the putative thalamic input to the cortical mantle. The spatial extent of this phenomenon was compatible with the two anatomically defined thalamocortical pathways: the spatially diffuse matrix pathway and the locally selective core pathway. These results highlight the importance of thalamocortical projections in shaping the spindle evolution and define the spatial extent of the functional influence of these projections. These findings will help elucidate the mechanisms underlying spindle generation and the functional role of thalamocortical loops, their possible role in sleep maintenance and memory, and their disruption in neurological disorders.

Title: Sleep deprivation sex-dependently increases myocardial sensitivity to ischemic injury

Authors: ***A. KRIVENKO**[1], M. E. FRY[1], J. D. LAWSON[1], L. E. STONER[1], E. D. EISENMANN[1], B. L. JOHNSON[1], M. L. HEMBREE[1], R. M. ROSE[1], C. J. LOMBARDI[1], M. R. HUNTLEY[1], S. SEELEY[2], A. D. BUI[2], B. R. RORABAUGH[2], P. R. ZOLADZ[1]; [1]Psychology, Sociology, & Criminal Justice, [2]Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: Extensive work has shown that sleep deprivation can exert detrimental effects on physiology and behavior. Prolonged sleep deprivation can impair cognitive functions, metabolic processes and cardiovascular activity. The purpose of the present study was to examine the influence of sleep deprivation on myocardial sensitivity to ischemic injury. Male and female Sprague-Dawley rats were exposed to the "flower pot" method of sleep deprivation for 96 consecutive hours. Sleep-deprived rats were placed on a 6.5-cm (diameter) platform in a modified Plexiglas cage that was filled with water to 1 cm below platform level. Control rats were placed on a 13-cm platform in a standard Plexiglas cage that was also filled with water to 1 cm below platform level. Both groups of rats had access to food and water throughout the 96-hr time frame. Following 96 hours in the water-filled cages, rat hearts were isolated and exposed to 20 min ischemia and 2 hr reperfusion on a Langendorff isolated heart system. Sleep deprivation had no effect on pre-ischemic contractile function. However, post-ischemic recovery of contractile function and myocardial infarct size were sex-dependently influenced by sleep deprivation. Specifically, sleep deprivation attenuated post-ischemic recovery of rate pressure product and +dP/dT and resulted in greater post-ischemic diastolic blood pressure in female, but not male, rats. Sleep deprivation also led to greater infarct sizes in females only. These findings are consistent with preclinical and clinical research reporting greater sleep deprivation-induced increases in inflammation, as well as a greater relationship between sleep loss and hypertension, in females.

Title: CGRP neurons in the external lateral parabrachial nucleus regulate cortical EEG arousal to hypercapnia

Authors: *S. KAUR, J. WANG, D. KROEGER, P. FULLER, C. SAPER;
Neurol., Beth Israel Deaconess Med. Ctr. and Harvard M, Boston, MA

Abstract: We have reported that glutamatergic signaling from neurons in the lateral parabrachial region mediates cortical arousal to hypercapnia. This region contains a population of neurons in the external lateral subnucleus (PBel) that express calcitonin gene-related peptide (CGRP), which has extensive forebrain projections and which we hypothesized may be necessary relay for the hypercapnic signal to cause arousal. To test this hypothesis, we employed both opto- and chemogenetic methods to cause acute selective activation or inhibition of the CGRP-PBel neurons by using CGRP-CreER mice. All mice were instrumented for sleep recording and were injected intraperitoneally with tamoxifen (75mg/ kg) to express Cre. In one set of mice (n=5), we bilaterally injected an adeno-associated virus (AAV) containing a Cre-dependent hM3Dq-mCherry transgene targeting PBel, and investigated sleep-wake after Clozapine-N-Oxide (CNO; 0.3mg/kg and 0.1mg/kg, ip) that selectively activated hM3 expressing CGRP-PBel. Activation of CGRP-PBel neurons with CNO (0.3mg/kg) caused a 35% increase in wake ($p<0.05$) during the light phase and significantly suppressed sleep for 2h ($P<0.05$) after CNO injections compared to saline. In another set of mice (n=8), Cre dependent AAV containing Archaerhodopsin from Halorubrum strain TP009 (ArchT) and green fluorescent protein (AAV-FLEX-ArchT-GFP) was injected on one side of the brain targeting the PBel and on other side we deleted the CGRP neurons in the PBel by injecting a Cre dependent virus expressing the diphtheria toxin subunit A (AAV-FLEX-DTA). The ArchT injected side was implanted with optical fiber targeting the PBel. We investigated EEG arousals to 10% CO2 given for 30s every 300s, with and without inhibition of the PBel with a 593nm laser light. Laser light hyperpolarized the ArchT transduced CGRP-PBel neurons, and was on continuously from 20s before every 10% CO2 stimulus until 10s after it. Inhibition of CGRP-PBel neurons increased the average latency to arousal by CO2 by four fold (latency with laser- 69 ± 6 sec; latency without laser- 16 ± 0.6 sec; $P<0.05$), and 49 ± 5% of the trials showed failure to arouse to 30 sec of 10% CO2. Optogenetic inhibition of CGRP neurons did not change their response to acoustic stimuli. Thus, CGRP-PBel neurons mediate cortical EEG arousals to hypercapnia. These neurons project to the lateral hypothalamus, basal forebrain, and central nucleus of amygdala. We propose that these pathways are involved

in mediating the hypercapnic arousals. Current studies are underway to dissect the role of these targets of the CGRP neurons in the PBel in CO2 arousal.

Title: Temporal dynamics of intrinsic activity are reorganized during slow wave sleep

Authors: ***A. MITRA**[1], A. SNYDER[1], E. TAGLIAZUCCHI[2], H. LAUFS[3], M. E. RAICHLE[1]; [1]Washington Univ. Sch. of Med., Saint Louis, MO; [2]Goethe Univ., Frankfurt, Germany; [3]Schleswig Holstein Univ. Hosp., Kiel, Germany

Abstract: Introduction Sleep is essential for normal brain function, but the fundamental functions of sleep remain elusive. Electrophysiological studies have demonstrated multiple, slow (<1 Hz) patterns of propagated activity during slow wave sleep (SWS). Using resting state fMRI (rs-fMRI), we have recently demonstrated multiple patterns of propagated intrinsic activity in normal, awake (W) subjects. Here, we used rs-fMRI to compare and contrast patterns of propagated intrinsic activity in W vs. SWS. Methods 63 nonsleep-deprived subjects were scanned, with simultaneous EEG, in the evening. Hypnograms were inspected to identify epochs of contiguous sleep stages lasting at least 5 min. These criteria yielded 39 subjects. Included are 70 epochs of W and 38 epochs of SWS. Apparent propagation of intrinsic activity was assessed by applying our previously published methodology for computing lags between rs-fMRI time series (Mitra et al. 2014). Results Fig. 1A exhibits lag projection maps in W and SWS. Lag projections depict whether a voxel is early (blue) or late (red) compared to the whole-brain mean. The temporal scale is ±0.75 s. Although several features are preserved in W vs. SWS, there are also significant differences. One of the most prominent effects is in thalamus, which is early during W, but late during SWS. Fig. 1B exhibits thalamus-referenced lag maps, where each voxel is early or late compared to a mean thalamic time-course. The temporal scale is ±1 s. During W, cortex is late with respect to thalamus, whereas during SWS, cortex is early with respect to thalamus. Despite thalamo-cortical reversal, lags within the brainstem-thalamic axis

are preserved (pink circles). Conclusions Apparent propagation of slow intrinsic activity, as measured by rs-fMRI, is altered in SWS as compared to W. In particular, intrinsic activity propagates from thalamus to cortex during W, but in the reverse direction during sleep. These results are consistent with thalamic gating of sensory information during sleep, and shed light on the mechanisms of SWS.

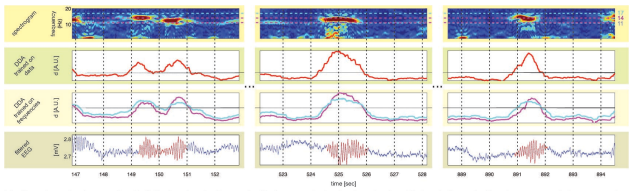
Title: Nonlinear dynamical sleep spindle detection using delay differential analysis

Authors: ***A. L. SAMPSON**[1,2], C. LAINSCSEK[1,2], S. S. CASH[3,4], E. HALGREN[2], T. J. SEJNOWSKI[1,2];

[1]Salk Inst. For Biol. Studies, La Jolla, CA; [2]UCSD, La Jolla, CA; [3]Massachusetts Gen. Hosp., Boston, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: Since nonlinear data analysis works upon the dynamical structure of the data, it allows for classification in near real time of raw data. Here, we use delay differential analysis (DDA), which is a time domain classification framework based on embedding theory. An embedding reveals the nonlinear invariant properties of an unknown dynamical system (here the brain) from a single time series (here electrocephalogram (EEG) data). The embedding in DDA serves as a low-dimensional nonlinear functional basis onto which the data are mapped. Since the basis is built on the dynamical structure of the data, preprocessing of the data is not necessary, and the low dimensionality removes the risk of overfitting. A model that was trained on a single EEG channel from one subject can be applied to a wide range of data from different subjects, channels, and recording systems. Given these desirable properties, DDA is ideally suited to the problem of sleep spindle detection. Sleep spindles are 11-17 Hz oscillations recorded in the EEG during stage 2 sleep. As sleep spindles are thought to arise from the activity of thalamocortical circuitry, they have become a subject of study for their potential roles in memory consolidation and other cognitive functions. In light of their potential importance, a method for reliably identifying spindles in real time is needed. DDA analyses were applied to intracranial recordings from patients with intractable epilepsy and compared to traditional wavelet methods. As a bridge between these two methods, an additional DDA classifier was built on simulated data (noise-diluted harmonics) to detect frequency bands. One single set of DDA parameters can be used for 15 tested recordings. The mean area under the receiver operating characteristic curve is 0.75. DDA is a powerful method for improving the sensitivity of EEG analyses to transitory time series features that does not rely on any post-hoc adjustment of outputs or tailoring to individual subjects.



The figure shows the abovementioned spindle detection algorithm results. The lowest row in the plot shows the data with the spindles marked by a human expert. In the next row, the DDA frequency band detector outputs are shown (in blue for a 11-17 Hz band and in magenta for a 11-14 Hz band). In the next row, the DDA output (trained on one channel from a different subject) is shown. We also show the spectrograms for reference.

Title: GABA receptors on orexin and MCH neurons are differentially regulated following sleep deprivation and recovery

Authors: *H. TOOSSI, E. DEL CID-PELLITERO, B. E. JONES;
McGill Univ., Montreal, QC, Canada

Abstract: Orexin (Orx) and melanin concentrating hormone (MCH) neurons play opposite roles in the regulation of sleep-wake states, Orx neurons discharging during waking (W) and MCH neurons reciprocally so during sleep, including slow wave sleep (SWS) and REM or paradoxical sleep (PS) (Hassani et al., 2009). In the present study, we examined in mice whether GABAA and GABAB receptors (Rs) are present on Orx and MCH neurons and might undergo differential changes as a function of their activity following sleep deprivation (SD) and sleep recovery (SR). Applying quantitative stereological image analysis of dual immunofluorescent stained sections, we determined that the proportion of Orx neurons bearing GABAARs was significantly higher following SD (~48%) as compared to sleep control (SC) and SR (~24% and ~27%, respectively) and that the luminance of the GABAARs was also significantly higher. In contrast, the average proportion of the MCH neurons bearing GABAARs was significantly lower following SD (~43%) in comparison to SC and SR (~54% and ~56%, respectively) and the luminance of the GABAARs was also significantly lower. Although, GABABRs were observed in all Orx and MCH neurons (100%), the luminance of these receptors was differentially altered following SD. The intensity of GABABRs in the Orx neurons was significantly higher after SD than after SC and SR, whereas that in the MCH neurons was significantly lower. The present results indicate that GABARs undergo dynamic and differential changes in the wake-active, Orx neurons and sleep-active, MCH neurons as a function of and homeostatic adjustment to their preceding activity and sleep-wake state.

Abstract: During stage II sleep, neocortical circuits exhibit transient epochs of narrowband oscillations in the 11-15 Hz frequency band. The physiological substrate for these "spindle" oscillations is the interplay of activity within the thalamus, providing transient synchronization across the neocortex through thalamocortical feedback loops. Although there is increasing evidence that spindles are involved in the consolidation of long-term memories, the specific neural mechanisms by which this occurs remain unclear. Evidence from electroencephalography suggests large-scale coherence across the cortex during spindles, but their specific spatiotemporal structure during natural sleep is not well understood. In this work, we study electrocorticogram (ECoG) recordings of patients during stage II sleep and apply phase-based methods to characterize the spatiotemporal dynamics. During spindling activity, the ECoG array exhibits a specific, robust spatiotemporal pattern: large-scale rotating waves traveling from parietal to temporal to frontal to parietal cortex. These recurring spatiotemporal patterns are observed in the left and right hemisphere of individual patients and extend over tens of milliseconds, placing the neural assemblies they synchronize on a timescale relevant to spike-time dependent synaptic plasticity. Finally, we introduce a method to detect phase-based motifs in narrowband signals, in order to study precise fluctuations of activity within these recurring spatiotemporal patterns. We find indeed that precise phase relationships during spindles on the electrode array recur across several minutes of sleep, further demonstrating the precision and importance of relative timing among electrodes during sleep oscillations in humans. --

Title: Reduced computationally efficient model for slow wave sleep activity

Authors: N. F. RULKOV[1], G. P. KRISHNAN[2], S. CHAUVETTE[3], I. TIMOFEEV[4], *M. V. BAZHENOV[5];

Abstract: During stage 3/4 of NREM sleep, brain activity is dominated by slow (0.2 - 1 Hz) oscillations consisting of periodic transitions between active (or Up) and silent (or Down) states in the membrane voltage of excitatory and inhibitory neurons. Experimental and modeling studies suggest that Up-states are initiated due to progressive accumulation of spontaneous miniature EPSPs, maintained by recurrent excitatory connections and terminated by progressive activation of the intrinsic inhibitory currents, synaptic depression and synaptic inhibition. Previous models based on Hodgkin-Huxley type models showed that the combination of the intrinsic and synaptic mechanisms is sufficient for recreating basic properties of slow oscillations. We previously developed a class of reduced and computationally efficient map-based neuronal models for large-scale neuronal simulations. In this study this approach was extended to capture intrinsic neuronal properties necessary to generate sleep slow oscillations. Map-models use difference equations capturing dynamics of a neuron in discrete moments of time with relatively large intervals (~0.5msec). It provides a significant reduction in computational resources that are required for computer simulation of neurons and large-scale

networks. We show that addition of nonlinear dynamical bias and activity dependent depolarization to the previously developed map-based model can mimic the effects of K+ leak and persistent Na+ currents , which are required for modeling sleep slow oscillation. A network of map-based pyramidal cells and inhibitory interneurons with synaptic connectivity similar to the cortical structure demonstrated the onset of slow oscillations that closely match the activity observed in experiments and in the conductance-based models. The high computational efficiency of this new approach makes it feasible for large-scale analysis of spatio-temporal dynamics and synaptic plasticity in multi-dimensional cortical models.

Title: Structural connectivity between cortex and thalamus determines temporal features of sleep spindles

Authors: *G. P. KRISHNAN[1], M. J. CHOINSKI[1], L. E. MULLER[2], D. J. HAGLER, Jr[3], S. S. CASH[5], T. J. SEJNOWSKI[2], E. HALGREN[4], M. BAZHENOV[6];

Hosp. and Harvard Univ., Boston, MA; [6]Cell Biol. and Neurosci., Univ. of California, Riverside, CA

Abstract: Sleep spindles are waxing and waning oscillatory activity (at 11-15 Hz) observed during stage II sleep. Individual spindles last about 0.3-2 seconds and recur at intervals from 2 to 15 seconds. MEG and EEG show significant differences in spindle occurrences, with about 50% of MEG spindles occurring without EEG spindles whereas only 15% of EEG spindles occur alone [1]. Spindles generated in the thalamus recruit cortical circuits. A core subsystem projects

focally to layer 4 of the cortex and a matrix subsystem projects more diffusely to apical dendrites of layer 5 neurons in layer 1. We previously hypothesized that difference between MEG and EEG signals may reflect difference between those projections [2]. In this study, we used computational modeling and laminar recordings from epilepsy patients to identify the mechanism that results in differences in spindle occurrence across different cortical layers. Laminar recordings showed higher probability of spindle occurrence (based on automated spindle detection) in middle layers (putative layers 3/4) compared to deeper layers (putative layers 5/6). Using a reduced thalamocortical model with only one cortical layer (with pyramidal and inhibitory neurons) and a corresponding thalamic network (thalamocortical and reticular neurons) we found that the interspindle interval and the probability of spindle occurrence in a given interval decreased with increases in the level of spontaneous miniature excitatory synaptic activity and increases in the fanout (number of efferent neurons connected) of thalamocortical and corticothalamic connectivity. We then simulated a multilayer cortex model, which included three layers for cortex (layer 3/4, 5 and 6) and separate thalamic neurons for core and matrix subsystems. The fanout of the thalmocortical and corticothalamic projections between matrix thalamic neurons to layer 5 neurons was made to be wider than the core thalamic neuron projections to layer 3/4. In the full model, spindles occurred more often in layer 3/4 than in layer 5, with a shorter median inter-spindle interval. In addition, the spindles in layer 5 were more synchronous across neurons compared to layer 3/4. Overall, this study demonstrates that differences in the projections between thalamus and cortex may determine the spatiotemporal features of spindle activity across cortical layers. References 1. Title: Enhanced sleep does not change light responsiveness

Authors: S. DISSEL[1], L. KIRSZENBLAT[2], J. DONLEA[3], M. KLOSE[1], R. WINSKY-SOMMERER[4], B. VAN SWINDEREN[2], *P. SHAW[5];
[1]Washington Univ. Sch. of Med., St. Louis, MO; [2]The Univ. of Queensland, Brisbane, Australia; [3]Univ. of Oxford, Oxford, United Kingdom; [4]Univ. of Surrey, Guildford, United Kingdom; [5]Anat. and Neurobio., Washington Univ. Sch. of Med. In St. Louis, Saint Louis, MO

Abstract: We recently reported that we could enhance sleep and thereby restore memory in the classic mutants rutabaga and dunce as assessed using both Aversive Phototaxic Suppression (APS) and courtship conditioning. In the APS, flies are individually placed in a T-maze and allowed to choose between a lighted and darkened chamber over 16 trials. During 16 trials, flies learn to avoid the lighted chamber that is paired with an aversive stimulus (quinine/ humidity). During review, an anonymous reviewer was adamant that our dataset was confounded: “Light responsiveness is influenced by sleep state, therefore, using a memory assay that is dependent on light response is a significant confound”. This claim was surprising since 1) sleep impacts all sensory modalities, 2) we test memory in awake behaving flies and 3) we included a large dataset demonstrating that sleep did not alter either photosensitivity or quinine sensitivity during waking. When queried further, the reviewer changed their minds noting that: ““it has long been known that light impacts sleep (Shang et al., 2008 and Shang et al., 2011)”. This was also surprising since this conclusion is contrary to the observation that sleep was increased primarily during the biological day when lights are on. Despite the large amount of contradictory evidence, both in our manuscript and the literature, we conducted a series of new experiments to further evaluate the reviewers’ hypotheses. We report that neither moderate nor extreme levels of sleep-induction impact photosensitivity over a range of light intensities ranging from ~100 lux to ~7,000 lux. Moreover, increased sleep did not alter fast phototaxis or the amount of locomoter activity following a light pulse. Importantly, sleep did not differentially alter the phase response curve following a 10 minute light pulse administered at either ZT-15 or ZT-21 compared to controls. Finally, we report that increased sleep does not change the response properties of PIGMENT DISPERSING FACTOR-neurons to dopamine as measured by Epac signaling as implied by the reviewers’ references. Consistent with our original results, we conclude that the increased sleep does not alter light responsiveness in flies.

Title: Possible human sleep replay of cortical activity patterns evoked by motor sequential learning

Authors: *J.-B. EICHENLAUB[1], X. WU[2], E. HALGREN[3], S. S. CASH[1];
[1]Neurol., Massachusetts Gen. Hospital, Harvard Med. Sc, Boston, MA; [2]Neurol., New York Univ., New York, NY; [3]Radiology and Neurosci., Kavli Inst. for Brain and Mind, Univ. of California, San Diego, CA

Abstract: It is now widely believed that the sleeping brain plays a key role in memory consolidation, and numerous studies have highlighted the occurrence of replay as a neural mechanism underlying such sleep-dependent consolidation. This concept, that neural activity during sleep recapitulates waking activity in a precise fashion, was first described in rodents with the identification of 'place cells'. These cells respond selectively to locations in space, and consequently fire in a sequential order while animals are trained to run along a given path. Importantly, these cells fire again in that same sequence during subsequent sleep, 'replaying' the initial run experience. In humans, neuroimaging studies have reported that brain structures involved in learning were reactivated during subsequent sleep, suggesting the occurrence of replay in human sleep as well. However, direct, electrophysiological evidence of replay in human is still lacking. Here, subjects implanted with macro-electrode arrays for long-term epilepsy monitoring were taught to produce a motor sequence before a nap. The task required the participants to press four numeric keys on a standard computer keyboard, repeating one sequence (e.g. 4-2-1-3-4-1) "as quickly and accurately as possible" for a period of 30 seconds. For each subject, the nap period following learning was scored off-line, and its hypnogram computed. Another sleep period, preceding the learning, was selected and used as baseline. NREM sleep (N2 and N3) were predominant during sleep periods. The analysis of the behavioral data revealed that the time to correctly execute the sequence decreased across 30s-trials, showing a gradual acquisition of the motor sequence during learning. To investigate the occurrence of

motor replay during sleep, we applied the template matching method developed by Louie and Wilson (2001). This method allows quantification of the degree of similarity between the spatiotemporal activity pattern during learning ("template") and those recorded during sleep periods ("targets"). Spatiotemporal patterns in the beta- (15-25Hz) and gamma- (70-110Hz) bands were analyzed separately. Our preliminary results show that the targets from a period of sleep after motor learning exhibit higher levels of similarity with the template than targets from a period of sleep preceding the learning, especially in the gamma band. These results suggest that the spatiotemporal dynamics of gamma activity that support motor learning are reproduced during subsequent sleep, providing direct, neurophysiological evidence for replay in human sleep.

Title: Behavior of noradrenergic A7 neurons during sleep and wakefulness

Authors: *V. B. FENIK[1,2], S. J. FUNG[1,2], M. H. CHASE[1,2], I. RUKHADZE[1];
[1]VA GLA Healthcare Syst., Los Angeles, CA; [2]WebSciences Intl., Los Angeles, CA

Abstract: The activity of hypoglossal motoneurons (HMs) is essential for maintaining upper airway patency. Therefore, a sleep-related depression of HM activity plays an important role in the pathogenesis of Obstructive Sleep Apnea. A loss of excitatory noradrenergic (NA) drive to HMs that is provided by pontine A7 neurons has been suggested to largely contribute to the depression of HMs during rapid eye movement (REM) sleep (Fenik et al., 2008). We sought to determine whether the behavior of A7 neurons during sleep and wakefulness supports their suggested role in sleep-related depression of HMs. Sprague-Dawley rats were chronically implanted for chronic recording of the EEG and neck EMG under surgical anesthesia. Experiments were conducted in head-restrained animals after they were fully adapted and displayed normal sleep-wake patterns. Spontaneous discharges of single units were isolated extracellularly in the A7 region (depth 6.6-8.5 mm from the cerebellum surface) on both sides using standard glass electrodes filled with sodium acetate that contained Pontamine Sky Blue to

iontophoretically mark recording sites. Brain sections were immunostained for tyrosine hydroxylase to visualize NA neurons and verify recording sites. Of the 30 units that were recorded in the A7 region, six were classified as A7 neurons based on the location of their recording sites, patterns of activity and durations of their action potentials. The A7 neurons were silent during REM sleep whereas other units that also had a state-dependent pattern of activity increased their firing rate during REM sleep (n=6), non-REM sleep (n=1) or during REM sleep and wakefulness (n=2). During non-REM sleep and wakefulness, A7 neurons had tonic low-frequency discharges. Their average firing rates were not different between non-REM sleep (0.97±0.4 (SE) spike/s) and wakefulness (1.06±0.2 spike/s, n=6, p=0.8, t-test). The average duration of their action potentials (including after-potentials) were larger than that of other units that were recorded with a bandwidth of 0-3000 Hz (2.2±0.2 ms (range: 1.8-3.1 ms, n=6) vs. 1.3±0.1 ms (range: 0.8-2.0 ms, n=10); $p<0.01$). Our findings suggest that A7 neurons are silent during natural REM-sleep. This is in agreement with their suggested role in the depression of HMs during REM sleep. Unexpectedly, we also found that the firing rates of A7 neurons are similar during both non-REM sleep and wakefulness. This finding does not support the role of A7 neurons in the inhibition of HMs during non-REM sleep and suggests that HMs are inhibited during non-REM sleep via different mechanisms.

Engin. and Sci., Massachussetts Inst. of Technol., Cambridge, MA

Abstract: During emergence from general anesthesia, the brain transitions out of the unconscious state and recovers its ability to process complex sensory information and coordinate behavior. Previous studies have suggested that this process is not simply the reverse of an anesthetic induction, but rather involves a distinct sequence of brain states. We studied emergence from general anesthesia in human subjects using both intracranial and scalp-based (EEG) measures of cortical activity. In the first study, we performed intracranial electrocorticography (ECoG) from 12 patients with pharmacologically intractable epilepsy, who had intracranial electrodes placed for clinical reasons. Patients were studied as they emerged from propofol general anesthesia, and the times of their first movement and first voluntary response to a verbal command were recorded. Auditory stimuli were presented every 3.5-4.5 seconds to assess the neural response to sensory information. We observed that after the propofol infusion was stopped, low-frequency power in cortex gradually decreased but patients remained unresponsive to stimuli for several minutes. During this period, a subset of auditory stimuli evoked large-amplitude field potentials lasting ~0.5-1.5 seconds. During these evoked responses, high-frequency (>30 Hz) power was suppressed, suggesting that auditory stimuli induced cortical DOWN-states. Both the morphology and spatial distribution of evoked waves were similar to K-complexes observed during non-rapid eye movement (NREM) sleep in the same patients. We next validated and extended these findings in healthy subjects using non-invasive EEG. We analyzed data from a previously reported study of 10 subjects in which 64-channel EEG was recorded during induction and recovery from propofol general anesthesia. Auditory stimuli were presented to subjects at 2 s intervals, and these stimuli included names, words and clicks. As in the intracranial recordings, we observed large-amplitude, slow (~1 s duration) sensory-evoked potentials during the recovery from general anesthesia, but before subjects regained the ability to respond to the stimuli. These results suggest that a brain state occurs during emergence from general anesthesia that shares some properties with stage 2 NREM sleep. In this state, slow oscillations are reduced compared with the anesthetized state and cortex is desynchronized and active, while sensory stimuli evoke cortical DOWN states. We propose that this phenomenon could be due to different recovery rates in cortical and thalamic structures, leading to a state in which cortex has recovered from anesthesia but thalamic nuclei remain suppressed.

Title: Understanding the mechanisms of hippocampal reactivation: from CA3 to CA1

Authors: *P. MALERBA[1], S. NAGL[2], G. P. KRISHNAN[1], J.-M. FELLOUS[2], M. BAZHENOV[1];
[1]Cell Biol. and Neurosci., UC Riverside, Riverside, CA; [2]Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Declarative memory consolidation involves interaction between cortex and hippocampus during sleep. Memory replay - repeatable sequences of pyramidal cell firing - has been demonstrated during sleep, and has been associated with characteristic brain oscillations, giving rise to the hypothesis that these may form the critical neural substrate of memory consolidation. The content of hippocampal replay can be biased during sleep, in what is called cued-reactivation, and such paradigms show enhanced memory performance in humans. Moreover, tampering with replay can disrupt memory formation and consolidation. Despite extensive evidence highlighting the importance of replay within the broader phenomenon of sleep-mediated memory consolidation, the neural mechanisms underlying hippocampal sequence replay are still unknown. During sleep, replay events are associated with specific patterns of neuronal oscillations. Replay is seen in cortex during slow oscillation - a rhythmic (< 1Hz) state in which periods of activity (active or Up states) alternate with quiet periods (silent or Down states), while replay in area CA1 of the hippocampus is associated with sharp-wave ripple events - brief irregular bouts of high frequency (>150 Hz) firing, driven by strong excitatory inputs coming from CA3, seen as a strong deflection in the LFP in the stratum radiatum (the sharp wave). We build on our previous research to develop a model of hippocampal spike sequence replay during sleep. In the past, we have introduced a model of CA1 ripples in which oscillations

are transients, mediated by the intrinsic frequency of CA1 basket cells driven by CA3 activation. In this work, we construct a model of CA3 in which stochastic intrinsic activation of pyramidal cells triggers a massive cell activation that results in a strong excitatory input to area CA1. We observe that sequential activation of a selected sub-group of CA1 pyramidal cells is driven by a less specific sequential activation in CA3. We use the model to study differences in CA3 and CA1 during sharp-wave ripples, and compare it to *in vivo* recordings in CA3 and CA1. We also characterize the mechanisms underlying sequence selection and reactivation within a sharp-wave ripple event. At the end, we use this hippocampal model to investigate the role of cortical inputs on ripple timing and their specific spike content. Our study illustrates the possible role of cortical Up states during slow oscillations in biasing hippocampal replay, which is a core component of the cortico-hippocampal interaction underlying memory consolidation.

Title: Interactions between cortical slow oscillations and hippocampal sharp-wave ripples during slow wave sleep

Authors: *P. SANDA, P. MALERBA, G. P. KRISHNAN, M. BAZHENOV;
Cell Biol. and Neurosci., Univ. of California, Riverside, Riverside, CA

Abstract: During stage 3/4 of NREM sleep the entire cortical network periodically alternates between silent (Hyperpolarizing, or Down) and active (Depolarizing, or Up) states with a period around 0.5-1 sec. In the CA1 region of hippocampus, activity bursts known as ripples emerge and are accompanied by sharp waves originated by activity in CA3 region and forming so called sharp wave ripples complexes (SWR). It has been proposed that information acquired during the day is quickly stored in the hippocampus and consolidated into long-term memory via

progressive sleep-mediated cortico-hippocampal interaction, in particular during slow-wave sleep. The exact mechanism of sleep-dependent consolidation is not yet understood, but experimental data suggest that hippocampal replay occurs during SWR. SWRs activity in CA1 is feed forward into cortex and interacts with its slow oscillatory dynamics, while cortical activity poses major input to the hippocampal complex, thus leading to a cortico-hippocampal loop. The precise form of the interactions within this loop is not known. In this study we present a computational model consisting of a thalamocortical network, which faithfully reproduces Up and Down states occurring during stage 3/4 NREM sleep in cortex and a hippocampal model including areas CA3 and CA1, which generates SWR activity. The SWR influenced the initiation of Up state in the cortical network with the likelihood of transition from Down to Up state increasing immediately following SWR. Further, the location of Up state initiation was dependent on specific firing of CA1 pyramidal cells during SWR. The effect of the SWR on the Up state initiation was dependent on the connectivity between hippocampal and cortical networks. Our study presents a model of how interaction between thalamocortical and hippocampal networks during sleep may organize timing of the major sleep elements - slow oscillation and sharp wave ripples complexes - as required for declarative memory consolidation.

Abstract: Sleep remains a mystery to neuroscience. Much has been learned from animal studies about the fundamental characteristics of sleep stages and the switching between them, establishing circuits in the brainstem, hypothalamus and the basal forebrain as important regulators of the sleep process, however the fundamental question of why we need to sleep is still left unanswered. Meanwhile, human evidence is compiling in favour of a strong and causal link between disordered sleep and mental illness, making the understanding of sleep more than an epistemological venture, and clinically highly relevant. Thus far, the isolated focus on the basic subcortical sleep regulators has been found insufficient in explaining the complex symptomatology of sleep disorders, and thus more recently attention has been directed towards the role of the cortical dynamics in sleep. The thriving development within the field of human neuroimaging, such as fMRI, EEG, and MEG, focussing on the large-scale patterns of spontaneous brain activity and characterising these in terms of functional connectivity, graph theory, and whole-brain computational modelling, has made it possible to test and apply more precise spatio-temporal hypotheses about the neuronal basis of sleep. One such hypothesis concerns the development of large-scale functional brain networks in the descent from wakefulness to deep sleep. Small-worldness is a global graph theoretical measure, which estimates the balance between integration and segregation of information in a network and has been successfully applied to describe structural as well as functional brain connectivity. Interestingly, large-scale networks derived from human sleep data recorded with EEG and fMRI respectively show conflicting results on this measure; with EEG sensor space networks becoming increasingly small-world from wakefulness to deep sleep across a range of frequency bands (Ferri et al 2008), and fMRI networks moving towards randomness in light sleep compared to wakefulness and deep sleep (Spoormaker et al 2010). Taking advantage of MEG's high temporal resolution, compared to fMRI, and robust source reconstruction methods, compared to EEG, we have revisited this question by applying state-of-the-art analysis methods of functional connectivity on MEG sleep data from 11 healthy participants. Estimating the small-worldness of source space networks in four different frequency carrier bands taken from periods of wakefulness, light sleep and deep sleep, we provide evidence in favour of the results from the fMRI study with a move towards randomness in light sleep being particularly clear in the theta and beta band.

Title: Evidence for human memory replay in cortex: an electrocorticographical study of spatiotemporal patterns in high gamma

Authors: *X. JIANG[1], I. SHAMIE[1], S. S. CASH[3], T. THESEN[4], E. HALGREN[2]; [1]Neurosciences, [2]Neurosciences/Radiology, UCSD, La Jolla, CA; [3]Neurol. Service, Massachusetts Gen. Hosp., Boston, MA; [4]Neurology/Radiology, New York Univ. Sch. of Med., New York, NY

Abstract: In slow-wave sleep, replay of hippocampal and neocortical activity that occurred in waking has been proposed as a mechanism of memory consolidation. Most previous studies have focused on the reactivation of spatio-temporal patterns comprising focal groups of neurons in the rodent hippocampus. However, given the broad activation of human neocortex in wakeful experiences and the high information volume in episodic memories, memory replay likely involves much larger neuron ensembles. In the human cortex, activities in the High Gamma band correlate with changes in local firing, and are associated with memory encoding. Recurrence of similar spatio-temporal High Gamma activity patterns in waking and in slow-wave sleep, therefore, may be indicative of memory replay. We analyzed long-term human electrocorticographical recordings to reveal consistent spatio-temporal pattern templates of highly distributed High Gamma activity in waking; these templates were used to match the High Gamma activity in the slow-wave sleep periods preceding ("Pre-sleeps") and following ("Post-sleeps") the waking period. In all subjects, the number of templates with more Post-sleep matches were significantly larger than that of templates with more Pre-sleep matches, providing evidence that human memory replay may occur in the cortex at a large scale.

Title: Distinct neural and cardiac parameters define the intermediate sleep state in mouse

Authors: *L. M. FERNANDEZ, A. LUTHI;
Univ. of Lausanne, Lausanne, Switzerland

Abstract: Human non-rapid eye movement sleep (NREMS) is subdivided into three major stages, each with distinct spectral characteristics and functional roles in sleep. In contrast, rodent NREMS is widely considered comparatively homogeneous. This notion is increasingly starting to change, as mouse NREMS not only shows on-going microarchitectural fluctuations (see Abstract by Lecci et al), but also exhibits a transitional period prior to REMS onset, also called Intermediate Sleep (IS). During IS, the cortex continues to show typical NREMS EEG features, such as sleep spindles (8-15 Hz), while oscillations characteristic for REMS, i.e. theta activity (6-10 Hz), already appear. To define whether IS represents a distinct sleep state, we asked: 1) Does IS display polysomnographic characteristics (EEG combined with EMG and ECG) distinct from consolidated NREMS? 2) Can we identify IS-specific neural circuit constellations generating distinct local field potential activity? 3) Can we attribute IS-specific neuronal discharge patterns in rhythm-generating neurons? 4) Does IS show cardiac activity patterns distinct from those of NREMS (high vagal tone) and REMS (high sympathetic tone)? To answer these questions, we explored sleep in habituated head-restrained mice, assessing behavioral states through conventional polysomnography (EEG/EMG), and we recorded simultaneously local field potentials (LFP) from high-impedance (~10-12 MOhm) electrodes chronically implanted in the dorsal hippocampus (dCA1) and in somatosensory (S1 and S2), auditory (A1), piriform (Pir), and medial prefrontal (mPFC) cortices. To establish IS structure (onset-offset) and spectral characteristics, common oscillatory events of NREMS and REMS were examined during IS: delta (1-4Hz), theta, spindles, ripples (150-250Hz), together with muscle tone progression toward REMS atonia, and the heart rate variability as an indicator of sympathovagal balance. The functional organization between areas and neural circuits was explored during IS and compared to NREMS and REMS. Furthermore, as spindles are prominent oscillatory events during IS, we recorded unit activity at their site of origin in the reticular thalamic nucleus. Our study broadens the view of rodent NREMS as a non-homogeneous state and identifies IS as a distinct constellation of neural and cardiac activities that point to a unique cortico-thalamic-hippocampal crosstalk associated with a switch in cardiac output.

Title: Elevating endogenous trace amine-associated receptor 1 tone promotes wakefulness

Authors: *M. D. SCHWARTZ[1], S. W. BLACK[1], J. B. PALMERSTON[1], S. B. SMITH[1], A. HARMEIER[2], M. C. HOENER[2], S. R. MORAIRTY[1], T. S. KILDUFF[1];
[1]Ctr. for Neurosci., SRI Intl., Menlo Park, CA; [2]Neurosciences Res., F. Hoffmann-La Roche, Ltd., Basel, Switzerland

Abstract: Trace amines (TAs) are endogenous amino acid metabolites that are structurally similar to the biogenic amines. TAs are endogenous ligands for trace amine-associated receptor 1 (TAAR1), a GPCR that modulates dopaminergic, serotonergic, and glutamatergic activity. Selective TAAR1 full and partial agonists exhibit similar pro-cognitive, antidepressant- and antipsychotic-like properties in rodents and non-human primates, suggesting TAAR1 as a novel target for the treatment of neurological and psychiatric disorders. Additionally, TAAR1 partial agonists are wake-promoting in rats, suggesting that TAAR1 is a previously-unrecognized component of an endogenous wake-modulating system. We previously reported that TAAR1 knockout mice (KO) exhibit increased sleep at lights-on and increased EEG gamma power (30-100 Hz) compared to WT littermates, and that the selective TAAR1 partial agonist RO5263397 increased waking and suppressed REM sleep in WT but not KO mice. Here, we report that TAAR1 overexpressing (OE) mice, in which TAAR1 is ectopically expressed throughout the brain, exhibit a complementary sleep/wake phenotype to TAAR1 KO mice and that the TAAR1 full agonist RO5256390 disrupts sleep in WT mice. TAAR1 KO, OE and WT mice were instrumented for EEG and EMG recording and implanted with telemetry transmitters for monitoring locomotor activity (LMA) and core body temperature. Following recovery, mice were recorded continuously under 12:12 LD conditions. OE mice spent more time awake over a 24h period compared to WT littermates and exhibited sustained waking during a 6h sleep deprivation compared to WT littermates. EEG spectral power was decreased in the theta (4-9Hz) and gamma bands compared to KO mice, with WT spectra intermediate between them. RO5263397- and caffeine-induced waking was potentiated in OE mice compared to WTs. In separate studies, the full agonist RO5256390 administered p.o. at ZT6 suppressed REM sleep, increased wake bout number and reduced NREM bout duration. In summary, elevating TAAR1 tone via overexpression or pharmacology tends to increase waking and decrease high-frequency EEG activity, whereas TAAR1 deletion has the opposite effect. TAAR1 partial agonism may

have greater wake-promoting efficacy than full agonism. Studies to evaluate the effects of these compounds on sleep-wake regulatory brain populations are in progress.

Title: Incomplete behavioral and neurological recovery following chronic short sleep

Authors: *S. C. VEASEY, R. XIN, P. FENIK, G. ZHAN, Y. ZHU;
Ctr. for Sleep, Suite 2100, Univ. Pennsylvania, Philadelphia, PA

Abstract: Chronic intermittent short sleep is pervasive in modern society, where it is generally believed that weekend catch up sleep restores brain function and health. We recently determined that short sleep across a 1 wk period results in metabolic injury to and loss of locus coeruleus neurons. Here we tested the hypothesis that metabolic injury, neuron loss and wake impairments do not fully recover with 4 wk recovery sleep. We found, not only a loss of locus coeruleus neurons (50% reduction, $p<0.001$), but also orexin neurons (40% reduction, $p<0.001$), yet the adjacent sleep-active melanin-concentrating hormone neurons conferred protection. Neuron stereologic counts remained reduced after 4 wk recovery, while wake impairments and metabolic stress persisted. Persistence of lipofuscin in wake-active locus coeruleus and orexinergic neurons along with reduced sirtuin type 1, support the concept that chronic intermittent sleep loss prematurely ages select populations of neurons, including locus coeruleus and orexinergic neurons. In light of the irreversible locus coeruleus injury and loss, the work provides a potential link between chronic short sleep and neurodegenerative processes.

Title: Global connectivity changes in procedural learning and cognitive training

Authors: ***A. NIKOLAIDIS**, T. TALUKDAR, A. BARBEY, A. KRAMER;
Univ. of Illinois Champaign Urbana, Urbana, IL

Abstract: Cognitive training aims to use paradigms that make demands on cognitive and motor systems such that participants improve on untrained tasks, a phenomenon known as transfer. These transfer effects show promise for future cognitive training research, yet they are often difficult to replicate. These failures to replicate are due to a lack of understanding how training induces changes in the brain, and subsequently how these changes drive transfer. Prior research suggests that over the course of training, the procedural, motor, and cognitive networks involved in task acquisition and performance should change as training progresses; however, experimental evidence and understanding of how training remodels these networks is lacking. In the current study, participants trained for 20 to 30 hours with a multimodal computerized training paradigm called Space Fortress that places demands on motor control, short-term memory, and executive control. At pre and post training, participants were scanned using fMRI while playing Space Fortress in the MRI scanner. We examine how global brain connectivity changes from pre to post training using multivariate distance-based matrix regression (MDMR). This analysis technique can be used to investigate whether inter-individual whole-brain connectivity patterns are related to variation in one or more phenotypic variables of interest (e.g. clinical diagnosis, behavioral performance, intervention groups). Using MDMR, we investigate which brain regions demonstrate significant changes in global connectivity profiles from pre to post training. We find a set of motor areas, such as the left precentral and postcentral gyrus, visual-attention areas, such as the lateral occipital cortex, and regions implicated in executive function, such as the anterior cingulate cortex and paracingulate cortex, which change significantly in global connectivity from pre to post training (FDR corrected $p < 0.05$). Using descriptive post hoc analyses, we extract graph theoretic properties of the networks involved in these regions, and assess what network topological properties change as a function of training. These results characterize network

reorganization that occurs as a function of a complex multimodal cognitive training paradigm, and motivate future work into descriptions of network plasticity during training.

Title: Focus of attention has differential effects upon short-latency afferent inhibition across practice

Authors: L. Y. SUZUKI, *S. K. MEEHAN;
Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Instructions orienting the attention of the learner towards elements of the environment (an "external focus") rather than the action of their body (an "internal focus") have been shown to enhance learning. While the benefits of an external focus have been quantified extensively using behavioral measures the neural substrates of the external focus are less understood. The purpose of the current study was to investigate changes in motor cortical networks throughout motor practice under different foci of attention. Two groups of participants practiced a discrete sequence of finger movements under differing instructions that emphasized and internal or external focus of attention. The external focus (EXT) group was instructed to concentrate on pressing the correct keys. The internal focus (INT) group was instructed to concentrate on moving the correct fingers during the sequence. To determine changes in intracortical networks, the magnitude of short-latency afferent inhibition (SAI) was quantified in first dorsal interosseous muscle (FDI) using motor evoked potentials elicited by single pulse TMS at various points during practice. For both groups retention of both behavior and changes in SAI was assessed 24 hours post-practice. We hypothesized that SAI of FDI MEPs would be reduced across practice for both groups, however, the extent of SAI reduction would be greatest for the EXT group. Further, we hypothesized that SAI of FDI MEPs evoked during key presses in the sequence not involving the FDI would be reduced for the EXT but not INT group during late practice blocks and the retention test. Preliminary results support our hypotheses, SAI was reduced to a greater extent in the EXT compared to INT group on elements in the sequence that required index finger movement following practice. Further, for elements of the sequence not involving the FDI, the reduction in SAI in the FDI was greater for the EXT group compared to

the INT group. These results suggest that an external focus of attention promotes greater plasticity and formation of muscle synergies.

Title: Cognitive processes contribute to behavioral gains during motor reconsolidation

Authors: ***N. F. WYMBS**[1,3], A. J. BASTIAN[2,3], P. A. CELNIK[1,2];
[1]Physical Med. and Rehabil., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Kennedy Krieger Inst., Baltimore, MD

Abstract: Reconsolidation mediates the updating of consolidated memory. We have recently shown that a motor skill is strengthened when the reactivated skill is practiced in an environment that promotes increased sensorimotor variability. This gain appeared to be mediated by top-down strategic processing. Since strategy is supported through cognitive control processes, we wondered if taxing these processes could affect the expression of skill strengthening. To test for the role of cognition during motor skill reconsolidation, we used a dual-task procedure during the reconsolidation intervention. In 3 sessions (4 blocks of 30 trials each), participants learned to control the lateral displacement of a cursor to a sequence of 5 targets using a logarithmic transduction of pinch force (SVIPT). Following the initial session (0 hr), participants returned after a 6-hour delay (period needed to consolidate the task) and the following day (24 hr). During session 2 (6 hr), participants reactivated the skill and then either continued to train on the original SVIPT, or instead, on a modified version of the original SVIPT that we have previously shown to strengthen skill through reconsolidation. During this session participants also performed a secondary auditory frequency discrimination task. This required deciding if the last tone in a series was higher or lower in frequency than the first tone. We manipulated cognitive load: one group received high load, hearing as many as 4 tones in series, whereas a second group received low load and always heard 2 tones. We quantified the effect of the intervention, or skill

strengthening, as the pre/post intervention change in original SVIPT skill (first block 24 hr - last block 0 hr). We found that skill strengthening was blocked when performing the modified SVIPT under high cognitive load, but preserved when participants were exposed to the modified SVIPT under low cognitive load. Similar to our previous results, we found that repeated training on the original SVIPT during the intervention had little effect on skill strengthening. Further, the high load condition blocked within-session (session 2) performance improvement regardless of exposure to the modified or original SVIPT intervention. However, low load did not affect within-session improvement during the modified SVIPT. Interestingly, we found that participants that benefitted the least from the modified SVIPT intervention also had the lowest accuracy on the tone task when tested under high load. These findings suggest that strengthening of a motor skill following reconsolidation involves top-down strategic processing after the reactivation of a consolidated skill.

Title: The effects of action observation on obstacle avoidance strategies in patients with chronic stroke

Authors: *Y.-G. SONG[1,3], J.-H. PARK[2];
[1]Korea Univ., Seoul, Korea, Republic of; [2]Physical Educ., Korea Univ., Seoul, South Korea, Korea, Republic of; [3]Dept. of Sport Sci., Sungkyunkwan Univ., Gyeonggi, South Korea, Korea, Republic of

Abstract: Functional locomotor disability is a common consequence of stroke and much attention has been recently given to the use of alternative training strategies to promote motor rehabilitation for individuals with stoke. This study was designed to investigate how task-oriented training using action observation influence rehabilitation of locomotor behaviors during obstacle crossing in stroke patients. Eighteen patients with chronic stroke participated in the experiment and were divided into two groups: an action observation group (n=9) and a non-action observation group (n=9). Patients in the experimental group practiced obstacle crossing tasks after watching video clips showing a normal obstacle crossing action while patients in the control group underwent the same procedure of rehabilitation training except for the video clips.

Patients participated in a 6-week training program, 3 times per week for 1 hour per session. The primary finding indicated that there were greater increases in knee flexion in the experimental group particularly for increased obstacle heights after the training. In contrast, no significant change was found for other measures of gait parameters between groups following intervention. Taken together, these findings suggest that the use of action observation intervention strategy potentially optimizes functional locomotor performance such as obstacle crossings in stroke by incorporating motor imagery, especially when observing movements with intent to imitate.

Title: Visuomotor skill learning and accompanying changes in corticospinal excitability: Causal relation or epiphenomena?

Authors: *L. CHRISTIANSEN[1,2], E. BOJSEN-MØLLER[1,2], M. A. J. MADSEN[1,2], R. THOMAS[1,2], J. B. NIELSEN[1,2], J. LUNDBYE-JENSEN[1,2];
[1]Dept. of Nutrition, Exercise and Sports, Univ. of Copenhagen, Kobenhavn N, Denmark; [2]Dept. of Neurosci. and Pharmacol., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: *Objectives* Skill acquisition is accompanied by increased corticospinal excitability and motor cortical representations. It is unclear whether these changes relate to the process of skill acquisition or task performance as shown in expert musicians and athletes. To address this question we compared the effects of a progressive (PT) versus non-progressive (NPT) long-term motor learning protocol. We hypothesized that progressively increasing task difficulty during training would cause incremental increases in corticospinal excitability and improved motor performance. *Methods* Two groups of subjects practiced a visuomotor task requiring precise abduction-adduction control of the fifth digit. Task difficulty remained constant in the NPT group whereas it was progressively increased in the PT group. Corticospinal excitability was assessed through application of transcranial magnetic stimulation of the primary motor cortex prior to and following 2, 4 and 6 weeks of training and after 8 days of detraining. *Results* After 6 weeks, both groups improved visuomotor performance at the baseline task difficulty with no

between-group difference. In contrast, the PT group demonstrated significantly better visuomotor performance at an advanced task level. Both groups showed increased corticospinal excitability after 2, 4 and 6 weeks of training in terms of a decline in motor threshold, but only the PT group demonstrated larger maximal motor evoked potentials with long-term training. *Conclusions* The study demonstrates that progressively increasing task difficulty during visuomotor skill acquisition is accompanied by improved motor skill performance and additional changes in corticospinal excitability. The findings underline the importance of continuously challenging patients and athletes in order to maximize recovery and performance. Title: Increases in cognitive effort diminishes the contextual interference effect

Authors: C. A. AIKEN, A. T. MOSS, *A. W. VAN GEMMERT;
Kinesiology, Louisiana State Univ., Baton Rouge, LA

Abstract: Research has shown that practicing a task in the context of other tasks leads to improved retention performance of the task(s). This phenomenon is commonly referred to as the contextual interference effect (Shea & Morgan, 1979; Lee & Magill, 1985). A potential explanation for this phenomenon is that the amount of cognitive effort increases as the amount of contextual interference increases which results in improved learning (Lee, Swinnen, & Serrien, 1994). The purpose of this study was to investigate the effects of increased cognitive effort on the contextual interference effect. 47 individuals volunteered to participate in the study. All participants learned three variations of a graphic aiming task that required them to draw from one target (r=0.5cm) to another target (r=0.5cm) while avoiding a stationary barrier within exactly two, three, or four seconds. Each task was repeated 30 times; however, the schedule structure of training was either blocked (i.e., 30 trails of each task in sequence) or random (i.e., the three tasks randomly distributed across the 90 trials). Half of the participants performed these tasks

only, while the other half of the participants performed the timed aiming tasks with a secondary arithmetic task to increase cognitive effort (i.e., the 47 participants were distributed over the 4 groups). Five minutes following acquisition, a 6 trial random retention test was performed. The dependent variables were calculated using the criterion and movement time; i.e., absolute error (AE), constant error (CE), and variable error (VE). Acquisition was analyzed with separate 2 (schedule) x 2 (cognitive effort) x 2 (block: first and last block of acquisition) mixed factors ANOVAs for AE, CE, and VE. 2 (schedule) x 2 (cognitive effort) x 2 (block: first acquisition block and retention) mixed factor ANOVAs were applied to measure retention. During acquisition all groups significantly decreased AE ($p<.001$). Increased effort resulted in more bias, i.e., higher CE ($p<.01$). There was also a main effect of schedule ($p<.05$) and effort ($p<.05$) for VE. Increased effort with more interference resulted in less consistency during acquisition. During retention there was a main effect of effort for AE ($p<.05$) with increased effort having more error. There was also a main effect of schedule for VE ($p<.05$) with blocked practice having more error during retention. Random practice increased consistency but did not increase movement time accuracy, while the increase in cognitive effort diminished the contextual interference effect for the magnitude of error.

Title: Contributions of finger movements to cognitive tasks

Authors: *Y. ITAGUCHI, C. YAMADA, K. FUKUZAWA;
Waseda University, Psychology Dept., Shinjuku-Ku Tokyo, Japan

Abstract: The present study investigated the relationships between motor action and cognitive processing with particular reference to kanji-culture individuals. Kanji-culture individuals often move their finger as if they are writing when they are solving cognitive tasks, for example, when they try to recall the spelling of English words. This behavior is called kusho, meaning air-writing in Japanese. However, its functional role is still unknown. To reveal the role of kusho behavior in cognitive processing, we conducted a series of experiments, employing two different

cognitive tasks, a construction task and a stroke count task. Methods In total, 159 students participated in the experiments, and were assigned to one of four experiments: 1) kusho elicit tasks, 2) a character construction task, 3) other versions of the character construction task, and 3) a stroke count task. Except for the experiment 1, the participants executed the tasks in three hand conditions; participants were instructed to use either kusho, unrelated finger movements or do nothing during the response time. To isolate possible visual effects, two visual conditions in which participants saw their hand and the other in which they did not, were introduced. In the experiment 1, we examined the frequency of the occurrence of spontaneous kusho behavior, and in the other experiments we recorded the number of correct responses and response time as measures of the task performance. Results and Discussion The results showed that kusho behavior has different functional roles in the two types of cognitive tasks. In the construction task, the visual feedback from finger movement facilitated identifying a character, whereas the kinetic feedback or motor commands for the behavior did not help to solve the task. In the stroke count task, by contrast, the kinetic aspects of the finger movements influenced counting performance depending on the type of the finger movement. Regardless of the visual condition, kusho behavior improved task performance and unrelated finger movements degraded it. These results indicated that motor behavior contributes to cognitive processes.

Title: Primary motor cortex inhibition depresses non-motor procedural learning

Authors: *E. M. WASSERMANN[1], P. J. KOSHY[1], A. STEEL[2], D. BAGEAC[1], L. WILKINSON[1];
[1]NIH/NINDS, Bethesda, MD; [2]NIH/NIMH, Bethesda, MD

Abstract: Previous research has shown that inhibitory repetitive transcranial magnetic stimulation (rTMS) of the primary motor cortex (M1) impairs motor sequence learning, but not basic motor function, e.g., reaction time and movement speed. It is not known, however, if the effect is specific for motor forms of procedural learning or whether M1 stimulation affects

procedural learning in general. To investigate this question, we tested the effect of M1 inhibition on the weather prediction task (WPT), a probabilistic categorization task with no motor learning component, under two behavioral conditions. In a between groups design in healthy individuals, we delivered rTMS, using the continuous theta-burst (cTBS) paradigm, for 40 s with a real or sham coil, after which subjects performed the WPT. In the WPT, subjects are required to learn an arbitrary, probabilistic, association between a set of meaningless cue cards and arbitrary outcomes, i.e. if the weather will be rainy vs. fine or hot vs. cold. Subjects indicated their responses by pointing and clicking with a mouse. In the "Feedback" condition, subjects were told whether their response was correct and received monetary reward/punishment after each trial of 150 trials. In the "Observational" condition, subjects observed cue-outcome associations passively and were then tested on their knowledge with 150 trials without feedback. The conditions were performed in separate sessions. The proportion of correct responses was calculated for blocks of 50 trials. Compared to sham, cTBS over M1 reduced performance significantly in the last (3rd) block in the Feedback condition, while observational learning was unaffected. Inhibitory rTMS of M1 seems to impair procedural learning even when the motor demand of the task is minimal. Explicit (observational) learning appears to be spared. We infer that M1 is part of a network with a general role in procedural learning.

Title: Altered human memory modification in the presence of normal consolidation

Authors: *N. CENSOR[1,2], E. R. BUCH[2], K. NADER[3], L. G. COHEN[2];

Abstract: Following initial consolidation during which the memory is stabilized, subsequent modification of memory strength and its reconsolidation are crucial for further learning. Yet, it is not clear whether consolidation and memory modification are the same or different processes. Here, we report disrupted memory modification in the presence of normal consolidation of human motor memories, which relate to different structural features of white-matter integrity. Chronic stroke patients and healthy aged-matched controls performed a sequence of finger movements on three separate days. On Day 1 performance was tested immediately after training. On Day 2 subjects performed test trials to measure consolidation from Day 1 and to reactivate the originally trained memory. On Day 3, they performed retest trials to evaluate memory modification from Day 2. Patients showed efficient initial consolidation (mean performance gains between Days 1 and 2 of 25.6%±8.6% standard error, $P<0.03$). However, memory modification was impaired (no significant performance gains between Days 2 and 3, -8.9%±7.7%, $P=0.45$). Consolidation and memory modification magnitudes were significantly different ($P<0.03$). Impairments were evident only when the memory was reactivated and could not be explained by a ceiling effect on performance. Age-matched healthy controls showed efficient consolidation but showed also efficient memory modification (10.6%±2.6%, $P<0.004$), significantly higher than patients ($P<0.02$). Memory modification impairments were then related to structural network architecture using a graph-theoretical network analysis approach and to local white matter microstructural integrity using diffusion-weighted MRI. We measured the degree to which each nodal brain region integrates information between all other nodal pairs in the structural network, nodal betweenness centrality. Memory modification only correlated with the difference in nodal betweenness centrality between patients' and normals' networks in the contralesional medial-frontal gyrus (MFG, $r=0.83$; $P<0.005$). We then related memory modification with extralesional white-matter microstructural integrity, measured as fractional anisotropy (FA). Memory modification only correlated with FA in three contralesional hemisphere white-matter regions ($P<0.005$): underlying MFG, the vicinity of the precentral gyrus and the anterior intraparietal area. The results reveal mechanistic differences between consolidation and subsequent memory modification in human procedural learning. This knowledge may help guide interventional strategies to enhance brain function and resulting behavior.

Title: M1 activity during action observation co-varies with subsequent behavioral changes in spontaneous rate of execution

Authors: *N. ARIDAN[1], R. MUKAMEL[1,2];
[1]Sch. of Psychological Sci., [2]Sch. of Neurosciences, Tel-Aviv Univ., Tel Aviv, Israel

Abstract: Observation of people performing movements facilitates motor planning, execution and motor memory formation. Rate, an important feature in the execution of repeated movements, has been shown to vary following movement observation although the underlying neural mechanisms are unclear. The discovery of regions in the monkey and human brain which share representations of execution and observation of motor actions may provide the neural infrastructure for such adaptations. In this study, we examined whether: first, the rate of self-paced index finger-pressing is implicitly modified following passive observation of a similar action performed at a different rate; second, in which brain regions the fMRI BOLD signal during action observation co-varies with the change in the subsequent spontaneous rate of execution. In the first experiment, fifty subjects performed a finger pressing sequence with their right hand at their own pace before and after passive observation of a video depicting the task performed at 3 Hz by someone else. Across subjects, spontaneous execution rate had a bimodal distribution with modes of 2 and 4.2 Hz. Following video observation, the slower subjects performed the task at an increased rate. In the second experiment, an additional set of 15 subjects performed the task in the fMRI scanner and observed a 4 Hz video. We found positive correlation between fMRI signal in the left primary motor strip during video-observation and implicit behavioral change in task performance rate ($r=0.89$, corrected for $q(FDR)< 0.05$). We conclude that observing someone else perform an action at a higher rate, implicitly increases the endogenous rate of execution and that this implicit induction is mediated by activity in the contralateral primary motor-cortex.

Abstract: Sequence learning is a prominent component of skill learning, which is involved in obtaining not only motor but also cognitive and social skills. However, the neural basis of the formation of this fundamental learning mechanism still remains poorly understood. The present study aimed to investigate 1) the functional connectivity (FC) networks which promote successful implicit sequence memory formation 2) and the dynamical changes of network connectivity as a function of time during learning. Young adults (N = 28) performed the Alternating Serial Reaction Time (ASRT) task while 128 channel EEG recording was performed. ASRT can measure general skill and sequence-specific learning. Phase synchronization in 7 frequency bands was used to quantify FC between cortical regions during the first, second, and third part of the learning task. According to the results of linear regression analysis, the sequence-specific learning performance was associated with an increase of FC in the posterior brain regions exclusively mediated by fast brain oscillations (beta) together with a decrease of FC in the frontal network driven by slow oscillations (theta, delta). In line, a prominent decline of FC in slow oscillatory networks together with an increase of FC in fast oscillatory network was observed as a function of time elapse. Our results indicate that implicit learning processes are provided by fast oscillation in posterior cortices while frontal slow rhythms linked with attentional monitoring. In conclusion, a dynamic antagonist relationship between the brain networks of automatic and controlled processes may serve a hallmark of implicit sequence learning.

Title: Learning an internal representation of a deep convolutional neural network model for pose-based human action recognition

Authors: *J.-C. PARK, Y. JANG, C. NAM, J. JUN, H. CHOI, D.-S. KIM;
Dept. of Electrical Engin., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: How humans recognize and imitate others motor actions? It has been an important issue in the cognitive developmental robotics research to explain the internal mechanism of humans' action learning process and to make an intelligent robot mimicking an ability of humans. Hence, there have been computational studies using a neural network model to recognize and imitate human motor behaviors. A Deep Neural Networks (DNN) which consist of multi-layered Convolutional neural networks (CNNs) in these days has successfully extracted most relevant features hierarchically for recognizing visual objects. Moreover, they are learned positional-invariant feature by itself from dataset due to a subset of connection weight is shared. They also have been used to extract spatiotemporal features of time-series for an audio classification. In this study, we designed a deep neural network model which consists of a CNN, fully connected feedforward neural network and softmax neural network to be able to classify a sequence of human actions. The HDM05 dataset, which is a motion capture dataset containing more than 70 motion classes, was used to train our model. An input of the network, therefore, is a set of normalized vectors containing joint angles which length is T. The lengths of each input data T represents the lengths of the motor sequence. Due to duplication issue, we used 65 motion class reduced by merging redundant classes. To improve the robustness of the local movement (e.g. moving only left arm), the first layer is splitted into the five CNNs of which input are five sub-part of the whole body (head, left arms, right arms, body, left leg, and right leg). The network was trained with the backpropagation algorithm with a loss function which are reducing a classification error. As a result, the fully-trained network showed 75% of classification accuracy. Additionally, we visualized internal representation of the first convolutional layer, and relevant spatiotemporal motion features were found. It means that an agent equipped with a deep neural network can successfully recognize 65 different motor behaviors. Furthermore, it may memorize its experience as a set of primitive actions. To reveal this more precisely, we plan to investigate the internal representation of the higher layers by using up-to-date visualization technique for the deep convolutional neural networks for the future works.

Title: Effects of cerebellar transcranial direct current stimulation on fine motor sequencing skill

Authors: ***R. E. SHIMIZU**[1], A. D. WU[2], X. GUO[1], B. J. KNOWLTON[1];
[1]UCLA Psychology Dept., Los Angeles, CA; [2]UCLA Neurol. Dept., Los Angeles, CA

Abstract: The cerebellum plays a significant role in motor learning (c.f., Doyon et al., 2003) and performance (e.g., Horwitz et al., 2000). Anodal transcranial direct current stimulation (tDCS) applied to the cerebellum has been demonstrated to increase excitability (Galea et al., 2009). The current study examined the effect of cerebellar anodal tDCS on learning and performance on a fine motor sequencing task. During a training phase, participants practiced three 8-element key press sequences in a non-repeating, interleaved order while receiving either anodal ($N = 23$) or sham ($N = 21$) stimulation. A transfer phase immediately followed in which participants received three novel sequences in an interleaved order. No stimulation was given during the transfer phase. A main effect of stimulation condition was found such that the anodal group had faster response times compared to the sham group during the training phase ($p = .019$) and during the transfer phase ($p = .032$). Furthermore, the anodal group exhibited learning over time during the training phase ($p = .005$) but the sham group did not ($p = .449$). Thus, anodal tDCS to the cerebellum resulted in online enhancement of performance, and this effect continued to last after the cessation of stimulation. This post-stimulation benefit occurred for sequences that had not been practiced in the training phase when stimulation was delivered. These results suggest that tDCS may be a relatively inexpensive yet effective way to improve fine motor skills.

Title: Procedural memory is not uniformly intact in individuals with traumatic brain injury

Authors: *S. CROOKS, M. DUFF, N. KLOOSTER;
Communication Sci. and Disorders, Univ. of Iowa, Iowa City, IA

Abstract: Memory deficits are common following traumatic brain injury (TBI). A long held assumption is that declarative memory is disproportionately impaired while procedural memory is left intact. In fact, preserved procedural memory is often suggested as a possible mechanism to leverage in rehabilitation and efforts aimed at new learning (e.g., errorless learning; positive everyday routines). This assumption, however, has not received extensive empirical study, nor has there been a systematic examination of the different forms of procedural memory. Given that TBI is associated with diffuse neural damage, we hypothesized that the underlying neural structures supporting different forms and aspects of procedural memory would be vulnerable in TBI and some percentage of patients would have procedural memory deficits. The current study examines the acquisition and maintenance of different forms of procedural memory in a group of individuals with TBI (N=18) and a group of healthy comparison participants with no history of neurological disease or injury, demographically matched to each patient. Participants with TBI varied in severity from mild to severe, were at least 6-months post-injury and were recruited from the Iowa Traumatic Brain Injury Registry. All participants were tested on a comprehensive battery of procedural memory tests including Rotor Pursuit (RP), a measure of motor learning, Mirror Tracing (MT), a perceptual skill, and the Serial Reaction Time Task (SRT), which measures sequence learning, a cognitive skill. We repeated the battery on a subsequent visit 3 to 6 months later. On the initial visit, we found that 17 of the 18 (94%) participants with TBI were impaired on at least one of the procedural memory tasks (44% impaired on RP; 50% impaired on MT; 56% impaired on SRT) and that 8 of the 18 (44%) were impaired on 2 or more of the tasks. Those individuals with TBI who demonstrated learning on a given task on the initial visit were able to maintain this learning on the subsequent visit, indicating that leveraging procedural memory in rehabilitation efforts may benefit certain patients. These results suggest that the procedural memory system is not uniformly intact following TBI and challenges the traditional view that procedural memory is largely preserved in TBI. These results also suggest individualized interventions based on specific patterns of memory impairment (within and across memory systems) may be a more fruitful approach towards the rehabilitation of TBI.

Title: Spatiotemporal discrimination and recall in neural networks with short-term synaptic plasticity

Authors: *P. MILLER[1], B. SHLAER[2];
[2]Swartz Ctr. for Theoretical Neurosci., [1]Brandeis Univ., Waltham, MA

Abstract: Strongly coupled pools of cells in recurrently connected neural networks exhibit bistability, which allows for stimulus information to persist for very long times. However, it is difficult for such pools to encode temporal information about a sequence of stimuli without short-term synaptic plasticity. Synaptic depression is a biophysically described transient decrease in synaptic transmission strengths caused by increased presynaptic activity which destabilizes attractor states and thus causes the network to move along trajectories that depend on the temporal content of stimulus sequences. It has been shown that such a network can independently encode stimulus amplitude, duration, and numerosity (Miller, P., Front. Comput. Neurosci. 7:59, 2013), which makes it a strong candidate for successful encoding of spatiotemporal information. We demonstrate the capability of such a network to discriminate different spatiotemporal stimuli. We also show that such networks can perform both discrimination and recall tasks. Additionally, we demonstrate that the experimentally known phenomena of primacy (fewer task errors involving the first few stimuli) and recency (fewer task errors involving the last few stimuli) are reproduced in those networks able to accumulate information across long sequences of stimuli. Shown in the figure below is the neural activity within a network receiving two successive stimuli. Despite starting from the same state, the activity resulting from AB (top) is distinct from that resulting from BA (bottom). Additionally, stimulus A alone (top middle) or B alone (bottom middle) are distinct from all states, including the initial state (left of either).

Title: Caudate functional connectivity mediates the association between mindfulness and implicit learning

Authors: ***C. M. STILLMAN**[1,4], X. YOU[5], K. L. SEAMAN[7], E. C. RASMUSSEN[2], C. J. VAIDYA[2,6], R. S. TURNER[3], J. H. HOWARD, Jr.[8,3,9], D. V. HOWARD[2,9];
[1]Dept. of Psychology, [2]Psychology, [3]Neurol., Georgetown Univ., Washington, DC; [4]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [5]Neurosci., [6]Children's Natl. Med. Ctr., Washington, DC; [7]Psychology, Yale Univ., New Haven, CT; [8]Psychology, The Catholic Univ. of America, Washington, DE; [9]Ctr. for Brain Plasticity and Recovery, Washington, DC

Abstract: Accumulating evidence shows a positive relationship between mindfulness and explicit cognitive functioning, or that which occurs with conscious intent and awareness. However, two recent studies report a negative relationship between mindfulness and implicit types of learning, or those that occur without conscious awareness or intent (Stillman et al., 2014; Whitmarsh et al., 2013). This apparent dissociation between implicit and explicit processes raises the possibility that mindfulness may not be beneficial in all cognitive domains. The

negative relationship between dispositional mindfulness and implicit sequence learning (IL) reported in Stillman et al. 2014, and the potential neural mechanisms behind it, were the focus of the present fMRI study. Specifically, we examined whether the relationship is mediated by communication, or functional connectivity, of learning-relevant brain regions: the caudate and medial temporal lobe (MTL). Forty-two older adults (ages 60-90) completed the Mindful Attention Awareness Scale, followed by three event-related runs (15-min each) of an IL task, the Triplets Learning Task (TLT). In the TLT, participants respond to sequences of events in which a probabilistic regularity is embedded. Unbeknownst to them, some events occur with high (HP) and others with low probability (LP). IL is assessed by comparing reaction times to HP vs. LP events. Mindfulness was negatively associated with IL in the TLT, replicating the results of our earlier study. We next examined the neural basis of this relationship using an anatomically-defined bilateral caudate seed. Seed-based voxel-wise analyses were conducted in SPM 8 to generate connectivity maps of the seed for each subject on each run of the TLT. These maps were entered into a repeated-measures ANCOVA with session as the repeated factor and learning as the covariate of interest, and with age and overall task speed as nuisance covariates. Learning was positively associated with caudate connectivity to the MTL at all runs, as revealed by a main effect of learning in the left (peak MNI: x, y, z = -24, -13, -17; p 64, corrected) and right (x,y,z = 45, -13, -26; $p < .0005$, $k > 64$, corrected) MTL. In addition, the cross-run average connectivity between the caudate seed and both MTL clusters was negatively associated with mindfulness. Further, caudate/MTL connectivity significantly mediated the mindfulness-IL relationship. Thus, the degree of connectivity between the caudate and MTL, regions central to traditionally dissociable learning systems, may be a neural mechanism by which mindfulness impairs IL.

Title: Neural substrates of enhanced intermanual skill transfer during online manipulation of visual feedback

Authors: *O. OSSMY[1], R. MUKAMEL[2];
[1]Tel Aviv Univ., Tel Aviv, Israel; [2]Tel-Aviv Univ., Tel-Aviv, Israel

Abstract: In the realm of motor skill learning it has long been known that physical practice with one effector results also in performance gains of another (un-practiced) effector. Here, we examined the role of sensory feedback (visual and tactile), and its neural correlate, on the transfer of motor skills across hands in humans. To this end, we manipulated visual feedback of right-hand finger movement through the use of 3D Virtual Reality devices. 18 subjects learned a novel motor skill (sequence of finger movements) through physical training with their right hand, while real-time movement-based visual feedback of their left hand fingers was provided. We found that this manipulation facilitates inter-manual transfer and enhances performance gains with the untrained (left) hand. Additionally, we examined whether adding passive left-hand movement to the manipulated visual input can further enhance the transfer effect. Using a custom-built device, 18 additional subjects trained on a similar task by physical training with their right hand while their left-hand was passively moved in a yoked manner to these voluntary right-hand movements. We found that adding this passive training led to further increases in left hand performance gains. Finally, we collected functional magnetic resonance imaging (fMRI) data from an additional set of 18 subjects during physical training with the right hand, coupled with visual feedback of left-hand movement. We found that activity in the right Superior Parietal Lobule (rSPL) during training correlated with subsequent gains in left-hand performance. Optimizing the transfer of motor skills across limbs has key consequences on real-world learning (such as sports and music) and for the development of new approaches for rehabilitation of patients with unilateral motor deficits such as ALS or stroke. Our results point to the right SPL as an important node in this process.

Title: Disambiguation in the serial reaction time task

Authors: *J. L. HOELTER, C. M. KAIVER, S. J. HELD, C. E. ECHEVESTE, A. J. GREENE; Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Sequence learning is a ubiquitous aspect of learning in general, from way-finding, to procedural learning, to episodic narratives. The serial reaction time task (SRTT; Nissen & Bullemer;1987) is a widely used method to study sequence learning. In a typical task, participants respond to a sequence of repeated or random light positions with a corresponding button-press. Facilitation is observed when response latency decreases for items in repeated sequences. Generally, performance is thought to be implicit, and indeed Amnesic patients' perform at normal levels for both novel and repeated sequences. SRTT readily provides a means to address the disambiguation of related or similar sequences, (i.e. discrimination or pattern separation). As SRTT is presently used to examine implicit prediction or expectation (the previous items predict the upcoming item, which is the basis for facilitation; i.e., generalization or pattern completion), SRTT with novel and repeated sequences that include ambiguous sub-sequences, allows examination of implicit performance on task demands usually believed to require awareness. Moreover, sequence disambiguation has been demonstrated in other tasks (e.g., maze learning, which includes place learning, object identification, etc.) but as yet, not the SRTT, which is arguably the purest form of sequence learning. The present SRTT uses acoustic location, rather than visual, to examine repetition-facilitation and disambiguation. A 1 kHz tone is presented through a pair of sound-cancelling headphones, monaurally left or right, or binaurally center; participants responded with a position-corresponding button-press. The manipulation was a series of random presentations, used as a control, versus two series that included repeated sequences, each of which had an overlapping, ambiguous, middle sub-sequence. Participants were able to learn the repeated sequences, as performance button-presses were faster within repeated sequences than to random series. (c.f., REF). The critical finding is that in this auditory SRTT, participants successfully disambiguate without awareness being necessary.

Title: Activity in superior parietal lobule during training by observation predicts subsequent performance gains

Authors: O. OSSMY, *R. MUKAMEL;
Tel-Aviv Univ., Tel-Aviv, Israel

Abstract: A dominant idea in motor cognition links motor control with action observation. Previous behavioral and imaging studies in humans have shown that training by passive observation of actions can result in motor skill learning and performance gains. Nevertheless, the role of observed hand identity (left/right) during such training is unclear. Through the use of 3D Virtual Reality devices we generated visual input simulating the subject's real hands. 18 subjects trained on a novel motor skill (sequence of finger movements) while passively observing their virtual right or left hand performing the action. Gains in each hand (difference in performance level before/after training) were obtained. We found no difference in performance gains across hands following training by observation of left or right virtual hand. However, across subjects the correlation between left and right hand performance gains depended on the identity of the observed hand. Training by observation of the left hand yielded positive correlation between performance gains of both hands, while right hand observation resulted in a negative correlation. Next, we investigated the underlying neural mechanism of this phenomenon. We recorded functional magnetic resonance imaging (fMRI) data from an additional set of 18 subjects and found that activity in bilateral Superior Parietal Lobule (SPL) during training by observation correlated with subsequent performance gains. This was true for both tested hands and observational training condition. These results imply that in the absence of overt physical practice the bilateral SPL plays an important role in the process of learning by observation irrespective of the identity of the observed hand.

Title: Morphological changes in cortical microstructure of the brain by short-term training

Authors: ***Y.-W. SUNG**[1], D. KANG[2], U.-S. CHOI[3], S. OGAWA[2];
[1]Kansei Fukushi Institute, Tohoku Fukushi Universit, Sendai, Japan; [2]Kansei Fukushi Institute, Tohoku Fukushi Univ., Sendai, Japan; [3]Neurosci. Res. Inst., Gachon Univ. of Med. and Sci., Incheon, Korea, Republic of

Abstract: Most of the previous studies of neuroplasticity in system level by MRI were on long-term and intensive training such as music and physical exercise over years or months though few studies were over weeks. As for shorter timescales, several minutes of electrical and magnetic stimulation is known to cause morphological changes in the cortical microstructure of the brain. Some studies using diffusion-weighted MRI have demonstrated the microstructural changes in human. Recently a study reported microstructural changes in the motor area by short-term magnetic stimulation. In this study, we examined whether the similar period of training not by electrical or magnetic stimulation but by typical functional tasks such as finger tapping would cause the same kind of microstructural changes in the cortex. We used a paradigm in which subjects practiced a finger tapping task using both hands simultaneously and measured the brain by diffusion-weighted MRI. A series MRI scan consisted of gradient-echo echo-planar-imaging (GE-EPI) for functional MRI (fMRI), diffusion-weighted imaging (DWI) before and after the intensive finger tapping task for 15 minutes. For control, an additional scan for DWI was inserted before the training. In DWI measurements low and high b values, 300 s/mm^2 and 1200 s/mm^2, were interleaved in a measurement scan. For some subjects spin-echo images with two contrasts were acquired to examine a possibility of some other aspects of microstructural changes. DWI data were evaluated on activation maps by fMRI. Several motor areas showed statistically significant differences in DWI signals before and after the training but with no difference between two measurements before the training. Some areas of them showed the difference only for high b value and others for both low and high b values. These results suggest some microstructural changes by the training in the areas, especially the areas shown signal differences only for the high b value. This is parallel with the previous study used magnetic stimulation and shows the possibility of microstructural changes by a short period of tasks. In addition, the results give a caution about the evaluation of the data. The signal sources of the areas shown differences for both b values are considered to be large blood vessels rather than tissues.

Title: Impact of feedback valence during skill learning on dynamic and static functional connectivity

Authors: *A. D. STEEL[1,2], E. H. SILSON[1], C. J. STAGG[2], C. I. BAKER[1];
[1]NIH, Bethesda, MD; [2]Oxford Univ., Oxford, United Kingdom

Abstract: While valenced feedback (vFB), e.g. reward or punishment, aid performance and skill learning, we do not know how vFB is integrated in the brain. To examine the behavioral and neural changes associated with vFB, volunteers (HVs) were trained on a serial reaction time (SRT) task under three different feedback regimes (each n = 12): i) Reward (REW) - monetary reward if accurate and RT better then median reaction time (RT) on the last 100 trials, ii) Punishment (PUN) - began with $60 and money was taken away if they were inaccurate or slower than their median RT on the last 100 trials, and iii) Control (CON) - were told they would be given compensation based on their speed and accuracy and given pseudo vFB. In the SRT, a stimulus shown in 1 of 4 locations and HVs press the corresponding button. During certain trials the stimulus appears according to a fixed sequence. The difference between RT on random and sequence trials indexes skill memory, which was evaluated after short- (1-hr), intermediate- (24-48 hrs), and long- (30_ days) delays. Training was conducted inside the MRI scanner and to assess the impact of training, 20-minute resting state fMRI scans were taken before and after training. Behaviorally, during training, there was a benefit of vFB on RT irrespective of sequence type. Further, vFB (REW and PUN) benefitted early learning compared to CONT. All groups demonstrated retention across the testing sessions, with no difference between the vFB regimes. To evaluate functional connectivity, the time series from 148 ROIs were extracted. The ROI x ROI correlation was considered using the entire 20 minutes (static) or by evaluating the variation correlation pattern over time (dynamic). Static FC revealed an increase in FC between cortical and subcortical ROIs in REW, while cortical-cortical connectivity increased in CONT. PUN showed no change in static connectivity, but displayed an increase in connection variability across time. These results show that vFB differentially influences both static and dynamic FC.

Title: Combining speed- and accuracy-focused training prevents offline performance improvements in sequential motor skill

Authors: *S. K. SUGAWARA[1], Y. H. HAMANO[1,2], N. AOKI[1,2], H. YAMAZAKI-KINDAICHI[1,2], T. YOSHIMOTO[1,2], N. SADATO[1,2];
[1]Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan; [2]SOKENDAI (The Grad. Univ. for Advanced Studies), Hayama, Japan

Abstract: Motor skill is developed over time through both online and offline learning processes (Robertson et al., 2004). Motor performance can be measured by speed and accuracy. Both performances in the sequential motor skill markedly improve after the post-training offline period (Walker et al., 2002, 2003). Most of previous studies used the speed-focused training, because the accuracy-focused training is less effective according to our pilot data. However, it remains unknown whether the combination of speed- and accuracy-focused training benefit for online and offline learning process in the sequential motor skill or not. One hundred seven healthy right-handed volunteers participated in this study for two consecutive days. On the first day, two experimental groups were designed corresponding to the different types of training. On the combined group (n = 60), participants trained one sequential finger-tapping skill with both accuracy-focused mode, in which they were asked to repeatedly tap the sequence as accurate as possible for 15 sec, and speed-focused mode, in which they were required to tap same sequence as accurate and as fast as possible for 30 sec. On the other hand, in control group (n = 47), participants trained same sequential motor skill only with the speed-focused mode as well as previous studies (Walker et al., 2002; Sugawara et al., 2012). 24 hours after the training, participants in both groups came back to laboratory again and performed the surprised recall test. Two performance indexes were calculated according to previous study: speed and accuracy (Debas et al., 2010). Post-training performance by means of accuracy was significantly more prominent in combined group compared with control group ($p < .001$), while there was no group difference by means of speed ($p = .60$). For the offline learning process, 24 hours later, performance of speed and accuracy were significantly improved in control group ($ps < .001$). However, combined group did not show any significant offline improvement by means of speed or accuracy ($ps > .53$). According to these results, we concluded that the combination of speed-

and accuracy-focused training facilitate accurate motor execution across the online training, but paradoxically prevents the offline learning process. Present findings suggest that speed- and accuracy-focused trainings interact each other in the sequential motor skill formation.

Title: Different cognitive functions determine visuomotor adaptation performance during time course of learning. A correlational approach

Authors: *A. M. SIMON, O. L. BOCK;
Inst. of Physiol. and Anat., German Sport Univ. Cologne, Cologne, Germany

Abstract: A recent learning model by Chein and Schneider (2012) proclaims three stages of learning, each associated with different cognitive abilities. In the first (formation) stage, learning is proposed to be associated with cognitive flexibility, creativity and a frequent change of strategies. In the intermediate (controlled execution) stage, learning is associated with inhibition and selective attention abilities. In the last (automatic execution) stage, it is related to automatic representation of previously established behaviours. The present studies use a correlational approach to evaluate whether the Chein and Schneider model can be applied to visuomotor adaptation. The cognitive functions supposedly related to the three learning stages were assessed by the Abbreviated Torrance Task for Adults (creativity index), Alternative Uses Task (divergent thinking), switching task (cognitive flexibility), Stroop task (higher-level inhibition), Go/No-Go task (lower-level inhibition), and choice reaction time tasks (automated psychomotor processing). Sensorimotor adaptation was assessed by a pointing task with 60° rotated visual feedback. Participant's adaptive performance (pointing error at movement onset) exhibited correlations with cognitive scores. Correlations with divergent thinking and with inhibition were high at the onset of learning and decreased later on. The correlation with automated processing was low at the onset of learning and increased thereafter. We conclude that cognitive abilities are differently associated with adaptive performance at different times of learning. The pattern of associations suggests that at least two of the three learning stages proposed by Chein and Schneider (2012) may apply to visuomotor adaptation. References Chein JM, Schneider W

Title: Mindfulness and two forms of implicit learning in healthy young adults

Authors: ***E. L. RABINOVICH**[1], C. M. STILLMAN[2], J. H. HOWARD, Jr.[3], D. V. HOWARD[2];
[1]Psychology, Cognitive Aging Lab., Washington, DC; [2]Psychology, Georgetown Univ., Washington, DC; [3]Psychology, The Catholic Univ. of America, Washington, DC

Abstract: Dispositional mindfulness refers to a person's propensity to be attentive to stimuli in the present while disengaging from habitual actions and thought tendencies (Brown & Ryan, 2003). Previous behavioral and neuroimaging data have shown that dispositional mindfulness is associated with higher performance on explicit cognitive functions, or those requiring goal-directed intent and awareness (Robins et al., 2009). However, recent evidence suggests there may be a negative relationship between dispositional mindfulness and implicit learning, a type of learning that occurs without goal-directed intent or awareness (Stillman et al., 2014; Whitmarsh et al., 2013). The present study had two aims: First, we sought to replicate the negative relationship between mindfulness and visuospatial implicit sequence learning in a new sample and, second, we examined whether the negative relationship would extend to another type of implicit sequence learning: language sequence learning. We predicted that both kinds of implicit learning would be negatively related to mindfulness. Twenty-eight adults (M ± SD = 23.2 ± 1.54; 5 M) completed a widely used questionnaire assessing mindfulness and two tasks measuring implicit sequence learning in visuospatial and language domains. The Triplets Learning Task (TLT) assessed visuospatial sequence learning; participants view a horizontal row of four open circles, which fill in sequentially red, red, then green in discrete 3-event sequences called triplets.

Participants observe the first two red cues and respond via button press to the green targets. Unbeknownst to them, certain triplets occur with high probability (HP), and others with low probability (LP). Learning is measured via a difference score of accuracy and/or reaction time to HP vs. LP triplets. An adapted version of a statistical learning task (Saffran et al., 1996) was used to measure language sequence learning; participants are exposed to a five-minute stream of nonsense syllables comprising words from an artificial language. Afterwards, they rate their familiarity with words and part-words from the language on a five-point scale. Learning is assessed via difference scores of ratings to words vs. part-words. In both tasks, a greater difference score indicates more learning. We replicated the negative relationship between mindfulness and implicit learning in the visuo-spatial domain, but this relationship was not observed in the language domain. Therefore, the negative relationship between mindfulness and implicit learning may only generalize to specific types of implicit learning.

Title: The cortico-striatal network holds the memory of the sequential motor skill during the early training stage

Authors: *Y. H. HAMANO[1,2], S. K. SUGAWARA[1], H. YAMAZAKI-KINDAICHI[1,2], N. AOKI[1,2], T. YOSHIMOTO[1,2], N. SADATO[1,2];
[1]Natl. Inst. For Physiological Sci., Okazaki, Aichi, Japan; [2]SOKENDAI (The Grad. Univ. for Advanced Studies), Hayama, Japan

Abstract: Previous neuroimaging studies showed that the primary motor cortex (M1) and striatum increase their task related activation with the progression of sequential motor learning over 5 days, suggesting chronic learning dependent plastic change (Penhune et al, 2002). To test if this type of plastic change occurs in early learning stage in the order of 30 min training, we conducted functional MRI with sequential finger tapping learning by execution with maximum speed interleaved with execution with constant speed. Given the memory trace is reactivated by

retrieval (Nyberg et al. 2000), we assumed that the activity of the brain region that hold the memory trace of the motor skill increases as the learning progress when participants perform the skill with constant speed. A total of 55 normal volunteers participated, who underwent training of sequential finger tapping task with their non-dominant left hand. There were two modes: constant speed mode with 2 Hz controlled by external cue, and maximum speed mode in which participants were required to tap as fast and as accurate as possible. The task included 25 blocks of constant speed mode and 12 blocks of maximum speed mode, and was arranged in order of 3 blocks of maximum speed mode every 5 blocks of constant speed mode. The behavioral performance in the maximum-speed mode was progressively enhanced, confirming the successful acquisition of the sequential motor skill (Walker et al., 2002). During the constant-mode, the task-related activities in bilateral lenticular nucleus, and right primary motor area were linearly increased as learning proceeded. The activation of M1 was significantly positive at the first block of the learning, while that of the lenticular nucleus was not. This indicates that M1 is related to both execution and learning (Karni et al., 1995; Muellbacher et al. 2001) whereas the lenticular nucleus represents the memory trace of learned sequence rather than execution per se. Learning related decrease was observed in the bilateral cerebellum, dorsal premotor area, inferior and superior parietal lobule, right inferior frontal gyrus, dorsolateral prefrontal cortex, and left supra-marginal gyrus. Decreased activity in cerebellum suggests that the workload of error-correction decreases with learning progress. Likewise, the decrease in the fronto-parietal network may indicate the reduced need for monitoring the ongoing behavior (Albouy et al. 2012). We conclude that the memory trace of the sequential motor skill is distributed in the cortico-striatal network during early acquisition stage.

Title: Different formation of muscle synergies associated with the desired motor output: simulation study using neural network model including muscle synergies

Authors: *S. HAGIO[1,2], M. KOUZAKI[1];
[1]Grad. Sch. of Human and Envrn. Studies, Kyoto Univ., Kyoto, Japan; [2]Res. Fellow of the Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Introduction The concept of muscle synergies was supposed to simplify redundancy in motor control, which modularly organizes huge number of muscles (Hagio and Kouzaki, 2014; Tresch et al, 1999). Given that the central nervous system (CNS) organizes muscle synergies in the neural circuitry to adapt various external environments, it is hypothesized that the formation of muscle synergies would depend on the desired motor output. The neural network simulation comparing the adaptive process of muscle synergies to the different motor output would make it possible to clarify the hypothesis during the adaptation of muscle synergies. Therefore, the purpose of the present study was to reveal the formation mechanism of muscle synergies associated with the desired motor output using neural network model. Methods We used the previously-constructed neural network model including three intermediate layers, which corresponded to 1000 neurons in primary motor cortex (M1), several spinal interneurons regarded as muscle synergies and 26 muscles spanning the elbow and/or shoulder joint, respectively (Hagio and Kouzaki, 2014, SfN). The synaptic weights between M1 neurons and muscle synergies and between muscle synergies and muscles were updated to minimize the total squared error between desired input and output torques using an error back-propagation algorithm (Rumelhart et al., 1986). In the control simulation, the network was trained to produce appropriate elbow and/or shoulder torque in an isometric condition, which were uniformly distributed 12 target torques on the 2-dimensional joint torque plane with the same intensity. In the test simulation, the distribution of the desired torques was biased to 1st and 3rd quadrants or 2nd and 4th quadrants on the torque plane. We then compared the formation of muscle synergies and cortical system, which were constructed depending on the different desired torques. Results & Discussion The preferred directions of muscle synergies, in which the muscle synergy was most active, were biased to the more trained direction. According to the change of the preferred directions, the synaptic weights between muscle synergy and muscle layers were varied. These results would represent one of the most important factors to describe the previous results that a few muscle synergies were different across individuals, which CNS were adapted in the different environments (Hagio et al., 2015). Therefore, the CNS flexibly organizes muscle synergies and cortical system depending on the desired motor output. Our results also provide the significant suggestion that the neural system would reflect movement experience.

Title: Acute exercise and motor memory consolidation: The role of exercise intensity and timing

Authors: *R. THOMAS[1,2], L. K. JOHNSEN[1,2], S. S. GEERTSEN[1,2], L. CHRISTIANSEN[1,2], M. ROIG[3], J. LUNDBYE-JENSEN[1,2];
[1]Dept. of Nutrition, Exercise & Sports, [2]Dept. of Neurosci. & Pharmacol., Univ. of Copenhagen, Copenhagen, Denmark; [3]Sch. of Physical & Occup. Therapy, Fac. of Med., McGill Univ., Montreal, QC, Canada

Abstract: Background A single bout of high intensity cycling (~90% VO_{2peak}) immediately after motor skill training enhances motor memory consolidation. It is unclear how different parameters of exercise may influence this process and the underlying mechanisms are poorly understood. We hypothesize that the effects of exercise on consolidation are time-dependent with a decreasing positive effect of exercise post acquisition and investigate the role of exercise intensity and timing on motor memory consolidation. Furthermore, we explore the potential role of transient changes in corticospinal excitability (CSE) accompanying skill learning and exercise. **Methods** Sixty able-bodied male subjects (20-35 years) were randomly assigned to one of five groups that practiced a visuomotor accuracy task. 20 min post motor skill learning (MSL), subjects in Experiment A performed either a single bout of aerobic exercise at 45% (EX45) or 90% (EX90) of peak oxygen consumption (VO_{2peak}) or rested (CON). In Experiment B, two additional groups performed the same exercise protocol at 90% VO_{2peak} at 1hour (EX90+1h) and 2 hours (EX90+2h) post MSL. Randomization was stratified to ensure that the groups were matched for VO_{2peak} and baseline motor performance. Delayed retention tests of motor skill were tested 24 hours (R24) & 7 days (R7) post acquisition. Transcranial magnetic stimulation (TMS) was applied to the primary motor cortex to obtain measures of CSE, intracortical inhibition (SICI) and facilitation (SICF) before and after MSL, following exercise and in delayed retention tests. Motor-evoked potentials (MEPs) were recorded from the extensor carpi radialis muscle. **Results** Analysis of motor performance revealed no differences between groups during MSL, but differences in delayed retention tests. In Experiment A, EX90 showed a higher level of retention at R7 compared to CON. In Experiment B, EX90+2h demonstrated a level of retention at R24 and R7 equivalent to CON. **Discussion** In line with recent findings, the results show that exercise can promote motor memory consolidation. The results of Experiment A demonstrate that exercise intensity plays an important role for motor memory consolidation in favour of higher intensity aerobic exercise, while Experiment B indicates that timing of exercise is also important, with exercise immediately following motor skill learning being more efficient. Motor performance in retention tests were not related to measures of CSE at any time point indicating

that further studies are necessary to understand the physiological mechanisms leading to improvements in motor memory relating to exercise.

Title: Visuomotor learning in stable versus random task environments

Authors: *E. R. BUCH, V. P. BUCH, L. G. COHEN;
Human Cortical Physiol. Section, NINDS, NIH, Bethesda, MD

Abstract: During skill learning, the human brain modulates neural interactions to generate appropriate actions for specific sets of intrinsic goals and task constraints. It is known that these network interactions are optimized through experience to generate a directed action with a high likelihood of achieving the goal, a process called visuomotor learning. Typically, visuomotor learning is studied through the application of a visual feedback perturbation that remains constant over time. In fact, multiple perturbations can be learned in a single session, albeit with some interference. In real-world tasks however, perturbations are rarely constant, but instead vary with time. Here, we investigated the behavioral and brain network features associated with learning multiple perturbations with unpredictable time-courses. We hypothesized that learning improvements would be driven by strategies that improved utilization of early movement sensory feedback, and that minimized the cost for subsequent corrective submovements. Furthermore, we attempted to differentiate network patterns that relate to performance gains in stable versus random task environments. Using MEG, we measured cortical activity while subjects performed a center-out joystick task. On each trial, subjects were instructed to move a screen cursor from a central home position to a peripheral target in as straight a line as possible. On some trials, the screen cursor feedback was rotated with respect to the joystick movement. In this case, the subject was required to learn to initiate a new action that corrected for the rotation. The perturbation was applied in two separate blocks of trials. In one block, the rotation was constant allowing participants to learn to compensate for the visual deviation (stable environment). In the

other block, the direction of the applied perturbation was randomized. We used a machine learning classifier approach to differentiate network states for each of the two conditions. We find two key results. First, in the random task environment a majority of participants evolved strategies that initially reduced the potential cost of subsequent submovement corrections. Second, further performance gains were achieved through a reduction in the initial submovement, suggesting that improved utilization of the sensory information was realized. Networks spanning prefrontal, frontal and posterior parietal regions showed specific patterns of activity depending upon the task perturbation context. These results suggest that separable functional brain networks are engaged during visuomotor learning in a manner that is dependent upon the stability of the environment.

Title: Modulation of task demands suggests that semantic processing interferes with the formation of episodic associations

Authors: *N. M. LONG, M. J. KAHANA;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Although episodic and semantic memory share overlapping neural mechanisms, it remains unclear how our pre-existing semantic associations modulate the formation of new, episodic associations. When freely recalling recently studied words, people rely on both episodic and semantic associations, shown through temporal and semantic clustering of responses. We asked whether orienting participants toward semantic associations interferes with or facilitates the formation of episodic associations. We compared electroencephalographic (EEG) activity recorded during the encoding of subsequently recalled words that were either temporally or semantically clustered. Participants studied words with or without a concurrent semantic orienting task. We identified a neural signature of successful episodic association formation whereby high frequency EEG activity (HFA, 44 - 100 Hz) overlying left prefrontal regions increased for subsequently temporally clustered words, but only for those words studied without

a concurrent semantic orienting task. To confirm that this disruption in the formation of episodic associations was driven by increased semantic processing, we measured the neural correlates of subsequent semantic clustering. We found that HFA increased for subsequently semantically clustered words only for lists with a concurrent semantic orienting task. This dissociation suggests that increased semantic processing of studied items interferes with the neural processes that support the formation of novel episodic associations.

Title: Neural context reinstatement during episodic memory retrieval with scalp electroencephalography

Authors: *K. HEALEY[1], M. J. KAHANA[2];
[1]Univ. Of Pennsylvania, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: To account for the behavioral dynamics of episodic recall, memory models often posit a neural representation of the temporal context in which words are studied that gradually evolves as a function of the sequence of experienced and recalled items. A key prediction of these models is that retrieving a memory triggers reinstatement of the neural context representation that prevailed when the item was originally experienced. We have previously tested this prediction by examining intracranial electroencephalogram (EEG) data obtained from neurosurgical patients. Here we show that the same neural context reinstatement can be observed using high-density scalp EEG with healthy young adults. We recorded scalp EEG while participants studied lists of words for immediate or delayed free recall. To directly test the context-reinstatement hypothesis, we compared the oscillatory activity recorded as each item was recalled with the pattern of activity recorded when the items were originally studied. In two independent experiments we found that the pattern of activity just prior to an item's recall is similar to the pattern of activity that characterized the item's presentation, but also similar to the

activity associated with items presented near it in the list in a temporally graded fashion, replicating the intracranial EEG findings. These results establish that the neural features of content and context representation, and their dynamics, can be resolved in both intracranial and scalp EEG.

Title: Investigating the neural oscillations involved in processing new "foil" semantic and phonological information

Authors: *D. A. VOGELSANG[1], M. GRUBER[2], Z. BERGSTROM[4], C. RANGANATH[3], J. SIMONS[5];
[1]Dept. of Psychology, Psychology, Cambridge, United Kingdom; [2]UC Davis, Davis,, CA; [3]UC Davis, Davis, CA; [4]Univ. of Kent, Canterbury, United Kingdom; [5]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: In order to remember a past event, it is often helpful to use strategic control processes in order to constrain what comes to mind during retrieval. Behavioural studies have supported this idea by demonstrating that incidental learning of "foil" words in a recognition test is superior if the subject is searching for items that were semantically encoded than if s/he is searching for items that were phonologically encoded. Here, we used electroencephalography (EEG) to understand the neural mechanisms underlying this behavioural effect. First, participants studied words using both semantic and phonological encoding tasks. Next, they performed a blocked old/new memory test, which allowed us to manipulate whether they were orienting retrieval towards semantic or phonological information. Finally, participants performed a surprise old/new recognition test on foil items that were incidentally learned during the previous semantic and phonological testing blocks. Behavioural results showed that recognition memory performance on the final old/new recognition test, was significantly better for semantic foils than phonological foils, despite the fact that these two item types only differed with respect to the type of information participants oriented towards in the first memory test. Preliminary results from time-

frequency analysis of EEG data during the first test phase revealed oscillatory activity patterns that differentially predicted successful memory for semantic and phonological foils on the final foil recognition test. Further analyses will characterize these effects in more detail with respect to frequency, spatial topography, and temporal duration in order to extend our understanding of the role of neural oscillations in memory encoding and retrieval.

Title: Early Oscillatory correlates of the problem-size effect - an event-related synchronization/ desynchronization (ERS/ERD) analysis

Authors: *E. T. MULUH[1], L. JOHN[2], E. MULUH[3];
[1]9 Cumnor Court, 292 Main Road Kenilworth, Cape Town, South Africa; [2]Univ. of Cape Town, Cape Town, South Africa; [3]Cape Peninsula Univ. of Technol., Cape Town, South Africa

Abstract: Aim: Little is known about the early oscillatory dynamics of neuronal networks involved in strategy selection during the processing of large- and small-size arithmetic problems. Our study was aimed at investigating this early oscillatory dynamics. Method: Electroencephalography (EEG) data were collected during mental arithmetic processing of single-digit addition problems in the Arabic format. Event-related synchronization/desynchronization (ERS/ERD) components where derived from the data and individual alpha frequencies (IAFs) for each subject determined and used in filtering data into lower and upper alpha bands. Intervals of interest (IOI) for statistical analysis were then determined from the onset/offset phases of the global field power (GFP) index of the obtained components and a high-resolution exact-statistical technique employed for the evaluation of oscillatory dynamic differences. Latencies of components were measured at maximum ERS/ERD post-question presentation. Results: Early ERS in lower alpha at pre-fronto-frontal electrodes resulted in significant differences between large- and small-size problems. We interpreted this as a differential selection of strategy (retrieval vs. procedural strategies) to be

employed in the two problem sizes. ERD was very pronounced in upper alpha at occipito-parietal electrode locations resulting in a bilateral with a more left tendency significant difference. We interpreted this as representing strategy execution and memory retrieval or quantity manipulations. The type of strategy selected/employed significantly modulated the latencies of both ERS and ERD components. Conclusions: Selection and execution of strategies during mental arithmetic processing can be captured by oscillatory activity in individually determined alpha bands. Significant: The amplitude of ERS can be used to determine what type of strategy is selected for an arithmetic problem. Key words: Event-related synchronization, Event-related desynchronization, mental arithmetic, problem-size

Title: Memory related theta gamma coupling in human hippocampal CA1 subfield

Authors: *N. TCHEMODANOV[1], A. TITIZ[2], E. MANKIN[2], I. FRIED[2], N. A. SUTHANA[2,3]; [1]Biomed. Engin., [2]Neurosurg., [3]Psychiatry & Biobehavioral Sci., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Growing evidence suggests that coupling between the phase of theta (3-8 Hz) and amplitude of gamma (30–125 Hz), known as phase-amplitude cross frequency coupling (CFC), may play a role in hippocampal-dependent memory [1-4]. The hippocampus consists of smaller subregions CA1-4, dentate gyrus (DG) and subiculum, which show differential roles in learning and memory [5], yet the ability to selectively record from these regions in humans is limited by both recording and imaging technologies. Therefore, whether CFC occurs within human hippocampal subfields and relates to memory is currently unknown. Here we used microwires to record local field potentials (LFPs) from human hippocampal subfields in 5 epilepsy patients implanted with intracranial depth electrodes. LFP activity was recorded while subjects completed

an object recognition task, where they learned novel images (targets) and later identified targets and similar (lure) images as OLD or NEW. Hippocampal CFC was calculated during learning of subsequently recalled images (i.e. target later identified as OLD and lure identified as NEW) compared to missed images where targets were incorrectly identified as new. CFC strength was calculated via modulation indices (M), which were computed using theta (3-8 Hz) phase and high gamma (80–125 Hz) amplitude during the 4 sec period after stimulus onsets and z-scored against 1000 surrogate distributions [1-3, 6]. Microelectrode localization to hippocampal subfields was done via a 3-way registration using postoperative CTs, high-resolution magnetic resonance images (MRI), and whole brain MRI. We found significant theta-gamma coupling in CA1 during learning of subsequently recalled trials (z_{recall} =3.37, p<0.001) but not during missed trials (z_{miss} =1.38, p=0.084). Furthermore, we found a significant difference in CFC strength between recalled and missed conditions (recall>miss, t_{stat} = 4.74, p<0.001). We did not find these effects in CA23DG (recall>miss, t_{stat} = 1.96, p=0.059; z_{recall} =0.41, p=0.34; z_{miss}=-0.086, p=0.53) or subiculum (recall<miss, t_{stat} = -1.3, p=0.21; z_{recall} =-0.02, p=0.51; z_{miss}=0.356, p=0.36). These results suggest a specific role for theta gamma coupling in the human hippocampal CA1 subfield during learning of subsequently recollected items and support the idea that theta gamma coupling is associated with optimal learning in humans. Title: Hemispheric differences in short-term relational memory after unilateral temporal lobe resection for epilepsy

Authors: *E. GAGNON, A. J. RYALS, J. L. VOSS;
Northwestern Univ. Feinberg Sch. of Medicin, Chicago, IL

Abstract: Bilateral hippocampal lesions have been shown to disrupt relational memory performance across even brief retention intervals (seconds). In a previous test of spatial reconstruction for arrays of 2-5 objects with 3-second retention intervals, hippocampal amnesics have shown a disproportionate tendency to commit "swap errors." These errors involve switching the relative positions of objects during array reconstruction, as opposed to purely spatial errors such as increased distance between locations of studied items and reconstructed items. However, little is know regarding effects of lesion hemisphere on spatial versus relational errors. In the present study, we measured reconstruction ability in individuals who had undergone unilateral temporal lobe resection for intractable epilepsy. Participants learned and reconstructed five-item arrays containing either namable objects or novel abstract shapes, with retention intervals of several seconds. Reconstruction errors of interest included swap errors, reflecting relational memory, as well as several spatial memory measures (item misplacement, edge resizing, and item rearrangement). As expected, participants exhibited significantly more errors for reconstructions of novel-shape compared to familiar-object arrays. Individuals with right-lateralized lesions tended to make more memory errors than individuals with left-lateralized lesions, without marked distinction between swap errors specifically and more general spatial memory errors. These preliminary findings are consistent with a greater role of right than left hippocampus in spatial memory, without striking evidence for hemispheric differences in relational memory. Comparisons of performance for lesion subjects with matched healthy controls will also be discussed.

Hosp., Beijing, China; [6]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Previous neural imaging studies have shown that the perception and retrieval of musical information are associated with activations of overlapped brain regions, including inferior frontal lobe, supplementary motor area, premotor cortex, superior temporal gyrus and supra-marginal areas. However, little is known about how the network of brain areas dynamically represents the time course of listening and recall of musical pieces and how the activations of specific brain areas are related to particular musical information. To explore cortical activity patterns associated with music listening and recall, we recorded electrocorticography (ECoG) from Chinese-speaking epilepsy patients with implanted subdural electrode arrays while they were listening to or imagining familiar musical melodies without lyrics. Subjects were asked to first listen to the initial segment of a familiar music piece and then complete the rest of the piece (2 or 5s) by auditory imagery. Subjects indicated the completion of the imagery by pressing a response button. We analyzed the neural activities of the onset phase (0-500ms) and the sustained phase (after 500ms) of music listening and recall separately. For the onset phase, we observed different sequential delay orders of neural activities between music listening and recall. Initialization of the onset cortical activity related to music listening first happened in posterior temporal lobe and supra-marginal area, followed by middle temporal and pre-central areas, and finally reached frontal lobe. In comparison, the cortical activity related to the onset of music recall first appeared in frontal lobe, followed by pre-central area and reached temporal lobe at last, showing a reversed sequential order. For cortical responses of the sustained phase, more brain regions were activated than during the onset phase, with dispersed brain regions activated in both music listening and recall including bilateral pre-central, supra-marginal area, left superior frontal lobe, and right anterior temporal lobe. During the sustained phase, the left temporal lobe and bilateral inferior frontal lobe were mainly involved in music listening, whereas the right superior frontal and superior temporal lobe were mainly involved in music recall. In addition, we found that high gamma band ECoG signal dynamically tracked the music intensity envelope in bilateral posterior superior temporal gyrus during music listening and in bilateral superior frontal lobe during music recall.

Title: Reducing interference between overlapping memories

Authors: *A. J. CHANALES, B. A. KUHL;
New York Univ., New York, NY

Abstract: Memories for past events will often share overlapping features. This overlap can lead to interference during memory retrieval, which has long been established as a powerful contributor to forgetting. Although the negative effects of interference are experienced during retrieval, the way in which experiences are encoded is likely to influence the degree to which interference occurs at retrieval. In particular, by forming across-event associations (event integration), interference effects at retrieval may be dramatically reduced or even eliminated (Anderson and McCulloch, 1999). We developed a behavioral paradigm to measure the degree to which overlapping events interfered with one another during memory retrieval. We then considered how various behavioral learning manipulations and neural encoding factors influenced expressions of interference at retrieval. In our paradigm participants initially learned to associate words with pictures of either a face, scene, or object (A-B learning). During a subsequent learning phase (A-C learning), all of the previously learned words (A) were paired with new pictures (C). Memory for the new associations (A-C) was then tested in the presence or absence of an explicit reminder of the B image. Specifically, A-C recall trials were preceded by a briefly presented (200 ms) image that was either (1) the corresponding B image, (2) a novel image from the same category as the B image, or (3) a phase scrambled version of the B image. We found that reminding participants of the B image (i.e., an overlapping memory) interfered with retrieval of the C associate as reflected by reduced recall accuracy and longer reaction times relative to control conditions. Having established a reliable interference effect, we ran a modified version of the paradigm to test whether reminding subjects of the A-B association during A-C learning would influence interference effects at retrieval. Indeed, this manipulation to A-C learning eliminated the ‘cost’ of presenting the B item during A-C retrieval. In other words, when A-B and A-C associations were learned together, interference between B and C items at retrieval was eliminated. Finally, we ran an fMRI study to test whether spontaneous reactivation

of older associations (B items) during A-C learning predicted the degree of interference between B and C items during A-C retrieval.

Title: Episodic memory updating facilitated by sleep after reactivation and new learning

Authors: ***N. BRYANT**, L. NADEL, R. L. GOMEZ;
Psychology, The Univ. of Arizona, Tucson, AZ

Abstract: A growing body of evidence suggests that memories are not fixed entities; instead, an old memory can be reactivated, updated with a different experience, and reconsolidated to include both the old and new information. Furthermore, updating of previously-consolidated memories with novel experiences appears to be a time-dependent process, which may implicate offline memory processes occurring during sleep. Sleep-dependent memory processes have been investigated within the framework of consolidation in general, as well as procedural memory updating in particular; however, the role of sleep in episodic memory reconsolidation remains unexplored. Given that sleep has been shown to facilitate veridical episodic memory, it could also play a role in the updating and reconsolidation of old representations with new learning. We tracked the sleep of 25 undergraduates using accelerometers and daily sleep diaries during a week of testing using the reconsolidation paradigm. In this paradigm, subjects learn two sets of objects separated by 48 hours (Sets 1 and 2). Before learning the second set, participants are reminded of the first learning experience (reactivation). At test 48 hours later, subjects are assessed on their memory for the objects and the day on which they were learned. Previous work has implicated the reminder in greater attribution of Set 2 objects to the Set 1 memory (intrusions) than Set 1 objects to the Set 2 memory (errors), demonstrating reconsolidation of the old memory with the new items. The current study found amount of sleep is significantly associated with intrusions $R2=.34$, $F(2,22)=5.75$, $p<.01$. In particular, less sleep after learning Set 1 ($\beta=-.52$, $p<.05$) and more sleep after learning Set 2 ($\beta=.52$, $p<.05$) predicts the number of Set 2 objects attributed to Set 1. However, no relationships were found between sleep amount and errors, or Set 1 items misattributed to Set 2. Our results mirror prior findings that memory consolidation is benefitted by a night of sleep; however, in this case sleep enhanced

reconsolidation of a prior memory with new learning. Interestingly, the opposite effect was observed after learning Set 1, such that getting less sleep after learning increased updating. These results imply that memories that are not fully consolidated by a night of sleep are perhaps "weaker," and thus more susceptible to reactivation and updating. Importantly, sleep was not related to errors in the other direction, or misattribution of old items to the new experience. The next phase of this research will use electroencephalography to investigate sleep-dependent brain mechanisms underlying memory reconsolidation.

Title: Change in effects of odor contexts over time that modify mental timeline in relation to the order of remote and recent past episodes

Authors: ***M. ABE**[1], Y. TAKI[2], Y. UGAWA[3];
[1]Inst. of Development, Aging and Cancer, Sendai-Shi, Japan; [2]Dept. of Nuclear Med. and Functional Neuroimaging, Inst. of Development, Aging and Cancer, Sendai, Japan; [3]Dept. of Neurology, Fac. of Med. Fukushima Med. Univ., Fukushima city, Fukushima, Japan

Abstract: Humans often have an incorrect impression from memory that they might have experienced past events a moment or a long ago that had occurred years or minutes ago in real world, when they are currently under the situations the same as or different from ones in which these events had really occurred. Thus contexts which consist of background of situations can modify order of past events in memory representations in respect to which events preceded or followed. Memories are dynamically altered over hours or days. Whether contextual effects on memory in respect to order of past events would change over time is unknown. Here, we demonstrated different effects of context on order of past events in memory immediately and hours after end of events. Young, adult, healthy volunteers participated in this study. Different lists of English words were visually presented in two sessions separated by a 10-min interval. While subjects judged whether presented words belonged to living or nonliving things, different odors were administrated in each session. After one or 6 hours delay, subjects were asked to

choose which words were presented in the second session (i.e. recent past) or in the first session (i.e. remote past), under conditions in which odors the same as ones exposed in the first or second session, or different new ones (i.e. control) were administrated. Performance errors were measured in three odor contexts. At one hour, subjects made more incorrect responses that they might have seen words in the second session (i.e. recent past) that were physically presented in the first session (i.e. remote past) when the same odor conditions as ones exposed in the first session were applied, compared with other two contexts. At 6 hours, subjects made more incorrect responses to recall that they might have seen words in the first session (i.e. remote past) that were physically presented in the second session (i.e. recent past) when the same odor conditions as ones exposed in the second session were applied, compared with two other contexts. These results revealed different effects of odor contexts on memory in respect to order of past events at 1 hr and 6 hr time points. We conclude that effects of odor contexts on memory in respect to order of past events dynamically change, probably through progressive processes of memory formation.

Title: How does consolidation influence neural and behavioral integration?

Authors: ***A. TOMPARY**, L. DAVACHI;
Dept of Pychology, New York Univ., New York, NY

Abstract: Systems-level consolidation is theorized as the transfer of neural traces of episodic memories from the hippocampus to distributed cortical regions over time. This distribution is thought to rely on the repeated extraction of information from hippocampus to cortex, a mechanism that may be well suited to facilitate the integration of memories with shared information. However, little research to date has studied how consolidation influences the neural integration of memory traces and how this relates to behavior. We developed a two-day fMRI

study to test whether memories of objects in overlapping sequences would become more behaviorally integrated over time, and how changes in memory representations might reflect this integration. Each day, subjects incidentally learned a different set of objects presented in a continuous sequence. The sequences were ordered such that some objects were always preceded by the same sequence of two objects. Immediately after the day 2 encoding session, participants completed a recognition memory test with objects from both encoding sessions. Critically, trials were ordered such that we could test for the integration of objects in overlapping sequences via priming. Preliminary behavioral data show that recognition of an object was faster when preceded by successful recognition of an object studied in an overlapping sequence. Importantly, this priming benefit only emerged for objects learned 24 hours prior to the test. These initial results suggest that consolidation might enhance the integration of memory representations with overlapping information. Planned fMRI analyses will employ pattern similarity to characterize how consolidation influences memory representations related to behavioral measures of integration.

Title: Neural pattern similarity between encoding and retrieval correlates with memory-based visual task performance

Authors: ***S. OH**[1], K.-H. CHUANG[1], C. TAN[2], P.-J. HSIEH[3];
[1]Singapore Bioimaging Consortium, Singapore, Singapore; [2]Inst. for Infocomm Res., Singapore, Singapore; [3]Duke-NUS Grad. Med. Sch., Singapore, Singapore

Abstract: The current study examined which cortical areas correlate with behavioral performance in a memory-based task, using functional magnetic resonance imaging (fMRI) and representational similarity analysis (RSA). Specifically, we tested if pattern similarity between encoding and retrieval correlate positively with memory-based task performance. Participants performed encoding and retrieval tasks for the same set of visual objects. The activation patterns for each of the visual objects were extracted separately from encoding and retrieval task sessions.

The activation pattern similarities between the two task sessions were then calculated for each of the visual objects. The results showed that the degree of neural pattern similarity between encoding and retrieval sessions in multiple brain areas correlates positively with subsequent memory-based task performance for the studied visual objects. The brain areas that showed the positive correlation include areas in medial temporal cortex, superior parietal cortex, and prefrontal cortex.

Title: Reinstating mental context with closed-loop neurofeedback

Authors: ***M. T. DEBETTENCOURT**, N. B. TURK-BROWNE, K. A. NORMAN; Princeton Univ., Princeton, NJ

Abstract: Prior work has shown that reinstating contextual information during to memory retrieval benefits recall performance (for a review, see Manning, Kahana, & Norman, 2014). In this study, we sought to investigate how contextual reinstatement can be enhanced, with the goal of improving recall. During a real-time fMRI session, participants completed multiple runs of a memory task. Each run was subdivided into three phases: study, neurofeedback, and recall. During the study phase, participants studied lists of words with photographs (e.g. scenes) interleaved between the words as context. After encoding the words into memory, participants were briefly distracted to prevent them from rehearsing items or their contexts. Then, participants were cued to start reinstating the context from the lists - that is, to think back to the photographs that had been presented during that list (e.g., to reinstate the scenes from a list with scene photographs). During this time, we applied a multivariate pattern classifier trained on voxels in the temporal lobe to decode whether they were reinstating photographs from the correct category. To help participants reinstate the correct context, we provided them with feedback

based on the output of the classifier, which reflected how strongly the correct category was represented in their brain. For feedback purposes, the participant was presented with a series of composite photographs (e.g. face/scene), and the proportions of the image categories in the mixture were manipulated. If the classifier outputs suggested they were reinstating the correct category, then the proportion of this category in the mixture increased. In other words, the stimuli were used to externalize our measures of the participant's internal context, in turn biasing subsequent internal processing in a helpful direction. If they were reinstating the incorrect category, the feedback served to provide an error signal, helping participants redirect their reinstatement. After this neurofeedback, participants were probed to freely recall as many items as possible from one of the lists. In the "valid" condition, they were probed to report the words from the list whose context they reinstated. In the "invalid" condition, they were probed to report the words from another list. Overall, memory was better on valid tests, consistent with the idea that contextual reinstatement boosts recall. Moreover, the more that participants were able to reinstate the context during neurofeedback, as indicated by classifier output, the more words were recalled. Future control experiments will explore the specific role of neurofeedback in fostering contextual reinstatement.

Title: Enhancement of numerical processing by combining phase coupled transcranial alternating current stimulation and training

Authors: *A. LEBEDEVA[1], R. COHEN KADOSH[2], H. ARSLANKOÇ[1], M. FEURRA[1]; [1]Natl. Res. Univ. Higher Sch. of Econ, Moscow, Russian Federation; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Cognitive training is undoubtedly efficient for improving arithmetical skills, but it is more effective when coupled with brain stimulation. We coupled training with brain stimulation in the form of Transcranial Alternating Current Stimulation (tACS), a noninvasive technique that modulates neural activity. Our study involved subjects who were trained for 3 consecutive days by using simple and hard arithmetical problems. At first all participants underwent pretest to evaluate their initial performance. Then they were divided into 4 groups: theta phase coupled

stimulation, theta anti-phase coupled stimulation, gamma phase-coupled stimulation and sham group. We showed that theta phase-coupled stimulation group had a robust improvement in terms of reaction times and ability to use retrieval strategy with respect to all other groups. Moreover, our subjects not only performed better in every day trained tasks , but also in untrained tasks, by showing transfer of cognitive skills to untrained problems. This evidence proves that phase coupled tACS may be used to modulate a cortical network, by inducing frequency specific improvement that lead to learning effects.

Title: Features of sleep architecture relate to the neural representation and behavioral stability of memories

Authors: *E. COWAN[1], A. LIU[2,3], S. KOTHARE[2,3], O. DEVINSKY[2,3], L. DAVACHI[1,4]; [1]Ctr. For Neural Science/ New York Univ., New York, NY; [2]Langone Sch. of Med., [3]Comprehensive Epilepsy Ctr., [4]Dept. of Psychology, New York Univ., New York, NY

Abstract: Theories of systems memory consolidation posit that memories are stabilized as they become more distributed throughout the cortex. Sleep has been linked with successful memory consolidation, and evidence suggests particular features in the architecture of sleep may relate to sleep-dependent memory enhancements. Recent evidence suggests a 24-hour delay promotes more distributed memory traces, as measured by hippocampal-cortical functional connectivity, in

manner predictive of subsequent behavioral resistance to forgetting, indicating a specific role in memory stabilization. However, it remains unknown what aspects of sleep architecture are related to the distribution of memory traces, and the effect this has on behavioral measures of memory. To investigate this relationship, we designed a three-day experiment utilizing overnight measurements of polysomnography, fMRI, and behavior. Subjects were asked to repeatedly encode sets of word-image pairs with an intervening period of overnight sleep (Sleep List), or a brief wakeful period (Awake List), thus differing in the opportunity for potential consolidation. During the second presentation, subjects restudied the previously seen word-image pairs while in the scanner. Cued source recall was probed immediately following the scan and after a 24-hour delay, providing a measure of memory stability over time. Overnight sleep was classified into its component stages, revealing a selective relationship between duration of Stage 2 sleep and memory performance for the delayed test. Analysis of the fMRI data demonstrated a positive correlation between duration of Stage 2 sleep and univariate activity in ventromedial prefrontal cortex (vmPFC), left middle occipital gyrus, and left lateral occipital cortex, but a negative correlation with activity in the hippocampus, perirhinal and parahippocampal cortices, specifically for the successfully recalled Sleep List pairs. These findings suggest that the duration of Stage 2 sleep relates to a shift in activation patterns from medial temporal lobe regions to distributed cortical regions. Furthermore, activity in the vmPFC and left middle occipital gyrus regions was found to significantly correlate with memory performance only on the delayed test, indicating that activity in these regions may relate to the stability of the memory. Additional analyses will focus on the relationship of other oscillatory features of sleep architecture, including spindle density, with the neural representation and behavioral expression of memory traces.

Title: Intrusions in episodic memory: reconsolidation or interference?

Authors: *T. SOMMER[1], A. KLINGMÜLLER[1], J. B. CAPLAN[2];
[1]Univ. Med. Col. Hamburg Eppendorf, Hamburg, Germany; [2]Psychology Dept., Univ. of Alberta, Edmonton, AB, Canada

Abstract: It would be profoundly important if one could extend reconsolidation research in animals and in other memory domains to human episodic memory. Here we examine a procedure based on free recall of objects, with a contextual reminder cue (the testing room), that has been rallied to support the notion of reconsolidation in human episodic memory (Hupbach et al., 2007). We found that replication is not straight-forward, even when matching performance-level with prior studies (Experiment 1), which raises questions about the generality of the effect. Experiment 2 included two manipulations that pitted predictions of the reconsolidation account against accounts based on interference theory. Experiment 3 examined the effect of familiarity, or salience of the testing context. Using a highly unusual testing room as context, we were able to replicate the original findings to a certain degree. Finally, experiment 4 tested whether retrieval (followed by re-encoding) might occur at all during re-exposure to the context in the absence of interfering new learning, a critical assumption of the reconsolidation account. The pattern of findings across these experiments poses serious challenges for the reconsolidation account, and may be accommodated by alternative accounts that do not assume consolidation or reconsolidation, but instead, explain behavior in terms of the two lists interfering with one another during retrieval (Sederberg et al., 2011; Gisquet-Verrier and Riccio, 2012). Title: Schema representations in hippocampus and medial prefrontal cortex support generalization in novel contexts

Authors: *R. MOLITOR[1], M. L. SCHLICHTING[1], M. L. MACK[1], K. F. GUARINO[1], S. MCKENZIE[2], H. EICHENBAUM[3], A. R. PRESTON[1];

Abstract: Past experience often influences how we learn new information. Recent work suggests that existing memories can benefit new learning by providing a knowledge framework-or schema-into which new information can be integrated. For instance, rodent electrophysiology has shown that the hippocampus forms schematic representations of task structures that support both learning of related information and generalization to overlapping contexts. In contrast, evidence of schemas in human hippocampus has only been indirect. Neuroimaging studies have found increased activation in hippocampus, as well as medial prefrontal cortex (mPFC), during encoding of events that overlap with prior knowledge. While such findings indicate that these regions support encoding of events that relate to existing memories, they say nothing about the underlying structure of the encoded representations or how they are applied in new contexts. Here, we used pattern similarity analysis (PSA) to quantify hippocampal and mPFC representations of a well-learned task structure to determine whether such schemas are reactivated in novel contexts to support generalization. During fMRI scanning, participants learned which of two objects (e.g., A or B; C or D) was rewarded in two spatial contexts (C1 and C2). The correct choice was determined by a rule contingent on spatial context, such that an object rewarded in one context (e.g., C1: A+/B-) was not rewarded in the other context (i.e., C2: A-/B+). Training on the contextual rules was followed by a transfer task with two novel spatial contexts (C3 and C4). Critically, the rule structure overlapped between training and transfer, such that an object rewarded in one training context (e.g., C1: A+/B-) was also rewarded in a corresponding transfer context (i.e., C3: A+/B-). Using PSA, we calculated the neural similarity between each object, reward valence, and spatial context to create a correlational structure characterizing hippocampal and mPFC schemas formed during training. We compared these schemas to the same correlation matrix derived from hippocampal and mPFC activation patterns during transfer. We found that hippocampal and mPFC correlational structures were preserved from training to transfer, consistent with the application of the learned task schema to the new contexts. This finding suggests that generalization of contextual rules to novel events is supported by reactivation of hippocampal and mPFC schemas. By quantifying activation patterns according to task structure, the present approach provides a direct means of measuring schemas in the human brain and offers unique insight into how prior knowledge guides learning in new situations.

Title: Examining the differential course of rule learning using a Bayesian learning approach

Authors: *A. E. CHANG[1], A. S. WHITEMAN[1], A. JOHNSON[2], C. E. STERN[1];
[1]Ctr. for Memory and Brain, Boston Univ., Boston, MA; [2]Psychology, Bethel Univ., St. Paul, MN

Abstract: This study sought to understand individual differences in context-dependent rule learning. We developed a context-dependent rule learning task in which object pairs were presented in one of four quadrants (spatial context locations) on a screen. Participants learned to associate different object pairs with spatial context through trial and error. We tested two experimental conditions in which we varied stimulus presentation order. In the object oriented condition (N = 34), the associations for one object were shown across 4 spatial locations before the associations for another object. In the spatial oriented condition (N = 37), the associations for all objects were shown in 1 spatial location before the associations for a different spatial location. To analyze the data, we created learning curves (Gallistel et al. 2004, PNAS; Smith et al. 2004, J.Neuro), and used a Bayesian learning approach (Johnson et al. 2014, SFN) to examine the progression of hypotheses participants might be testing as they gradually learned the task. The results suggest participants acquired the correct task rules more quickly in the object oriented training condition than the spatial oriented training condition. The Bayesian learning analysis showed that while each of the training conditions resulted in the correct task representations by the end of training, the probability of the correct representation developed earlier and better predicted trial outcomes in the object training condition. We also examined the effects different priors had on inference in our Bayesian learning approach. Specifically, we used flat priors to simulate naïve learning, and U-shaped priors to express the idea that participants could be testing more systematic, elegant hypotheses about the task rules as they learn (i.e. that a candidate rule either always holds or it never holds). While under the naïve learning model, behavior was consistent simply with identification of the correct task representation; under the U-shaped prior model, behavior was more consistent with participants sequentially testing different possible rules. A preliminary analysis of reaction times, however, suggested that the flat prior model might account for learning marginally better than the hypothesis-testing prior across our sample.

This approach provides an intriguing framework to examine the differential course of rule learning representations and corresponding neural substrates within single individuals.

Title: Pattern separation of systematically similar stimuli during delayed matching to sample

Authors: ***R. K. NAUER**[1,2], M. F. DUNNE[3], A. S. WHITEMAN[1,2], C. E. STERN[1,2], K. SCHON[1,2,3];
[1]Dept. of Psychological and Brain Sci., [2]Ctr. for Memory and Brain, Boston Univ., Boston, MA; [3]Dept. of Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: Pattern separation is a putative computational process to orthogonalize overlapping stimuli. Previous neuroimaging studies in humans have demonstrated that hippocampal subregions DG/CA3 are critical for successful pattern separation (Bakker et al., 2008). Tests of long-term memory (LTM) and working memory (WM) have found increased DG/CA3 and CA1 activity during encoding may support pattern separation (Carr et al., 2010) while other areas in the medial temporal lobes (MTL) including subiculum, entorhinal cortex (EC) and CA1 maintain highly similar representations during a WM task (Newmark et al., 2013; Nauer et al., 2015). Here, we extend these studies by parametrically varying the level of stimulus similarity in the context of a WM task. We hypothesized that the degree of stimulus overlap would drive recruitment of MTL areas, and that high similarity levels would negatively modulate task accuracy. Participants performed a delayed-matching to sample (DMS) task during high-resolution fMRI optimized for examining MTL cortex and hippocampal subfield contributions. Stimuli consisted of gray scale images of human faces. For each trial, two sample stimuli were shown in succession (2 s each), followed by a delay (10 s), followed lastly by a test stimulus (2 s). Participants were asked to judge whether the test face was a match to the first sample face or the second sample face, or was a nonmatch. Critically, similarity of the face stimuli was systematically varied by trial. Each trial belonged to one of three conditions: low similarity (10%

stimulus overlap), medium similarity (30% stimulus overlap), or high similarity (50% stimulus overlap). Regions of interest (ROIs) included EC, perirhinal cortex, parahippocampal cortex, and hippocampal subfields (CA1, DG/CA3, subiculum). Behavioral analysis (N=24) of accuracy showed a negative main effect of stimulus similarity, denoting accuracy decreased as similarity increased. Importantly, accuracy was above chance for all similarity levels indicating subjects were able to disambiguate stimuli successfully. Additionally, we found an interaction between similarity and trial type such that similarity had a greater negative impact on accuracy for nonmatch trials. These results suggest that participants are able to disambiguate varying degrees of overlapping stimuli and lead us to hypothesize that successful disambiguation during WM may be supported by the same putative pattern separation mechanisms that have been demonstrated in LTM. Ongoing functional neuroimaging data analysis is focused on the contributions of ROIs during the components of the DMS task related to accuracy and the degree of stimuli similarity.

Title: Resolving the paradox of mixed positive and negative correlations between confidence and accuracy in memory

Authors: *P. MASSET, A. KEPECS;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The capacity to learn and recall previously encountered objects or situations are central to adaptive behavior at timescales beyond those of sensory systems. The ability to know when to trust recalled memories and when to doubt them allows us to make plans about current and future actions. Although the ability to assign appropriate level of confidence to recalled memories confers an obvious evolutionary advantage but the accuracy of such confidence reports has been questioned in the literature. Some studies have reported strong correlations between confidence and recall accuracy while others have found no or even negative correlations. Here

we present a model that addresses this paradox. We specifically consider results from experiments revealing that confidence is positively correlated with recall accuracy for correct identifications but is negatively correlated for false identification of distractors. We present a statistical explanation and an implementation inspired by signal detection theory to show that the presence of negative correlations is expected when categorizing the data according to properties only available to the experimenter. Memories (targets or distractors) are assumed to be encoded along a decision axis with a decision boundary separating the two categories. Memories generate percepts on this axis that are sampled from a distribution as a result of noise induced during memory formation and recall. Subjects categorize the percepts according to their position with respect to the decision boundary. The reported confidence is a monotonic function of the distance of the percept from the decision boundary. We demonstrate that this simple model can account for the paradoxical correlation structure of confidence and we fit it to previously published data. Within this framework, the negative correlations suggest that the individual subjects share a common discriminability measure across the population. We discuss the potential societal applications our predictions such as improved behavioral designs to evaluate the veridicality of confidence reports in eyewitness testimony.

Title: False memories are associated with the reactivation of conceptual gist-related information

Authors: *E. A. WING[1], B. R. GEIB[2], R. CABEZA[2];
[1]Dept. of Psychology & Neurosci., [2]Duke Univ., Durham, NC

Abstract: Although long term memory can support vast amounts of information in great detail, memory processes sometimes give rise to the retrieval of inaccurate or false information. In some instances, false memories are thought to be driven by the formation of an overall conceptual gist that makes discrimination amongst similar items difficult. This process may account for effects in the well-known Deese-Roediger-McDermott (DRM) paradigm, in which subjects encode lists of words strongly related to a specific (but unpresented) critical item, and are then more likely to falsely report having studied that critical item at test. Despite numerous investigations using this paradigm, there is surprisingly little neuroimaging evidence linking

false memories to the reinstatement of distributed gist-level information from encoding. To address this issue, we first compared the distributed pattern similarity for items pairs from the same lists to the similarity of between-list pairs. Greater similarity for within-list pairs was evident in left ventrolateral prefrontal cortex (VLPFC) and posterior midline, indicating that these regions are sensitive to semantic content. Importantly, the left VLPFC also showed greater similarity for cross-phase comparisons between encoding and critical false alarms, in contrast to matched correct rejections. These results offer initial evidence that false memories are driven by the reinstatement of conceptually-related gist information.

Title: Output format - as well as input format - significantly influences performance in a free-recall multiple trial task

Authors: *V. M. SOLIS, SR;
Psychology Dept. Natl. Univ. of Mexico, Mexico City, Mexico

Abstract: Several hypermnesia studies (incremental net recall across trials) illustrate how different input formats modify performance. Words, pictures, and Socratic stimuli (dictionary-like definitions) are respectively better remembered, and words are not generally hypermnesic. An interesting question is whether output format may influence memory performance. Dragone, Brown, Krane & Krane (1980) asked that question and crossed factorially input (pictures or words) with output format (also pictures or words). Levels of cumulative recall showed higher picture recall and higher recall across trials, but they reported cumulative recall, which invariably grows across trials. Our objectives are: To examine free-recall for words and pictures across 3 trials by factorially combining input (pictures or words), with output format (also pictures or words) and to assess net recall. Method Participants. 99 freshmen, Psychology Department, University of Mexico allocated to four groups. Materials. 40 concrete, frequent concepts presented either as words or pictures. Pictorial stimuli from Snodgrass & Vanderwart´s (1980) standardised list. Design. Mixed factorial 2 x 2 x 3. Input and output format varied between-

participant, 3 free-recall trials (R1, R2, R3) varied within-participant. Procedure. Participants tested in groups. Presentation rate: 5 s/stimulus; inter-stimulus interval: 1 s. A 3-min distractor task was followed by R1. There were 2 ten-min inter-trial intervals. Results Word-word group. Net recall grew significantly across trials, $F(2, 46) = 14.41$, $p < .0001$, $\eta p2 = .39$. Pairwise comparisons tests show no differences between R1 and R2, and significant R2-R3 and R1-R3 differences, $p < .001$. Word-picture group. Hypermnesia is even higher in this group, $F(2, 46) = 70.26$, $p < .00001$, $\eta p2 = .75$. Pairwise comparisons tests show highly significant differences among trials, $p < .001$; the same pattern occurred in the remaining groups and is not reported separately. Picture-word group. This group also shows highly significant hypermnesia, $F(2, 50) = 49.49$, $p < .0001$, $\eta p2 = .66$. Picture-picture group. Hypermnesia also emerged in this condition but with the highest levels of significance and of associative strength, $F(2, 48) = 227.39$, $p < .000001$, $\eta p2 = .91$. Discussion Output format seems to influence performance. We explored the contribution of input and output formats while maintaining other relevant factors constant. Our study suggests that, together with input format, output format may be an important factor in memory tasks. These results add to the extant literature on hypermnesia and also suggest some useful strategies to plan educational and training programmes.

Title: Functional organization of the human thalamus and thalamocortical connectivity estimated by intrinsic functional connectivity

Authors: *K. HWANG[1], M. BERTOLERO[2], M. D'ESPOSITO[1];
[1]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA; [2]Psychology, Univ. of California Berkeley, Berkeely, CA

Abstract: The thalamus relays information from peripheral sensory organs to the cerebral cortex, and may also mediate the exchange of information between cortical regions. Functional

interactions between the thalamus and cerebral cortex is therefore a critical component of brain network functions. Previous resting-state functional connectivity fMRI (rs-fcMRI) and diffusion imaging MRI studies have identified thalamic subdivisions that are preferentially connected with each cerebral lobe. Recent rs-fcMRI studies however indicate that cerebral functional networks are not confined to the anatomical division of cerebral lobes. Thus, it is unclear how thalamocortical pathways contribute to this distributed cortical network organization. To answer this question, we analyzed a large-sample of high-resolution resting-state fMRI data from the Human Connectome Project and the Brain Genomics Superstruct Study. Data from 568 human participants were included. We first applied a graph-theoretic modularity detection algorithm to identify cortical functional networks. Replicating previous studies, several distributed cortical networks were identified, each corresponding to a putative functional system. We then mapped the correlation between each thalamic voxel and each cortical functional network, and assigned each thalamic voxel to its most strongly correlated cortical network. Our approach revealed a symmetric and well organized topography of thalamic parcellation. This parcellation included (1) a ventral medial subdivision linked to the somatomotor network, (2) a posterior inferior subdivision linked to the visual network (3), an anterior subdivision linked to cingulo-opercular network, (4) a mediodorsal subdivision linked to the frontoparietal cognitive control network, and (5) a posterior superior subdivision linked to the dorsal-attention network. The parcellated thalamic subdivisions were then included as separate regions of interests for further whole-brain graph analysis. Consistent with the identified topography, thalamic subdivisions linked to fronto-parietal networks, which contain many connector hubs, also were identified as connector hubs. Connector hubs are nodes with diverse connections across networks. This pattern of thalamic organization suggests that in addition to unimodal sensory processing, the thalamus likely contributes to integrative heteromodal information processing.

Title: Dissociable functional connectivity of the frontal eye field for overt and covert shifts of attention

Authors: *M.-A. MACKIE[1], T. WU[2], P. R. HOF[3], J. FAN[2,4];
[1]Dept. of Psychology, The Grad. Center, The City Univ. of New Yo, New York, NY; [2]Psychology, Queens College, The City Univ. of New York, Queens, NY; [3]Fishberg Dept. of Neurosci. and Friedman Brain Inst., [4]Fishberg Dept. of Neurosci. and Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: It is well understood that the orienting of attention can be employed via overt or covert shifts, i.e. with or without eye movements, both accompanied by activation in the frontal eye field (FEF). However, due to the existence of various populations of neurons within the FEF, whether overt and covert shifts of attention rely on the same underlying neural mechanisms remains unclear. In this study, we used tasks to elicit overt and covert shifts of attention in response to both endogenous and exogenous cues, and employed functional magnetic resonance imaging to investigate the functional connectivity of the FEF underlying the two types of shifts. General linear model results replicated previously demonstrated overlap in areas of activation for the two types of shifts, particularly in the FEF. Psychophysiological interaction analyses with the FEF as seed region revealed differential patterns of functional connectivity for the two types of shifts. Compared to covert shifts, overt shifts of attention elicited greater connectivity of the FEF to striate and extrastriate areas, as well areas near and along the intraparietal sulcus. In contrast, compared to the overt shifts, covert shifts elicited greater connectivity of the FEF to superior frontal gyrus and subcortical structures such as superior colliculus and caudate nucleus. These results demonstrate that although there are shared brain regions involved in both overt and covert shifts of attention with the FEF as the key region, the connectivity supporting these two types of orienting are different.

Title: Frontal Eye Fields TMS causes visual cortex excitability to phase-align at beta frequency

Authors: *D. VENIERO[1], S. MORAND[1], F. DUECKER[2,3], A. T. SACK[2,3], J. GROSS[1], G. THUT[1];

[1]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom; [2]Fac. of Psychology and Neuroscience, Dept. of Cognitive Neurosci., [3]Maastricht Brain Imaging Ctr., Maastricht Univ., Maastricht, Netherlands

Abstract: The human frontal eye fields (FEFs) are a main node of the attentional network. TMS studies have demonstrated that FEFs activation modulates visual cortex excitability, and attention has been shown to phase-align occipital brain rhythms at specific frequency bands. However, the oscillatory nature of changes in visual cortex excitability induced by FEF-TMS has never been examined. To this end, we employed a bifocal Transcranial Magnetic Stimulation (TMS) protocol. The first pulse was used to activate the FEFs projections to visual areas, whereas the second pulse was applied to test the resulting excitability changes in primary visual cortex (V1) or extrastriate cortex (V5) via measuring phosphenes perception as a function of the time delays between the two pulses. If FEFs activation phase-aligns oscillatory activity over the occipital cortex, one would expect a periodicity in phosphenes perception locked to the FEF-TMS pulse. Fifteen participants were enrolled to assess right FEF-right V1 (rFEF-rV1) (8 participants) or rFEF-rV5 (7 participants) interactions at 19 time delays (30 to 300 ms in steps of 15 ms). The specificity of the results to FEF-occipital area interactions was controlled for by means of two additional bifocal TMS conditions (vertex-rV1, vertex-rV5). To test for a cyclical pattern in phosphene perception rate, a curve-fitting procedure was applied fitting all cosine models ranging from 7 to 25 Hz. R-squared values were statistically evaluated using a bootstrapping procedure. For any observed periodicity we tested whether phase consistency across participants could be found, by extracting the phase of the best fitting cosine model for each participant and condition. For the rFEF-rV5 condition, cosine models in the beta-frequency range (from 14-18 Hz) significantly fitted the behavioural data. Notably, when directly testing for a phase locking to the FEFs stimulus, we found significant phase consistency for the beta band (17Hz) in the FEF-V5 condition ($p<0.01$), whereas no significant phase consistency emerged for any frequency in any of the other conditions. In conclusion, FEFs can modulate V5-by changing its excitability over time as revealed by the modulation of TMS-induced phosphene perception. We show that FEFs exert a causal influences over V5 by phase resetting oscillatory activity in the beta band. This is in line with findings suggesting that beta oscillations are mainly involved in top-down interactions within cortical networks.

Title: The effect of TMS to the frontal cortex on the relationship between arousal, attention, brain state and behaviour

Authors: V. RAZDAN[1], *W. LEGON[2], W. J. TYLER[3];
[1]Virginia Tech. Carilion Sch. of Med., Roanoke, VA; [2]Physical Med. and Rehabil., Univ. of Minnesota, Minneapolis, MN; [3]Arizona State Univ., Phoenix, AZ

Abstract: Introduction: Behavioural performance is related to the attention directed at the task. Over extended periods of time attention naturally waxes and wanes and performance can follow these attentional states. The frontal cortex is thought to contribute substantially to attentive state and has also been implicated in contributing to arousal and autonomic state. It is the purpose of this research to examine how brain state relates to autonomic state, attention and task performance. Methods: We employed counterbalanced transcranial magnetic stimulation (TMS) or sham stimulation to the left frontal cortex in 17 healthy participants before they performed the graduated continuous attention task. During the task, performance, EEG and heart rate were continuously monitored. Results: TMS had no effect on group level reaction time, coefficient of RT, nor did it affect overall errors of commission or omission. However, TMS to the left frontal cortex ameliorated the strong positive relationship between lapse rate and coefficient of RT ($r = 0.71$, $p = 0.001$ to $r = 0.24$, $p = 0.34$). Though TMS did not reduce the group level number of errors of omission or group level coefficient of RT the relationship between the two was severed. This suggests that something has changed and this may be related to arousal and brain state during the task. Examination of heart rate variability (HRV) showed a group level effect of TMS such that TMS increases HRV compared to sham stimulation ($p<0.007$). Analysis of EEG power spectra in frontal and parietal areas revealed TMS to affect the normal brain reaction to hits, misses and false alarms. Finally, analysis within task performance revealed that in general, instances of high coefficient RT are associated with high HRV and an increase in beta/gamma power. Conclusions: The precise relationship between performance, attention, arousal and brain state is not a simple one. However, based on the results of this study, times of high attention are associated with better performance and lower HRV and an idling of beta/gamma power in both frontal and parietal areas. Instances of low attention lead to increased errors and increase in HRV concomitant with an increase in beta/gamma power in frontal and parietal cortices. TMS to the left frontal cortex disrupts these normal relationships, increases HRV in general and alters the normal brain response during task demands. Thus, it may be that TMS to the left frontal cortex alters synaptic dynamics that also affects the autonomic system to produce less of a cognitive reaction to instances of both high and low performance.

Title: Isolating regions involved in conflict monitoring and cognitive control: A multi-modal approach to reducing variability in regions of interest

Authors: *S. A. HOLMES[1], M. PETRIDES[1,2], L. M. KOSKI[1,2];
[1]Neurol. and Neurosurg., [2]Psychology, McGill Univ., Montreal, QC, Canada

Abstract: Background: Adaptation to brain injury involves a transition in how information is processed in the brain. As emerging pathways over-ride existing ones, conflicts in co-activation may be resolved through cognitive control. The accurate localization of frontal brain regions underlying conflict monitoring and cognitive control is critical to understanding such functional adaptation. Unfortunately frontal cortical regions host diverse neuronal populations and structural connectivity, making global definitions unsuitable for structural and functional analysis. Objective: To identify the anatomic and stereotaxic location of regions within the anterior cingulate cortex (ACC) and non-cingulate frontal cortex (NFC) involved in conflict monitoring and cognitive control, as indexed by the Stroop interference task. Method: We performed a review of functional neuroimaging studies using a Stroop interference task in the following databases: PubMed, Brainspell and BrainMap. Exclusion criteria included: clinical populations, population <18 years of age, and studies in non-human subjects. All coordinates reported within the NFC and ACC were extracted and converted to a common (MNI) space. Coordinates in the ACC and NFC were divided into left and right hemispheres and cluster analyzed with an indicator coordinate (IC) reflecting an a priori postulate concerning the approximate locations of our regions of interest (see Cieslik et al., 2013, Cerebral Cortex 23:2677). Target clusters containing our IC were extracted, anatomically validated with respect to morphological landmarks and wrapped using a convex hull. Results: Four hundred and twenty nine articles were identified of which 29 were retained for coordinate extraction. One hundred and two independent coordinates were isolated in the NFC and 27 in the ACC. Cluster analysis identified five clusters in the left NFC, seven in the right NFC, and three in each of the left and right ACC. Target clusters in the NFC were located in the intermediate frontal sulcus (left hemisphere - vertical segment; right hemisphere - horizontal segment); whereas target clusters in the ACC were located in the paracingulate sulcus (left) and the cingulate sulcus (right).

Conclusions: Accurate interpretation of functional network activity is contingent on accurate description of an ROI's location relative to anatomic landmarks as well as stereotaxic coordinates. We have demonstrated a novel method for isolating functionally relevant ROIs. This technique is useful when confronted with a large degree of variability in the location and anatomic labeling of regions identified in the functional neuroimaging literature.

Title: Dissimilar spatiotemporal activation patterns for multiple attention tasks revealed by representational similarity analysis of EEG and fMRI data

Authors: *V. SALMELA[1,2], E. SALO[1], J. SALMI[1], K. ALHO[1,2,3];
[1]Inst. of Behavioural Sci., Univ. of Helsinki, Helsinki, Finland; [2]Advanced Magnetic Imaging Centre, Aalto NeuroImaging, Aalto Univ., Espoo, Finland; [3]Swedish Collegium for Advanced Study, Uppsala, Sweden

Abstract: We conducted identical experiments with electroencephalogram (EEG) and functional magnetic resonance imaging (fMRI) in order to examine the spatiotemporal dissimilarities in neuronal representations associated with auditory-visual attention and distractor stimuli. Our event-related experimental setup consisted of 1-back visual and auditory discrimination tasks. Orientation discrimination of a sinewave grating and pitch discrimination of sinewave tone were performed by healthy adult participants separately (selective attention), with or without concurrent stimuli in the non-attended modality, or simultaneously in both modalities (divided attention). Task difficulty and stimulus discriminability in each modality was kept at 70% threshold using an adaptive staircase method. Stimulus detection served as a control task. On 1/3 of trials, additional novel distractors, spectrally complex sounds and textures, coincided with the target stimuli. In total, there were 28 trial types corresponding to combinations of the attended modality, distractor modality, and attention task. The dissimilarities across trial types were analyzed with multivariate representational similarity analysis (RSA). Behavioral results showed that thresholds increased to two-fold in the divided-attention condition in comparison to

selective-attention condition. The distractors increased reaction times and decreased the amount of correct responses. Distractors within the attended modality interfered task performance more that distractors in the non-attended modality. Representational dissimilarity matrices (RDMs) across trial types were calculated and compared with model RDMs based on the experimental manipulations. Temporal RDMs were calculated from event related potentials (ERPs) occurring in EEG using consecutive 10-ms time windows. Significant peaks of correlation between measured and model RDMs were found at several time periods after stimulus onset, depending on the model: stimulus modality (140 ms), novelty processing (270 ms), and attention tasks (370, 430, and 520 ms). For fMRI data, a 3D searchlight (radius 3 voxels) method was used to find voxel clusters in which the activity patterns correlated with model RDMs. Stimulus-modality- and novelty-related voxel clusters were found in auditory and visual cortices and in parietal areas. Several attention-task-related voxel clusters were found in the dorsolateral prefrontal cortex. The results show separable temporal and spatial activity profiles for different trial types and suggest that attention modulates activity patterns in attention networks depending on the cognitive task.

Title: Distinct frontoparietal contributions to goal maintenance and goal directed orienting in visual search

Authors: ***J. M. G. VROMEN**[1], S. I. BECKER[1], R. W. REMINGTON[1], J. B. MATTINGLEY[2,1];
[1]Sch. of Psychology, [2]Queensland Brain Inst., The Univ. of Queensland, St Lucia, Australia

Abstract: Human visual attention is subserved by a distributed frontoparietal brain network. The contributions of different cortical regions within this network to feature-driven attentional control remain to be clarified. We investigated which frontoparietal regions are associated with goal maintenance and goal directed orienting. We had 18 participants perform a visual search task while undergoing functional magnetic resonance imaging (fMRI). The visual search

displays were identical across conditions. Instructions were varied across blocks to independently manipulate the difficulty of goal maintenance (single- versus double-component target-set) and goal directed orienting (pop-out versus conjunction target search). As a first analysis step, an independent functional localizer was used to identify regions of interest (ROIs) that were active during goal maintenance and goal directed orienting. These ROIs were located mainly within a frontoparietal network, and included frontal cortex (bilateral cingulate gyri, middle frontal gyri, and right medial frontal gyrus) and parietal regions (bilateral superior parietal lobules and insula). Next we examined activity within the ROIs as a function of the level of difficulty of goal maintenance and goal directed orienting. Increased demands on goal maintenance were associated with greater activity within anterior frontal regions, including the left anterior middle frontal gyrus, bilateral middle frontal gyri, and the right insula. By contrast, increasing the difficulty of goal directed orienting was associated with larger increases in activity within more posterior frontal and parietal regions, including the left cingulate gyrus and the right superior parietal lobule. Our findings suggest that different cortical regions within the fronto-parietal attention network make distinct contributions to goal directed orienting and goal maintenance during visual search. These findings have important implications for understanding attentional deficits that arise after focal lesions (e.g., due to stroke), and for approaches to the management and treatment of such disorders.

Title: Dissociable effects of attention and expectation during orientation discrimination

Authors: *N. RUNGRATSAMEETAWEEMANA, S. ITTHIPURIPAT, J. SERENCES; UCSD, La Jolla, CA

Abstract: Top-down factors such as attention and expectation have been shown to modulate visual discrimination by improving the quality of sensory processing. However, few studies have examined these factors within the same experiment to determine if they operate via similar or

independent mechanisms (e.g., Kok et al., 2012). A previous psychophysical study has shown that the effects of attention and expectation on behavioral performance during orientation discrimination are dissociable depending on the amount of relevant sensory information available in the display. One possible explanation that could account for this finding is that attention and expectation may affect sensory evidence accumulation differently. To test this hypothesis, we presented subjects with a display containing moving dots, half of which were blue and half of which were red. On each trial, some percentage of the dots was rendered to move in the same direction. We manipulated attention (behavioral relevance) by cueing subjects to monitor either the red or blue lines (focused attention) or to monitor both (divided attention). Expectation of the target-defining motion direction was also manipulated by varying the ratio between target directions presented in a given block of trials. Finally, we examined interactions between the strength of sensory evidence and attention/expectation by manipulating the fraction of dots moving in the same direction on the target display across two levels (low and high coherence). Subjects were instructed to indicate their response using a flight-simulator joystick, while EEG data were recorded. Past studies suggested that the rate of the central parietal positivity (CPP) build-up during stimulus viewing is a neural correlate of sensory evidence accumulation (Kelly & O'Connell, 2013). We evaluated the effects of focused attention, expectation, and motion coherence, on the CPP to dissociate the impact of each factor on the rate of sensory evidence accumulation.

Title: Granger causal connectivity associated with attention network test

Authors: ***H. CHO**, M. KWON, J. CHOI, S. JUN;
Sch. of Information and Communications, Gwangju Inst. of Sci. and Technol. (GIST), Gwangju, Korea, Republic of

Abstract: The Attention network test (ANT) is an experimental paradigm to provide an assessment of alerting, orienting, and executive network via specific reaction time (RT).

Functional magnetic resonance imaging results have shown the anatomy of attentional networks. Studies of event-related potentials (ERP) associated with ANT also showed increased posterior N1 (alerting and orienting) and modulated P3 (executive). At present, it is unclear how the brain regions are communicate each other on different attentional states. Here, we show, with Granger causal connectivity (GCC) analysis, causal flow of three different attention networks can be measured by Electroencephalogram (EEG). Thirty-two healthy participants conducted ANT experiment. We calculate the ERP for cues and targets and then the MATLAB toolbox for GCC analysis was applied. For behavioral results, averages of alerting, orienting, and executive effect are 0.0356, 0.0744, and 0.0827 sec and the effects were significant ($p < 0.01$). We observed bigger cue-locked target N1 from alerting at Pz channel and modulated P3 at Fz as figure 1(A). Furthermore, the significant ($p < 0.01$ with Bonferroni correction) GCCs were plotted as figure 1(B). As previous studies reported that right frontal and parietal areas are active during the alert state, the activation of P3 causes Fz, F3, and F4 amplitude for center cue. The pulvinar, superior colliculus, superior parietal lobe, and frontal eye fields are often activated during the orienting state. For spatial cue, Pz amplitude causes central and posterior channels and Cz cause C3. As the anterior cingulate gyrus is an important part of the executive network, GCC in our results after incongruent target shows strong frontal connectivity compare to the congruent. In summary, we succeed to show ERPs and causal flows for three attentional networks and hope these measures can be applied to diagnosis patients with attention deficit

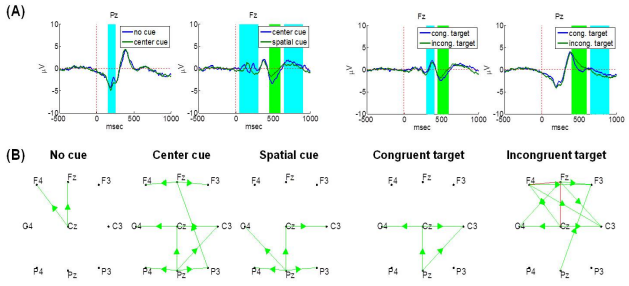

Figure 1. (A) Cue-locked target ERP. (B) First to fifth GCC plots are calculated from 0 to 2 sec after the no cue, center cue, spatial cue, congruent target cue, and incongruent target cue. Green and red lines mean unidirectional and bidirectional connectivity.

Title: Investigating brain connectivity with simultaneous TMS-fMRI

Authors: *D. RAHNEV, J. RIDDLE, D. SHELTRAW, B. INGLIS, M. D'ESPOSITO;
UC Berkeley, Berkeley, CA

Abstract: Characterizing the temporal and spatial pattern of brain connectivity is one of the critical challenges in cognitive neuroscience. Most current approaches take a correlational approach and are highly susceptible to artifactual findings stemming from confounds such as motion. This highlights the need for causal approaches in which a signal induced in one brain region can be observed to influence remote regions independent of subject motion. Simultaneous TMS-fMRI provides exactly such an approach. Nevertheless, its use has been limited due to (1) technical challenges and (2) insufficient knowledge of the effects of parameters such as stimulation intensity and number of pulses. To address some of the technical challenges in simultaneous TMS-fMRI, we developed a method to ensure microsecond level precision in the delivery of TMS pulses. This was done through a dedicated microntroller, which received TTL pulses from the scanner. The precision allowed us to employ a conventional EPI sequence without introducing temporal gaps for the TMS stimulation, as done previously. Instead, we targeted the crusher gradients, which come before and after the fat saturation pulse and last approximately 3.5 ms. Data from a phantom and human subjects demonstrated that TMS delivered in this way does not cause any artifacts in the BOLD signal. Next, we performed a series of experiments to characterize the influence of stimulation intensity and number of pulses on activity both under the coil and in remote regions. For each subject, we identified the location of the frontal eye fields (FEF) and middle frontal gyrus (MFG) based on their anatomical scans collected in a previous session. In different experiments we delivered 1, 2, 5, or 10 pulses at intensities between 50 and 120% of the subject-specific resting motor threshold (rMT). Stimulation was delivered at 11 Hz. We found that both higher intensity and higher number of pulses produced a monotonic increase in BOLD activations under the coil and in remote regions. We discuss the potential neural differences between equivalent BOLD activations produced by higher number of pulses delivered at lower stimulation intensity. The technical improvements and the characterization of BOLD response as a function of stimulation intensity and number of TMS pulses paves the way for introducing simultaneous TMS-fMRI as a mainstream technique in the toolbox of cognitive neuroscientists, and provide experimental support for its ability to characterize the pattern of brain connectivity.

Title: Source-localized EEG phase neurofeedback and its impact on brain activity - an exploratory simultaneous EEG-fMRI study

Authors: *B.-S. RAUCHMANN[1], D. KEESER[1,2], V. KIRSCH[3], B. STAMM[1], P. REIDLER[1], T. KARALI[1], R. THATCHER[4], S. KARCH[2], O. POGARELL[2], B. ERTL-WAGNER[1];

Abstract: In previous studies it was shown that EEG neurofeedback (NFB) can be used to modulate brain activity. The aim of this study was to determine whether healthy subjects are able to modulate their neural activity using source-localized EEG phase NFB training. FMRI and EEG functional connectivity networks as well as task-based fMRI and EEG (Go- NoGo paradigm) were used to evaluate possible changes for real EEG-phase NFB compared to sham EEG-phase NFB. 27 healthy male subjects (19-30 years) underwent a 30 min. single session of LORETA based EEG-phase NFB (8 rounds à 3 min., 1 min. breaks between the sessions) in a sham-controlled experimental cross-over design. The NFB-protocol was based on bilateral hemispheric phase-synchronization of the alpha1, alpha2 and beta1-band (8-15 Hz) in the Brodman Area's (BA's) 7, 8, 9, 40 and 39. If subjects were able to increase EEG-phase synchronization for at least 1 sec. a visual feedback reward was given. Simultaneous EEG-fMRI recordings were done prior and post to real and sham EEG phase NFB followed by a Go- NoGo task. EEG recordings and Go- NoGo ERPs were also recorded outside the 3T MRI scanner. The preliminary results of the fcMRI measurements indicate that there is an up-regulation in the BA's 21 and 47 for the frontal-parietal network (FPN) and the default mode network (DMN) and a down-regulation in the BA's 45, 46, 9, 38, 20, 21, 22, 23 for the auditory network and the dorsal attention network (DAT) after real NFB compared to sham NFB. There were bigger clusters of reduced connectivity patterns (320 voxels) compared to increased functional connectivity clusters (79 voxels). The preliminary resting-state EEG results showed a global reduction in absolute power of the delta-band and the high-beta-bands and increased alpha-band EEG activity after real vs. sham NFB. For the ERPs we did not find a significant difference between real vs.

sham NFB. However, we found a reduced amplitude at Fz for the N2 component for the Go condition and an increased latency. The reaction time decreased for the Go trials for real NFB vs. baseline whereas there was no significant effect for the sham condition. The results also suggest that increased EEG alpha activity is negatively associated with the BOLD-signal in frontal-temporal brain regions. Furthermore, increased EEG alpha phase was associated with reduced delta- and theta-EEG power. Based on our results we conclude that EEG-phase neurofeedback may change brain activity in the short term. Behavioral and neurophysiological alternations support this conclusion. The changes in EEG and fMRI networks are widespread and should be confirmed in further studies.

Title: The effect of transcutaneous direct current stimulation (TDCS) on brain connectivity and vigilance

Authors: *L. M. LI[1], R. BRAGA[2], C. DENTON[2], G. SCOTT[2], P. HELLYER[2], R. LEECH[2], D. J. SHARP[2];
[1]C3NL, Fulham, United Kingdom; [2]C3NL, Imperial College London, United Kingdom

Abstract: Background: Non-invasive brain stimulation such as transcranial direct current stimulation (tDCS) can modulate brain function. Weak electrical currents are applied to the brain via scalp electrodes, resulting in transient changes in neuronal excitability. The mechanism by which tDCS might influence cognitive function is unclear, but functional MRI (fMRI) can be used to investigate its effects on brain network function. Our previous work has suggested that the functional connectivity of the right inferior frontal cortex (rIFC) is particularly important for cognitive control (e.g. Bonnelle et al PNAS 2012; 109(12): 4690-95), with increased

connectivity associated with greater attention. Therefore, we aimed to investigate the effect of tDCS on rIFC functional connectivity and attention. Methods: We conducted a single-blinded, cross-over, sham-controlled tDCS-fMRI study. Healthy right-handed subjects (n=12) underwent 2 sessions of 20mins of rIFG tDCS stimulation (sham or anodal). Sessions were separated by 60minutes and the order was randomised. The anode was placed over F8 and the cathode over the left shoulder. During each session, subjects performed the Choice Reaction Task (CRT) to assess processing speed and sustained attention. Subjects had resting state fMRI before and after each stimulation session. Functional connectivity was analysed using a dual regression approach in FSL. Results: Anodal tDCS to the rIFC increased functional connectivity between the stimulated area and superior parietal parts of the dorsal attention network (DAN) compared to baseline. Compared to sham stimulation, anodal tDCS produced effects of borderline significance on functional connectivity, with increased connectivity to areas involved in cognitive control network, including lateral occipital and temporoccipital areas. Compared to baseline, sham stimulation produced no significant changes in functional connectivity. Anodal tDCS improved vigilance level towards the end of CRT performance, when sustained attention typically falls. However, this effect was also seen with sham stimulation. Conclusion: Our results suggest that anodal tDCS of the rIFG can modulate connectivity within a network of regions involved in cognitive control, with the strongest effects seen as increased connectivity to the dorsal attentional network.

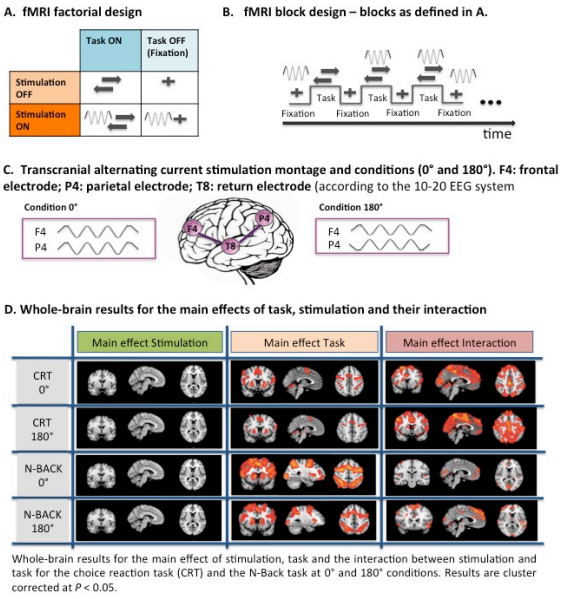
Title: Phase dependent modulation of cortical activity produced by transcranial alternating current stimulation

Authors: *I. R. VIOLANTE[1,2], L. M. LI[1], T. REED[1], D. W. CARMICHAEL[3], J. C. ROTHWELL[2], D. J. SHARP[1];
[1]Dept. of Med., Imperial Col. London, London, United Kingdom; [2]Inst. of Neurol., [3]Inst. of Child Hlth., UCL, London, United Kingdom

Abstract: Background: Transcranial brain stimulation is an increasingly popular tool used to influence brain function and cognition. However, its mechanism of action is usually unclear. Although technically challenging, combining stimulation with functional (f) MRI allows direct measurement of its effect on neural activity. Here, we report a pioneering study combining intermittent transcranial alternating current stimulation (tACS) and fMRI. A factorial design (Figure A) allowed us to test the hypothesis that the influence of tACS on brain activity depends on cognitive task performance and the phase of stimulation. Methods: Concurrent tACS and fMRI was acquired in a single-blinded, cross-over study on 20 healthy participants. TACS was targeted to regions involved in cognitive control and delivered over the prefrontal and parietal cortices at 6 Hz in two conditions: "synchronized" (0° phase difference) or "desynchronized" (180° phase difference) (Figure C). Participants performed the Choice Reaction (CRT) and the N-back Tasks. Stimulation was delivered in a counterbalanced and pseudorandom fashion during task (30 s) and rest (20 s) (Figure B). Standard FSL analysis of fMRI using ANOVA GLM was used. Results: TACS showed effects on brain activity that were dependent on cognitive task performance and stimulation phase (Figure D). Expected patterns of activity were observed for the CRT and N-back. A significant interaction between task and stimulation was present for both tasks, as the result of increased brain activity during stimulation. Moreover, phase dependent changes in cortical activity were observed in the direct comparison of 0° and 180° conditions. Participants were not able to distinguish blocks of stimulation from blocks of no stimulation. Importantly, fMRI images were not contaminated by tACS artefacts. Conclusion: We demonstrate that tACS modulates brain activity in a phase-dependent way that interacts with cognitive task performance. Combined TACS/fMRI acquisition is a powerful method to understand the mechanistic effects of brain stimulation.



Whole-brain results for the main effect of stimulation, task and the interaction between stimulation and task for the choice reaction task (CRT) and the N-Back task at 0° and 180° conditions. Results are cluster corrected at $P < 0.05$.

Title: Electroencephalographic correlates of lateralized spatial attention

Authors: *R. CHACKO[1], A. DAITCH[1], N. SZRAMA[1], M. CORBETTA[2], E. C. LEUTHARDT[2];
[1]Washington Univ. In St. Louis SOM, Saint Louis, MO; [2]Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Humans can covertly deploy attention to locations they are not foveating on. This cognitive function is important for planning eye movements and is damaged in stroke patients with hemispatial neglect. Goal-directed shifts in spatial attention are governed by a pair asymmetrical, inter-hemispheric brain networks. The temporal dynamics of these networks are investigated in the present study with electrocorticography (ECoG), which has emerged as an investigative tool for understanding cortical dynamics. We hypothesize that parietal-occipital alpha and gamma power will best predict the locus of attention. The objective of this study is to characterize the spectro-spatial predictors of lateralized covert spatial attention in ECoG. Seven patients with intractable epilepsy were implanted with subdural ECoG grids. ECoG activity and behavioral responses were recorded while subjects performed a modified version of the Posner spatial cueing task. During each trial a central cue directed subjects to attend to a locations to the left or right of the cue. Subjects were required to identify the target, which appeared at the cued location 80% of the time. We use a Gabor wavelet filter bank for spectral decomposition. We cluster-based permutation test to identify spectro-spatial predictors of lateralized covert spatial attention. We found that spectral power changes in the alpha, beta and gamma bands over parietal, temporal and sensorimotor cortices are correlated to task demands. Network-mapped electrodes reveal opposing power dynamics across attentional networks.

Title: Neural correlates of attentional benefits and costs: an fMRI study

Authors: *H. C. LÜCKMANN, F. DUECKER, V. VAN DE VEN, H. I. JACOBS, A. T. SACK;
Cognitive Neurosci., Maastricht Univ., Maastricht, Netherlands

Abstract: Covert shifts of attention to a cued location speed up detection and discrimination processes at that location (attentional benefits) and increase the time needed to react to stimuli at uncued locations (attentional costs). The magnitude of these attentional benefits and costs varies in healthy subjects and is altered in patients with attentional disorders such as spatial neglect. Studies of the neural network mechanisms underlying these interindividual differences considerably contribute to our understanding of spatial attention. Previous neuroimaging studies investigating spatial attention have often omitted a neutral cue condition, therefore not being able to differentiate benefits and costs. However, this is important, as the neural mechanisms underlying benefits and costs seem to be at least partially independent. Here, we investigated the relationship between functional mechanisms in large-scale neural networks and attentional benefits and costs on the individual level. We used an endogenous spatial cueing paradigm with central symbolic cues. Participants ($N = 15$) performed an orientation discrimination task. On each trial, either one (directive) or both (neutral) hemifields were cued, and directive cues predicted subsequent target location with 75% validity. We recorded and analysed cue effects on reaction times (RTs). Whole-brain functional MRI data of participants was acquired at a fieldstrength of 3T. We obtained participant-specific maps corresponding to well-known functional networks. These individual maps were fed into higher-level analyses to find network characteristics that show a relationship with individual attentional benefits and costs. Attentional benefits and costs were observed in all participants, with variable magnitude of the cue effects. We associated these interindividual differences with functional variations in the investigated networks. Results contribute towards a more complete account of the neural correlates of spatial attention. Considering that attention is one of the core cognitive mechanisms needed for

everyday functioning, and that it is frequently impaired in neuropsychiatric diseases, our findings are of particular interest for the development of neuromodulatory interventions targeting large-scale brain networks to boost cognition in health and disease.

Title: Longitudinal modulations of cortical responses during a visual continuous performance task: Effects of practice or intensive meditation training?

Authors: *C. E. POWERS[1], A. P. ZANESCO[2], K. R. WINEBERG[1], B. G. KING[2], K. A. MACLEAN[1], S. R. AICHELE[3], M. SAGGAR[4], D. A. BRIDWELL[5], T. L. JACOBS[1], A. WALLACE[6], C. D. SARON[1];
[2]Dept. of Psychology, [1]UC Davis Ctr. For Mind and Brain, Davis, CA; [3]Univ. of Geneva, Geneva, Switzerland; [4]Stanford Univ., Stanford, CA; [5]Mind Res. Network, Albuquerque, NM; [6]Santa Barbara Inst. for Consciousness Studies, Santa Barbara, CA

Abstract: Intensive meditation training that involves sustained selective attention on a target (e.g. breath) increases perceptual sensitivity and enhances vigilance to an extent that improves response behavior on a 32 minute continuous performance task (CPT) involving detection of

brief line length differences set to perceptual thresholds (Maclean et al, 2010). Here we aim to identify patterns of neural activity obtained during the CPT that are consistent with these behavioral data. We analyzed 88-channel event-related potentials (ERPs) recorded from 10 participants who performed the CPT six times: as a matched control group before, during, and after a 3-month meditation retreat training consisting of ~6 hours of meditation per day, and 3 months later as they underwent identical meditation training and completed the CPT before, during, and after their own 3-month retreat. Visual ERPs to unchanging non-targets (90% probability, ISI ~2 s) were expected to be modulated in response to training. This would reflect top-down control of perceptual sensitivity to non-target- (and target-) related visual information. Scalp topographic maps of current source density (CSD) obtained from the first CPT assessment of each subject as either control or trainee and were used to identify, on a per hemisphere/individual basis, the electrode closest to the current focus of the peak intensity of N1 ERP component. CSD waveforms from each hemisphere/individual/testing condition (control vs. trainee) were overlain and the N1 examined. Practice effects were observed in half the sample with considerable variability that showed patterns of both decreasing and increasing N1 negativity (current inflow) with task repetition. N1 onset or offset latency did not vary systematically with practice. In contrast, these same subjects, as trainees, showed a marked and consistent pattern (9 of 10 Ss for the right hemisphere) of N1 modulation by training of onset and/or offset latency. We interpret this training-related effect as due to efficient regulation of attentional resources and visual processing in support of task goals. These data will be discussed in relation to prestimulus alpha oscillatory patterns to investigate whether the training-related N1 changes are due to proactive up-regulation of attentional focus prior to stimulus presentation that begets increased perceptual sensitivity to targets to an extent that facilitates target detection. This work helps identify neurocognitive aspects of attention that are affected when attentional skills are cultivated with intensive meditation training and how such training may affect performance in other attention-demanding tasks.

Title: Resting EEG θ/β ratios increase reliably over the course of intensive three-month meditation retreats

Authors: A. C. SKWARA[1,2], B. G. KING[1,2], A. P. ZANESCO[1,2], C. E. POWERS[2], K. R. WINEBERG[2], M. SAGGAR[3], S. R. AICHELE[4], D. A. BRIDWELL[5], T. L. JACOBS[2], K. A. MACLEAN[2], B. K. SAHDRA[6], E. FERRER[1], B. A. WALLACE[7], *C. D. SARON[2];

Network, Albuquerque, NM; [6]Australian Catholic Univ., Sydney, Australia; [7]Santa Barbara Inst. for Consciousness Studies, Santa Barbara, CA

Abstract: Despite evidence that contemplative training is associated with improved attentional capacity and emotional well-being, the physiological bases of these trait changes remain unknown. To approach this question, we investigated changes in resting EEG activity across a 3-month residential meditation retreat (R1). Trainees (N=30) received instruction in shamatha meditation, aimed at cultivating attentional stability and beneficial aspirations for self and others. They practiced meditation ~6 hr/day and completed a battery of self-report and laboratory assessments pre-, mid-, and post-retreat. Matched wait-list controls (N=30) were flown to the retreat center for these same assessments and 3 months later underwent their own separate 3-month retreat (R2). Here we focus on EEG θ/β ratios in 2 min of eyes-open rest. θ/β has been implicated as a marker of attentional and affective traits. Increased θ/β is associated with disorders of attention and reduced emotion regulation capacity, and has been hypothesized as a marker of decreased cortical control of approach motivation (increased impulsivity). Mean CSD values (73-chan) were extracted for each subject and timepoint. Four 6-electrode clusters, left and right frontal (**F**) and parietal (**P**), were created. Cluster means were log-normalized and θ/β was calculated for each timepoint. Mixed effects models for **F** and **P** clusters with hemisphere as a factor tested longitudinal changes in θ/β across timepoint and group status (trainee, control). In R2, significant main effects were found for Timepoint in **F**, $F(2,237)=20.8, p<0.0001$, and **P**, $F(2,237)=16.99, p<0.0001$, and Status in **F**, $F(1,237)=48.5, p<0.0001$, and **P,** $F(1,237)=54.3, p<0.0001,$ clusters, as well as an interaction of Timepoint x Status in **F,** $F(2,237)=9.2$,

p=0.0001, and **P**, *F(2,237)=7.5, p=0.0007*. Mean **F** and **P** θ/β increased pre- to post-retreat in trainees, but not controls. All effects replicate in R1. Analyses comparing R1 to R2 *trainees only* revealed a main effect of Timepoint in **F** and **P** clusters, but no effect of Group or Group x Timepoint interaction, indicating consistency across retreats. Despite links between increased θ/β and difficulty with cognitive-affective regulation, previous analyses of these trainees have revealed improved response inhibition and decreased self-reported difficulty with emotion regulation following training. These findings suggest a potentially complex relation between cognitive-affective regulation and θ/β in intensive meditation training such that increased θ/β may not reflect regulation difficulty per se, but rather a greater trait-like capacity to engage with and flexibly attend to one's present-moment experience.

Title: Attention-modulated neural responses to a dynamic visual selective attention task

Authors: ***S. BRESSLER**[1], L. BONACCI[2], J. A. KWASA[2], B. SHINN-CUNNINGHAM[1]; [1]CompNet, [2]BME, Boston Univ., Boston, MA

Abstract: Successful interaction with the outside world is guided by an individual's ability to selectively attend rapidly changing targets while ignoring interfering stimuli. In the auditory domain, our lab has shown that selective attention enhances the neural representation of attended sounds while simultaneously suppressing the representation of competing stimuli. While auditory attention studies require subjects to attend a target stream over time, visual attention studies, by comparison, typically require subjects to detect a single change to a static image at a prescribed spatial location. In this study, we asked whether the temporal dynamics of auditory selective attention could be observed in an analogous visual task. Two competing sequences of flashing arrows were presented to the left and right of a central fixation point (4.8 degrees

eccentricity). In each sequence, the arrow orientations varied, creating trajectories that were either rising, falling, or zig-zagging. A cue at the start of each trial instructed subjects either to covertly attend to the left sequence (1/3 of trials) or right (1/3 of trials) sequence and identify the shape of the corresponding arrow trajectory, or to withhold responses (passive control; 1/3 of trials). The onsets of the arrows in the two streams were staggered, allowing the event-related potentials (ERPs) evoked by each arrow to be isolated temporally. Scalp potentials were simultaneously recorded using a 64-channel EEG setup. The N1 amplitudes evoked by arrows in the attended stream were greater than those evoked by arrows in the ignored stream. This effect was greatest in right parietal-occipital scalp electrodes when the stimulus was presented in the left visual field, consistent with a contralateral representation of external space in occipital lobe. N1 responses in the passive control condition were smaller than in either attend condition. Changes in ERP strength were paralleled by changes in alpha oscillations (8-12 Hz), which were stronger in parietal-occipital sensors contralateral to the ignored stream. The observed top-down modulation of ERPs evoked by events in ongoing visual streams and the associated changes in alpha oscillations are similar to those previously observed in an analogous auditory task. Based on findings from a cross-modal fMRI study from Michalka et al. (under review), we suggest that stimuli rich in temporal features engage similar spatial attention networks in intraparietal sulcus. Understanding how visual and auditory attention operate can yield insight into the different brain networks engaged by attention.

Title: Auditory-biased and visual-biased attentional subdivisions in the cerebellum revealed by functional magnetic resonance imaging

Authors: *E. J. LEVIN[1], A. L. NOYCE[1], S. W. MICHALKA[1], J. A. BRISSENDEN[1], M. A. HALKO[2], D. C. SOMERS[1];
[1]Psychological and Brain Sci., Boston Univ., Boston, MA; [2]Harvard Med. Sch. and Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Increasing evidence from behavioral and neuroimaging studies implicates the cerebellum in higher-order cognitive processes. Our laboratory has recently observed that within the caudo-lateral frontal cortex there exist visual-biased and auditory-biased attention subdivisions within a greater multiple demand network (Michalka et al.). This includes two frontal regions biased for visual-attention, superior precentral sulcus (sPCS) and inferior precentral sulcus (iPCS), interdigitated with two regions biased for auditory-attention, transverse gyrus intersecting precentral sulcus (tgPCS) and caudal inferior frontal sulcus (cIFS). Ongoing work from our lab has also shown that visual working memory and sustained visual attention tasks recruit specific regions of the cerebellum. Prior work (Buckner et al., 2011) demonstrates that resting-state functional connectivity networks in the cortex also extend to include sub-networks within the cerebellum. We found that attentional recruitment is specific to cerebellar nodes that exhibit strong intrinsic functional connectivity with the cortical dorsal attention network. The present research investigates whether these 'cerebellar nodes of the dorsal attention network' possess sub-regions biased for auditory attention or visual attention, similar to our observations in lateral frontal cortex. We used fMRI to investigate whether cerebellar attention regions are biased for audition versus vision, or are unbiased (multiple demand). Subjects performed a 2-back task on auditory and on visual stimuli. The contrast of auditory 2-back vs. visual 2-back revealed interdigitated visual-biased and auditory-biased regions in lateral frontal cortex as well as sensory-biased regions in posterior cortex (see Noyce et al., this meeting). Additionally, we employed resting-state functional connectivity using the cortical visual-attention network and auditory-attention network to define regions of interest within the cerebellum. We observed segregated auditory-attention and visual-attention sub-regions within the posterior lobe of the cerebellum. Bilateral visual attention activation was observed relatively dorsal and medial to the bilateral auditory attention activation within the cerebellar vermis. More dorsal regions of the cerebellar vermis exhibited stronger multiple demand characteristics. Our results indicate that a pair of sensory-biased attention networks recently observed in cortex extends to include regions of posterior cerebellum. More broadly, our results contribute to a growing body of evidence demonstrating cerebellar contributions to higher-order cognition.

Title: Auditory attention modulates frontal and temporal oscillatory dynamics in humans: Evidence from electrocorticography

Authors: *R. VAN DER MEIJ[1], A. BIDET-CAULET[2,3,4], J. PARVIZI[5], N. CRONE[6], E. CHANG[7], R. T. KNIGHT[3,4], B. VOYTEK[1];

Sch. of Med., Baltimore, MD; [7]Dept. of Neurolog. Surgery and Physiol., Univ. of California San Francisco, San Francisco, CA

Abstract: The brain needs to flexibly route information in distributed neuronal networks to meet the needs of rapid environmental changes. This selective communication between neuronal populations could be achieved via oscillatory dynamics. One such oscillatory phenomenon is phase-amplitude coupling (PAC), which reflects the hierarchical modulation of oscillations at different frequencies, but also the phase-coupled modulation of local neuronal spiking activity. The latter, manifested as high gamma activity (HG; 70-250 Hz) is modulated by oscillations at multiple frequencies dependent on task demands. HG can be observed as broadband increased power in the power spectrum of micro- to mesoscale measurements in human electrocorticographic data obtained from subdural recordings (ECoG). Recent evidence suggests that the power spectrum, which reflects both oscillatory and non-oscillatory processes, can provide insight into the dynamics supporting goal-directed behavior. Notably, an upward rotation (flattening) of the power spectrum could reflect a shift in neuronal resources from a regime of tight oscillatory inhibition towards one of increased sensitivity to incoming signals. Local HG activity has been shown to be modulated by low frequency rhythms that are coherent over broader regions suggesting that power spectral changes could be coordinated in a similar manner. To investigate this, we obtained ECoG recordings from 8 epilepsy patients undergoing resective

surgery while they performed a dichotic attention task. They had to detect deviant sounds within a relevant stream while ignoring an irrelevant acoustic stream. A third condition (control condition) was added in which all sounds received the same amount of attention. We found that fronto-temporal HG activity increased, frontal theta increased, and temporal alpha decreased as a function of attention. Additionally, we also observed upward rotations (a flattening) of the power spectrum at temporal electrodes, which captures both the decrease of temporal alpha, and the increase of temporal HG activity. Moreover, this spectral flattening was found to be phase-locked to distributed frontal theta rhythms, suggesting temporally coordinated changes in neuronal recruitment. Taken together, these results show the modulation of local neuronal activity by distributed oscillatory rhythms as a function of task demands. Importantly, this modulation occurred (1) on timescales as short as several 100ms, and (2) between distinct regions including auditory cortex and frontal areas. The results provide evidence that oscillatory dynamics provide a key mechanism for routing of information in the brain.

Title: Act based on what you expect: Cue-induced expectancy modulates alpha and theta oscillations

Authors: K. A. BANGEL[1], H. A. SLAGTER[2], *D. DENYS[1], A. MAZAHERI[1,3];
[1]Academic Med. Ctr. Univ. of Amsterdam, Amsterdam, Netherlands; [2]Dept. of Psychology, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: We are constantly guided by our expectations about upcoming events, which significantly influence what our attention is focused on. A number of previous studies have examined how expectation modulates the neural responses to an expected event. In contrast, the objective of this study was to explore how expectation influenced neural processes related to preparation. We investigated how expectancy about task difficulty in a visual search task

modulated oscillatory activity in the EEG, and the consequence of this modulation on the filtering of task-irrelevant information. Specifically, we examined how expectation about task difficulty modulated oscillatory activity in the theta (3-5 & 5-7 Hz), alpha (8-12 & 12-16 Hz), and beta band (16-20 Hz) prior to the onset of the visual search array. A number of previous findings have shown that the disengagement of a sensory system not important for a given task is achieved by an increase in oscillatory alpha and beta activity. In contrast an increase in theta activity has been linked to higher cognitive executive functions such as cognitive control. EEG was recorded from 14 participants who performed a visual letter search task under varying task demands. Audiovisual low and high load cues were used to generate expectancy about the likely load of the upcoming visual search task (i.e. task difficulty; Sy et al, 2014). We found a transient increase in alpha (~200-300 ms) and beta power (~370-410 ms) over sensorimotor areas following high load cue onset in the pre-stimulus interval. A transcient increase in theta power over occipital regions (660-990 ms) followed. Validly cued high load targets induced a transient increase in midline theta power about 960 ms after stimulus onset. Post-stimulus theta power positively correlated with task performance measured in reaction times on a trial-by-trial basis. We speculate that the increase in alpha power induced by high load cues indexes preparatory blocking of task-irrelevant processes as a way to allocate cognitive resources to the more difficult task. The increase in theta power with high load cues, and its positive correlation with reaction times could be related to higher response monitoring and more careful response strategies. These results together suggest that expectancy created by cue evaluation may adjust the brain for the upcoming task by inhibiting task-irrelevant processing and engaging online control processes. Title: Influencing visual target detection with oscillatory phase-specific stimulus presentation

Authors: *R. J. GOUGELET[1], T. DONOGHUE[1], M. PIPER[2], A. ALTHOFF[3], T. P. URBACH[1], B. VOYTEK[1];
[1]Dept. of Cognitive Sci., [2]Dept. of Philosophy, [3]Dept. of Computer Sci. and Engin., UCSD, La Jolla, CA

Abstract: We investigated the extent to which ongoing electroencephalography (EEG) neural oscillations emanating from fronto-parietal and occipital scalp regions in the theta (3-7 Hz) and alpha (8-12 Hz) frequency ranges contribute to the detection of visual stimuli in humans. We first observed how subject-specific alpha phase affects the detection of a cued, near-threshold visual target such that the visual cortical alpha phase at the time of visual stimulus onset biased target detection, replicating previous reports. We extended these observations by presenting visual targets at specific phases of the ongoing oscillatory alpha using a real-time oscillatory phase tracking system. We implemented online phase tracking in two ways, and compare the efficacy of them both. In the first, we sampled the ongoing EEG datastream and peak filtered it using a phase- and group-delay compensated Parks-McLelland FIR digital bandpass filter, centered at the predetermined maximum amplitude and center frequency of the subject-specific ongoing alpha oscillation. Periods when the ratio of alpha/broadband power reached a predetermined threshold were isolated for phase detection. Peaks and troughs of the filtered datastream were then extracted to determine the periodic timing of the ongoing alpha phase. We extrapolated the timing characteristics of the detected peaks to predict peak and trough phase intervals beyond the causal window of the datastream, and presented stimuli during such intervals in real-time. In the second, we recorded a few minutes of resting EEG to identify individual visual cortical alpha center frequency. These data also allow us to identify alpha peaks and troughs using a simple thresholding procedure wherein the top and bottom 0.1% of the sorted amplitude values of the raw, ongoing EEG reflect, with high accuracy, individual alpha peaks and troughs. Given the stability of the alpha occipital rhythm over short time frames, we attempted to present stimuli during specific phases of the dominant oscillatory alpha using this method as well.

Title: Oscillatory visual cortical alpha disruptions in age-related working memory impairments

Authors: ***T. TRAN**[1], N. HOFFNER[2], B. VOYTEK[3];
[2]Neurosciences Grad. Program, [3]Dept. of Cognitive Sci., [1]UCSD, San Diego, CA

Abstract: Neural oscillations in the visual cortex play an important role in attention and memory. Oscillations, in particular 8-12 Hz alpha activity, support interregional communication, and ongoing fluctuations in alpha power and phase bias perception and cognition. While these phenomena are fairly well characterized individually, here we examine the overlap between visual attention and working memory and how these oscillatory processes are affected by healthy aging. We used electroencephalographic (EEG) recordings to compare behavioral performance and alpha activity of younger and older adults (20-30 and 60-70 years old) during a lateralized, visual working memory task. In this task, subjects were first presented with a non-informative, foveally-presented alerting cue indicating the beginning of a trial. This cue was followed by brief presentation of a visual working memory array and a delay period. Subjects then reported if a second, test array was the same as or different from the memory array. In this task, older adults showed increased reaction times overall and decreased accuracy in high memory load trials. Both groups showed decreased contralateral delay activity with increasing memory load. Analysis of extrastriate alpha power revealed decreased contralateral power during the delay period in both groups. While older adults also showed decreased ipsilateral alpha power, younger adults showed increased ipsilateral power instead, revealing significant lateralized alpha power differences as a function of age. Analysis of alpha phase revealed that, while memory array presentation equally increased extrastriate phase-resetting (or intertrial coherence, ITC) in both groups, younger adults showed strong alerting-cue-induced ITC that was nearly absent in older adults. These results suggest that in performing this task, older adults make less use of the

alerting cue than do younger adults, and older adults may rely more heavily on bilateral visual cortical attention systems than do younger adults.

Title: Intracranial EEG signatures of conscious visual experience

Authors: ***W. R. XIAO**[1], R. E. SMITH[1], G. J. TOULOUMES[1], C. L. HORIEN[1], A. RAJA[1], E. C. MORSE[1], R. E. WATSKY[1], S. A. WEISS[1], S. A. WEISS[1], W. C. CHEN[1], D. D. SPENCER[2], J. L. GERRARD[2], H. BLUMENFELD[1,3,4];
[1]Neurol., [2]Neurosurg., [3]Neursurgery, [4]Neurobio., Yale Univ., New Haven, CT

Abstract: Recent advances in brain imaging have begun to show the whole-brain anatomy of areas involved in forming a conscious experience of visual awareness that results in subsequent report. Direct human electrophysiology techniques can also be used to uncover the temporal progression of neural activity throughout the brain during these events. We have developed a visual threshold perception task that elicits brief conscious events using a target face stimulus with contrast calibrated to a 50% detection rate. These events are validated by subsequent report of perception and location. The Yale Epilepsy Surgery Program implants some 100-300 subdural intracranial electrodes sampled at 1024 Hz in patients undergoing observation for intractable epilepsy. Eight such patients were recruited to perform our behavioral task during their inpatient stay. Stimulus perception rate was 55% (±3% SEM) when the target was present whereas false positive rate was 18% (±6% SEM) for blank trials. In true positive perception trials, subjects could correctly indicate the location of the stimulus in 1 of 4 quadrants 87% (±3% SEM) of the time. In true negative perception trials, the location accuracy was only 28% (±3%), close to chance levels. These behavioral results demonstrate appropriate subject engagement and performance in the task. Analysis of electrocorticography (ECoG) results show that perceived

and correctly located ("confirmed perceived") trials compared to not perceived and incorrectly located ("confirmed not perceived") trials have largely divergent event-related potentials (ERPs) in higher visual processing areas as well as fronto-parietal cognitive and medial temporal memory networks as early as 200 ms and beyond 1000 ms post-stimulus despite same contrast level. However, the early (<200 ms) ERPs in electrode contacts located directly in primary visual cortex show identical waveforms between confirmed perceived and confirmed not perceived trials. The late latency ERPs are sometimes also accompanied by high-frequency (65-115 Hz) power changes, suggesting higher-order cognitive processing in neurons at those locations. Lower frequency alpha and theta-range oscillations are found to be phase-locked to stimulus onset for confirmed perceived trials and phase-shifted for confirmed not perceived trials. These findings suggest that state-related fluctuations in the brain may gate the access of primary visual sensory information to higher cortical circuits necessary to form a conscious experience. Additional analyses of the temporal sequence of these signals may uncover network-related changes that are responsible for producing brief conscious events.

Title: Alteration of inhibition of return in involuntary visuospatial attention in the patients with rapid-eye movement sleep behavior disorder

Authors: ***M. JEONG**[1], K. CHA[1], J. CHOI[1], J.-S. KYONG[2], B. LEE[2], B.-W. LYU[2], D. JUNG[2], S. KU[2], T.-J. KIM[2], J.-S. SUNWOO[2], J.-I. BYUN[2], K.-Y. JUNG[2], K. KIM[1];
[1]Yonsei Univ., Wonju, Korea, Republic of; [2]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Rapid eye movement (REM) sleep behavior disorder (RBD) is a sleep disorder characterized by dream enactment behavior and the loss of muscle atonia during REM sleep. Recent neuropsychological tests reported abnormality in visuospatial attention in the patients with RBD. However, neurophysiological evidence about the abnormality has not been reported yet. In this study, we investigated cortical activities associated with abnormal visuospatial attention in RBD patients, focusing on neural synchronies in theta-band rhythms. Drug-naïve idiopathic RBD patients and healthy controls were involved in this study. Subjects performed Posner's cueing paradigm in which they were asked to discriminate targets (red or yellow asterisk, with 50:50 probability) and to respond by button press. The targets were presented in two boxes located at each side of central fixation. Before targets were presented, border of the box was highlighted so that subjects could covertly turn their attention to the box (cue). The time intervals between cue and target (stimulus onset asynchrony, SOA) were 200ms and 1000ms with 50:50 probability. Sixty channel electroencephalograms (EEGs) were recorded during the task. In addition to target-elicited event-related potential (ERP) analysis, evoked theta-band activity (TBA) and theta-band phase synchronization (TBPS) were analyzed to investigate local- and long-range neural synchronies. Significant TBPS patterns were analyzed using weighted graph theoretical measures, including the degree (*K*), clustering coefficient (*C*) and global efficiency (*E*). For short SOA task, the reaction time (RT) was reduced for valid condition compared to invalid condition, in both control and RBD groups (cuing effect). To the contrary for long SOA task, the RT was delayed for valid condition (inhibition of return, IOR effect). In both control and RBD groups, behavior cueing effect for short SOA was accompanied with an increase of P1 ERP component, strong TBA and TBPS, as well as more efficient theta-band network for valid condition. On the other hand, behavior IOR effect for long SOA was associated with a decrease of N1 ERP component, weak TBA and TBPS and less efficient theta-band network for valid condition. The phenomenon for long SOA was shown only in control. We found that several neural activities reflected the well-known cueing and IOR effects during visuospatial attention tasks in healthy controls. The measures reflecting cueing effect were varied in the same manner in RBD patients as in controls. However, the measures reflecting IOR effect was found only in controls. This may imply the dysfunction of attentional inhibitory system in RBD patients.

Title: The impact of unexpected salient sounds: increase in arousal versus attentional capture

Authors: *A. BIDET-CAULET[1,2];
[1]INSERM U1028, BRON, France; [2]Lyon Neurosci. Res. Center, Brain Dynamics and Cognition Team; CRNL, INSERM U1028, CNRS UMR5292, Univ. of Lyon 1, Lyon, France

Abstract: Studies investigating behavioral distraction have found inconsistent results with significant cost (see Escera et al. 2000; Escera et al. 2003 for reviews), or benefit (see Parmentier 2014 for a review) in reaction times to targets when preceded by a so-called distracting sound. These results suggest that distracting sounds would not only trigger a detrimental attentional capture but could also produce a facilitation effect. We investigated the impact of unexpected salient sounds on the processing of a target sound, by manipulating the delay between the two sounds. We could evidence that distracting sounds trigger several phenomena that produce opposite effects on the reaction time to a subsequent target: a cost by an attentional capture mechanism, and a benefit due to an increase in arousal. Moreover, the analysis of the event-related potentials revealed that (1) increasing task load in top-down attention reduces early processing of the distracting sound (N100 and early frontal P3), but not bottom-up attentional capture mechanisms indexed by the late P3 response, (2) the bottom-up attentional capture by distracting sounds on target processing results in a delayed latency of the N100 sensory response to target sounds mirroring increased reaction times. Further analysis showed that the early frontal P3 amplitude is related to the arousal content of the distracting sounds and may index the arousal increase triggered by these sounds. Therefore, this work provides evidence for different mechanisms triggered by unexpected salient sounds both at the behavioral and electrophysiological levels.

Abstract: OBJECTIVE: Arousal, or wakefulness, is a fundamental brain process on which all cognitive functions rely, and which has important clinical applications. However, the neurobiology of arousal in humans remains incompletely characterized. The underlying neuroanatomy can be studied through focal lesions that induce coma, with evidence suggesting that such lesions commonly involve the pontine tegmentum. However, the precise location of the brainstem region critical for arousal remains unclear. Furthermore, the brainstem is thought to promote arousal through ascending projections to a distributed network, but the nodes of this network in humans are poorly defined. METHODS: To identify the brainstem region critical for arousal and its associated network in humans, we integrated a lesion overlap analysis with resting state functional connectivity MRI (rs-fcMRI). We collected 36 focal brainstem lesions: 12 lesions caused coma, and 24 control lesions caused motor deficits with preservation of

consciousness/arousal. By overlapping the coma lesions and subtracting the control lesions, we identified a coma-specific region of the brainstem. We then used rs-fcMRI collected from 98 healthy individuals to identify the functionally connected network of this coma-specific region. RESULTS: The coma-specific region of the brainstem localized to the lateral pontine tegmentum, overlying the medial parabrachial nucleus (PB). The rs-fcMRI analysis revealed two functionally connected nodes: the agranular insula (AI) and anterior cingulate cortex (ACC). These regions exhibited significantly more connectivity to coma lesions than control lesions. Based on connectivity to the AI and ACC, the PB most closely resembled the coma-specific region, compared to other nearby nuclei. CONCLUSIONS: Coma-causing lesions appear to involve the PB, which exhibits connectivity to the AI and ACC in a three-node network. Damage to the PB region may therefore be integral to the pathophysiology of coma; as the PB is critical to arousal in non-human animals, our findings suggest a homologous neural system of arousal between animals and humans. The AI and ACC are the primary sites of Von Economo neurons, and have been implicated in conscious awareness in humans. Our findings therefore link a brainstem nucleus of arousal to cortical regions associated with human awareness, offering a neural basis for integration of these two processes.

Title: Increase in the brain's functional small-worldness with the capture of attention

Authors: *D. GODWIN[1], R. MAROIS[1,2,3];
[1]Psychology, [2]Vanderbilt Vision Res. Ctr., [3]Ctr. for Integrative and Cognitive Neurosci., Vanderbilt Univ., Nashville, TN

Abstract: The initial presentations of salient, task-irrelevant unexpected events can powerfully capture our attention, disrupting ongoing goal-directed behavior and transiently blinding us to other events (Asplund et al., JEP:HPP, 2010). Here, we tested the hypothesis that the extensive psychophysiological and cognitive changes associated with such attention capture are related to widespread changes in the brain's functional connectivity. Specifically, we used graph theory analysis combined with fMRI to characterize the large-scale community structure of functional connectivity data associated with the capture of attention by salient, task-irrelevant 'oddball' stimuli. Thirty participants were scanned while they searched for a target letter in a rapid serial visual presentation (RSVP) stream of distractor letters. Without warning to participants, oddball stimuli were presented during the search periods of six of the 40 trials. The presentation of these oddballs in the RSVP stream strongly captured attention and reduced detection accuracy of subsequently presented targets (Asplund et al., Nat Neurosci, 2010; Asplund et al., JEP:HPP, 2010), an effect that quickly attenuated with repeated oddball presentations. Functional connectivity between each region of interest (ROI) was assessed via pair-wise psychophysiological interactions (PPI) analysis (Mclaren et al., NeuroImage, 2012; Godwin et al., PNAS, 2015) in order to examine the interaction of connectivity seed and oddball processing. Cortical ROIs were defined using a published set of 264 coordinates (nodes) parsed into 14 identified cortical networks (Power et al., Neuron, 2011). Analyzed as a whole, the six oddball presentations produced an increase in functional modularity (measuring separability of cortical networks) and local efficiency (measuring functional distance between a node's neighbors), as well as an increase in the small-worldness of the cortical graph system driven by an increase in the clustering coefficient (measuring the number of recurrent triad connections between nodes). Importantly, the first two oddball presentations showed the greatest changes in modularity, local efficiency, clustering and small-worldness, while the later oddball presentations showed a shift towards graph metrics similar to those seen during search trials with no oddball presentations, mirroring the decrease in behavioral capture effects exhibited by repeated oddball presentations. These findings suggest that the powerful and extensive capture of attention by a salient, task-irrelevant event may result from rendering the brain's functional network connectivity a small(er) world.

Title: Functional organization of the temporoparietal cortex

Authors: *K. M. IGELSTROM, T. W. WEBB, M. S. A. GRAZIANO;
Psychology Dept. and Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: The human temporoparietal junction (TPJ) is a topic of intense research. Imaging studies have identified TPJ activation in association with many higher-order functions, such as theory-of-mind, episodic memory and attention, causing debate about the distribution of different processes. One major challenge is the lack of consensus about the anatomical location and extent of the TPJ. Here, we address this problem by using data-driven analysis to test the hypothesis that the bilateral TPJ can be parcellated into subregions. We applied independent component analysis (ICA) to task-free fMRI data within a local region around the bilateral TPJ, iterating the ICA at multiple model orders and in several datasets. The localized analysis allowed finer separation of processes, and the use of multiple dimensionalities provided qualitative information about lateralization. We identified four subdivisions that were bilaterally symmetrical and one that was right-biased. To test whether the independent components (ICs) reflected true subdivisions, we performed functional connectivity analysis using the IC coordinates as seeds. This confirmed that the subdivisions belonged to distinct networks. The right-biased IC was connected with a network often associated with attentional processing. One bilateral subdivision was connected to sensorimotor regions and another was connected to auditory regions. One subdivision that presented as distinct left-biased and right-biased ICs was connected to frontoparietal regions. Another subdivision that also had left- and right-biased ICs was connected to social or default mode networks. Our results show that the TPJ in both hemispheres hosts multiple neural processes with connectivity patterns consistent with well-developed specialization and lateralization.

Title: Selective reorienting response of the left hemisphere to invalid visual targets in the right side of space

Authors: *F. DORICCHI[1,2], M. SILVETTI[5], A. DRAGONE[3,6], S. LASAPONARA[6], E. MACALUSO[4];
[1]Universita' Di Roma la Sapienza - Dept. Di Psicologia, Rome, Italy; [2]Neuropsychology, [4]Neuroimaging, [3]Fondazione Santa Lucia IRCCS, Rome, Italy; [5]Psychology, Univ. of Ghent, Ghent, Belgium; [6]Universita' "La Sapienza", Rome, Italy

Abstract: In a recent fMRI study [1] we have highlighted anatomically overlapping though functionally separated BOLD responses to invalid and valid targets in the TPJ and IFG areas of the left hemisphere. Previous studies have usually compared directly the BOLD responses between invalid and valid targets, thus leading to the reciprocal cancellation of these functionally different responses in the left hemisphere [2]. On the contrary we have showed that when BOLD responses to invalid targets are compared to those evoked by neutrally cued ones, clear activations in the left TPJ and IFG are found. This suggests a role of the left hemisphere in reorienting. Based on this evidence, in two fMRI studies we have re-investigated: a) the preference of the two hemispheres in reorienting attention to the left and the right side of space; b) whether the overlapping responses to invalid and valid targets in the left hemisphere are generated by functionally segregated populations, i.e. MPVA of the BOLD signal. The results of these two investigations show that: a) the left hemisphere reorients attention only to the right side of space while the right hemisphere toward both sides of space; b) the responses of the left TPJ and IFG to invalid and valid targets are generated by functionally segregated populations. These findings provide the first fMRI evidence supporting the hypothesis that the higher incidence of contralesional neglect after right brain damage is linked to the preferential reorienting response of the left hemisphere to events occurring in the right side of space [3, 4]. 1. Title: Visual field asymmetries reflect the retinotopic nature of parietal cortex

Authors: *S. L. SHEREMATA[1], G. L. MALCOLM[2], S. SHOMSTEIN[3];
[1]Psychology, Florida Atlantic Univ., Boca Raton, FL; [2]Natl. Inst. of Mental Hlth., Bethesda, MD; [3]George Washington Univ., Washington, DC

Abstract: Visual attention (Sheremata & Silver, 2015) and short-term memory (Sheremata, Bettencourt, & Somers, 2010) modulate posterior parietal representations of the visual field. With increasing task demands, right, but not left parietal cortex representations reflect spatial locations across the visual field. As predicted by these hemispheric asymmetries, memory performance varies across the visual field according to task demands (Sheremata & Shomstein, 2014). In order to link visual field biases directly to parietal activity, it is necessary to show that such biases reflect properties of the parietal cortex. One such property, retinotopic organization, predicts that visual field asymmetries should be eye-position dependent. In a set of experiments, this assumption was tested by monitoring eye position while subjects performed a color change-detection task. Memory items were presented on the left or right side of the monitor while subjects fixated either the center of the screen (control condition) or locations peripheral to the stimuli. If visual field biases reflect retinotopic representations in the parietal cortex, performance should reverse when subjects fixate peripheral visual field locations. Results demonstrated that visual field asymmetries occur in retinotopic coordinates, as evidenced by a reversal of visual field asymmetries in the peripheral fixation condition compared to the control condition. Further manipulations revealed visual field asymmetries even when stimuli were presented sequentially at a single location and therefore could not be maintained in retinotopic coordinates, suggesting that visual field biases do not solely reflect maintenance of visual information. These results demonstrate that visual field asymmetries reflect underlying neural constraints and can be used to estimate asymmetries in the brain.

Title: Auditory and visual biases in 'multiple-demand' regions of human lateral frontal cortex

Authors: *A. L. NOYCE[1], S. W. MICHALKA[2], B. G. SHINN-CUNNINGHAM[2], D. C. SOMERS[1];
[1]Psychological and Brain Sci., [2]Ctr. for Computat. Neurosci. and Neural Technologies, Boston Univ., Boston, MA

Abstract: Lateral frontal cortex (LFC) is often characterized as domain-general or multiple-demand, due to its recruitment in a wide range of cognitive tasks (e.g. Duncan 2010; Fedorenko et al., 2013). We have previously used fMRI to identify discrete interleaved structures within LFC that show a preference for sensory modality during attention tasks (Michalka et al.). Here, we performed a replication test of that finding, and further investigated the sensory-biased versus multiple-demand nature of these regions. In our first experiment, we compared auditory to visual selective spatial attention. Subjects (n = 10) monitored one of two visual and two auditory stimulus streams for digits interspersed among letters. In our replication experiment, we compared auditory to visual nonspatial working memory. Subjects (n=14) performed visual 2-back (faces) and auditory 2-back (animal calls) tasks. In a direct contrast of auditory to visual task activations, both experiments identified four bilateral interdigitated regions with significant sensory modality preferences in a majority of subjects. Visual-biased superior precentral sulcus (sPCS) and inferior precentral sulcus (iPCS) alternate with auditory-biased transverse gyrus intersecting precentral sulcus (tgPCS) and caudal inferior frontal sulcus (cIFS). In the subjects who participated in both experiments (n = 7), the locations of these sensory-biased frontal lobe regions were stable over the >1 year between scans. We defined a broad lateral frontal cortical ROI in each hemisphere that encompassed all four of these structures as well as adjacent areas of LFC, and identified vertices that were significantly activated in either 2-back task (vs. passive). Approximately 25% of these vertices were activated only by visual working memory, 25% only by auditory, and 50% were significantly activated in both tasks (multiple-demand). Roughly half of these multiple-demand vertices showed a strong bias towards either the visual (36%) or auditory (19%) 2-back task. Therefore, a substantial majority of the LFC vertices that were activated in either the visual or auditory 2-back tasks exhibited a bias for sensory modality; only about 25% were activated to a similar degree in both tasks. These findings help to reconcile our

report of strong LFC bias for attended sensory modality with prior findings of multiple-demand responses in LFC: multiple-demand and sensory-biased functioning are not mutually exclusive characteristics. LFC is likely multiplexing multiple sources of information in order to support flexible responses to a rich sensory environment.

Title: Modulation of intracranial field potential responses during a spatial attention task reveals a functional hierarchy of processing in the human attention network

Authors: *A. B. MARTIN[1], L. WANG[1,2,3], Y. B. SAALMANN[1,2,4], A. SHESTYUK[5,6], N. E. CRONE[7], J. PARVIZI[8], R. T. KNIGHT[5,6], S. KASTNER[1,2];

Abstract: Spatial attention is mediated through a large-scale network that includes occipital, temporal, parietal and frontal cortical regions. While the network architecture has been well characterized using neuroimaging methods, less is known about the temporal dynamics in local regions and across the network. Here, we explored the modulatory effects of spatial attention throughout this cortical network by analyzing intracranial field potentials recorded from 729 ECoG electrodes implanted in 8 epilepsy patients. We examined the effects of attention using a variant of the Eriksen flanker task, where subjects had to differentiate between two shapes. An explicit cue indicated the spatial location of an upcoming target shape which, after a variable delay period, was presented embedded in a circular array of shapes. Specific cue-related broadband high frequency activity indicated constrained response fields in 70 electrodes (10%). We examined response modulation from those electrodes during the delay period of the task when subjects either attended to or away from the response field. We found that covert spatial attention differentially affected low frequency (4-30Hz) and broadband high gamma (50-200Hz) power during the delay, with specific profiles that developed through the delay period. Delay activity was sustained with attention across the network, with the duration of the activity shortest in visual compared to parietal and then frontal areas. We used the temporal progression of these responses to develop a functional hierarchy of activity along the dorsal pathway through nodes of the fronto-parietal attention network, from V1 through intraparietal sulcus areas IPS0-IPS5 and the frontal eye fields.

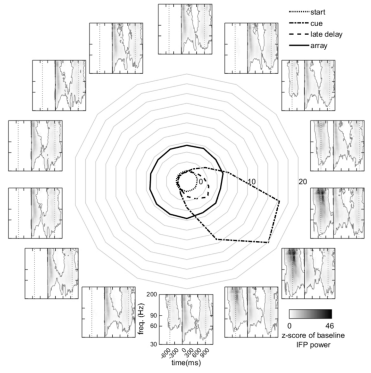

Figure 1. Example broadband high frequency selectivity during the cue and delay periods from an electrode implanted over left visual cortex. Time-frequency spectrograms show z-scored power relative to baseline (300ms prior to trial start) for trials cued at each location, aligned to array onset (0ms). Contours indicate clusters of significant activity compared to baseline ($p<0.001$, corrected for multiple comparisons). Inset polar plot shows for each cue location the mean z-score of high frequency power (70-170Hz) in the 300ms following the trial start (dotted), cue (dot-dash), and array (solid). Late delay activity is shown (dashed) for the 300ms prior to array onset. Note the significant cue and delay selectivity in the lower-right quadrant.

Title: Frontoparietal determinants of visuospatial attention

Authors: *T. J. WILSON, J. J. FOXE;
Albert Einstein Col. of Med., Bronx, NY

Abstract: Background: Selective attention facilitates neural processing of attended information at the expense of irrelevant or distracting inputs. To this end, selective attention relies on a number of mechanisms, like gain-control, oscillatory synchrony and selective entrainment, which are coordinated by the Frontoparietal Attention Network (FPAN). While much recent inquiry clearly supports a direct role for the FPAN in the deployment of attentional mechanisms like alpha oscillations and selective entrainment, the mechanisms underlying this deployment remain largely ambiguous. Also relatively unexplored is the relationship between attentional indices and the FPAN's white matter structure. Methods: Our work pairs the temporal resolution of electroencephalography (EEG) with magnetic resonance imaging (MRI) methods to reveal the nuanced relationships between the structural anatomy of the FPAN, the FPAN's temporal dynamics, downstream deployment of attention (indexed by occipital alpha oscillations and selective entrainment), and behavioral performance. Specifically, these relationships are characterized in the context of a sustained visuospatial attention task with rhythmic visual stimulation. Results: EEG evidence suggest that bilateral Frontal Eye Fields (FEFs; nodes of the FPAN) selectively entrain to rhythmic environmental stimuli. Additionally, entrainment over frontal electrode sites significantly correlates with Fractional Anisotropy (FA) of the right Superior Longitudinal Fasciculus (rSLF), indicating that this white matter tract plays an important role transmitting rhythmic attended information from occipital to frontal lobes. Lastly, selective entrainment shapes the temporal profile of ongoing activity in the alpha band (8-12 Hz) over occipital electrodes. Specifically, cross-frequency coupling is observed as a result of attention to a rhythmic stimulus. Conclusion: Entrainment of task-related neural networks to environmental stimuli may aid attempts to dissect their dynamics. The analysis presented here highlights structural and functional characteristics of the FPAN that predict task performance across individuals. Further, as it appears that that the structural characteristics of the FPAN correlate with EEG metrics of network-level activity, we hope this work will pave the way for development of non-invasive biomarkers of FPAN function for eventual clinical use in assessing disease-related risk and impairment and to monitor rehabilitation and recovery of FPAN function.

Title: Voxel-wise functional connectivity profiles support task-demand specific network motifs in multiple demand region "Inferior Frontal Junction" (IFJ)

Authors: *P. STIERS[1], A. GOULAS[1,2];
[1]Fac. of Psychology and Neuroscience, Maastricht Univ., Maastricht, Netherlands; [2]Res. Group Neuroanatomy and Connectivity, Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: A multitude of fMRI studies confirms the existence of a dedicated brain network for the execution of attention demanding task. A subset of nodes in this network exhibit the multiple demand characteristic: their activity is modulated by cognitive effort, regardless of the specific task demands. How this characteristic emerges is yet unknown. Recently, we showed that voxels within multiple-demand nodes exhibit consistent task preference profiles and therefore do distinguish between different task demands (Stiers ea NeuroImage 52:252). Moreover, voxels with similar task preferences throughout the multiple demand network show stronger functional coupling during execution of preferred and non-preferred tasks. This suggests that different task demands are processed in the network by parallel subnetworks of anatomically interconnected neuron population. A reason of existence for such subloops in multiple demand nodes could be that loop-constituting cell groups connect to different brain structures outside the network, engaged by different task demands. We used voxel-wise functional connectivity analysis in 10 healthy adult participants to investigate this hypothesis. Participants performed alternating short blocks of back-matching, response switching and flanker interference in a 3 Tesla fMRI scanner. In two runs the difficulty level of the tasks was varied to identify co-activated voxel clusters with the multiple demand property. Our analysis focused on the inferior frontal junction (IFJ) node. In four additional runs only difficult blocks of the tasks were included to independently identify the task preference profiles of the IFJ multiple demand voxels. Lastly, for each IFJ multiple demand voxel the functional connectivity (FC) profile with the rest of the brain was computed from 10 minute unsmoothed resting state fMRI data. Analysis of voxel FC profiles revealed that FC similarity (eta^2) between same preference voxels was significantly higher than between different preference voxels in the same cluster (with matched inter-voxel distances) in 10 of 10 participants, and between interhemispheric voxels in 8 of 10 participants. Moreover, whole brain

GLM analysis of FC maps averaged per participant and task preference revealed unique FC patterns associated with each task preference voxel class over participants. These results support the notion that separate subpopulations of neurons within IFJ bind different brain structures to the multiple demand node, depending on the specific demands imposed by a task. Moreover, they provide insight into the mechanism of how motifs within a larger network can be assembled for particular task demands.

Title: Examining network connectivity associated with the Sustained Attention to Response Task

Authors: *J. NAIM-FEIL[1,2], E. MOSES[1], M. RUBINSON[1], N. LEVIT-BINNUN[2];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Sagol Ctr. for Brain & Mind, Interdisciplinary School (IDC), Israel

Abstract: A key objective of cognitive neuropsychology is to examine the neural architecture underlying cognitive function. Advances in neuroimaging techniques show that adequate cognition requires recruitment of an interconnected network of brain regions. Until recently, however, it was difficult to obtain a concise quantification of the extensively interconnected human brain. To meet this limitation, neurophysicists have proposed a model of network connectivity in which topological measures based on Graph Theory can be applied to quantify complex networks of the brain. These network metrics examine the global network architecture of the brain by quantifying measures of local connectivity between cortical regions, characterizing network efficiency and identifying significant hubs of the network. Surprisingly, only a small number of studies have applied network theory to explore the network connectivity associated with cognition, and its resilience. Our study aimed to quantify network metrics associated with cognition and examine whether network analysis is sensitive to the network differences associated with cognition. We administered the Sustained Attention to Response Task (SART) to 29 healthy controls while simultaneously measuring electroencephalography (EEG). Our first objective was to examine whether the globally emergent network properties of the baseline condition (no task) differ from the effortful task condition. Our second objective was

to explore whether the network analysis could identify different network dynamics associated with the GO condition (sustained attention) relative to the NOGO condition (response inhibition). Our study demonstrated that at baseline there was a significant dampening of network metrics reflecting a less connected and global efficient network relative to the effortful task conditions. Within the effortful task condition, the GO condition was represented as a more connected, globally-efficient and resilient network than the NOGO condition. Additionally, the topological distribution of the network metrics (mean degree and clustering coefficient) was increased around frontal and parietal areas in the GO condition relative to the NOGO condition, while the NOGO condition was increased around central electrodes. Given these network metrics and the topological measures, we suggest that sustained attention relies on a widely distributed and globally efficient network, while response inhibition relies on a smaller but more centralized network dynamics. Therefore, network analysis is emerging as a useful tool for the quantification of the global networks that are fundamental for cognitive function.

Abstract: A unifying function of the default mode network (DMN), activated during rest compared to active task conditions in human and monkey has been difficult to define. In humans, it is engaged during internal modes of high level cognition. However, this DMN definition is difficult to sustain in other animal species such as monkeys or rats. As an answer to this, it has recently been proposed that, at least in monkeys, attention shifts trigger activation of posterior DMN areas (SFN 2014, Abstract nr. 11931). Here we aimed to assess to which degree shifts in spatial attention may explain DMN function in human, by comparing attention shift and default mode networks within and across species. Monkeys (N=3) and humans (N=22) performed the same covert selective attention task in the MR scanner, with interleaved periods of shifts and sustained attention (Caspari et al., 2015; Molenberghs et al., 2007). Two pairs of shapes were presented on the horizontal meridian (9.25 deg) and each pair contained a relevant and irrelevant shape. Subjects fixated centrally and responded manually when the relevant stimulus dimmed. An event consisted of the replacement of the current stimulus pair by the next. In 1/3 of the trials, this change elicited a spatial shift in attention as the relevant stimulus was replaced by an irrelevant one. Monkeys were scanned (1.25 mm isotropic) using MION contrast agent, and humans were scanned measuring BOLD (2.75 x 2.75 x 3.5 mm) in a 3T MR scanner. In monkeys, a mixed effects analysis revealed a high degree of overlap (>70%) in cortex posterior to the central sulcus (CS), between shift-related activations and the monkey DMN as defined by Mantini et al. (2011) (comparing rest vs. active task conditions in 15 experiments). In contrast, shift-related activations anterior to the CS overlapped marginally with the DMN (8.15%). In human, a random effects analysis revealed an overlap of 27% posterior to the CS, between shift-related activations and the DMN defined by Laird et al. (2009), using a meta-analysis of an activation likelihood estimation on 1711 neuroimaging publications. Similarly as in monkey, overlap in frontal cortex was small (3%). Sustained contralateral attention, compared to the DMN, activated an entirely different set of areas in both species, except for lPFC, portions of ACC and IPS in monkey. Our results indicate a functional subdivision of the DMN in both species whereby the posterior but not anterior DMN overlapped with shift but not sustained attention activations. The smaller percentage of the posterior DMN core activated for shifting in humans is in line with a large expansion of this part of cortex and, likely, an additional gain of function as compared to monkeys.

Title: Examining the effects of long-term high-intensity aerobic training on behaviors associated with the prefrontal cortex, hippocampus and striatum using electroencephalography

Authors: *J. C. BASSO, C. CROSTA, T. R. LEE, A. MCHALE, N. PAYNE, S. SHEN, N. SINGH, W. A. SUZUKI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Long-term voluntary exercise in rodents causes anatomical, physiological and behavioral changes in a variety of brain regions, namely the hippocampus (Hpc), striatum (Str) and prefrontal cortex (Pfc). Investigations of exercise-induced improvements in cognition in humans have focused on the Pfc, and few studies have sought to determine the electrophysiological correlates of such changes. In this randomized controlled trial, we examined the effects of long-term aerobic exercise on behaviors associated with the Pfc, Hpc, and Str at both a behavioral and electrophysiological level. Healthy, low-fit male and female subjects, ages 35 to 59, were randomly assigned to participate in high-intensity aerobic exercise (indoor cycling) or video gaming for 3 months. Each subject participated in three 45-minute exercise or video game sessions per week. Before and after this intervention, subjects were tested on a variety of neuropsychological tests that tapped the functioning of various brain regions while having their brain activity recorded through electroencephalography (EEG). These computer-based tasks included the Stroop Task, Reading Span Task, N-back Task, Spatial Navigation Task, Behavioral Pattern Separation Task, Pursuit Rotor Task, and Probabilistic Learning Task. Changes in mood and psychological state were also assessed through a variety of questionnaires administered before and after the intervention. Heart rate was captured during the majority of exercise and video game sessions and cardiopulmonary functioning was measured through maximal oxygen capacity (VO2 max) assessment at both pre- and post-intervention testing sessions. We predict that compared to their sedentary counterparts (video game subjects), those subjects engaged in the exercise intervention will show enhanced behavioral functioning in these brain-region specific tasks. Furthermore, those individuals that show greater enhancements in their cardiopulmonary functioning will show greater behavioral improvements. Through time-frequency and phase-amplitude coupling analysis of the EEG data, we predict that exercise will enhance alpha, beta and theta oscillations as well as coherence between low frequency bands and gamma during rest and cognitive challenge. Data is currently being collected (complete: n=3 exercise, n=4 control; enrolled: n=15 exercise, n=9 control), with a goal of n=66 (33 subjects per group) in total. At the beginning of the intervention, VO2 max scores were equivalent ($p>0.05$; mean = 16.73; SEM = 1.16). Exercise subjects expended an average of 542.2±25.48 calories per workout, resulting in an increase of up to 2.4 ml/kg/min over the 3-month period.

Title: Individual differences in alpha power modulation by verbal working memory load

Authors: ***Z. HU**, I. SAMUEL, M. DING;
J. Crayton Pruitt Family Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: During retention of verbal working memory, posterior alpha power is increased monotonically with memory load, providing a mechanism of proactive distractor suppression. In this study we investigated the individual differences in the modulation of alpha power by verbal working memory load. High density EEGs (128 channels) were recorded while healthy volunteers performed a modified Sternberg working memory scanning task. Seated in an acoustically and electromagnetically shielded chamber, the subject was shown a set of digits (0 to 9) on a CRT monitor for 1s. Following a 3s retention period, a probe digit was presented, and a “yes” (index finger in the dominant hand) or “no” (middle finger) button press was required to indicate whether the probe digit belonged to the set. Memory load was controlled by the size of the digit set which in this experiment was chosen to be 1, 3 or 5. Our main finding was that Cowan’s K as a measure of working memory capacity is negatively correlated with alpha power modulation. Specifically, the higher the working memory capacity, the less modulation of alpha by memory load. This finding suggests that subjects with lower WMC, being more susceptible to distractor interference, relies more on proactive mechanisms to suppress distraction.

Title: Adult-like resting state network connectivity but hyperconnectivity during visual working memory task in late childhood

Authors: P. JIANG[1,2], M. TOKARIEV[1,2], E. T. ARONEN[3], O. SALONEN[4], Y. MA[5], *V. A. VUONTELA[1,2], S. CARLSON[1,2];

Central Hosp., Helsinki, Finland; [5]Kunming Inst. of Zoology, Chinese Acad. of Sci., Kunming, China

Abstract: Recent developmental neuroimaging studies on brain networks have focused on the resting state functional connectivity (Power et al., 2010; Dennis and Thompson, 2013), whereas little is known about the developmental changes in the brain networks engaged in cognitive tasks. In the current study, we used functional magnetic resonance imaging to investigate the large-scale brain network differences between healthy 7-11-year-old children (n = 16) and young adults (n = 13) during both resting state and visual 1-back working memory (WM) tasks. In the WM tasks, the memoranda were either face or scenery images. We used independent component (IC) analysis, a data driven analysis method, coupled with dual regression (Beckmann et al., 2009) and permutation tests (Winkler et al., 2014). Among the ICs that were found during resting state in children and adults, we identified the major resting state networks (RSNs) including visual, auditory, sensorimotor, salience, frontoparietal, and default mode networks (Damoiseaux

et al., 2006; Smith et al., 2009). During tasks, we found ICs corresponding to several task-related networks. The between groups comparison of brain networks showed that 7-11-year-old children have already established adult-like RSNs. However, during task performance, children exhibited significantly stronger connectivity than adults in several brain networks ($p < 0.05$, Bonferroni corrected for multiple comparisons) including networks related to the default mode, sensory processing and movement. We also found that a visual IC that included the spatial cognition-related brain regions - the parahippocampal place area and the restrosplenial complex (RSC) - exhibited equivalent synchronization in the two age groups during resting state. During task performance, however, the RSC showed stronger within network connectivity in children than adults. These observations demonstrate that in 7-11-year-old children, adult-like intrinsic brain networks are already established, but the configuration of the brain networks engaged in the WM tasks is still subject to dynamic maturational changes that occur over development.

Title: Constructing partial representation of objects in visual working memory

Authors: *J. SAIKI[1], Q. LI[2];
[1]Kyoto Univ., Kyoto, Japan; [2]The Univ. of Tokyo, Tokyo, Japan

Abstract: Visual working memory (VWM) maintains task-relevant features of objects and suppresses others, but flexibility in dimension-selective maintenance and its neural mechanisms remain unclear. The current study investigated dimension specific memory maintenance using a change detection paradigm, and its neural correlates in humans using electroencephalography (EEG). Participants memorized objects defined by colors, shapes, and locations, and detected a feature swap between objects. Successful detection of the feature swap required memory for the

feature conjunctions. Performance in a BASELINE condition where all three dimensions are task-relevant was compared with conditions where a swap in color, shape, or location was ignored (COLOR, SHAPE, and LOCATION conditions). Behavioral data revealed that LOCATION condition impaired performance, but COLOR and SHAPE conditions improved performance, suggesting that locations are indispensable to form VWM representations. The neural activity data showed that indices known to be correlated with memory load reflect different aspects of VWM representations. During the maintenance period, contralateral delay activity (CDA) was correlated with the behavioral impairment in the LOCATION condition, whereas frontal midline theta (FMT) amplitude was correlated with the behavioral improvement in the COLOR and SHAPE conditions. Posterior lateralized alpha amplitude was sensitive to the task demand of excluding irrelevant dimension, regardless of behavioral impairment or improvement. Behavior impairment and reduction of CDA amplitude in the LOCATION condition was specific to the attend-right condition, indicating left-hemisphere specific impairment, but no such hemispheric asymmetry was observed in the behavioral improvement and FMT increase in the SHAPE and COLOR conditions. This difference in hemispheric asymmetry also suggests functional dissociation between exclusion of spatial and non-spatial features. These results indicate that VWM can form and maintain partial representations of multidimensional objects, and neural indices reflect different structural aspects of these representations. In particular, spatial and non-spatial features play dissociable roles in the construction of partial representation of objects.

Title: Attentional modulation of the contralateral delay activity (CDA) during working memory retention

Authors: ***D. CISLER**, M. N. JESSO, R. PARASURAMAN, P. GREENWOOD;
George Mason Univ., Fairfax, VA

Abstract: Interactions between attention and working memory (WM) are important for the fundamental cognitive processes involved in formation and retention of mental representations. We hypothesized that the role of visuospatial attention in WM involves enhancing the target figure and suppressing the ground. One prediction of this hypothesis is that a location precue closely encompassing the target of a WM task would result in a more accurate target mental representation andtherefore require less cortical activity to maintain target representation during the delay period. Cortical activity was measured in the contralateral delay activity (CDA), shown to index WM load (Vogel et al., 2005).On each trial,young adult participants (n=7) were first shown an arrow (300ms) above a fixation cross indicating which half of the screen they should attend. The arrow then disappeared and only a fixation cross was visible for 350ms before a bilateral rectangular bracket cue subtending 4.0 degrees, 6.5 degrees, or no cue, was presented for 500 ms.At cue offset, bilateral memory arrays consisting of 2 or 4 red and blue rectangleswere presented for 100 ms.Factors were memory load (2) and cue size (3). Following memory array offset, a 900ms delay interval began during which only the fixation cross was visible.Finally a test display appeared and participants made a speeded decision within 2 s indicating whetherthe test displaywas the same or different from the target.The CDA was calculated from PO3/PO4 difference waveforms and the voltage wasaveraged between 300-900 ms of the delay period. We found that as cues became more precise, the negative CDA became more positive (p=.09)andtarget discrimination RTbecame faster.The smaller CDA presumably reflectedthe amount of neural activity needed to maintain the mental representation during WM maintenance.Theseorderly findings suggest that the more precisely visuospatial attention isfocused on target location prior to encoding, the less neural activity is required to maintain the mental representation during the delay period.This is consistent with the hypothesized role of visuospatial attention in WM in enhancing target mental representation during WM maintenance.

Title: Characterizing frontal-medial activity in working memory with electrocorticography

Authors: *E. L. JOHNSON[1], S. M. SZCZEPANSKI[1], J. PARVIZI[2], J. J. LIN[3], R. T. KNIGHT[1];
[1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [2]Dept. of Neurol. & Neurolog. Sciences, Sch. of Med., Stanford Univ., Palo Alto, CA; [3]Dept. of Neurol., Univ. of California, Irvine, Irvine, CA

Abstract: Our ability to maintain and process information in an active state is a critical component of high-level cognition. While decades of research implicate the lateral frontal cortex as well as parietal, temporal, and/or occipital regions in neural networks that underlie working memory function, far less is known about the role(s) of frontal polar (FPC) and orbitofrontal (OFC) cortices, termed the frontal-medial network. Studies of FPC neurophysiology are uniquely limited because the most rostral region of the FPC is not developed in the closest non-human primates. We examined high-gamma (HG; 70-250 Hz) activity within frontal-medial regions using multi-modal electrocorticography (ECoG). ECoG yields data of unparalleled spatiotemporal resolution in human neuroscience, and that include an expanded range of frequencies over non-invasive electrophysiology. Importantly, HG activity has been linked to neuronal spiking and shown to represent individual stimuli in the cortex, and when coupled with low-frequency oscillations, may facilitate long-range information transmission. Subjects with subdural (n = 1) and/or depth (n = 3) electrodes maintained “what”, “where”, and/or “when” information online in preparation for an immediate test. They studied pairs of two colored shapes, presented one at a time in specific spatial and temporal positions. After a 900-ms maintenance period, they were given a test prompt - SAME (”what”), TOP/BOTTOM (”where”), or FIRST/SECOND (”when”) - and then a 900-ms processing period before indicating the response. We report the temporal dynamics of HG power during both 900-ms delay periods. In each subject, we found increases in HG power during processing compared to maintenance, consistent with findings that frontal-medial cells encode goals at the time of feedback. Two patterns of activity emerged during the processing period such that electrodes showed either information-selectivity or power increases irrespective of information type. All information-selective electrodes showed increased, transient HG power when subjects were processing “where” or “when” information, compared to “what” information. Furthermore, distinct subgroups of electrodes in a left FPC subdural grid revealed selectivity for “where” relative to “when” or “when” relative to “where” information. These “where”-selective electrodes were located in a relatively rostrolateral region, compared to “when”-selective electrodes, which were

dispersed in a more caudomedial array. We provide initial evidence of activity that is spatiotemporally distributed by information type within the frontal-medial network.

Title: Working memory for visual motion in human areas MT and MST

Authors: *A. D. SHELDON[1,2,3], B. KUNDU[3,2], B. ROKERS[1], B. R. POSTLE[1,4];
[1]Psychology, [2]Neurosci. Training Program, [3]Med. Scientist Training Program, [4]Psychiatry, Univ. of Wisconsin-Madison, Madison, WI

Abstract: How does the brain accomplish the short-term retention of visual motion? In the monkey, although the sample stimulus drives elevated spiking in area MT, this activity quickly returns to baseline during the delay period (e.g., Zaksas and Pasternak, 2006). Simultaneous recordings in three regions have revealed elevated delay-period spiking in dorsolateral PFC and in MST, and robust decoding of remembered direction of motion from these signals, as well as from the delay-period local field potential in MT (Mendoza-Halliday et al 2014). In the human, functional magnetic resonance imaging (fMRI) signal in "MT+" -- a region of interest (ROI) that does not differentiate MT from MST -- is phasically elevated to sample and probe stimuli, but returns to baseline during the delay, although multivariate pattern analysis (MVPA) decodes remembered information throughout the trial (Riggall and Postle, 2012), with a fidelity that predicts behavioral precision (Emrich, Riggall, et al. 2013). In the present study, we independently localized area MT and MST (Huk, et al., 2002). Subsequently we measured BOLD response during delayed recall for the direction of 1-sec samples of dots moving with

100% coherence in one of three directions. In a preliminary n of 5 subjects, fMRI signal intensity in the two regions showed comparable patterns of robust phasic responses to sample and probe events, and a return to baseline during the intervening delay period. MVPA decoding performance, above chance for both regions, was superior for MT. Thus, for the human, as in the monkey, the physiological bases of the short-term retention of motion information may differ between MT and MST.

Title: Delay-period activity of the parietal cortex depends on working memory load, not interference

Authors: ***M. J. STARRETT**[1], O. GOSSERIES[2], J. J. LAROCQUE[3], E. SAAD[2], N. COWAN[4], B. R. POSTLE[1,2];
[1]Psychology, [2]Psychiatry, [3]Med. Scientist Training Program, Univ. of Wisconsin-Madison, Madison, WI; [4]Psychological Sci., Univ. of Missouri-Columbia, Columbia, MO

Abstract: One of the striking findings to come out of recent multivariate pattern analysis (MVPA) studies of visual short-term memory (VSTM) and working memory is that elevated delay-period activity - long considered a correlate of the storage of information - often does not carry stimulus information. In some parietal regions, including the intraparietal sulcus, signal intensity and MVPA both instead reflect working memory load. Here, we tested two competing, current accounts of this activity using functional magnetic resonance imaging (fMRI). One hypothesis is that load-sensitive increases in fMRI signal correspond to increased inhibition among mental representations. A second is that this activity reflects the increased demands on the selection mechanisms of a domain-general attentional system, such that more activity is required to select and sustain attentional prioritization with each additional item that is added to the load. To adjudicate between increased-inhibition and increased-selection accounts, we compared patterns of activity associated with increasing load via the number of items within the same stimulus category versus increasing load via items drawn from different categories. On

load 1 trials, subjects viewed an aperture in which a group of dots moved coherently. On within-category load-3 trials, three directions of motion were presented serially; on between-category load-3 trials, one direction of motion and two colored circles were presented serially (and, across trials, in different order). On all trials, the recall probe appeared as a virtual dial with the digit at the middle of the dial indicating which item to recall ("1", "2", or "3") by rotating the needle to indicate either the recalled direction of motion or the appropriate location on a color wheel. Behavioral estimates of mnemonic precision for the direction of motion were highest on load-1, markedly lower on between-category load-3 trials, and lower-still on within-category load-3 trials. These findings are consistent with our expectation that within-category load-3 trials would generate more inter-item interference. MVPA of activity from MT+ and more posterior visual regions indicated that the fidelity of the neural representation of the critical direction of motion dropped markedly between load 1 and the load 3 conditions, but did not differ between the latter two. Delay-period signal intensity in parietal cortex also showed the expected load sensitivity, but, critically, with the highest signal for between-category load-3 trials. These findings suggests that this region supports an operation that is insensitive to inter-item interference/inhibition.

Title: Modeling current density distribution for transcranial direct current stimulation: effect of conductivity

Authors: *M. S. SHERWOOD[1,2], J. H. KANE[1,3], M. P. WEISEND[1,2,3];
[1]Wright State Res. Inst., Beavercreek Township, OH; [2]Biomedical, Industrial, and Human Factors Engin., [3]Neuroscience, Cell Biology, and Physiol., Wright State Univ., Dayton, OH

Abstract: The effectiveness of transcranial direct current stimulation (tDCS) is likely dependent on the intensity and direction of current through the cortex. Finite Element Method (FEM) models are used make predictions regarding the brain regions that will be stimulated in tDCS. FEM models are limited by the detail and accuracy of tissue segmentation as well as

conductivity values assigned to each tissue compartment. FEM's have progressed from simple concentric spheres to magnetic resonance imaging (MRI) based realistic models. However, a wide range of conductivity values has been reported in the tDCS modeling literature. To our knowledge, there has not been a report demonstrating the impact of this variance on the distribution of current density in FEM models. A discrete anatomical model derived from a high-resolution MRI was obtained from BrainWeb. The number of compartments of this model, subject 18, was reduced to 7 isotropic compartments and manually corrected. Two electrode pads each modeled as 2x2x0.2 cm^3 were positioned on the scalp (anode-C3 and cathode-right supraorbital) and a FEM model was generated. Current distributions were calculated with tissue conductances from four previous publications assigned to the compartments within the FEM. The conductivity of air and blood were maintained at 1e-15 and 0.67 S/m, respectively. Inward normal current density (2 mA total) was applied to the exposed surface of the anode, ground to that of the cathode, and all other external surfaces were electrically insulated. Model 1 (M1) served as the baseline for computing differences in percent change in current density magnitude and orientation. M1 and M2 showed a large variation in current density magnitude on the GM surface. However, orientation changes varied across all three models. The changes in the current density were primarily under the electrode site. In contrast, the changes in orientation impacted spatially disparate regions of cortex and interacted with gyro folding. At present interventions are being designed with FEM models, each model potentially suggesting different electrode montages. The conductivity values, model detail, and accuracy of segmentation should be either uniquely determined or standardized to developed accurate, realistic models.

Conductivity (S/m) of FEM tissue compartments.

Title: A synaptic theory of limited capacity of working memory

Authors: Y. MI[1,2], *M. V. TSODYKS[1];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China

Abstract: Working memory (WM) refers to the short-term storage of stimulus information for the purpose of processing a cognitive function. Cowan summarized the experimental evidence that human subjects can only memorize about four different chunks in a WM task. However, the neural mechanisms underlying the limited capacity of WM remain largely unknown. Recently, we proposed a synapse-based theory for short-term information storage in a neural circuit. In this model, memory is retained in the facilitated recurrent connections between neurons, as opposed to the conventional mechanism relying on persistent neural responses to encode information. Here, we investigate how this information storage mechanism restricts the capacity of WM. We consider a neural circuit, which consists of multiple excitatory neural clusters and an inhibitory neuron pool. Each excitatory neuron cluster represents a specific memory item, and its activation signals the recall of this item. All clusters are connected to the inhibitory neuron pool, so that their activities compete with each other and hence only one item can be recalled at any given moment. Within each excitatory cluster, neurons are strongly connected with each other and their synapses exhibit short-term synaptic plasticity. Meanwhile, all excitatory neurons receive a constant background input, reflecting the arousal signal when the neural system is engaged in a WM task. When a single cluster receives a brief excitatory input pulse (loading of the corresponding memory item into WM), it generates a population spike (PS); if furthermore the concurrent background input is strong enough (a strong arousal level), the neuron cluster dynamics falls into a periodic state, so that the memory item can be reactivated repeatedly. When several items are loaded sequentially, the corresponding neuron clusters coordinate their dynamical behaviors to generate PSs cyclically. The memory capacity of the system is therefore the maximum number of PSs that can be accommodated in the periodic activity state of the network. Our analysis and simulations show that WM capacity of the model depends chiefly on the parameters characterizing short-term synaptic plasticity and inter-cluster recurrent

connections. Moreover, for realistic choice of parameters, we found that our model is compatible with empirically obtained WM capacity.

Title: Evoked responses and alpha oscillations reflect the top-down modulation of working memory representations

Authors: ***S.-J. LIM**, M. WÖSTMANN, J. OBLESER;
Max Planck Res. Group Auditory Cognition, Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Selective attention is known to facilitate perceptual encoding of task-relevant stimulus into working memory (WM). Such facilitation is reflected in modulations of evoked potential responses and neural oscillations, especially in alpha frequency band (8-12 Hz), both serving as neural markers of attention-related perceptual processing and WM load. However, little is known about a beneficial role of selective attention directed towards objects maintained in WM: whether the orientation of attention to objects in WM improves representational quality of auditory WM and whether the attention-related neural correlates play specific roles in top-down modulations of representations held in memory. Using electroencephalography, we here investigate the underlying neural mechanisms of selective attention to auditory WM, in a syllable-pitch discrimination task with retroactive cues. On each trial, human listeners (N=20) encoded two distinct, sequentially presented syllables that were equally task-relevant. In some trials, a valid retro-cue was presented during the retention period to indicate which of the syllables in WM would be probed at the end of the trial. Other trials provided an uninformative neutral cue. Directing attention to specific syllable objects in WM in the valid cue trials led to faster responses and improved detection of precise acoustic change in the attended syllable. This benefit from selective attention to auditory WM objects was reflected in neural modulations of both evoked potentials and alpha oscillatory power. First, a sustained negative response during the retention period following the retro-cue was enhanced in amplitude. The extent of this

amplitude modulation predicted the behavioral benefits from a valid versus neutral cue quantified as perceptual sensitivity (d'). Second, compared to the neutral retro-cue, the valid cue induced suppression of centro-parietal alpha power. The extent of this alpha power suppression predicted inter-individual differences in precise recall of syllables maintained in WM. In sum, our results suggest that selective attention to auditory WM objects improves the representational quality of objects in WM. The extent to which participants benefit from directing attention to specific WM objects is predicted by modulations of evoked responses and alpha power.

Title: Working memory in mouse and man: novel genetic variants in the formiminotransferase cyclodeaminase (FTCD) gene identified in mice and assessed in humans

Authors: *K. D. SCHMIDT[1], R. JANKORD[1], M.-K. LIN[2], R. LIPSKY[2], R. PARASURAMAN[2], P. M. GREENWOOD[2];

Abstract: Working memory (WM) is important for real world cognitive functioning. Knowledge of specific genes modulating WM performance can be informative about underlying molecular mechanisms of memory formation and retention. WM has been found to be highly heritable (Ando et al., 2001). However, the only cognitive measure investigated in a genome-wide association study (GWAS) used IQ as a phenotype and found no single nucleotide polymorphisms (SNPs) reaching genome-wide significance (Davies et al., 2011). The GWAS approach is impractical for investigating the genetics of WM as large samples with required phenotypic information do not exist. Using a candidate gene approach, WM performance has been associated with several genes (e.g. Greenwood et al., 2014). However, a less biased approach is sought. We investigated the gene encoding the enzyme formiminotransferase cyclodeaminase (FTCD), the autoantigen recognized by anti-liver cytosol type 1 (LC1) autoantibodies in type 2 autoimmune hepatitis (AIH) patients. Its role in the biosynthesis of the neurotransmitter glutamate is not well understood. FTCD was hypothesized to modulate working

memory in humans based on Quantitative Trait Locus mapping of BXD mice for Morris Water Maze performance (Shea et al., 2013). The Allen Human Brain Atlas shows robust mRNA levels for the FTCD gene in the caudate, putamen, and globus pallidus, as well as the dentate gyrus. In a large sample of healthy people, we examined two SNPs in the FTCD gene, rs914246 and rs914245. These SNPs were selected based on clinical significance reported in the literature, minor allele frequency, SNP location on the promoter region of the FTCD gene, and potential for effects on microRNA binding sites. 790 healthy males and females, ages 17 - 90, participated in a delayed match-to-sample task manipulating memory load (1, 2, or 3 target locations) and discrimination difficulty (same or different location 2°, 4°, or 8° between probe and target). Participants were genotyped using TaqMan PCR. Group effects on accuracy (3 levels of load and 3 levels of difficulty) were marginal for rs914246 and significant for rs914245; the strongest effects of the latter were seen under high WM load with heterozygotes more accurate compared to both homozygote groups. The effect of microRNA silencing of reporter gene expression in mammalian cell lines and human primary neuron cultures are being used to validate these results and provide evidence on a mechanism of action for FTCD effects on WM. This mouse to human approach has the potential to increase knowledge of molecular mechanisms modulating WM--offering novel genetic predictors of WM performance and pathways for WM interventions.

Title: Features of neurodynamics of the human brain during a memory task depending on the level of emotional burnout

Authors: *S. TUKAEV[1], M. SYVASH[2];
[1]Natl. Taras Shevchenko Univ. of Kyiv, ESC, Kyiv, Ukraine; [2]Dept. of Human and Animals Physiol., Natl. Taras Shevchenko Univ. of Kyiv, ESC "Institute of Biology", Kyiv, Ukraine

Abstract: Emotional burnout refers to a syndrome caused by chronic stress. The formation of emotional burnout may lead to persistent changes in cognitive activity and particularly in memory and attention. As the power of human EEG-spectrum components varies significantly under cognitive testing, the aim of our study was to investigate the dynamics of changes of EEG

parameters under a memory task depending on the severity of burnout. 42 healthy volunteers (students aged 18 to 24 years) participated in this study. EEG was registered over a period of 3 minutes during the rest state and 10 minutes during a verbal memory task. The spectral power density (SPD) of all frequencies from 0.2 to 35 Hz was estimated. The Mann-Witney criterion was carried out for the comparison of the independent data samples. The correlations were estimated using the Spearmen's coefficient correlation. In order to determine the stages of burnout we used the test “Syndrome of emotional burnout” (by Boyko), adapted for students. We observed variations in parameters of EEG during memorizing and retention phases depending on the intensity of the burnout. The intensity of the Exhaustion stage varied inversely with SPD in alpha3 (parietal and temporal regions), beta1 (parietal regions) and beta2 (parietal, right occipital and temporal regions) during the memorizing phase. The formation of the Exhaustion stage of burnout was accompanied by a decrease in alpha3 (parietal, left occipital and right temporal regions), beta1 (parietal, occipital and left temporal regions) and beta2 (parietal regions) during the retention phase. Our data indicate that short-term memory depends on the emotional state of subjects.

Title: Facilitation of working memory training and transfer by prefrontal transcranial direct current stimulation (tDCS)

Authors: *C. PLEWNIA, P. RUF;
Univ. of Tuebingen, Tuebingen, Germany

Abstract: Background: Transcranial direct current stimulation (tDCS) applied to the dorsolateral prefrontal cortex (dlPFC) has been shown to modulate cognitive functions, particularly working memory (WM) performance. Since evidence regarding enhancement of WM-training by tDCS is less decisive, we set out to test efficacy, sustainability and transferability of a tDCS

augmentation of WM-training. As WM functions appear to be at least partially lateralized, we also addressed the interaction of task characteristics (spatial vs. verbal) and stimulation site (right vs. left). Methods: In two randomized, sham-controlled studies, 71 healthy, right-handed young adults were trained on an adaptive n-back task (Exp.I: spatial n-back: Exp.II: verbal n-back). Training was performed in six sessions comprising a baseline, three tDCS-enhanced trainings during one week, and two subsequent tDCS-free sessions (three days and three or nine months later). Anodal (1 mA, 20 min) or sham tDCS was applied to the left or right dlPFC parallel to the training. In sessions without tDCS (at baseline and the last two sessions), performance on a transfer-task (Exp.I: verbal 3-back: Exp.II: spatial 3-back) was tested. Results: Concurrent activation of the dlPFC by anodal tDCS improved learning of spatial and verbal n-back tasks when applied to the right and left dlPFC respectively. These effects were dependent on baseline performance. Most importantly, the tDCS-induced learning gains were found to be transferred to the untrained 3-back task and lasted for up to nine months. Conclusion: Our data clearly indicate that WM-training can be significantly enhanced by tDCS. The documented long-lasting, transferable, laterality- and task-specific effects of anodal tDCS point towards a behaviorally relevant and sustainable facilitation of underlying neuroplastic processes. This approach opens new perspectives for a targeted treatment of impaired executive functioning in various neuropsychiatric disorders.

Title: Distinct effects of dopamine and subthalamic nucleus stimulation in associative learning and retention in Parkinson's disease

Authors: *J. VENTRE-DOMINEY[1], H. MOLLION[2], E. BROUSSOLLE[2];
[1]INSERM, Bron, France; [2]Neurol. Hosp., Lyon, France

Abstract: Parkinson's disease (PD) can affect cognitive functions including visual memory and learning which deficits can be at least partially compensated by dopamine medication or subthalamic nucleus stimulation. The effects of these PD therapies differ according to the learning processes involving the dorsal versus ventral part of the striatum. In this study we investigated and compared the outcomes of dopamine versus stimulation treatment in PD

patients ability to acquire and maintain over successive days their performance in visual working memory. PD patients performed conditional associative learning embedded in visual (spatial and non spatial) working memory tasks over two consecutive days either ON or OFF treatment. While PD patients were faster in memory tasks ON versus OFF stimulation independently of the day of testing, performance in medicated patients differed depending on the medication status during the task acquisition. PD patients who learnt the task ON medication the first day were able to maintain or even improve their memory performance both OFF and ON medication on the second day after consolidation. These effects were specific of dopamine mediation as it was observed in all patients with dopamine replacement whatever the age of the PD group. This enhancement in memory performance after having learnt under dopamine medication and not under STN stimulation was most significant in visuo-spatial working memory tasks suggesting that dopamine replacement in the depleted dorsal striatum is essential for retention and consolidation of learnt skill.

Abstract: Working memory refers to the executive processes responsible for temporary storage and manipulation of various domains of information to guide goal-directed behavior. Much of the neuroimaging literature for working memory have focused on exploring neural mechanisms

of visuo-spatial working memory and little is known about the neural recruitment while processing temporal or sequential order information during working memory. In the present study, we employed functional magnetic resonance imaging (fMRI) to investigate the neural underpinnings of working memory for temporal order information and the effects of load on neural recruitment during memory encoding and maintenance. Participants were instructed to remember a sequence of the shapes with three level of working memory load (set size: 2-4) and responded to indicate whether or not the memory probe indicated the remembered order. Behavioral results showed slower reaction times and lower task accuracy during high load condition. A whole brain analysis revealed broad fronto-parietal activation during working memory encoding and maintenance for temporal order information, including left dorsolateral prefrontal cortex, middle frontal gyrus, and bilateral posterior parietal regions. Moreover, a significant load-related activation was observed in left inferior and superior parietal lobules, suggesting the capacity to modulate the neural resources in response to task demand. These findings are in line with findings from visuo-spatial working memory and provide additional evidence that posterior parietal region may play a functional role in modulation of working memory capacity for temporal order information.

Title: Neuroplasticity in the congenitally blind: Working memory training alters large-scale interactions of visual cortex

Authors: *J. M. RIMMELE[1], H. GUDI[2], G. NOLTE[1], B. RÖDER[2], A. K. ENGEL[1]; [1]Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Biol. Psychology and Neuropsychology, Univ. of Hamburg, Hamburg, Germany

Abstract: In a highly connected brain, large-scale interactions are likely to play a pivotal role in neuroplasticity. In visually deprived humans, neuroplasticity might result in the integration of the unused visual cortex into existing functional networks. We tested this assumption in a working memory (WM) training paradigm. WM training was expected to strengthen the integration of visual cortex into WM networks in congenitally blind (CB) compared to sighted control (SC) participants. This approach allows investigating the functional relevance of large-scale connectivity of visual cortex by measuring connectivity changes induced by WM training, rather than pre-existing differences. CB and SC participants were matched in age, gender, education and handedness. CB and SC participants either underwent a WM training with voices (condition 1), a WM training with tactile stimuli (condition 2) or an active training-control task (condition 3). Prior to and after the training, MEG and behavioral responses were recorded while participants performed a 2-back auditory WM task. A comparison of pre-post training related connectivity changes (using imaginary coherence) between the CB and SC, revealed group differences in beta- and theta-band connectivity. Beta-band connectivity effects mainly comprised group differences between visual cortex and brain areas involved in WM processing (frontal, parietal, insular) and brain areas involved in auditory processing (superior temporal cortex). Beta-band connectivity increased only in the CB in the auditory trained (condition 1) compared to the training-control participants (condition 3). A follow-up analysis showed that the beta-band connectivity increase particularly involved brain areas of the right ventral visual stream (fusiform face area). In contrast, theta-band mediated group differences in connectivity were mainly observed between brain areas typically associated with WM processing (frontal, parietal, insular) and auditory processing (superior temporal cortex). Theta-band connectivity increased only in SC in the auditory trained (condition 1) compared to the training-control (condition 3) participants. Thus, WM training resulted in an integration of visual cortex into WM networks in the CB group. The specific involvement of the ventral visual stream during a voice recognition WM task suggests that the functional specificity of visual cortex is preserved after neuroplastic changes. The findings provide evidence for changes in large-scale interactions as a mechanism of neuroplasticity after visual deprivation.

Title: A master map of visual-spatial working memory: meta-analysis of neuroimaging data

Authors: *Y.-F. LIANG[1], C.-M. HUANG[1,2,3];
[1]Inst. of Biomed. Engin., Natl. Chiao-Tung University,, Hsinchu, Taiwan; [2]Inst. of Mol. Med. and Bioengineering, [3]Dept. of Biol. Sci. and Technol., Natl. Chiao-Tung Univ., Hsinchu, Taiwan

Abstract: Neurophysiological studies in monkey and neuroimaging studies in human have suggested a functional division between two neural systems for supporting different aspects of visual information processing, with what neural system (ventral pathway) essential for object identification and where neural system (dorsal pathway) critical for spatial guidance. The brain areas devoted to what and where processing may communicate extensively when processing visuo-spatial information that requires temporary storage and active manipulation. Here, we investigate the effects of stimulus content on the ventral and dorsal neural pathways during visual-spatial working memory (VSWM) with a meta-analysis approach, using activation likelihood estimation (ALE) to compute statistically significant concordance with published coordinates across independent studies. Studies were categorized into the specific nature of visual stimuli: object, location, binding and task load. Meta-analytic results demonstrated that retrieval of items was associated with the activation in left middle frontal gyrus, left inferior parietal lobule and left precentral gyrus, whereas retrieval of location was related to the activation in bilateral superior parietal lobule, bilateral middle frontal gyrus and right cingulate gyrus. In addition, bilateral middle frontal gyrus, right superior frontal gyrus, bilateral precuneus and left insula are strongly associated with binding effects. Moreover, left middle frontal gyrus and right superior parietal lobule showed increased activity with higher level of memory load. These results provide a quantitative meta-analytic evidence and general view of how VSWM operates within the ventral and dorsal neural pathways.

Title: Distractor-resistant working memory representations revealed with MEG

Authors: K. KOMEK KIRLI, *K. K. SREENIVASAN;
New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: Visual working memory (WM) allows us to maintain high-fidelity visual representations over brief intervals. The nature of these representations is a topic of considerable debate. An essential feature of WM is the ability for maintained visual representations to persist despite incoming visual input. Thus, a complete account of how WM is instantiated requires an understanding of how these representations survive distraction. To investigate how visual WM representations survive distraction, we recorded magnetoencephalographic (MEG) data from participants as they performed a WM task for orientation. On each trial, participants were presented with a lateralized oriented sample grating. They were instructed to remember the sample orientation over a retention interval. During this retention interval, distractor grating with a different orientation than the sample was presented at the same location as the previous sample; participants were instructed to ignore the distractor. At the end of the interval, participants reported the maintained sample orientation. We employed a forward encoding analysis of the MEG data in order to reconstruct the orientation of the sample grating (1) during the presentation of the sample, (2) during the retention interval prior to the onset of the distractor, and (3) during the retention interval following the offset of the distractor. The forward encoding analysis maps the MEG frequency data across sensors to putative orientation channels tuned to different orientations. We used this procedure to identify this mapping between sensor data and orientation channels and used these estimates to calculate the response of these orientation channels in independent data derived from our three time points of interest. Channel responses were then used to reconstruct the orientation at our three time points of interest. We separately analyzed sensors contra- and ipsilateral to the sample and distractor gratings. We were able to reconstruct the sample orientation using MEG data across multiple frequency bands - most prominently in the beta (15-30 Hz) range. Reconstruction was successful at all three time points in ipsilateral and contralateral sensors. Estimates of orientation reconstructed from contralateral sensors exhibited a shift in the direction of the distractor orientation following distractor presentation. Critically, orientation estimates reconstructed from ipsilateral sensors were unaffected by the distractor. Our results suggest that recruitment of the ipsilateral hemisphere may be a potential mechanism by which WM representations are protected from corruption by irrelevant visual input.

Title: Moving dipoles analysis and it's implication during stroop task : MEG Study

Authors: *S.-J. HWANG[1,2,3], W. CHANG[1], B. KIM[4], J. CHANG[1,2];
[1]Dept. of Neurosurgery, Yonsei University, Col. of Med., Seodaemun-Gu, Seoul, Korea, Republic of; [2]Grad. Sch. of Med. Science, Yonsei Univ. Col. of Med., Seodaemun-Gu, Seoul, Korea, Republic of; [3]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ., Seodaemun-Gu, Seoul, Korea, Republic of; [4]EIT/LOFUS R&D Ctr. Intl. St. Mary's Hospital, Catholic Kwandong Univ., Incheon, Korea, Republic of

Abstract: BackGround & Purpose : Magnetoencephalography is a functional neuroimaging technique for mapping brain activity by recording magnetic fields produced by electrical When the name and color are matched, we called 'congruent', is not 'incongruent' currents occurring naturally in the brain. MEG is a very effective way of spatial and temporal analysis of the number of nerve activity in the brain. While performing the cognitive task that we want to find area of the brain is activated and the reaction by the analysis of neural activity. Stroop; working memory task is a cognitive task that we will track to the movement of the dipole generated during the tasks Methods : Stroop effect is a demonstration of interference in the reaction time of a task. When the name of a color (e.g., "blue", "green", or "red") is printed in a color not denoted by the name (e.g., the word "red" printed in blue ink instead of red ink), naming the color of the word takes longer and is more prone to errors than when the color of the ink matches the name of the color. When the name and color are matched we called 'congruent', aren't matched 'incongruent'. 6 people were included in the analysis. Recording the MEG data during the stroop task and make the ERP and find the dipoles. Results : In the behavior response, Congruent and incongruent reaction time showed a difference. Congruent reaction time is more faster than incongruent. Percentage of correct answers in the case of some falling trend seems incongruent. But not the trend seems to be common from all subjects. The dipole analysis in the period of stroop task, dipole be formed in the same area of brain. And also we can find the difference of dipole strength between congruent and incongruent. The difference of reaction time between 'congruent' and 'incongruent' causes delay neuronal activity process in a particular parts of the brain. It will be frontal of the brain. So we can find dipole delaying of the brain during the stroop task.

Title: Energy drinks effects on cognitive performance as measured by auditory event-related potentials and quantitative EEG in college students

Authors: C. WALLACE, *N. R. CAPRILES;
Kentucky State Univ., Frankfort, KY

Abstract: Popularity of energy drinks (EDs) has dramatically increased among college students in recent years. This increase may be associated to beneficial effects, such as improved alertness and concentration that EDs claim to provide. Event-related potentials (ERP) and quantitative EEG (qEEG) are cutting edge cognitive measures that allow real-time recordings of cortical brain activity, and were used to investigate the pro cognitive effects of EDs. The present study investigated: 1) pattern of consumption of EDs in college students; 2) college student's perception of ED effects; 3) ED effects on ERP and qEEG measures; and 4) contribution of sugars to the cognitive effects associated to ED. Thirty college students participated in this study. Subjects were screened for their pattern of consumption of caffeinated beverages by answering a forty questions survey. Subsequently, equal numbers of participants were randomly assigned to one of three experimental conditions: ED (regular ingredients), ED (sugar free), or placebo. The testing protocol consisted of two sessions where ERP evoked by auditory stimuli and 3-min of resting EEG were recorded: pretest (baseline) and test (60-min after treatment). Preliminary results show that the classic ED improved ERP measures of memory, focal attention and executive function. Reaction time and accuracy associated with the target detection task of the ERP test were also affected. Finally classic ED significantly increased peak alpha frequency, a qEEG measure that correlates with performance in cognitive tasks and is inversely related to aging. Analysis of the contribution of sugars on the effects of ED is underway.

Title: Dual task of working memory in action video game players: prefrontal eeg correlation

Authors: *J. C. LLAMAS, M. L. ALMANZA-SEPÚLVEDA, M. HERNÁNDEZ-GONZÁLEZ, M. A. GUEVARA;
Inst. of Neurosci., Guadalajara, Mexico

Abstract: Constant practice in action video games has been shown to improve different cognitive process such as working memory. Action video games require the optimization of executive control skills to coordinate two different tasks. Considering that prefrontal cortex, specially frontopolar and dorsolateral areas are closely related to the functioning of working memory and dual tasks performance, the aim of this study was to characterize prefrontal EEG correlation in action video game players (AVGPs) during the performance of a working memory dual task. The EEG from frontopolar (F1-F2) and prefrontal (F3-F4) areas was recorded in young men of the AVGPs and of the subjects of a control group conformed by non-video game players (NVGPs) under four conditions: 1) basal eyes open, 2) N-back condition (1-back), 3) Corsi Block-Tapping task in forward condition and 4) during dual task of both conditions. Significant differences were found between groups in the performance of the dual task, AVGPs retained a higher maximum number of items in memory and had a higher number of correct answers than NVGPs. Only the AVGPs showed a higher left and right intrahemispheric frontopolar and prefrontal correlation (F1-F3) (F2-F4) in the beta 2 (20-30 Hz) and gamma (31-50 Hz) band as well as a higher interhemispheric EEG correlation (F1-F2) during dual task performing. These data shown that the experience in action video games change the coupling degree between prefrontal cortex, especially in frontopolar and dorsolateral prefrontal areas, which play a main role in working memory and dual task performance. It is probable that this higher degree of coupling in prefrontal cortices could represent a characteristic pattern of brain functionality in AVGPs when they process, retrieve, manipulate and optimize information during the performance of dual task with a working memory component.

Title: Comparison of conventional electroencephalography (EEG) and inexpensive wireless EEG systems during a working memory task

Authors: *G. NOTARO[1], J. M. QIU[1], P. GIACOMETTI[1], J. D. SARGENT[3], T. F. HEATHERTON[2], D. GILBERT-DIAMOND[4], S. DIAMOND[1];

Abstract: In recent years, the emergence of inexpensive electroencephalography (EEG) devices has broadened the potential scope of applications for neurophysiological study. However, before inexpensive, wireless EEG devices can be used reliably in neuroscience research, the data quality of each device should be assessed through comparison to research-grade EEG systems. Consequently, we compared a conventional wired ANT Neuro EEG system to the low-cost, wireless OpenBCI EEG system. The OpenBCI system was selected over other low-cost EEG systems due to its greater flexibility in electrode placement. All electrodes were positioned using a rubber head cap, designed by our lab previously, to secure the EEG electrodes according to the 10-20 electrode montage. Electrodes from the OpenBCI system were secured at eight coincident positions with the electrodes for the ANT system [F3, F4, C3, C4, P3, P4, O1, O2] using matching reference and ground positions. Since preliminary data suggest no interference between the ANT and OpenBCI systems during simultaneous data collection, subjects were recruited for experimental testing. A letter-based N-back working memory task was selected for our study due to its frequent use in neuroscience research. An N of two was selected for moderate difficulty and maximal task attention, and was implemented using PsychoPy. Both upper- and lower-case letters [b, B, d, D, g, G, p, P, t, T, v, V] were selected to reduce visual and phonological strategies during the task. During simultaneous EEG recording, letters were presented in sequence to the subject at the center of the screen, following an initial fixation period to collect baseline data. All data were processed offline using Matlab. Signals recorded by the ANT Neuro and OpenBCI EEG systems were compared during baseline fixation and task conditions using both time and frequency domain analyses. Signal-to-noise analyses revealed comparable performance below 40 Hz but larger high-frequency noise by a factor of 10 in the OpenBCI system. The overall correlation of EEG waveforms between the two systems in the 4 to 40 Hz range was low ($R2 = 0.05$), suggesting that the two systems are independently noise dominated. Coherence analysis was also performed between signals from the two devices to examine the frequency dependence of the correlations. The magnitude squared coherence peaked at 0.25 in the alpha band of the occipital electrodes. Performing these comparative tests on inexpensive EEG devices is critical in order to understand signal quality issues for designing future studies. This foundational work will enable future studies by our group on the neurophysiology of children in naturalistic environments.

Title: Intracranial oscillatory activity in patients performing an object-in-place scene memory task

Authors: *J. J. YOUNG[1], A. FAZL[1], L. V. MARCUSE[1], M. C. FIELDS[1], M. G. BAXTER[2]; [1]Dept. of Neurol., [2]Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Patients with medically refractory epilepsy are sometimes considered for surgical intervention, and an important pre-operative procedure in the treatment of these patients is an intracranial electroencephalogram (EEG). Patients undergoing this procedure also provide a valuable resource for understanding how oscillatory activity supports memory and decision making in humans. Subjects undergoing intracranial EEG underwent cognitive testing using an object-in-place scene memory test, a task where the subject was required to recognize sets of correct targets on a colored background. Their performance on this task was compared to the oscillatory activity in their brain. Spectral power across frequencies, comodulation of different frequencies, and coherence in oscillation between brain regions were compared to determine the types of activity most predictive of good performance.

Title: Title:Study of working memory capacity by cerebral blood flow changes : study using reading span test

Authors: *K. TAKI, T. HIROYASU;
Doshisha Univ., Kyotanabe, Kyoto, Japan

Abstract: [Purpose]The capacity of working memory (WM) is different depending on the person. Up to now, evaluation method of WM capacity of the brain function measurement has not been established. Therefore, we examined the relationship between performance of reading span test (RST) and brain regions involved in WM. [Method]Cerebral blood flows changes in subjects 20 people during RST were measured. Whole brain (116 measurement channels) was measured as the measurement range by near infrared spectroscopy. In order to analyze, subjects were classified to high performance group and the low performance group by a score of RST. Then hemodynamic model was created by convolution of hemodynamic response function (HRF) and rectangular function that based on the experimental design. In consideration of individual differences, parameters of HRF were determined by the optimization in order to match as much as possible the measurement data and hemodynamic model. Based on dynamic time warping (DTW) distance between the measurement data and the hemodynamic response model created, difference in brain activity between high performance group and the low performance group was examined. [Results]In the performances of top six people and the performance of subordinate six people, there was a major difference by t-test ($p < .01$). Differences in brain activity between these groups were examined. We consider that the measurement channel is not active if DTW distance between the hemodynamic response model created and the measurement data is large. DTW distance between the two groups measurement channel was compared by t-test. When the p-value is low, the difference between the two groups of DTW distance is greater. Through the result of the examination, a significant difference was found in DTW distance between the prefrontal dorsolateral, Wernicke's area in left hemisphere and motor cortex. Thus, it is found that regions involved in WM performance of the top person are more active than the low performance person. It is suggested that these relationships regions brings a difference in performance. [Discussion]The comparison result high performance group DTW distance between the hemodynamic model and the measured data showed more active than regions of low performance group. Comparing peak arrival time of blood flow between these areas, peak of the prefrontal dorsolateral (central executive) is earlier than the peak of Wernicke's area. This result indicates that activity of Wernicke’s area is weak because of inadequate control of the central executive. [Conclusion]The present study showed that the high performance group has a high ability to control by the central executive to RST.

Title: The contralateral delay measures spatial working memory and is altered with encoding strategy

Authors: *L. RABBITT, M. S. PETERSON, C. G. MCDONALD;
George Mason Univ., Fairfax, VA

Abstract: Spatial working memory capacity is limited in the number of items that can be maintained over time. However, similar to verbal working memory, previous research has demonstrated that spatial working memory (SWM) can be improved when stimuli are organized into familiar patterns. The current study examined the neural correlates of SWM, specifically if SWM could be measured with the contralateral delay activity (CDA), an event-related potential known to index visual working memory. Additionally, the study investigated whether or not task instruction would alter the amplitude of the CDA. In the current study, participants performed a SWM change detection task that required participants to remember the locations of colored squares on one side of the screen, indicated by a cue prior to the beginning of the trial. Participants were given one of two instruction types: to remember the location of the squares, or to remember the constellation of the squares. Results of this study demonstrate that the CDA is able to index SWM capacity; as the number of items in SWM increases, the amplitude of the CDA increases. The manipulation of task instruction also had an effect on the amplitude of the CDA. Examining the amplitude change from two to four items, the spatial instruction CDA increased for both high and low working memory individuals. In contrast, for the constellation CDA, as individuals' capacity increased, their CDA amplitude difference decreased. These results indicate the CDA can measure SWM and how encoding strategy affects the electrophysiological measures of SWM.

Title: Neural correlates of signal detection parameters for working memory

Authors: *T. KARPOUZIAN, H. BREITER, J. REILLY;
Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Objective: Working memory (WM) involves the temporary mental maintenance and manipulation of information to support higher order cognitive operations. The neural circuitry supporting WM is well established; however, it is not clear which regions underlie the ability to maintain signal from noise as characterized by signal detection theory. To evaluate the neural basis of these WM component processes, we conducted an event-related fMRI study in which we parametrically manipulated the amount of information (i.e., load) held in WM and characterized performance according to the signal detection parameters of d', the ability to maintain segregation of signal and noise distributions, and B, a measure of response bias in allowing false alarms. Methods: Twenty-one healthy adults completed a WM task while undergoing fMRI. Subjects were briefly presented with a stimulus array consisting of 3, 5, or 7 items. After a variable delay period, a probe item was presented and the subject decided if it appeared in the same location as one of the array items. d', B, and response time, as a measure of efficiency of response selection, were calculated for each load level. fMRI analyses identified regions of activation during correctly performed trials, and how activation changed over increasing WM load. Results: A RM-ANOVA revealed that WM accuracy (d') parametrically declined with increasing load ($F_{(2, 38)}$ =18.69, $p < .001$), individuals were more conservative in allowing False Alarms (B) as load increased ($F_{(2, 38)}$ =9.23, p<.001), and response time increased as load increased, ($F_{(2, 38)}$ =22.77, $p < .001$). fMRI analyses demonstrated activation during correctly performed trials in the superior parietal lobule, insula, dorsolateral prefrontal cortex, anterior cingulate cortex, and thalamus. A RM-ANOVA revealed a significant increase in percent signal change across WM load in the parietal lobe ($F_{(2, 38)}$=4.692, p=.015). Correlation analysis revealed a significant correlation between change across WM load in d' and activation in the insula and temporal lobe. Discussion: An increase in WM capacity demands lead to a diminished ability to separate signal from noise, a greater bias towards becoming more conservative in allowing false alarms, and longer response times. This increase in WM is associated with an increase in BOLD activation across the WM circuit to correctly maintain information, particularly in the parietal lobe. The ability to separate signal from noise with increasing WM load was associated with increased activation in the temporal lobe and the insula. These findings suggest differential roles within the WM functional circuitry to support component processes of WM ability.

Title: A whole report approach improves assessment of item precision in visual working memory

Authors: *B. PETERS[1], B. RAHM[2], C. BARNES[1], J. KAISER[1], C. BLEDOWSKI[1]; [1]Goethe-University, Frankfurt Am Main, Germany; [2]Univ. Med. Ctr., Mainz, Germany

Abstract: Visual working memory (vWM) is highly capacity limited. Both the nature of its limitations and their neuronal origins remain highly debated. The effect of capacity limitation is typically assessed by asking participants to reproduce a single item of those held in vWM and examining the precision of this report dependent on memory set size. This procedure, however, does not yield specific information about within-trial variations of the precision of individual memory representations, which may be used to evaluate competing models of vWM capacity. We implemented a whole-report vWM task asking subjects to successively report each of the previously encoded items in a continuous recall format. We thus obtained estimates of individual item-precision data and were better able to separate them from performance fluctuations across trials. A series of behavioral experiments was conducted, providing a detailed characterization of the sequence of recall precisions. We found that subjects were able to recall the orientation of visual gratings above chance even at set size six and that the total amount of retrieved information was independent of whether the recall sequence was defined by the experimenter or chosen by the participant. Precision, however, varied systematically with recall order and set size. The first item in a recall sequence was reported with the highest precision. This was comparable to the typical situation where only one item has to be reported. Precision was increasingly diminished for subsequently reported items, whereby the reduction in precision from the first to the second recalled item was much steeper than for further items. This special status of the first recalled item was eliminated when subjects attended interfering visual stimuli before recall, but not by a longer memory delay. These results show that the whole report procedure is feasible and yields information about within-trial variations of item precision that is not available from standard single report paradigms. By accounting for the interference of the whole-report sequence, we were better able to separate the distribution of within-trial information from across trial performance fluctuations. This in turn improves evaluation of

competing models of vWM capacity that make different predictions regarding within-trial correlations of item precisions. Item-wise precision information can be related to concurrently recorded brain activity using, e.g., magnetoencephalography.

Title: Distractor resistance for precise visual working memory

Authors: *E. S. LORENC[1], K. K. SREENIVASAN[2], D. E. NEE[1], A. R. E. VANDENBROUCKE[1], M. D'ESPOSITO[1];
[1]Neurosci., UC Berkeley, Berkeley, CA; [2]New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: Visual working memory (VWM) is essential for our ability to maintain information about stimuli that are no longer in view. In daily life, we rely on this skill to maintain relevant information about objects in our environment and manipulate that information in the service of goal-directed behaviors. Previous research has suggested that both the prefrontal cortex (D'Esposito et al., 1995, 1996) and stimulus-selective primary sensory cortices (Harrison & Tong, 2009) support visual working memory maintenance. So-called "sensory recruitment" models (D'Esposito, 2007; Postle, 2006) posit that the same brain regions responsible for primary stimulus processing continue to maintain visual information over a short delay. However, these models do not explain how the brain maintains VWM representations when subsequent visual input is processed. Therefore, this study investigates whether VWM distractor-resistance is supported by distributed cortical representations outside those areas particularly involved in initial perception. In this experiment, participants performed a VWM task in which they had to remember the precise orientation of a lateralized sine wave grating over a long delay period (~20s) and report their memory contents via a method-of-adjustment procedure. On 2/3 of trials, a distractor grating appeared midway through the trial in the same spatial location as the initial memory cue, which participants were instructed to ignore. Functional magnetic resonance

imaging (fMRI) data was collected during this task. A forward encoding modeling approach (Brouwer & Heeger, 2011; Ester et al., 2013) was used to iteratively reconstruct tuning functions reflecting the accuracy and precision of orientation information held in working memory throughout each trial. Reliable stimulus perception-related orientation tuning curves were recovered in the contralateral, but not ipsilateral, early visual areas (V1-V2). However, the memory representations spread to include the ipsilateral early visual areas over the course of the first delay interval. After distractor presentation, reliable tuning functions remained in a subset of early visual areas in both hemispheres, despite the new visual input. These results converge with earlier fMRI evidence that VWM representations do not exhibit the same level of retinotopic specificity as visual perception (Ester et al., 2009), and suggest that this loss of spatial specificity may support the continued maintenance of precise visual details through subsequent visual input.

Title: The neural correlates of unattended working memory representations

Authors: *A. R. VANDENBROUCKE[1], E. S. LORENC[1], D. E. NEE[1], F. P. DE LANGE[2], M. D'ESPOSITO[1];
[1]Psychology, Univ. of California, Berkeley, Berkeley, CA; [2]Donders Inst. for Brain, Cognition and Behavior, Nijmegen, Netherlands

Abstract: In daily life, humans use visual working memory to remember and perform cognitive operations on visual objects in their environment. Over the last few decades, research has shown that both prefrontal (D'Esposito et al., 1995, 1996) and visual cortex (Harrison & Tong, 2009; Serences et al., 2009) support visual working memory maintenance. Whereas prefrontal areas are mainly associated with task set and goals associated with working memory (Nee & Brown, 2013), visual cortex is thought to be involved in the actual storage of memory items (Riggall & Postle, 2012). However, paradigms used to investigate storage of visual working memory typically require the maintenance of a single item in the absence of distraction. This does not

seem to mimic the demands that are usually placed on visual working memory systems. The current study examines which cortical regions support the concurrent maintenance of two items, especially when participants switch attention between the two. In this study we recorded neural activity using fMRI while participants remembered either one or two orientation gratings. After simultaneous presentation of two lateralized gratings, a cue (100% valid) was presented that indicated which item would first be probed (left or right), and whether the second item should be maintained in working memory for later recall (green cue) or not (red cue). After a 10-second delay period, participants performed a change detection task on the first cued item. Then, either a new trial started or the second item was cued, and after another 10-second delay period participants performed a change detection task on the second cued item. To investigate whether the attended (first cued) and unattended (second cued) memory item were neurally represented in visual cortex, we used a forward encoding modeling approach (Brouwer & Heeger, 2011; Ester et al., 2013). In this approach, the orientation selectivity of each voxel is modeled using hypothetical channels with an idealized tuning curve. After training the model on a subset of the data, the remaining data can be used to reconstruct the remembered stimulus orientation. Preliminary results show that in the first memory delay, we are able to reconstruct the representation of the two stimuli from activity in corresponding retinotopic locations in early visual cortex. However, reconstruction from the second memory delay is not as pronounced. Current analyses focus on determining if the memory representations can be detected in cortical areas outside the specific retinotopic regions involved in initial stimulus perception, including other areas of visual cortex, as well as the intra-parietal sulcus and prefrontal cortex.

Title: Relationship between large-scale cortical networks estimated by structural covariance and resting-state functional connectivity MRI

Authors: *E. DUPRE, N. SPRENG;
Human Develop., Cornell Univ., Ithaca, NY

Abstract: Large-scale distributed cortical networks are a central feature of human brain organization. These large-scale networks can be observed by examining the low-frequency oscillations of fMRI blood-oxygen level dependent (BOLD) signal. Additionally, structural covariance networks can be observed by examining covariation in interindividual differences in regional brain structure. In this study, we sought to examine the convergence of these network methods. Using structural T1 images and resting-state BOLD timeseries data from the Human Connectome Project, we investigated structural covariance and resting-state functional networks across the motor, visual, dorsal attention, salience, frontoparietal control, and default networks. For all analyses, networks were extracted using four literature-defined seeds. For structural covariance networks, Partial Least Squares, a multivariate analytical technique, was used to derive structural covariance networks. This approach provides individual subject values, 'brain scores', representing a global estimate for the structural integrity of the system identified at the group level. For resting-state analyses, time courses were extracted from each network seeds, correlated, and averaged across correlations to derive a network level value. In associating these two measures, we found that structural and functional results correlated in only a subset of the networks. The most robust association was with the frontoparietal control network. Structural covariance measures were more reliable predictors of self-report behavioral measures. Structural frontoparietal control network scores were associated with Openness, a big five personality factor closely associated with intelligence. Overall, there is not a strict equivalence between resting state functional connectivity networks and structural covariance networks, potentially reflecting the differential timescales exhibited at each level of organization. Greater association with behavior may reflect the longer time scales at which trait-level behaviors are present.

Title: Function follows form: Relating brain anatomy and physiology to cognition and psychology

Authors: *C. KERR[1,2,3], R. M. STUART[4], K. F. TURNER[5];
[1]Physics, Univ. of Sydney, Sydney University, Australia; [2]Dept. of Physiol. and Pharmacol.,

State Univ. of New York Downstate Med. Ctr., Brooklyn, NY; [3]Brain Dynamics Ctr., Westmead Hosp., Sydney, Australia; [4]Dept. of Mathematical Sci., Univ. of Copenhagen, Copenhagen, Denmark; [5]Dept. of Mathematics, Univ. of Chicago, Chicago, IL

Abstract: For over two centuries, scientists have yearned to explain differences in cognition and psychology through differences in anatomy and physiology -- from the galling pseudoscience of phrenology to more sober techniques such as diffusion tensor imaging. Modern studies have typically focused on the existence of specific correlations, such as between gray matter volume and performance on a given cognitive task. However, recent improvements in data recording and storage, coupled with advances in data mining and other statistical techniques, have enabled the creation and analysis of large databases, allowing more general principles to be extracted. In this study, we analyzed data from 1498 subjects drawn from the Brain Resource International Database (www.brainnet.net), the largest available library of standarized, cross-modal human brain measures. Almost 300 separate measures were available for each subject, including demography (age, sex, etc.), mood (anxiety, depression, etc.), personality (extroversion, openness, etc.), cognition (verbal memory, reaction time, maze completion, etc.), electroencephalography (EEG; eyes-open and closed power spectra), and structural magnetic resonance imaging (MRI; gray and white matter volumes). We answer several of the most basic -- and most important -- questions that can be addressed with this dataset: How much of the variation in cognitive and psychological measures can be explained by variation in brain anatomy and physiology? Which of these measures have the strongest explanatory power? How do the measures covary with age? A generalized linear model (GLM) was able to explain a significant fraction of the total variation in the cognitive, mood, and personality measures, with much of the explanatory power attributable to the EEG and MRI variables. On average, measures within a given modality tended to be strongly correlated with each other (e.g., gray matter volumes in different parts of the brain). There were statistically significant age effects for task performance, EEG power, and gray and white matter volumes, including some striking parallels between very young and very old subjects. In summary, to our knowledge, this work presents the most comprehensive picture to date of the interrelations between anatomical, physiological, cognitive, and psychological measures of the human brain.

Title: The relationship between individual difference factors and brain activity varies across tasks and brain regions

Authors: *B. O. TURNER, M. B. MILLER;
Dept of Psych & Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Between-participant variability in brain activity is frequently treated as a nuisance to be minimized so that the "true" activity can be revealed. However, a long line of research has demonstrated that, in many cases, group-level activity maps bear little resemblance to the map of any individual. Moreover, by comparing brain activity within and between participants performing multiple tasks, it is clear that a substantial proportion of the brain activity observed for any individual is due to intrinsic, rather than task-related, factors (Miller et al., 2009). Accordingly, this variability in activity between participants has been shown to be related to a variety of individual difference factors, including demographics, anatomy, task strategy, and performance (Miller et al., 2012). Here, in a large-scale (N=95) study of recognition memory, we extend this line of research in two ways. First, the number and variety of individual difference factors measured for each individual is greatly expanded to include well over 100 measures. Second, in addition to whole-brain activity patterns, we explore between-participant similarity at a regional level. We expect that multiple realizability may result in some regions whose activity is highly influenced by these individual difference factors; in other regions, activity may be conserved across individuals. In each region, we computed between-participant similarity in the regional pattern of brain activity for each pair of participants. These similarity scores were then entered into a hierarchical regression, with groups of variables from domains including brain measures, cognitive factors, demographics, state of mind, mental health, performance, and personality, operationalized as between-participant similarity on each measure. Finally, we determined the unique portion of variance accounted for by each group of variables in each region. Our results demonstrate that, as predicted, regions vary markedly in terms of what types of variables influence brain activity. Of particular interest is how these relationships interact with the memory task. For example, in a condition putatively requiring a high degree of cognitive control, performance-related factors had the most explanatory power, while in a separate condition with lower cognitive demands, several other groups of variables including personality and state of mind surpassed performance-related factors. These results speak to the need to interpret neuroimaging results through the lens of the individuals being studied. This research was supported by the Institute for Collaborative Biotechnologies under grant W911NF-09-D-0001.

Title: A polygenic risk profile for schizophrenia is associated with intrinsic connectivity of the dorsolateral prefrontal cortex and general cognitive ability

Authors: *J. MILLER[1], M. SCULT[2], Q. CHEN[3], D. WEINBERGER[3], A. HARIRI[2]; [2]Psychology & Neurosci., [1]Duke Univ., Durham, NC; [3]Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Using data from the ongoing Duke Neurogenetics Study, we tested for associations between a recently constructed schizophrenia polygenic risk score (Schizophrenia Working Group of the Psychiatric Genomics Consortium. Nature. 2014 Jul 24;511 (7510):421-7) and variability in the intrinsic connectivity of the dorsolateral prefrontal cortex. We further explored associations between risk scores and general cognitive ability. Resting-state fMRI data, polygenic risk scores, and a factor-derived measure of general cognitive ability were available for 332 non-Hispanic Caucasian young adults. Analyses revealed significant modulatory effects of the polygenic risk score on dorsolateral prefrontal cortex intrinsic connectivity and general cognitive ability. Furthermore, effects of the polygenic risk score on cognitive ability were partially mediated by variability in prefrontal connectivity. We discuss these findings with regard to pathophysiologic mechanisms of risk in schizophrenia as well as the general neurogenetic architecture of general cognitive ability.

Abstract: Inner speech plays a role in the rehearsal process of verbal working memory (Baddeley, 1992), planning (Lidstone, et al., 2010), and self-awareness (Morin & Michaud, 2007). We previously reported correlations between aspects of inner speech and schizotypal personality traits. However there has been little work investigating relationships between qualities of inner speech and overall verbal ability or with other endophenotypes of other neurological disorders. Participants (n = 110; 74.5% female) were assessed for inner speech qualities, schizotypal personality traits, empathizing and systemizing; SAT scores were also obtained. Individuals with higher verbal ability, as measured by SAT verbal scores, had more dialogic inner speech (r (74) = .236 p = .040) and less condensed verbal speech (r (74) = -.269 p = .019). Males with higher math ability as measured by SAT math score also had less condensed inner speech (r (20) = -.477 p = .025). Additionally, individuals that scored higher on systemizing had more evaluative/motivational inner speech (r (110) = .270 p = .004), and more likely to report others in their inner speech (r (110) = .263 p = .005). Overall, there seem to be significant relationships between verbal ability and qualities of inner speech.

Title: Dissociable effects of different strains of cannabis on the human brain's major resting-state networks

Authors: *M. B. WALL[1,2,4], R. A. POPE[2], T. FREEMAN[2], C. MOKRYSZ[2], C. HINDOCHA[2], W. LAWN[2], M. BLOOMFIELD[3,5], A. MOSS[2], D. J. NUTT[4], H. V. CURRAN[2];

Abstract: Two main constituents of cannabis are delta-9-tetrohydrocannabinol (THC) and cannabidiol (CBD). THC is the primary psychedelic component, while CBD may buffer the user somewhat against the effects of THC, and be therapeutically useful. Recent evidence has suggested that relatively new strains of cannabis that are high in THC and contain little or no CBD may be associated with negative effects of cannabis use (addiction, psychosis). Two strains of cannabis were tested against placebo in a double-blind three-way crossover design (N=17), and their effects on the brain's major networks examined using resting-state fMRI. One strain had 13% THC and <0.1% CBD, the second had 6.5% THC and 8% CBD; double the quantity of the second was administered so that total THC content was the same for both conditions. Placebo cannabis contained no psychoactive compounds but contained terpenines so it smelled the same as active cannabis. Seed-based functional connectivity analyses were used to examine effects in the Default-Mode Network (DMN; posterior cingulate seed-region), the Executive Control Network (ECN; posterior cingulate seed, anticorrelation) and the salience network (anterior insula seed). The two active strains produced relatively comparable effects on the DMN, showing network disruption in the hippocampus and superior parietal regions, relative to placebo. Effects on the ECN were also similar, with disruption in the left dorso-lateral prefrontal cortex (DLPFC). However, effects on the salience network were markedly different, with the 'balanced' (THC+CBD) strain showing minimal effects, and the pure THC strain producing widespread disruption of the network in orbitofrontal cortex, the putamen, left DLPFC and the frontal pole. Subsequent ROI analysis of these regions showed strong correlations between the posterior cingulate DMN activity, and subjective measures of the drug effect (visual analogue scale items: 'high', 'feel drug effect', 'dry mouth' 'enhanced auditory perception'; all $r>0.6$, all $p<0.01$) for the pure THC condition, but these relationships were not present in the balanced (THC+CBD) condition. The left DLPFC also emerged as an important region in the correlation analyses, being associated with negative subjective ratings such as 'mentally impaired' ($r=0.62$, $p=0.008$; ECN) and 'paranoid' ($r=0.67$, $p=0.003$, salience network) in the pure-THC strain, but not in the balanced strain. These results suggest the posterior cingulate may be a key region involved in the subjective effects of cannabis, while disruption in the left DLPFC may contribute to more negative effects. Also, CBD does appear to buffer the user from the effects of THC.

Title: Years of use of marijuana and episodes of consumption during the last month reduce efficiency in procedural learning

Authors: *U. CABALLERO SÁNCHEZ[1], T. V. ROMÁN-LÓPEZ[1], H. I. GUILLERMO-MONTIEL[1], C. B. ROSAS-ESCOBAR[1], E. I. ORTEGA-MORA[1], J. A. GONZÁLEZ-BARRIOS[2], O. PROSPERO-GARCÍA[3], A. E. RUIZ-CONTRERAS[1];
[1]Univ. Nacional Autónoma De México, Mexico City, Mexico; [2]Lab. de Medicina Genómica, Hosp. regional 1° de Octubre, ISSSTE, Mexico City, Mexico; [3]Lab. de Cannabinoides, Dpto. de Fisiología, Fac. de Medicina., Mexico City, Mexico

Abstract: Procedural learning is the acquisition, gradual and unconscious, of new abilities which operate automatically. It has been observed that marijuana consumption, together with Human Immunodeficiency Virus, decreases procedural learning. However, marijuana's effect alone was not reported to modify procedural learning. One of the marijuana active components, the Δ9-THC, binds to cannabinoid receptor 1 (CB1) which is widely distributed in the brain, including the striatum, cerebellum and hippocampus. These areas have been associated with procedural learning. The aim of this study was to test if variables such as the onset age of marijuana consumption (less than 17 vs. 17 or more years old), the number of years of consumption (less vs. 6 or more years) and the mean number of episodes of consumption for a month during the last six months (less vs. 30 or more episodes), affect procedural learning. Marijuana consumers solved the mirror drawing task during six trials. This task consisted in drawing a line within the double contour of a star. Subjects were not able to watch their own hand, the pencil or the star directly, only through the mirror. Completion time of drawing was the dependent variable. The onset age of marijuana consumption did not have an effect on procedural learning. Marijuana consumers with six or more years of consumption had longer completion times than subjects with less than six years of marijuana consumption. Also, completion time was longer for those

subjects whose consumption of marijuana was more than 30 episodes than those who consumed less than 30 episodes. All these effects were not due to a generalized motor slowness, which was evaluated with a control task. These results indicate that marijuana consumption diminished performance on procedural learning, i.e., when there is a prolonged consumption (i.e. 6 years or more), and when the consumption is larger than 30 episodes during a month. This study was conducted with the support of the following grant: DGAPA PAPIIT IN223314 to AERC and IN224314 to OPG.

Title: Genetic variation of the cannabinoid receptor 1 is associated with the distraction vulnerability in marijuana users and non-users

Authors: *C. B. ROSAS ESCOBAR[1], U. CABALLERO-SÁNCHEZ[1], E. I. ORTEGA-MORA[1], H. I. GUILLERMO-MONTIEL[1], T. V. ROMÁN-LÓPEZ[1], J. A. GONZÁLEZ-BARRIOS[2], O. PROSPÉRO-GARCÍA[3], A. E. RUIZ-CONTRERAS[1];

Abstract: Attention is the ability to select relevant information from the environment and, at the same time, to inhibit distracting or irrelevant information. The selection process can fail, during a selective attention task when a distractor appears, the efficiency is reduced. It has been reported that marijuana users are more prone to distraction when marijuana-related distractors is presented. Deltha-9-tetrahydrocannabinol (Δ9-THC) is the most studied marijuana's component, which binds to the cannabinoid receptor 1 (CB1). CB1 receptor is distributed along cerebral areas associated with attention. The CB1 is coded by the CNR1 gene. One polymorphism of this

gene, the rs2180619 (A>G), is located in a potentially regulatory region and has been associated with attention and working memory in control subjects. The present research evaluated if the polymorphisms of the rs2180619 of the CNR1 gene were associated with distraction vulnerability in marijuana users and non-users. The distraction vulnerability was measured in both groups with a Singleton Task, which evaluates "attentional capture". A main effect of genotype was found for percentage of correct responses, GG subjects had less accuracy than AG subjects, regardless of marijuana use. For reaction times, there was a significant interaction between group and genotype: the AG marijuana users had longer reaction times than AG non-users. Also, the AG marijuana users had longer reaction times than AA users. However, the marijuana use modified the effect of genotype of rs2180619, specifically in A carriers. These results suggest that G carriers are more vulnerable to distraction than AA subjects, and marijuana use modifies this relationship. This study was conducted with the support of the following grants: DGAPA PAPIIT IN224314 to OPG and CONACYT 176196 to AERC.

Abstract: Working memory is defined as the maintenance and manipulation of information in a goal-directed behavior. It has been observed that efficiency in working memory decreases when

deltha-9-tetrahydrocannabinol (Δ9-THC) is administered. The Δ9-THC is one of the most studied marijuana psychoactive components, which binds to cannabinoid receptor 1 (CB1). The CB1 receptor is coded by the CNR1 gene. The rs2180619 (A>G) is a single nucleotide polymorphism (SNP) which is located in a potentially regulatory region of the CNR1 gene. This SNP has been associated with differential efficiency in working memory in control subjects. The aim of this research was to study if the association between rs2180619 and working memory performance was modified by the use of marijuana. Working memory was measured by means of the Sternberg Paradigm, which is mainly a maintenance task. This paradigm consists of the presentation of several sets of letters. In each set, 1, 3 or 5 letters were presented at the beginning of a trial; the subject is instructed to remember these letters. After a delay period, a sequence of individual letters is presented and the subject has to indicate if each of these letters were present or not in the initial set. Only marijuana users participated in this research. AA genotype was compared to AG or GG (G carriers) subjects. It was observed that the G carriers had a higher accuracy in the Sternberg task compared with AA subjects. These results suggest that having at least one G allele in marijuana users is associated with a higher efficiency in maintenance of information in working memory. This study was conducted with the support of the following grants: DGAPA PAPIIT IN224314 to OPG and CONACYT 176196 to AERC.

Title: Interaction of rs2180619 of the CNR1 gene, sex and marijuana use in executive attention

Authors: *E. I. ORTEGA MORA[1], C. B. ROSAS-ESCOBAR[2], U. CABALLERO-SÁNCHEZ[2], T. V. ROMÁN-LÓPEZ[2], H. I. GUILLERMO-MONTIEL[2], J. A. GONZALEZ-BARRIOS[3], O. PROSPERO-GARCIA[4], A. E. RUIZ-CONTRERAS[2];

Abstract: Attention is the ability to select relevant information and, at the same time, inhibit distractor stimuli according to an objective. One way of evaluating this ability is with the Attentional Network Task (ANT), where alerting, orientation and executive attention indices are measured. In this task, the participants had to indicate the orientation of the center target arrow, among four flanker arrows. This task has two trial types: congruent (where the target and the flanker arrows are in the same orientation) and incongruent (where a conflict occurs because the target arrow is in a different orientation from the flanker arrows) trials. A conflict effect is observed reflected by a lower accuracy and longer reaction times in incongruent vs. congruent trials. Marijuana users' performance in ANT is worse than non-users. Deltha-9-tetrahydrocannabinol (Δ9-THC), the most studied component of the marijuana, is an agonist of cannabinoid receptor 1 (CB1). The CNR1 gene codes for the CB1 receptor; a polymorphism of a single nucleotide in this gene, rs2180619 (G>A), localized on a potentially regulatory region of the CNR1 gene, has been associated with addiction and, more recently, with cognitive functions. The aim of this study was to test whether efficiency in the ANT is associated with the polymorphism of the rs2180619 in marijuana users and non-users. Our results showed a main effect of genotype: A carriers showed a low percentage of correct responses in incongruent vs. congruent trials. Nonetheless, GG subjects did not present the typical conflict effect. An interaction among genotype, sex and marijuana use was observed. Only female AA marijuana users had lower percentage of correct responses for incongruent trials than female AA non-users. These results show that the alternative genotypes of rs2180619 are associated differentially with the ability to respond to the conflict in ANT, regardless of marijuana use. However, marijuana use interacts with rs2180619 and sex variables to affect performance in incongruent trials.

Title: Fractional anisotropy in the left uncinate fasciculus and the inferior cingulum differentially predict memory and executive functions in older adults

Authors: *M. B. SCHMIT, K. KAWA, A. STICKEL, L. RYAN;
Univ. of Arizona, Tucson, AZ

Abstract: Fractional Anisotropy (FA) as measured by diffusion weighted imaging is associated with white matter changes and cognitive functioning in older adults (Ryan et al. 2011). However, relatively few studies have investigated tract-specific FA values' impact on cognition. The present study investigated FA measures in three tracts - the uncinate fasciculus, the left inferior portion of the cingulum and the left superior longitudinal fasciculus (SLF)- and two cognitive tasks -memory (verbal paired associate delayed recall) and executive functioning. Letter-number sequencing was used as the measure of executive functioning because it incorporates both maintaining verbal material in working memory and task switching. FA was calculated from diffusion weighted MR images obtained in 25 directions from 38 older adults (Age 61-88 years, mean=71.6). Diffusion images were aligned using DTI-tk, which employs local tensor information for improved alignment. Tracts were defined using deterministic tractography (Wakana et al. 2007) and warped into native space for extracting FA from each tract. General linear models were created to predict delayed recall and letter-number sequencing. Predictor variables were global FA (an average of FA across all white matter), left uncinate fasciculus FA, left superior longitudinal fasciculus FA, and cingulum FA, while controlling for age and education. The letter-number sequencing model (GLM $p<.005$) showed not only global FA as a predictor ($p<.005$) but also an independent contribution of left uncinate fasciculus ($p < .005$), and left superior longitudinal fasciculus ($p<.05$). FA in the cingulum was not predictive. Delayed recall scores were significantly predicted (GLM $p < .01$) specifically by FA in the cingulum ($p<.01$) and education ($p<.05$) and not by any other factors. Global FA, left uncinate fasciculus, and left superior longitudinal fasciculus were not predictive of performance. The association between letter-number sequencing and the uncinate fasciculus may reflect the recruitment of frontal and temporal areas for the verbal nature of the task, while the frontal-parietal connections of the left superior longitudinal fasciculus mediate the working memory component. The cingulum, predictive of delayed recall, includes white matter through the temporal stem adjacent to the subiculum of the hippocampus. The relationship between FA values and cognitive performance is strongly dependent on which tract is being measured. Individual changes in memory and executive functioning with age may be mediated by white matter changes in specific regions, rather than global decline.

Title: Exploring the neurocognitive mechanisms underlying trigger failures in the stop-signal paradigm

Authors: *W. BOEKEL[1], D. MATZKE[1], A. HEATHCOTE[2], B. U. FORSTMANN[1];
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Univ. of Tasmania, Hobart, Australia

Abstract: The interplay between inhibition and attention is pivotal for everyday functioning. As we interact with our environment, we suppress most of the incoming information as well as prepotent responses that stand in the way of the current goal. In order to accomplish our goals, attentional resources have to be devoted to the task at hand. In this study we examine temporary fluctuations in attention in a context requiring inhibition of a preprotent response. We model so-called “trigger failures” in a stop-signal paradigm: Subjects are asked to respond to a left or rightward pointing arrow presented on a monitor. Occasionally, auditory tones (the stop signal) prompt the subjects to withhold their response to the corresponding arrow. In order for the stop signal to elicit the appropriate suppression of the motor response, sufficient attentional resources have to be allocated to incoming auditory information. Fluctuations in this allocation of attention contribute to the success or failure to inhibit prepotent responses in this paradigm. Here, we investigate the most extreme fluctuations in attention, in which the suppression of the prepotent responses is not initiated due to a lapse in attentional focus towards the auditory stop-signal. We use a recently developed Bayesian method which allows us to estimate the entire SSRT distribution, as well as a trigger failure parameter which represents the individual propensity for failing to trigger the stop process. In our fMRI analyses, we replicate earlier findings linking the right inferior frontal gyrus (rIFG) to efficacy of the stopping process measured through the stop-signal response time (SSRT). Finally, we show that activity in this region can additionally be explained by individual differences in the propensity for trigger failure. In sum, these results contribute to our understanding of the intricate interplay of inhibition and attention.

Sci., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: We designed a dual-task paradigm combining concurrent verbal working memory with an oculomotor task. These two tasks are known to share common fronto-parietal (FP) networks in our brain. Two levels of memory load (5- or 10-words) and three oculomotor tasks (eye fixation, predictive & random smooth pursuit eye movement) generate different dual-task combinations. We assumed that different combinations would generate different attentional demands and accordingly require different levels of cognitive strategy under limited cortical resources. This may resulted in different neural activation patterns as well as behavioral performances during dual-task situations. To investigate this hypothesis, we measured oscillatory brain activity and phase synchronization using simultaneous EEG and MEG recording in normal subjects subdivided by their innate working memory capacity (WMC). Results showed the distinct patterns of frontal midline theta (4-6Hz) synchronization and parietal upper alpha (10-12Hz) desynchronization among the dual-task conditions during the word retention period. Findings also showed different amounts of FP alpha phase synchronization. All these findings showed individual differences between high and low WMC groups. Distinct neural networks of each oculomotor task might affect the attentional load imposed on the FP network and generate different neural activation patterns as well as behavioral performances. In conclusion, varying

attentional demands and WMC seem to affect the dynamic cortical resource allocation strategy during our dual-task scenario.

Title: Functional and anatomical dissociation of interhemispheric transfer in human sensory systems

Authors: ***E. GENC**, P. FRIEDRICH, S. OCKLENBURG, O. GÜNTÜRKÜN;
Ruhr Univ. Bochum, Bochum, Germany

Abstract: Signals from sensory half-fields are processed separately in the two hemispheres but give rise to coherent percepts due to interhemispheric communication. A valid method to measure the latency of interhemispheric transmission in humans is the EEG Poffenberger paradigm. In this paradigm a lateralized stimulus is presented to observers. Based on the anatomical architecture of sensory systems, this stimulation induces an evoked potential (EP) in the contralateral followed by a second delayed EP in the ipsilateral hemisphere. This delay, computed as time difference between ipsilateral and contralateral EP, is interpreted as the interhemispheric transfer time (IHTT). Here, we used DTI and EEG measurements in different sensory domains to test whether IHTTs are related to each other and are predicted by the integrity of specific callosal segments. We determined for each participant (N=52) three different IHTTs using the EEG Poffenberger paradigm in the visual (vIHTT), auditory (aIHTT) and tactile (tIHTT) domain. In addition, DTI measurements of the same participants were acquired to estimate the microstructural integrity as indexed by radial diffusivity (RD) of specific callosal segments. A geometry-based method was applied to determine the microstructural integrity of five callosal segments. These segments were the anterior third (AT), anterior midbody (AM), posterior midbody (PM), isthmus (IS) and the splenium (SP). Statistical analyses showed that the three IHTTs were independent of each other. We found no significant correlation between vIHTT and aIHTT ($r = -.00$, $p = .98$), vIHTT and tIHTT ($r = .24$, $p = .09$) and aIHTT and tIHTT ($r = -.01$, $p = .94$). Further, we tested whether each distinct IHTT is predicted by the architecture of topographically specific callosal segments. In a multiple-regression analysis with segment

RDs as independent variable and vIHTT as dependent variable, only RD of the SP segment provided a unique contribution to the vIHTT prediction (SP segment, ß = -.39, p = .03; other segments p > .11). In contrast, for the aIHTT only the RD of the PM segment provided a unique contribution to the aIHTT prediction (PM segment, ß = -.51, p = .02; other segments p > .41). For the tIHTT only the RD of the IS segment provided a trend for a unique contribution to the tIHTT prediction (IS segment, ß = -.34, p = .07; other segments p > .66). Our study demonstrates for the first time that, for a given observer, the *in vivo* conduction velocity of callosal transmission is distinct for different sensory domains. Importantly, we showed that this dissociation also holds on the anatomical level: Each distinct callosal transmission was shaped by the layout of specific callosal connections.

Title: The effect of hemispheric asymmetry and handedness on p300 responses

Authors: *P. CHUA[1], M. TAN[1], Y. YANG[2], F. TEY[1];
[1]DSO Natl. Labs., Singapore, Singapore; [2]ST Engin., Singapore, Singapore

Abstract: In visual oddball studies, distinctive event-related potentials (ERPs) such elevated P300 spikes have been found to occur when a target stimulus suddenly appears during a presentation sequence of repetitive non-target images. Given the range of individual differences in hemispheric laterality, the waveform of these signals may differ between individuals (Eskikurt et al., 2013). Hemispheric asymmetries may manifest in behavioural traits such as handedness (Polich & Hoffman, 1998); thus the purpose of this study was to investigate the links between handedness and P300 readings collected during a visual oddball task. For this study, handedness was determined using the Edinburgh Handedness Inventory (Oldfield, 1971). Three groups of participants were recruited (4 left-handed, 4 right-handed and 5 ambidextrous). ERPs were recorded from up to 32 cortical sites while participants conducted the visual oddball task. Statistical analysis was conducted using the non-parametric Mann-Whitney test. Findings were correlated with the location of the cortical sites in relation to general lateralisation of brain signals. When an asymmetrical electrode layout was used (with higher concentration over the

right motor region), significant differences were found between between the right- and left-handed groups (U = 0.500, p = 0.029). However no differences were found between the right-handed and ambidextrous groups (U = 7.500, p = 0.566) or the left-handed and ambidextrous groups (U = 4.000, p = 0.190). When a symmetrical layout was used (with electrodes spread equally over the left and right hemispheres), there was no significant difference found between all the groups. Taken together, these results suggest that behavioural asymmetries (such as handedness) may provide a useful guide for determining optimal electrode placement in tasks such as the visual oddball paradigm. Title: Distinct patterns of interactions between resting state networks are related to different facets of Theory of Mind

Authors: *N. T. GALLAGHER[1], A. RIGON[2], M. M. SWIFT[3], M. C. DUFF[4], M. W. VOSS[3,2]; [1]Univ. of Iowa Dept. of Psychology, [2]Interdisciplinary Grad. Program in Neurosci., [3]Dept. of Psychological & Brain Sci., [4]Dept. of Communication Sci. and Disorders, Univ. of Iowa, Iowa City, IA

Abstract: Theory of Mind (ToM) is the ability to infer others' beliefs, feelings, and intentions to better understand and predict their future behaviors. For humans, the ability to execute effective social interactions is a crucial part of individual well-being and quality of life. ToM represents a pivotal component of this process and ToM deficits are also the hallmark of several psychiatric disorders. ToM can be assessed with tasks presented in different modalities (e.g., self-report vs. visual), often with markedly different results in behavioral performance. In the current study, we sought to investigate the reasons behind such modality differences by examining whether performance on a visual task and a self-report task are associated with distinct or similar

functional brain networks. To this end, we administered to a non-clinical population (N=20) of young adult females 1) the Interpersonal Reactivity Index (IRI) Perspective Taking scale, and 2) the Reading the Mind in the Eyes (EYES) test. As commonly found in ToM tasks, we noticed considerable inter-individual variability both in IRI scores (M=19.9, SD=4.58, range=12-27) and EYES performance (EYES= 28.45, SD=2.1, range=24-32). We chose to use resting state fMRI (rs-fMRI) to examine patterns of functional connectivity (FC) at rest: due to its task free nature, rs-fMRI is an ideal technique to explore how a given trait (e.g., ToM ability) corresponds to different patterns of brain activity. In particular, we examine FC in the Default Mode Network (DMN), Mirror Neuron System (MNS), and frontal executive network (FEN) given their purported relationship with ToM ability. These networks were chosen due to their role in self-referential thought, understanding others' actions, and externally oriented cognition. Our results indicated that participants with higher self-reported ToM ability had greater FC between FEN and DMN (r=.545, p<.01), while EYES performance was higher in participants who had greater FC between the MNS and DMN (r=.556, p<.01). Our findings support the involvement of large-scale resting state networks (previously identified as networks contributing to ToM processing by task-related studies), working together to process ToM. In addition, the current study furthers our understanding of the way different brain systems interact and play different roles to allow the complex nature of ToM to take form, suggesting that different facets of ToM may have different neurobiological underpinnings.

Title: Amygdala and insula response to social and non-social affective scenes in women with different trauma types

Authors: *O. KLESHCHOVA[1,2], S. A. YOON[1,2], M. R. WEIERICH[1,2];
[1]The Grad. Center, City Univ. of New York, New York, NY; [2]Hunter College, City Univ. of New York, New York, NY

Abstract: Interpersonal trauma (IPT) is associated with more trauma-related symptoms and greater risk of psychiatric diagnosis than non-interpersonal trauma (NPT). IPT also has been linked to distinct abnormalities in affective processing and salience detection, as well as structural and functional aberrations in the limbic system, particularly in the amygdala and insula. However, potential differences in affective processing at the level of neural circuitry between people with IPT and NPT are not known. We hypothesized that women with IPT would display greater amygdala and insula response to complex social affective scenes than women with NPT. Fourteen women with IPT, 6 women with NPT, and 11 no-trauma controls viewed affective social and non-social scenes during an fMRI scan. We performed a priori ROI analyses for the bilateral amygdala and insula, and conducted an ANOVA to test differences between the three groups. In addition, we conducted an ANCOVA between the two trauma groups with trauma type as a predictor and number of trauma-related symptoms as a covariate. Women with NPT showed decreased right insula activation to positive non-social scenes versus baseline compared with women with IPT and controls ($F(2,28)=5.51$, $p=.01$). The NPT group also displayed greater right insula activation to positive social vs. non-social scenes than the other two groups, who showed a similar response to both positive social and non-social scenes ($F(2,28)=4.49$, $p=.02$). When controlling for number of trauma related symptoms, women with NPT showed lower left amygdala response to social ($F(1,17)=6.12$, $p=.024$), particularly positive, ($F(1,17)=5.15$, $p=.037$) scenes and non-social negative scenes ($F(1,17)=4.98$, $p=.039$) than women with IPT. Counter to our predictions, salience network activity in the IPT group was more similar to controls than the NPT group. Women with NPT showed lower amygdala and insula activation to positive social and non-social scenes, respectively, suggesting that exposure to NPT might be associated with lower affective response to positive information. In addition, the NPT group displayed less affective response to non-social negative information. Together, these data suggest that non-interpersonal trauma might be associated with greater affective blunting compared with interpersonal trauma.

Title: Culture traits affect our perceptual processing to social cues

Authors: *Y.-C. LEE[1], P.-S. HO[2,3], H.-L. LIU[4], P.-C. SHIH[1], H.-W. HUANG[5], C.-M. HUANG[2,3], C.-T. WU[1,6];

Abstract: Culture is an important predictor that reflects how people interact with their environments and gregarious societies, which seems to be capable of further shaping how people perceived the outer world. Increasing evidence suggests that individuals from collectivistic cultures are more sensitive to relationships between objects and their contexts, whereas individuals from individualistic cultures are more sensitive to focused objects of the environment. However, how cultural traits influence an individual's social attention and its underlying neural mechanisms remains unclear. To address this issue, we enrolled participants who showed varying degree of individualism and collectivism, as defined by the Singelis Self-Construal Scale (Singelis, 1994), to participate in a gaze flanker task during fMRI scan. For each trial, we presented a central face gazing toward the left or the right side simultaneously flanked with 4 peripheral faces gazing toward the same (congruent condition) or different (incongruent condition) direction of the central face. Participants were instructed to pay attention to the central face and respond its gaze direction with button presses. Our results showed that, when dealing with incongruent situations, both groups (individualistic and collectivistic participants) exhibited an increased hemodynamic response in the dorsolateral prefrontal cortex. Notably, only the collectivistic group showed significant signal changes in brain regions implicated in both error detection/conflict monitoring and attentional processing of visual stimuli, including the anterior cingulate cortex, the inferior frontal gyrus, and the occipital lobe. These findings provide evidence that our perceptual processing to social cues are modulated by cultural traits and suggest that people from a collectivistic culture indeed are easier to be affected by the interrelationship between objects and their contexts than people from an individualistic culture.

Title: Culture-related differences in the contextual processing of visual scene: an fMRI study

Authors: *P.-S. HO[1,2], Y.-C. LEE[3], H.-L. LIU[4], D.-J. TSENG[1,2], Y.-J. CHANG[1,2], R. DOOLE[1], C.-T. WU[3,5], H.-W. HUANG[6], C.-M. HUANG[1,2];

Hosp. & Col. of Med., Hsinchu, Taiwan; [6]Dept. of Applied Chinese Language and Culture, Natl. Taiwan Normal Univ., Taipei, Taiwan

Abstract: There is growing interest in how differences in culturally based social and cognitive environments influence the way people perceive the visual world. Converging behavioral and neuroimaging evidence indicates that individuals from collectivistic/interdependent sociocultural system are more sensitive to contextual information, whereas individuals with individualistic/independent representation have a tendency to process focal and discrete objects of the environment. In the present study, we employed functional MRI to investigate whether the cultural values of collectivism and individualism influence the contextual processing of visual scenes by manipulating the congruence of the pictures presented. Each participant's degree of endorsement of individualistic and collectivistic values was assessed by their self-report on the Singelis Self-construal Scale (Singelis, 1994). Both individualistic (IND) group and collectivistic (COL) group were scanned in this event-related-design experiment as they made animacy judgments for the scenes in which the salient object was either congruent or incongruent with the background. We found that COL group showed greater activity in bilateral occipital complexes than IND group when viewing incongruent pairs. The result suggests that, when the scenes were incongruent, COL group may have devoted more brain and/or cognitive resources to object processing due to their enhanced sensitivity to the entire scene. This finding provides clear neuroimaging evidence that cultural differences in ventral visual function are not only limited to variations in attentional focus on objects and backgrounds separately, but also associated with variations in processing of semantic relationships between object and contextual information during visual recognition.

Title: Neural responses to masked and unmasked threat faces in children at risk for anxiety

Authors: *A. D. GILMORE, B. C. TABER-THOMAS, E. AUDAY, X. FU, K. E. PEREZ-EDGAR;
Psychology, Pennsylvania State Univ., State College, PA

Abstract: Behavioral inhibition (BI) in young children is a temperamental trait characterized by social withdrawal, attention bias towards threat, and risk for anxiety (Fox et al, 2001; Pérez-Edgar & Fox 2005). Attention bias toward threat may moderate the association between BI and risk for anxiety (Pérez-Edgar et al., 2013; Bar-Haim et al., 2007). Attention bias toward threat is often quantified using the dot-probe task (Mogg & Bradley, 1999), which presents two faces simultaneously (either neutral-neutral or a neutral-threat pair), for 500ms (supraliminal) or 17ms (subliminal), followed by a probe. Neuroimaging research has found that anxious individuals show greater engagement of prefrontal regions involved in emotion regulation for supraliminal threat (Monk et al., 2006; Telzer et al., 2008), and greater activation of limbic regions involved in emotion processing and salience detection for subliminal threat (Monk et al., 2008). No study has compared neural responses to subliminal and supraliminal threat in individuals varying in level of anxiety or risk, which has the potential to inform our understanding of the neural processes underlying threat bias. Participants were children, ages 9-12 (Current N=29, 17 female, M_{AGE}=11.27), screened for behavioral inhibition (BI) as part of an ongoing study examining the role of early temperament and attention in the emergence of anxiety. Participants completed supraliminal and subliminal dot probe in a 3T MRI scanner. Functional imaging data were preprocessed and analyzed in SPM8 and the MarsBaR toolbox. Results: Attention bias was not significant across the sample (p=.46) and did not differ between BI groups (p=.57). Contrasting subliminal threat versus neutral trials, BI was positively correlated right cerebellar activation (r=.410 p=.024) and negatively related to left dlPFC activation (r=-.603 p<.001). Comparing the subliminal to supraliminal tasks, cerebellar response to subliminal threat related to greater supraliminal threat bias (r=.678 p=.045) and less dlPFC activation to supraliminal threat-

congruent trials (r=-.547 p=.023). Greater left dlPFC activation to subliminal threat negatively correlated with right dlPFC activation in supraliminal incongruent-versus-congruent trials (r=-525 p=.007). Previous studies have investigated neural correlates of subliminal attention bias and conscience attention bias separately in anxious individuals. Analyzing both subliminal and conscious response to threat cues between behavioral inhibited children and non-behaviorally inhibited children may better clarify the neural processes underlying biased attention to threat and development of anxiety.

Title: Intrinsic functional connectivity correlates of frontal EEG asymmetry and risk for anxiety

Authors: *B. C. TABER-THOMAS, P. GALINSKY, A. GILMORE, N. THAI, S. MORALES, K. E. PEREZ-EDGAR;
Pennsylvania State Univ., University Park, PA

Abstract: Right frontal EEG asymmetry is one of the strongest biomarkers of risk for psychopathology (Fox et al., 1994). Behavioral inhibition (BI) is one of the strongest behavioral predictors of anxiety (Pérez-Edgar & Fox 2005), and frontal EEG asymmetry moderates the relation between BI and later anxiety_among BI (but not non-BI) children, greater right asymmetry relates to greater anxiety (Fox et al., 1994). However, the neural networks related to frontal asymmetry remain unknown. Furthermore, given that frontal asymmetry has distinct implications for individuals at risk for psychopathology, the underlying neural correlates may also vary. Here we examined data-driven analyses of intrinsic functional connectivity (iFC) related to EEG asymmetry in BI and non-BI children at risk for anxiety. Children (ages 9-12; N BI=18; N non-BI=26) provided resting EEG and resting-state fMRI data. From fMRI data we computed global iFC, or average iFC for each voxel to all other voxels in the brain (Martuzzi et al., 2011). Whole-brain between-subjects analyses were conducted to reveal regions where global iFC related to asymmetry across the whole sample (amygdala, motor cortex, and

precuneus) and where the global iFC-asymmetry relation was moderated by BI status (all results corrected for multiple comparisons at FDR $p<0.05$, with a height threshold of $p<0.005$). Less right asymmetry related to global iFC in amygdala, motor cortex, and precuneus. More right asymmetry related to global iFC in motor and somatosensory corticies for the BI group, and in bilateral frontal pole and left middle temporal gyrus for the non-BI group. These global iFC regions were then used as seeds in seed-based iFC analyses to reveal the broader networks related to right asymmetry across all participants (motor, amygdala, dlPFC), and only in the BI (somatosensory, amygdala, insula, striatum) or non-BI (lateral prefrontal, parietal, and temporal corticies) groups. Of the 11 regions where iFC related to right asymmetry in the BI group, 10 were in the limbic lobe. Of the 18 regions where iFC related to right asymmetry in the non-BI group, only 1 fell within the limbic lobe. Right frontal asymmetry related to a common intrinsic brain network across all participants that included limbic, motor, and prefrontal regions. For BI children, right asymmetry was more strongly related to limbic iFC while for non-BI children right asymmetry was more strongly related to lateral cortical iFC. These findings suggest that the neural correlates of EEG asymmetry differ among BI and non-BI children, and these distinct neural networks may be an underlying mechanism for individual differences in risk for anxiety.

Title: Breakfast consumption and mental rotations performance

Authors: *P. T. ORR[1,2], J. L. BACHMAN[3];
[1]Psychology Dept., [2]Neurosci. Program, [3]Dept. of Exercise Sci., Univ. of Scranton, Scranton, PA

Abstract: Breakfast consumption is known to play an important role in the academic performance of young children and adolescents. Some propose that these cognitive effects of breakfast are due to increased availability of glucose to the central nervous system. Experimental fasting has demonstrable effects on mental rotation ability, but it is not known if these fasting-related effects are differentially affected by different types of breakfasts. In the current study, 12 participants (6 male) were asked to fast overnight and were subsequently tested on mental rotations on three separate occasions. Approximately one hour prior to testing, participants were

fed a low glycemic index, high glycemic index, or no breakfast. Blood glucose levels were measured at the start of every session and these measurements continued at 30 minute intervals. Type of breakfast had a significant effect on blood glucose levels immediately prior to behavioral testing ($F(2, 18) = 12.136$, $p < .001$) and on overall accuracy during mental rotations task ($F(2, 20) = 4.424$, $p = .026$). Further, there was a significant interaction between sex and type of breakfast on mental rotations accuracy ($F(2, 20) = 6.147$, $p = .008$). Females had lower accuracy on the mental rotations task after eating a low glycemic index breakfast. These data offer support for the hypothesis that glucose availability is a critical factor mediating the relationship between breakfast and cognitive ability and suggest that there may be sex-specific relationships between breakfast consumption and cognition.

Title: Social company modulates conditioned disgust in male rats

Authors: *N. BOULET, C. J. CLOUTIER-DUKE, M. KAVALIERS, P. OSSENKOPP; Western Univ., London, ON, Canada

Abstract: Disgust responses are observed across numerous species and are considered to have their origins in defenses against toxicity and pathogens. Disgust encompasses a wide range of behavioral responses, including those associated with vomiting or emesis. Non-emetic species, such as the rat, lack the musculature and brainstem pathway needed to expel harmful toxins. Instead, rats display distinctive disgust reactions when given a taste previously paired with sickness. Of these disgust reactions, the gaping reaction is the most reliable. Results of comparative, evolutionary and neurobiological investigations have supported the gape display as an indicator of disgust. It has been further shown that, in the absence of illness, exposure to a context previously paired with a toxin elicits gaping in rodents. Here we consider whether social factors can also serve as cues for the display of anticipatory disgust in rats. Over 4 conditioning days (72 hours apart), 44 naïve male Long-Evans rats were intraperitoneally injected with either 128 mg/kg LiCl (0.15M) or 0.9% isotonic saline (NaCl). Each of these treatment groups was

further subdivided into LiCl and NaCl-treated rats exposed to either the conditioning context only (Groups LiCl-Alone and NaCl-Alone), or exposed to the conditioning context plus a specific stimulus rat (Groups LiCl-Social and NaCl-Social).72 hours following the last conditioning day, rats were tested over 2 drug-free test days (48 h apart). On test day 1, rats were re-exposed to the stimulus rat in a novel striped context for 10 minutes while aversive behaviors were analyzed. During test day 1, a significant effect of conditioning group (social versus alone) on gaping ($p < .01$) was observed. The mean number of gapes for the LiCl-Social condition, significantly differed from the mean number of gapes for the LiCl-Alone condition ($p = 0.013$). However, on test day 2, when the rats were placed back in the conditioning context in the absence of the social partner, there were no significant differences between groups. The LiCl-Alone group also showed significantly more aversive behaviors on test day 2 relative to test day 1 ($p = 0.007$). Social behaviors were also analyzed and it was determined that the LiCl-Social group initiated significantly more social interactions with their social stimulus compared to the NaCl-Social group ($p = 0.021$). Our results demonstrate that, in a distinct context, a rat treated with LiCl in the presence of a familiar social partner displays more gaping reactions, compared to LiCl treated rats paired with an unfamiliar social partner. These findings suggest that social factors can both elicit and modulate anticipatory disgust reactions.

Title: Patterns of oxytocin receptor expression in the rodent central nervous system

Authors: ***M. MITRE**[1], B. MARLIN[2], S. NORDEN[3], E. MORINA[3], C. AOKI[5], R. FROEMKE[4], M. CHAO[6];
[1]Physiol. and Neurosci., [2]NYU Sch. of Med., New York, NY; [3]New York Univ. Sch. of Med., New York, NY; [4]New York Univ. Sch. of Med., new York, NY; [5]NYU Ctr. for Neural Sci., New York, NY; [6]new York Univ. Sch. of Med., New York, NY

Abstract: Oxytocin is an essential neuropeptide that regulates social behaviors such as maternal care and parent-infant bonding. Peripheral release into the systemic circulation is responsible for its classical physiological functions of milk ejection and initiation of parturition, whereas central

release seems to modulate social cognition in animals, and has been implicated in maternal behavior, aggression, anxiety, fear, interpersonal trust, autism spectrum disorders, schizophrenia, and depression. It is believed that the forebrain distribution of oxytocin receptors is responsible for its effect in modulating certain social behaviors and cognition; however, the precise expression pattern of oxytocin receptors and the downstream effects of oxytocin receptor signaling both remain unclear. We examined the distribution of oxytocin receptors in the rodent brain and their mechanism of action. To follow the distribution of the oxytocin receptor, we generated antibodies against unique sequences of the mouse oxytocin receptor and identified cells expressing these receptors in the lateral septum, cortex, medial amygdala, hippocampus, and hypothalamus of male and female mice. No labeling was detected in oxytocin receptor knockout animals. We addressed which cell types and neural circuits are directly sensitive to oxytocin and also used oxytocin-ires-cre mice to determine the projection pattern of oxytocin fibers. We found that the receptors were largely expressed on inhibitory neurons, and using electron microscopy, we identified the receptor localized in axons and at synaptic terminals. Work in the Froemke lab has determined that parental experience interacts with oxytocin-based neuromodulation to affect the response of neural circuits of the adult mouse auditory cortex to neonatal vocalizations (Marlin et al. Nature, 2015). In particular, the left auditory cortex is functionally sensitive to oxytocin for the expression of pup retrieval behaviors in females. Interestingly, we have found that oxytocin receptor expression in left auditory cortex is higher than right, both at the protein and mRNA level, and this might be part of the cellular mechanism for specialized processing of pup calls. This evidence suggests that oxytocin modulation in cortex (and perhaps other brain regions) is important for control of local inhibition, providing a potential mechanism by which oxytocin regulates perceptual salience of social information.

UNINOVE CAPES PROSUP

Title: Study of post-pubertal social behaviors in males and females coming from maternal hypothyroidism: a link for neurodevelopmental aspects in autism-related conditions?

Authors: *C. A. PENATTI[1], J. C. SILVA[2], M. O. RIBEIRO[3], G. GIANNOCCO[4]; [2]Postgraduate Program in Med., [1]UNINOVE - Univ. Nove De Julho, São Paulo, Brazil; [3]Ctr. for Hlth. and Biol. Sci., Mackenzie Presbyterian Univ., São Paulo, Brazil; [4]Biol. Sci., UNIFESP - Federal Univ. of São Paulo, São Paulo, Brazil

Abstract: Subtle maternal thyroid dysfunction and thus subclinical maternal hypothyroidism may facilitate fetal neurodevelopmental disarrangements, which share similarities to some of the cognitive and behavior alterations manifested in the autism spectrum disorders (ASD). To date, however, there are few studies, which approach in detail the many aspects in sociability and oral communication of the post-adolescence individuals and their sex differences subjected to maternal hypothyroidism during pregnancy. Using a C57black6 mouse model of discrete maternal hypothyroidism, we investigated the social interaction of both male and female matched-offspring after puberty across several animal behavioral paradigms to look for differences in motor locomotion, anxiety, maternal care, offensive aggression and vocalization based on innate social behavior display for that mouse strain. Although there were no changes in motor locomotion and offensive aggression, we show that first generation male but not first generation female offspring from hypothyroid dams has increased anxiety levels tested at post-pubertal age using plus-maze paradigm when compared with control offspring. In addition, they displayed reduced total vocalizations towards females mainly due to the lack of emitted complex harmonic ultrasounds in a sex-oriented setting. In order to look for specific differences in the display of maternal behavior regardless of pregnancy status, we used the paradigm of foster mothers. First generation female descendants at post-pubertal age from discrete maternal hypothyroidism condition spent less time and provided less care towards the three-day old foster pups when compared with age-matched controls. Accordingly, these same females born from discrete hypothyroidism-induced dams demonstrated insufficient performance in the nest-building paradigm, which may indicate diminished sense for self-care and wellness. Thus, our findings strongly suggest that subtle maternal hypothyroidism during early pregnancy may facilitate social behavior disarrangements in the offspring in a wide array of animal behavior display in a sex-dependent manner. Moreover, fine aspects of altered social behaviors manifest at later ages such as in post-puberty and late adolescence as well as in adult life in both sexes. Finally, we speculate that our experimental behavioural findings correlate with the neuropsychological manifestations in ASD and may favor medical and psychological advances in understanding children's neurodevelopment among the ASD individuals.

Title: Social involvement modulates the response to novel and adverse life events in mice

Authors: *A. LEVINE[1], S. GRULEAU[2], L. COLNAGHI[1];
[1]Columbia Univ., New York, NY; [2]Neurosci., CAMH, Toronto, ON, Canada

Abstract: In life, we tend to experience situations differently in the presence or absence of social involvement. This is especially important in relation to how we perceive adverse life events since negative experiences play a determining role in the pathophysiology and time of onset of mental illness. However, not all people who experience adverse events go on to suffer physical and emotional negative consequences that lead to psychiatric conditions, and among the various genetic and environmental factors that could mitigate the potential negative outcome of adverse events exposure, social involvement is one of them. For example, living conditions with greater social involvement, such as neighborhoods with higher average household occupancy and churches per capita, are associated with a lower incidence of mental disorders. While increased perceived interpersonal social support ameliorated the pathogenic influence of exposure to traumatic life events on psychopathology, enhancing individuals' general mental and physical well-being, both in daily life and upon exposure to negative life events. Finally, low social support is one of the most common post-event risk factors for developing post-traumatic stress disorder. Together, these findings support the idea that the response to negative experiences may be affected by social involvement. However, how social involvement confers protection against negative experiences remains poorly understood and a neuronal mechanism for this effect remains to be elucidated. In this work we set out to examine, in a mouse model, whether social involvement modulates the response to an adverse environment or event and whether it changes the way these events are registered in the brain to affect future behavior. We therefore examined whether mice respond to adverse experiences differently in the presence and absence of cage-mates in several behavioral tests: (a) exposure to a novel well-lit new environment, (b) standard elevated plus maze (EPM) test following one habituation trial, (c) exposure to a strong foot-shock during contextual fear conditioning. We find that social involvement is associated with increased movement when mice are exposed to a new environment, increase in time spent in the open arms of the EPM after an obligatory exposure to the EPM open arm and decreased freezing time in response to a foot shock as well faster fear extinction. This is a first description of a mouse model that demonstrates that social involvement plays a role in mitigating adverse life events.

Title: Oxytocin neuromodulation of pyramidal cells in CA2

Authors: ***N. N. TIRKO**[1], M. MITRE[2], B. J. MARLIN[2], R. C. FROEMKE[2], M. V. CHAO[2], R. W. TSIEN[1];
[1]NYU Neurosci. Inst., [2]Skirball Inst., NYU Sch. of Med., New York, NY

Abstract: Oxytocin neuromodulation plays important roles throughout the mammalian brain, in many cases influencing social behavior. We have seen robust oxytocin receptor (OTR) expression in CA2, a distinct hippocampal area that is critical for social memory in mice. We also have evidence that CA2 is directly targeted by axonal projections from oxytocin-producing cells of the periventricular nucleus, highlighting the potential significance of the peptide in this region. In many cases oxytocin modulates inhibitory cell function exclusively, leading to the suggestion that interneurons expressing OTR might even be considered as a distinct category of interneurons. Direct actions of oxytocin on excitatory neurons have rarely been seen, but here we report that very scenario in CA2. In this particular area, unlike CA1, we find that OTR activation dependably excites pyramidal cells, as well as neighboring interneurons. Whole-cell recordings were made from CA2 pyramidal cells, identified by their distinct electrophysiological and morphological properties. We find that application of a selective oxytocin receptor agonist (TGOT) depolarizes CA2 pyramidal cells (by ~5 mV; 100% of cells recorded) and also increases membrane resistance, R_m (by ~75 MOhm). Consequently, cell excitability is increased as indicated by elevation of action potential (AP) frequency upon depolarization by step current injection. Additionally, the shape of APs changes significantly. Spike amplitude decreases and half-width widens, while the incidence of spontaneous spike doublets and bursts increases. The OTR is a G_q-protein coupled receptor that is poised to activate the phospholipase C (PLC) pathway. As might be expected, inhibition of PLC prevented the TGOT-induced pyramidal cell depolarization and change in AP shape. However, inhibition of the downstream enzyme protein

kinase C (PKC) only blocked the change in AP shape, not the depolarization. We hypothesize that OTR activation of PLC is upstream of two effects: first, inhibition of an outward potassium current, which increases R_m and permits cell depolarization, and second, activation of PKC, which is known to phosphorylate sodium channels and lower peak currents, thus reducing AP amplitude. These findings help clarify the effects of oxytocin on CA2 pyramidal cell behavior and thus set the stage for addressing the more general question of how oxytocin activity in CA2 alters hippocampal circuit function and social behavior.

Title: Oxytocin in the bed nucleus of the stria terminalis and central amygdala regulates social behavior in sex-specific ways in rats

Authors: *K. M. DUMAIS, A. G. ALONSO, T. C. GILLESPIE, D. CHO, R. BREDEWOLD, A. VEENEMA;
Psychology Dept., Boston Col., Chestnut Hill, MA

Abstract: Oxytocin (OT) is a neuropeptide known to regulate social behavior in rodents and humans in sex-specific ways. This may be due to sex differences in the brain OT system. In support, we recently found robust sex differences in OTR binding densities in several forebrain regions of the rat, with higher densities observed in males over females. Here, we aimed to determine whether sex differences in OTR binding density (i) are involved in sex-specific regulation of social behavior and (ii) are associated with sex-specific OT release in the brain. We selected two brain regions: a region which shows a robust sex difference in OTR binding (the bed nucleus of the stria terminalis; BNST), and a region which shows no sex difference in OTR binding (the central amygdala; CeA). We investigated the sex-specific role of OT in the BNST and CeA in regulating social recognition (the ability to discriminate between a novel and familiar

rat) and social investigation (amount of time spent investigating a novel rat), as these behaviors are important for appropriate social functioning. We found that OT regulates social behavior in sex-specific ways, irrespective of a sex difference in OTR binding density. In detail, exogenous OT injected in the BNST prolonged social recognition in males, but not in females. Moreover, a specific OTR antagonist injected in the CeA reduced social investigation in males, but not in females. We next examined whether these behavioral effects are due to sex differences in local OT release. Although there were no sex differences in baseline OT release in either the BNST or CeA, both regions showed sex-specific OT release patterns during social behavior. Specifically, males showed higher OT release in the BNST during social recognition compared to females. Moreover, OT release in the CeA correlated positively with social investigation time in females, but not in males. In conclusion, the OT system shows idiosyncratic sex differences in the BNST and CeA associated with sex-specific regulation of social behavior. These results further suggest that males may be more susceptible to OT modulation in mediating social recognition in the BNST and social investigation in the CeA.

Title: 16p11.2 deletion mice display cognitive deficits in touchscreen learning and novelty recognition tasks

Authors: *M. YANG[1], F. C. LEWIS[2], G. M. FOLEY[2], M. S. SARVI[2], J. N. CRAWLEY[2]; [1]MIND Institute, Dept. of Psychiatry and Behavioral Sci., [2]UC Davis Sch. of Med., Sacramento, CA

Abstract: Deletion of a ~600 kb region in chromosome 16p11.2 is found in approximately 0.4% of people with intellectual disability. Approximately 18% of 16p11.2 deletion carriers are diagnosed with autism. We previously reported that the Dolmetsch line of 16p11.2 heterozygous

(+/-) mice exhibited a robust novel object recognition deficit, normal social approach and juvenile reciprocal social interactions, and impaired social sniffing and ultrasonic vocalizations during male-female interactions, along with normal general health, olfaction, anxiety-like behaviors, and locomotion. The present study extended our previous findings on novel object recognition to additional novelty recognition tasks dependent on different neuroanatomical regions. Pairwise visual discrimination and reversal tasks using the Bussey-Saksida operant touchscreen equipment was used to evaluate cortical-dependent recognition learning and memory. Robust learning deficits and cognitive inflexibility were detected in the touchscreen test. In the acquisition phase of the pairwise visual discrimination task, 16p11.2 +/- required significantly more training days than their wildtype littermates (+/+) to reach criterion, and made more choice errors and more correction errors than +/+. In the reversal phase of pairwise visual discrimination, all +/+ reached the criterion of 85% choice accuracy, whereas most of the +/- failed to reach criterion by the 30-day cut-off. +/- also made more correction errors without making more choice errors, indicating cognitive inflexibility. Contextual and cued fear conditioning, a hippocampal and amygdala-dependent task, revealed no genotype differences. Robust novel object recognition deficits were replicated in two cohorts of 16p11.2 +/- mice, confirming previous findings. A similarly robust deficit in object location memory was discovered in +/-, indicating impaired spatial novelty recognition. Generalizability of recognition task deficits in 16p11.2 deletion mice was further tested with the preference for social novelty task. +/- exhibited impaired preference for social novelty when the familiar mouse and the unfamiliar mouse were of the same strain (129Sv/ImJ), but not when the two stimulus mice were of two genetically distant strains (129Sv/ImJ and C57BL/6J), indicating a mild deficit in social recognition. These several cognitive phenotypes in the Dolmetsch 16p11.2 deletion mice are consistent with cognitive deficits in humans with 16p11.2 deletion syndrome, and support the use of 16p11.2 deletion mice as a model system for discovering biological mechanisms underlying intellectual disabilities in 16p11.2 deletion syndrome.

Title: GWAS of foraging behavior in *Drosophila* melanogaster

Authors: *Q. YANG[1], W. CHI[2], Y. G. LEE[3], W. DU[4], C. KEMKEMER[3], S. A. TURKSON[2], M. LONG[3], X. ZHUANG[2];

Abstract: Efficient foraging behavior is crucial for the survival of an organism. Identifying the molecular and neural pathways responsible for such a trait as well as understanding the underlying genetic architecture is critical for addressing fundamental questions of economic decision-making. Here, we assessed natural variation in the foraging efficiency in 200 sequenced inbred lines of the *Drosophila* melanogaster Genetic Reference Panel (DGRP), derived from the Raleigh, NC populations. We measured the survival rate of young male flies kept individually in small chambers with unlimited, but hard to locate, food sources. Only flies that can locate food sources efficiently can survive. We observed significant variation of foraging efficiency (fifth-day survival rate varies from 0% to 100%), which was not correlated with variation in starvation resistance of these strains. We performed genome-wide association (GWA) analysis on single nucleotide polymorphisms (SNPs) and identified 89 significant SNPs (p value < 10e-5). Several of the top associated genes are highly expressed in *Drosophila* nervous system, providing promising candidates for functional examination. We found a mammalian SPAK homolog, fray, is essential for foraging efficiency. Targeted RNAi-knockdown of fray in elav-GAL4 neurons (pan-neuronal) led to severe foraging deficits in adult flies. Fray encodes serine/threonine kinase and has been previously proved to be essential for axonal ensheathment. Our findings suggest a novel signaling mechanism involving fray kinase in energy balance, and also provide insight into the adaptive evolution of foraging behaviors.

Title: Differentially expressed glutamate and dopamine receptors in two sister species of wild birds with widely divergent cognitive abilities

Authors: *J.-N. AUDET[1], L. KAYELLO[1], S. DUCATEZ[1], E. D. JARVIS[2], L. A. O'CONNELL[3], L. LEFEBVRE[1];

Abstract: Research on humans and model species of lab animals suggests that glutamate and dopamine receptors have key roles in cognition. In wild birds and primates, innovation rate has been proposed as an estimate of cognition in the field, while problem-solving tasks are valid experimental measures of innovativeness in captivity. We captured wild Loxigilla barbadensis and Tiaris bicolor, two sympatric sister species that have a similar social structure, but show extreme divergence in opportunism and innovation in Barbados. We assessed their problem-solving abilities using two different tasks and quantified the expression of dopamine (D1 through D5) and glutamate receptors (NMDA, AMPA, Kainate and metabotropic) using *in situ* hybridization and RNA-Seq data. In problem-solving tasks, we found that L. barbadensis outperformed T. bicolor in an all-or-none manner. At the RNA level, the two techniques concordantly revealed that three NMDA receptors (NR1, NR2A and NR2B), but only one dopamine receptor (DRD5), were differentially expressed in the two species. Kainate, metabotropic and AMPA receptor expression did not differ between L. barbadensis and T. bicolor. This work is a first step towards identifying the molecular differences that characterize wild species that have evolved divergent cognitive strategies.

Title: Extinction of spatial navigation in the Morris water task: The effect of brief reminders

Authors: *T. DONALDSON[1], C. M. MAGCALAS[1], D. BARTO[1], K. G. AKERS[2], D. A. HAMILTON[1];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Wayne State Univ., Detroit, MI

Abstract: Spatial navigation is a fundamental process for all living organisms. The Morris water task (MWT) is commonly used to investigate spatial navigation abilities of laboratory rodents. Previous studies have examined the processes involved in spatial learning and memory using the MWT, however, little is known about extinction of spatial responding or the factors that influence extinction. The current study investigated extinction of spatial responding when the platform is removed during multiple no-platform probe trials, and the influence that brief reminder treatments, in the form of platform placement, have on the rate of extinction of spatial responding. Extinction of spatial responding will be characterized by decreased accuracy in navigation and searching behavior during successive probe trials. To confirm that extinction operated in this testing situation spontaneous recovery of performance was assessed in probe trials after an hour interval of rest. Adult male Long-Evans rats were given 1, 2, or 4 days of training (12 trials per day). One day after the completion of training, rats received either a brief reminder treatment (30 sec placement on the platform in the trained location) or no treatment, followed by two consecutive 60 sec no-platform probe trials. Latency and path length to enter and time and distance spent within a critical region (50cm diameter, centered on the platform location) were measured for each probe trial. Rats that did not receive a platform placement reminder exhibited increased latency and path length to enter the critical region, while rats given the reminder did not display a robust decline in these measures across the two probe trials. While platform placement has been shown to improve some aspects of performance during subsequent training, available literature does not definitively support the idea that platform placement in the absence of active swimming to the platform can result in unambiguous spatial navigation in the MWT. Collectively, these observations suggest that extinction occurs in the MWT and that brief reminders reduce the rate of extinction.

Title: Development in a novel maze-task device for macaques to explore the neural mechanisms underlying motor skill learning

Authors: R. YASUKOCHI, K. INOUE, *M. TAKADA;
Primate Res. Institute, Kyoto Univ., Inuyama, Aichi, Japan

Abstract: Motor skills are quite often use d in our daily life. Such skills are considered to be sequences of multiple elemental movements. The motor skills are usually acquired through a process of trials and errors, and, once acquired, they are kept as procedural memory for a long time. To explore the neural mechanisms underlying motor skill learning, the use of macaque monkeys is highly meritorious because of their capacity of controlling hand movements smoothly and accurately. A motor learning task for the monkeys would allow analysis of the process and pattern of progress in motor skills. Recently, we have developed a novel maze-task device for analyzing how to achieve motor skills. Our device is composed of a maze, made up of a five-by-five grid creating four vertical and four horizontal intersecting tracks, with a cursor that the monkeys can manipulate to move around the grid. After successful navigation of the cursor from the start to the goal through a correct route, the monkeys receive a small food reward. The cursor has an infrared light at the bottom for detection of its position. To test this device, a monkey was trained for 300 trials per day over a month. We then analyzed three recorded parameters: the success rate of movement, the speed of movement, and the degree of motor smoothness to reveal their changes in the process of motor skill learning. We found that the success rate of movement increased to 100% very rapidly within the first few days. By contrast, the speed of movement and the degree of motor smoothness increased more slowly and showed different patterns of improvement. The present results indicate that our maze-task device is useful for clarifying the neural mechanisms of motor skill learning.

Title: Operant conditioning in neuroscience: Testing beyond motor and sensory deficits

Authors: *M. M.-M. ANDREWS[1], S. PERUZZARO[1], J. ROSSIGNOL[1,4,2], G. DUNBAR[1,4,3], M. REILLY[3,1];

[1]Neurosci., [2]Col. of Med., [3]Psychology, Central Michigan Univ., Mount Pleasant, MI; [4]Field Neurosciences Inst., Saginaw, MI

Abstract: Pre-clinical investigations into the mechanisms of neurodegenerative diseases, nervous system injuries, or pharmacological interventions primarily depend on motor and sensorimotor tasks in order to assess behavior. Consequently, deficits extending beyond motor and sensory domains may be difficult to detect and appropriately assess, resulting in missed opportunities for discovery and understanding. Capitalization upon the procedures of operant conditioning may help detect deficits that are often overlooked by some of the more conventional behavioral tests. Not only could the use of operant conditioning procedures provide an avenue to detect additional behavioral deficits, some procedures are able to control for common confounding variables, such as motor impairment. Operant techniques can provide a broad testing environment which is capable of detecting an overall decline in learning capabilities. Such procedures have been shown to detect long-term deficits in a rodent stroke model weeks after rotorod, beam balance tests, spontaneous rotation, and other such tests show recovery of function. Operant paradigms can measure complex behavior, such as impulsive decision making, perseveration, memory function, inhibition and more. Many tests that are used for neurological evaluation in humans can often be mimicked in an operant chamber, providing greater validity to the results obtained. The purpose of this poster is to present an overview of operant procedures used in neuroscience research. Matching specific operant tasks with a particular dysfunction is needed to assess potential therapies more effectively and will provide invaluable opportunities to accurately study behavior beyond the current standard of testing.

Title: Effects of combined adenosine A2A and dopaminergic receptor antagonism on within-session concurrent discrimination learning

Authors: *B. A. CORGIAT, A.-J. PISCAPELLO, M. GORSICH, A. GARCIA, M. MISHKIN, J. TURCHI;
NIMH/NIH, Bethesda, MD

Abstract: In a previous study, monkeys were trained on a short-ITI version of a concurrent visual-discrimination learning task. Stimulus pairs were repeated not only across daily sessions but also several times within each session (with roughly 4-min ITIs). Such within-session learning is served by concomitant recruitment of both a visuo-striatal circuit and an independent visuo-rhinal circuit. Baseline discrimination learning rates are significantly reduced in this short-ITI version, from ~11 trials/pair to criterion on the 24-h ITI version of this task to ~5 trials/pair on the 4-min ITI version. Reflecting the two distinct circuits involved, systemic injections of either the dopaminergic antagonist haloperidol (HAL) or muscarinic receptor antagonist scopolamine (SCOP) impair this more rapid learning (~16 trials/ pair and ~12 trials/ pair, respectively). The HAL-induced impairment is accompanied, however, by profound increases in response latencies. To examine the cognitive effects of dopaminergic antagonism isolated from the extrapyramidal side effects, we compared the effects of separate and combined administration of haloperidol (10.0 and 17.8 μg/kg, i.m.) and the selective A2A antagonist SCH 58261 (0.32 - 1.0 mg/kg, p.o.). As previously noted, systemic administration of haloperidol alone dose-dependently increased response latencies as well as trials/pair to criterion. In contrast, co-administration of the selective A2A antagonist afforded dose-dependent attenuation of the HAL-induced increases in response latencies as well as relative number of trials to attain criterion. These findings corroborate other studies showing that selective A2A antagonism effectively counters hypoactivity induced by systemic dopaminergic blockade. Further, in the context of reports describing the complex regulation of D2 receptor profiles by adenosine, this study sets the stage for local examination of adenosine-dopamine interactions within the striatum and frontal cortices serving within-session learning.

Title: Dopamine D3 receptor antagonism contributes to the reversal of PCP-induced NOR deficit by blonanserin and induces cortical dopamine and acetylcholine efflux

Authors: *M. MIYAUCHI, M. HUANG, S. KWON, N. M. NEUGEBAUER, L. RAJAGOPAL, Y. OYAMADA, H. Y. MELTZER;
Northwestern Univ., Chicago, IL

Abstract: Background: Blonanserin (Blon) is an atypical antipsychotic drug (AAPD), which unlike most AAPDs, is a slightly more potent dopamine (DA) D2 than 5-HT2A antagonist. It is also a potent DA D3 antagonist, with comparable affinity to DA D2. DA D3 receptors are expressed in mesencephalic, limbic, and cortical areas, all relevant to cognition and cognitive impairment associated with schizophrenia (CIAS). It has been suggested that DA D3 receptor blockade enhances emotional processing, executive function, flexibility, and social behavior. It has previously been shown that AAPDs enhance cortical DA and acetylcholine (ACh) release, which may contribute to cognitive enhancement. The purpose of this study was to determine the ability of Blon to enhance cortical DA and ACh efflux and to clarify the role of DA D3 antagonism in that process. We also determined the ability of DA D3 antagonism to improve the novel object recognition (NOR) deficit in sub-chronic (sc) phencyclidine (PCP)-treated rats, a model of schizophrenia. Materials and Methods: Male C57BL/6 mice were used for the microdialysis study. Guide cannulae with dummy probes were aimed at the medial prefrontal cortex (mPFC) and dorsal striatum (dSTR). Dialysate samples were collected every 30 minutes and analyzed using UPLC-MS/MS methods. Following baseline sample collection, drugs were administered and neurotransmitter efflux was monitored for 180 minutes. Female Long-Evans rats received vehicle or PCP (2 mg/kg, b.i.d.) for 7 days, followed by a 7-day washout for the NOR study. Rats received DA D3 receptor antagonist, NGB2904 (NGB, 0.3, 1, 3 mg/kg) or Blon (0.3, 1 mg/kg) 30 min prior to acquisition. Another group of rats received combination of sub-effective doses (SED) of NGB (0.3 mg/kg) and SED Blon (0.3 mg/kg) 30 minutes prior to acquisition. Results: Blon, (10 mg/kg, i.p.) increased DA, norepinephrine (NE) and ACh efflux in mouse mPFC and dSTR. NGB (3 mg/kg) increased DA and ACh, but not NE efflux, in mPFC and DA efflux in dSTR. Both NGB (3 mg/kg) and Blon (1 mg/kg) improved the scPCP-induced NOR deficit. In addition, the combination of SED NGB (0.3 mg/kg) and SED Blon (0.3 mg/kg) improved the scPCP-induced NOR deficit. Discussion: The results suggested that DA D3 receptor blockade may contribute to the ability of Blon to increase cortical ACh and DA efflux, as well as to restore scPCP-induced deficit in NOR. DA D3 receptor blockade may be an important component of the efficacy of Blon to enhance neurotransmitter efflux and improve cognition. DA D3 receptor blockade alone, or as an add-on to AAPDs, may serve as a therapeutic target for the treatment of CIAS.

Title: Haloperidol injected in thalamic reticular nucleus induces cognitive deficits evaluated in Morris maze in rat

Authors: *E. C. CHUC-MEZA, D. MORALES-MARTÍNEZ, G. AVILA-VELARDE; Natl. Sch. Biolog Sci. IPN, Tlalnepantla De Baz, Mexico

Abstract: Thalamic reticular nucleus (TRn) is formed by GABAergic neurons with the suitable connectivity to filter the thalamic afferent information to cortex (Crick, 1984; McAlonan et al. 2006). In the rat caudal sectors of TRn are involved in this attention process but besides rostral limbic sector could be participating in anxiety. In this regard an anxiolytic effect, measured in burying behavior and plus maze tests, was induced by chronic depletion of dopamine in this región (Picazo et al. 2009). Anxiety and memory are associated by neural structures and functional aspects. For example amygdala participates in anxiety and emotional learning and both are affected by benzodiazepins producing anxiolysis and inducing amnesia (Canteras et al. 2009). Respect to this TRn limbic sector has afferents from anterior thalamic nuclei and cingulate and retrosplenial cortices (Lozsadi, 1994; 1995) structures linked to memory (Mitchel & Dalrymple-Alford, 2006; Frankland et al. 2004) and in case of cingulate cortex also to anxiety

(Holzschneider & Mulert, 2011) . So, to evaluate the involvement of dopamine and TRn in memory, rats trained in the submerged platform option of Morris test were unilaterally canulated in rostral TRn. After recovery haloperidol (5μM in 0.4 μL) or vehicle was injected and rats were tested removing the platform (group I) o changing the platform location (group II). It was found in group I a significant reduction of time spent in the quadrant where platform was placed and an increment in latency to locate platform in group II. These results suggest the involvement of D2 like receptors in limbic TRn in modulation of cognitive abilities as spatial reference and working memories.

Title: RP5063 reverses and prevents sub-chronic phencyclidine-induced declarative memory deficits and increased dopamine efflux in the prefrontal cortex region in C57BL/6J mice

Authors: *S. KWON, L. RAJAGOPAL, M. HUANG, E. E. MICHAEL, H. Y. MELTZER; Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Background: RP5063 is a potent, selective dopamine-serotonin stabilizer with partial agonist properties at dopamine (DA) D2, D3, and D4 receptors (Rs), and serotonin (5-HT) 5-HT1A, and 5-HT2A Rs. It also has antagonist activity at 5-HT6 and 5-HT7Rs. Although RP5063 differs from most atypical APDs, in being partial agonist at both 5-HT2A and D2Rs, its multi-receptor profile includes a number of mechanisms which have the potential to improve cognitive impairments in schizophrenia(CIS), e.g. 5-HT1A and 5-HT7 antagonism. Sub-chronic (sc) treatment with NMDAR antagonist, phencyclidine (PCP; 10 mg/kg; i.p; b.i.d. for 7 days;7 days washout), produces pervasive and enduring deficits in cognitive function, including novel object recognition (NOR), an analog of human declarative memory(DM). Atypical, but not typical APDs through an ability to enhance cortical DA efflux in the prefrontal cortex (PFC) and hippocampus, ameliorate scPCP-induced NOR deficits in rodents. Hence, we sought to determine if acute and post PCP scRP5063 could reverse the scPCP-induced NOR deficit in C57BL/6J mice as well as to determine the effect of RP5063 on neurotransmitter efflux in PFC

and dorsal striatum (STR) using microdialysis technique. Methods: Four cohorts of male C57BL/6J mice (N=8-9 per group) were used in these studies. NOR and microdialysis methodologies are described in detail elsewhere (Horiguchi and Meltzer; Psychopharmacology; 2012: 221(2):205-15 and Huang et al., J Neurochem. 2014: 128(6):938-49). Results: Acute reversal: Male C57BL/6J mice given acute RP5063 (1.0 mg/kg), but not (0.3 mg/kg) 30 min prior to beginning NOR significantly reversed scPCP-induced NOR deficit ($P<0.01$). Prevention paradigm: Animals given scRP5063 (5 mg/kg; i.p. b.i.d, 7 days) 30 min prior to each injection of PCP (10 mg/kg) on days 1-7, and tested on day 15, showed significant prevention of NOR deficit, lasting one week ($P<0.001$). Enduring reversal paradigm: Animals given scPCP followed by scRP5063 (5 mg/kg; i.p. b.i.d, 7 days) on days 15-21 and tested on day 22, showed reversal of scPCP-induced NOR deficit, again, lasting one week ($P<0.001$). Furthermore, RP5063 significantly increased DA, but not acetylcholine efflux in mPFC at 0.3, 1.0, and 3.0 mg/kg ($P<0.05$). Conclusion: These results indicate that RP5063, via multi-receptor mechanisms ameliorates scPCP-induced DM impairment. The potential of RP5063 to delay or prevent the emergence of cognitive impairment is suggested by prevention paradigm. Increasing cortical DA efflux, in one of the regions implicated in DM, may contribute to the beneficial effect of RP5063 in cognition. The clinical testing of its effects on CIS is indicated.

Title: Effects of the NMDA receptor antagonists CPP and Ro 25-6981 on performance of the trial-unique, delayed nonmatching-to-location (TUNL) task in rats

Authors: *D. A. DAVIES, J. L. HURTUBISE, J. G. HOWLAND;
Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: The trial-unique, delayed nonmatching-to-location (TUNL) task measures spatial discrimination and working memory in touchscreen-equipped operant chambers. During the task, rats are required to perform delayed non-matching to location trials by touching illuminated regions of a touchscreen. The cognitive load of individual trials can be varied during the task by manipulating the distance between the locations to be discriminated and by increasing the delay between the sample and test phases of a given trial. By varying these parameters, the TUNL task has been proposed to dissociate processes necessary for pattern separation and working memory in a single session. Previous research has linked pattern separation and working memory performance to the activation of NMDA receptors; however, the effects of NMDA receptor antagonists on performance of the TUNL task have not been assessed. Therefore, we tested the effects of the broad spectrum NMDA receptor antagonist 3-(2-Carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP) or the selective GluN2B subunit-containing NMDA receptor antagonist Ro 25-6981 on performance of the TUNL task using a within subjects design in well trained Long Evans rats. After shaping the rats to nose-poke an illuminated stimulus in a touchscreen for food reward, rats were trained in the delayed nonmatching-to-location procedure. A correct selection was rewarded with food whereas an incorrect selection resulted in a time out. After rats consistently achieved 80% correct with large distances between sample and test stimuli (2 s delay), drug treatments were initiated. Injections of CPP (10 mg/kg; i.p.; n = 8) significantly impaired accuracy on trials with a 2 s delay at large distances (vehicle = 90.4% correct; CPP = 74.1%) and small distances (vehicle = 71.0%; CPP = 57.8%). CPP did not significantly impair performance for trials conducted with a 6 s delay (large distance trials, vehicle = 72.0%, CPP = 58.0%; small distance trials, vehicle = 66.0%; CPP = 64.0%). The latency of rats to enter the food port, or respond (correct or incorrect) did not differ among the treatments or delays. Ro 25-6981 (6 mg/kg or 10 mg/kg; i.p.; n = 16) did not affect performance on at either delay or distance. Latency of incorrect responses was significantly decreased following Ro 25-6981 (10 mg/kg). The present results demonstrate a critical role for NMDA receptors in the TUNL task. Future experiments will examine whether NMDA receptors in medial prefrontal cortex and hippocampus make dissociable contributions to the observed impairments in the delay vs. spatial aspects of the task.

Abstract: The acute and delayed impact of N-methyl-D-aspartate (NMDA) receptor inactivation on cognitive function has been explored recently in the context of animal models of depression and schizophrenia. There are multiple NMDA receptor subtypes that differ in physiology and expression patterns. There is considerable interest in determining the specific functional roles for the different subtypes and, in particular, whether specific subtypes may be targeted for the development of new drugs to treat neuropsychiatric dysfunction. In the present study, locomotor, exploratory, and memory function were examined in male Sprague-Dawley rats 25 min after administration of the NMDA nonselective antagonist ketamine or the selective antagonist for the 2B subunit of the NMDA receptor, traxoprodil mesylate (CP-101,606). In addition, patterns of c-fos expression were examined in the hippocampus, amygdala, bed nucleus of the stria terminalis, the paraventricular nucleus of the hypothalamus and in the medial prefrontal cortex. Our results showed that ketamine reduced locomotion, exploration, and acquisition of spatial memory in the Morris water maze, while CP-101,606-treated rats did not differ from saline-treated rats on these behavioral measures. Ketamine reduced c-fos expression in the mPFC, in CA3 and dentate gyrus subregions of the hippocampus, in the CeA subregion of the amygdala, and in the PVN while CP-101,606 decreased activity only in the prelimbic cortex, the BLA subregion of the amygdala, and in the PVN. These results begin to establish a database correlating unique behavioral effects of NMDA receptor inhibition with neural activity patterns. These relationships will be further explored in subsequent studies.

Title: Bumetanide demonstrates amelioration of learning and memory deficits induced by ketamine administration in a neonatal rat model

Authors: *R. STEVENS[1], S. KOKANE[2], B. BUTLER[1], A. WOMACK[2], Q. LIN[2];
[2]Psychology, [1]Univ. of Texas At Arlington, Arlington, TX

Abstract: Ketamine, a non-competitive N-methyl-D-aspartate receptor (NMDAR) antagonist, is widely used as a pediatric anesthetic. Studies reported by our and other groups have shown that neonatal exposure to ketamine causes persistent deficits in learning and memory, and alterations in NMDAR functioning. Additionally, these deficits have been attributed to widespread neuroapoptosis seen in the neonatal brain following ketamine exposure. In adult brains, γ-aminobutyric acid (GABA) neurotransmitter is primarily inhibitory. In contrast, GABA is excitatory upon activation of $GABA_A$ receptors in immature neurons. This is due to greater Na^+-K^+-$2Cl^-$ co-transporter (NKCC1) and weak K^+-Cl^- co-transporter (KCC2) expression in the cell membrane. Thus, bumetanide - an NKCC1 inhibitor - may prevent intracellular Cl^- accumulation rendering GABA inhibitory in immature neurons. We propose that excitatory GABAergic synaptic transmission has a distinct role in mediating ketamine-induced toxicity of neonatal brain neurons, resulting in a significant impact on learning and memory later in life. Therefore, we hypothesized that bumetanide may serve as a neuroprotectant via interfering with this GABA excitatory pathway through inhibiting NKCC1 to minimize ketamine-induced neuroexcitotoxicity. Seven-day-old Sprague-Dawley rats were administered ketamine subcutaneously (S.C., 20 mg/kg, 6X at 2 h intervals); and bumetanide was administered intracerebrally (I.C., 0.02 mg/kg, 3X at 4 h intervals) concurrently with ketamine or vehicle. There were four groups total with various combinations of the aforementioned drug treatments including a vehicle (control) group. Three weeks following treatment, all groups were tested for spatial learning and memory deficits using the Morris water maze (MWM). Animals were trained for 5 days, followed by a probe trial on day 6 to measure short-term spatial memory recall. Impaired learning and memory abilities as compared with the control were indicated by a prolonged latency to find the platform during the 5-day training phase. Prolonged latency was

especially noted in the ketamine treated animals during the training phase, and showed significant deficits in recall of the target platform location during the probe. However, the bumetanide co-treatment group showed a learning rate similar to the control and statistically outperformed the ketamine treated animals. These findings were also confirmed via the probe trial. Thus, these results suggest a new mechanism by which neonatal ketamine-induced learning and memory deficits can be alleviated through reducing hyperactive GABAergic-excitatory neonatal synaptic signaling.

Title: A generalized multisensory binding impairment in ketamine-treated rats: Reversal by α4β2 nicotinic receptor stimulation of the GABAergic system within the orbitofrontal cortex

Authors: *J. M. CLOKE, S. DE LISIO, A. DRUMM, K. BARTON, B. D. WINTERS; Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Schizophrenia is associated with atypical multisensory integration. We have developed a rodent multisensory oddity paradigm (MSO), which enables testing of binding abilities across multiple modalities (tactile-visual & olfactory-visual); in MSO, sets of objects are presented, and normal rats spend significantly more time exploring the one ('odd') object in the set that contains a unique configuration of multisensory features. The present study used the MSO tasks to assess multisensory binding in ketamine-treated rats, a model of schizophrenia. We also investigated the remediating effect of nicotinic acetylcholine receptors (nAChR) and their interaction with GABA systemically and in the orbitofrontal (OFC) and medial prefrontal (mPFC) cortices. Rats were sub-chronically treated with the NMDA receptor antagonist ketamine (30 mg/kg) or saline for 10 consecutive days, after which they were implanted with indwelling cannulas during the 10-day washout period. Ketamine-treated rats were selectively

impaired on the tactile-visual and olfactory-visual MSO tasks; performance on tactile-, visual-, and olfactory-only oddity tasks was spared. Systemic administration of nicotine (0.05, 0.2, & 0.8 mg/kg) reversed the selective MSO impairment in treated rats. The effect of nicotine appeared to be mediated by the α4β2 nAChR, as systemic administration of the α4β2 nAChR agonist ABT-418 (0.06, 0.1, & 0.6 mg/kg) remediated the impairment, but the α7 nAChR agonist GTS-21 (0.3, 1, & 3 mg/kg) did not. Furthermore, intra-OFC, but not intra-mPFC, nicotine (0.5, 1, & 2 μg) reversed the MSO impairment in treated rats. Intra-OFC administration of the α4β2 nAChR agonist ABT-418 (0.3, 1, & 3 μg) also ameliorated the MSO impairment in treated rats; this was blocked by systemic co-administration of the $GABA_A$ antagonist bicuculline (0.5 mg/kg). These results suggest that α4β2 nAChR activation of the GABAergic system within the OFC underlies the remediation of a generalized multisensory binding impairment in ketamine-treated rats. Ongoing studies aim to further elucidate the interaction between nAChRs and GABA in ketamine-treated rats.

Title: Synergistic interaction of NMDA and muscarinic receptors in simple response learning

Authors: *I. M. WHITE, Z. ABBOTT, W. WHITE;
Psychology, Morehead State Univ., Morehead, KY

Abstract: Hypofunction of the N-methyl-D-aspartate receptor (NMDAR) and of the muscarinic receptor have been implicated in cognitive deficits and in the pathophysiology of psychiatric disorders. The present study examined NMDAR and muscarinic receptor interaction in simple response learning in rats. Prior to testing, rats were trained on a fixed-ratio 5 (FR5) until their performance reached a behavioral criterion. Systemic injection of an NMDA receptor antagonist, MK-801, and a muscarinic receptor antagonist, scopolamine, disrupted FR5 performance. MK801-induced deficits were partially reversed by SCH23390, a dopamine D1 receptor antagonist, whereas scopolamine-induced deficits were worsened by MK-801, indicating

synergistic interaction of NMDA and muscarinic receptors. Moreover, intra-accumbens infusion of scopolamine did not influence behavior, whereas intraperitoneal administration of scopolamine (0.5mg/kg) increased locomotor activity and impaired simple response learning. Our data suggest that activation of NMDA and muscarinic receptors are required for successful performance in simple response learning and retrieval of learned responding. The nucleus accumbens does not seem likely to be involved in the mechanism that underlies synergistic interaction of NMDA and muscarinic receptors.

Title: An intra-amygdala injection of the GABAA agonist, muscimol, prevents fear-induced underestimation of duration

Authors: *T. KAMADA, T. HATA;
Psychology, Doshisha Univ., Kyotanabe, Japan

Abstract: Interval timing, time perception in the seconds-to-minutes range, is known to be altered by emotions such as fear. The neural circuits underlying this effect, however, are not yet well understood. In the present study, we investigated the role of the amygdala in fear-induced alternations in interval timing. Rats were trained on a self-initiated temporal bisection task in which they were required to choose one lever (i.e., the “short lever”) after a 2-s tone and the other lever (i.e., the “long lever”) after a 8-s tone to obtain a food reward. Following sufficient training, the rats were subjected to differential fear conditioning using two tones with different pitches as conditioned stimuli (CSs), i.e., one pitch (CS+) was paired with an electric foot shock (unconditioned stimulus; US), whereas the other (CS-) was not. The rats were infused with either vehicle (artificial cerebrospinal fluid; aCSF) or the gamma-aminobutyric acid (GABA)A agonist, muscimol (4.4 nmol), into the bilateral amygdala before the fear conditioning session, and then tested on the bisection task using the CS+ and CS- as to-be-timed stimuli. In vehicle-infused rats, the CS+ induced a rightward shift in the psychophysical functions and an increase in the point of subjective equality (PSE) without a change in a difference limen (DL) or the range of the psychophysical functions compared with the CS-, suggesting that conditioned fear induces underestimation of duration. Interestingly, this result is in contrast to human studies, which

report fear-induced overestimation of duration. During the presentation of a to-be-timed stimulus, well-trained rats exhibit a stable temporal behavior, i.e., they initially stay in front of the short lever, wait a period of time, and then shift toward and remain in front of the long lever. So, we also conducted a single trial analysis using the time of arrival at the long lever (i.e., the "arrival latency") to investigate the dynamics of the effect of conditioned fear within a session. In vehicle-infused rats, the arrival latency in the CS+ increased in the early phase of the test session but gradually decreased as the test session progressed, suggesting that the effect of conditioned fear is extinguished by repeated presentation of the CS+. However, muscimol-infused rats in which fear was presumably not conditioned did not show a change in PSE and arrival latency in the CS+ throughout the test session. Taken together, these results suggest that fear-induced underestimation of duration is mediated by the amygdala.

Title: Distribution of 5-HT_6 receptor mRNA in the rat brain and effects of the 5-HT_6 antagonist idalopirdine on extracellular levels of neurotransmitters and neuronal oscillations

Authors: *A. MORK[1], G. SMAGIN[2], L. HELBOE[1], K. F. HERRIK[1], M. A. FORASTER[1], D. SONG[2], D. P. BUDAC[2], H. ARMANDI[1], I. E. M. DE JONG[1];
[1]H. Lundbeck A/S, Copenhagen-Valby, Denmark; [2]Lundbeck Res. USA, New Jersey, NY

Abstract: The 5-HT_6 receptor (R) is almost exclusively expressed in the CNS. Combining a 5-HT_6 R antagonist with an acetylcholinesterase inhibitor (AChEI) represents a promising new approach for symptomatic treatment of Alzheimer's disease. A recent phase 2 trial showed that the selective 5-HT_6 R antagonist idalopirdine (Lu AE58054) improved cognitive performance in patients with moderate Alzheimer's disease on stable donepezil treatment. In the present study we examined cell type specific expression of 5-HT_6 R mRNA and effects of idalopirdine on levels of neurotransmitters and local field potentials in the rat brain. QuantiGene® ViewRNA platform from Affymetrix was applied to perform *in situ* hybridization in brain sections of male

Sprague Dawley rats. Following total mapping 5-HT_6 R mRNA visualization was combined with probes for a range of neurotransmitters or interneuronal markers. Extracellular levels of neurotransmitters in the medial prefrontal cortex (mPFC) of freely moving male Sprague Dawley rats were measured by microdialysis; samples were analyzed by HPLC with electrochemical detection or LC/MS/MS.In anesthetized male Sprague Dawley rats local field potentials were recorded with tungsten electrodes in the mPFC, while brainstem (nucleus pontis oralis) electrical stimulation was applied (0.3ms square pulses, 6s, 250Hz) every 100s. Recordings were transformed using a modified continuous wavelet transform to yield the power of oscillatory activity.The majority of 5-HT_6 R expressing neurons were glutamatergic or GABAergic principal neurons. A subset of GABAergic interneurons expressed 5-HT_6 R mRNA, the majority of which belonged to the 5-HT_{3a} R expressing subpopulation. Subpopulations of calbindin- and calretinin-positive GABAergic interneurons also expressed 5-HT_6 R mRNA. Administration of idalopirdine alone (10 mg/kg po) increased extracellular levels of monoamines and glutamate in the mPFC but did not affect acetylcholine (ACh) levels. The AChEI donepezil at 1.3 mg/kg (sc) increased the ACh levels and co-administration of idalopirdine and donepezil seemed to further increase the cortical ACh levels compared to donepezil alone. Pretreatment with idalopirdine at 2 mg/kg (iv) potentiated the effect of donepezil at 0.3 mg/kg (iv) on gamma oscillations in the mPFC.The localization study suggests that the 5-HT_6 R is positioned to regulate the balance between excitatory and inhibitory signaling. The enhancements by idalopirdine of levels of several neurotransmitters and the potentiation of the effects of donepezil may contribute to the idalopirdine-improved cognitive performance of patients on stable donepezil treatment.

Title: Serotonin (5-HT)7 receptor antagonists reduces cortical and striatal glutamate efflux and reverses cognitive impairment induced by phencyclidine

Authors: *M. HUANG, L. RAJAGOPAL, S. KWON, E. E. MICHAEL, H. Y. MELTZER; Psychiatry and Behavior Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Background: There is extensive preclinical evidence that serotonin (5-HT)7 receptor blockade is a promising target for treatment of cognitive impairment and major depression. However, there is also evidence that 5-HT7 agonists have pro-cognitive properties. We have reported that atypical antipsychotics (APDs), e.g. lurasidone, clozapine, risperidone, and amisulpride, which are potent 5-HT7 receptor antagonists, in a 5-HT7 dependent manner, can prevent the cognitive impairment induced by sub-chronic phencyclidine (scPCP), a widely studied rodent model of cognitive impairment of schizophrenia. All have been reported to improve some domains of cognition in schizophrenia patients. Atypical APDs have been shown to suppress acute effects of PCP to increase cortical glutamate (Glu) and 5-HT efflux, possibly contributing to their pro-cognitive actions. Methods: We have now studied the ability of SB 269970, and a novel 5-HT7 antagonist, JNJ 18038683 ((3-(4-chlorophenyl)-1,4,5,6,7,8-hexahydro-1-(phenylmethyl)pyrazolo[3,4-d]azepine 2-hydroxy-1,2,3-propanetricarboxylate)) to reverse the deficit in novel object recognition (NOR), a hippocampus and prefrontal cortex dependent task, induced by scPCP, as well as on the PCP-induced efflux of Glu, 5-HT and other neurotransmitters, in mouse medial prefrontal cortex (mPFC) and dorsal striatum (dSTR). Results: Both SB 269970 (1 mg/kg, i.p.) and JNJ18038683 (1 mg/kg) reversed the scPCP-induced deficit in NOR. Data on the ability of the selective 5-HT7 antagonists to affect NOR in normal animals and to block acute PCP-induced impairment in NOR will be presented during the meeting. SB 269970 (3 mg/kg) and JNJ 18038683 (3 mg/kg), given alone, significantly, increased Glu and 5-HT efflux in mPFC and dSTR. Both increased dopamine (DA) efflux in the mPFC, but only SB 269970 increased DA in the dSTR. SB 269970 and JNJ 18038683 increased cortical but not dSTR 5-HT efflux. When given 30 min before PCP (10 mg/kg), both compounds significantly suppressed the PCP-induced Glu efflux in both regions. Moreover, JNJ 18038683 suppressed norepinephrine efflux in both regions; SB 269970 did so only in dSTR. Neither compound affected PCP's ability to enhance acetylcholine, 5-HT and DA efflux in either region. Conclusion and Discussion: These results provide additional support for 5-HT7R antagonism as a promising target for the treatment of cognitive impairment, possibly via effects on glutamatergic, serotonergic, dopaminergic and noradrenergic neurotransmission, all of which participate in memory formation and retrieval.

Title: The selective serotonin (5-HT)7R antagonist, SB269970 prevents and reverses declarative memory deficits produced by sub-chronic phencyclidine in mice and normalizes hippocampal long-term potentiation

Authors: *L. RAJAGOPAL[1], H. FERNANDES[2], M. HUANG[3], A. CONTRACTOR[4], H. Y. MELTZER[5];
[1]Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Physiol., Norhtwestern Univ., Chicago, IL; [3]Psychiatry and Behavioral Sci., Northwestern Univ., chicago, IL; [4]Physiol., [5]Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Introduction: The selective serotonin (5-HT)7R antagonist, SB269970 (SB269), as well as atypical antipsychotic drugs, e.g. lurasidone and amisulpride with high 5-HT7R affinity, have been shown to ameliorate sub-chronic (sc) phencyclidine (PCP)-induced cognitive deficits in rats in a 5-HT7R dependent manner. The scN-methyl-D-aspartate receptor (NMDAR) antagonist, PCP, produces enduring deficits in novel object recognition (NOR), an analog of human declarative memory. We have recently shown that scPCP causes long-lasting metaplastic changes in the inhibitory principal neurons in the hippocampus (HIP) that results in impaired long-term potentiation (LTP). The present study investigated the ability of acute or sc SB269 to reverse or prevent scPCP-induced NOR deficits in C57BL/6J mice and to ameliorate the impairment in LTP in slices from the HIP-CA1 region in scPCP-treated mice. Methods: Four cohorts of male C57BL/6J mice (N=8-10 per group) were used. The NOR and electrophysiology methods are described elsewhere (Horiguchi et al., 2012, Nomura et al., 2015). The same drug treatment protocol was carried out for both behavioral and electrophysiological studies (ES). For ES, the animals were sacrificed for HIP brain slice recordings (BSRs) 30 minutes after SB26 injection in acute studies and on day 15 for prevention studies (PS). In the acute reversal study, animals were given saline, scPCP (10 mg/kg; b.i.d. for 7 days, 7 days washout), or scPCP+SB269 (0.3, 0.5, or 1 mg/kg) 30 min prior to NOR. In PS, the animals were given scSB269 (4 mg/kg; i.p. b.i.d, 7 days) prior to PCP on days 1-7, 7 days washout. NOR testing was

done on day 15. In enduring reversal study (ERS), animals were given scPCP on days 1-7; 7 days washout. scSB269 was given on days 15-21 and NOR began on day 22. Results: In the acute reversal study scPCP-induced NOR deficit was significantly reversed by SB269, 1.0, but not 0.3 or 0.5 mg/kg ($P<0.001$). scPCP impaired LTP at HIP-CA1 region was restored in acute SB269 mice ($P<0.001$). In the PS, scSB269, 4 mg/kg, prevented scPCP-induced NOR deficits for at least 8 weeks ($P<0.05$-$P<0.001$) and prevented scPCP-induced impairment in LTP at HIP-CA1 region ($P<0.001$). In the ERS, scSB269, 4 mg/kg reversed scPCP-induced NOR deficit for 3 weeks ($P<0.05$-$P<0.01$), after which the deficit returned. Conclusion: The results reported here provide important new evidence for the role of 5-HT7R blockade to ameliorate NOR deficit in scPCP-treated mice. 5-HT7R blockade can prevent the development of PCP-induced cognitive deficit and can acutely reverse it once established. 5-HT7R blockade can also enable the circuitry that can restore NOR for a prolonged period of treatment.

Title: Differential hippocampal expression of 5htr1a in conditioned suppression of fear memory

Authors: C. R. ZAMBERLAM, L. MORAES, J. M. CERUTTI, *S. M. CERUTTI;
Univ. Federal De Sao Paulo, Sao Paulo, Brazil

Abstract: In this study, we investigated whether the expression of genes that were previously associated with acquisition of fear memory or anxiety and that are modulated following short-term standardized extract of Ginkgo biloba (EGb) treatment are also regulated following acquisition or extinction of CER in the DH. The 5-HT1A receptor (5-hydroxytryptamine receptor subtype 1A) is differently expressed in DH of rodents and humans and it was associated with both short and longterm memory. Male adult Wistar rats were treated with one dose before fear conditioning of EGb (250 mg.Kg-1, 500 mg.Kg-1 and 1000 mg.Kg-1),vehicle (Tween® and Saline), agonists (10.0mg.Kg-1 Buspirone) or antagonists (0.3 mg.Kg-1 (S)-WAY100135) of the 5-HT1AR or antagonists+EGb ((S)-WAY+EGb) (n=10/group). Rats were fear conditioned in a

lick-operandum chamber. The behavioral procedure was conducted for eight or ten days, according experimental design to access acquisition or extinction of conditioned emotional response (CER). One half of the rats (n=5/group) were decapitated 3 hours after acquisition test (8th Day). Other half (n=5/group) was submitted to extinction training (9th day) and extinction retention test (10th day). Three hours after retention test Test (8 th day) extinction retention text (10th day) the rats were decapitated and the DH was extracted within 40-60 s with a magnifying glass, immediately frozen on dry ice, and maintained at -80oC until gene expression analysis. The analysis of gene expression of 5htr1a receptors in the DH was performed by quantitative polymerase chain reaction (qPCR). RNA samples had been previously extracted and the cDNA obtained for the quantitative analysis. Group treated with 500mg.Kg-1 EGb resulted in the overexpression of 5htr1a (Re = relative expression, Re=5,36) in the extinction of fear conditioning when compared with Tween group (Re=1,0;P<0.05) and manipulated (Re= 0,35: P<0.001). 5htr1a was increased in the DH to groups treated with ((S)-WAY before EGb, at three doses, (250 mg.Kg-1; Re=89,92; 500 mg.Kg-1 Re=56,29; 1000 mg.Kg-1;Re=38,96, p<0,0001), when compared to the control group (Sway; Re=0,94; Tween Re=1,10; p<0,0001). Further, comparative analysis among groups treated with EGb and (S)-WAY+EGb, showed that treated with antagonist before EGb resulted in overexpression of 5htr1a, at three doses, according to ANOVA followed by a Bonferroni post hoc test. Altogether, our findings contribute to the view that EGb modulated the serotoninergic neurotransmission in DH, which seems to be involved in the extinction of conditioned fear of dose-dependent manner.

Title: Brain functions and dysfunctions: memory, serotonin and neural markers

Authors: *A. MENESES;
Cinvestav - IPN, Mexico, Mexico

Abstract: Diverse neuropsychiatric disorders present dysfunctional memory and no effective treatment exits for them, likely related to the absence of neural markers associated to memory. Neurotransmitter systems and signaling pathways have been implicated in memory formation,

dysfunctional memory and forgetting; however, their role is poorly understood. Herein, neural markers and cerebral functions and dysfunctions are revised. To our knowledge no previous systematic works have been published addressing these issues. Hoping offering new insights, examples illustrating the interaction among behavioral tasks, control groups and molecular changes and/or pharmacological effects are briefly mentioned. Actually, serotonin has pharmacological tools and well characterized downstream signaling in mammals' species, and serotonin is one of the best characterized neurotransmitter, hence the role of this monoamine in memory is the focus but other neurotransmission systems and downstream signaling are discussed. Promissory and abundant findings exist supporting the use of neural markers for cerebral functions and dysfunctions. Certainly, at least 5-HT1A, 5-HT4, 5-HT6 and 5-HT7 receptors as well as SERT (serotonin transporter) seem to be useful neural markers and therapeutic targets. Likewise, hypothesis and theories might provide appropriate limits and perspectives of evidence. If the mentioned evidence is replicated, then the translatability of diverse approaches of preclinical and clinical studies to neural changes might be confirmed

Abstract: Alzheimer's disease (AD) and dementia are the widely known causes for the loss of memory in the elderly people. Currently, there are only symptomatic treatments available for the above mentioned conditions. M1 agonist compounds evaluated in past though showed cognitive improvement, had limited clinical utility due to cholinergic side effects hypothesized to result from non -selective action on M2 to M5 subtypes. Due to the conservative nature of the

orthosteric M1 site, we explored the possibility of identifying the positive allosteric modulators of M1 receptor. SUVN-I1411030, a hydrochloride salt compound is one of our lead molecules. SUVN-I1411030 caused a leftward shift of acetycholine when tested in the reporter gene assay method. SUVN-I1411030 was found to be orally bioavailable (60%) with an adequate brain penetration index (~0.46) in rats. SUVN-I1411030 reversed the time and scopolamine induced memory deficit in rat. Sub efficacious dose of SUVN-I1411030 in combination with donepezil showed procognitive activity. SUVN-I1411030 also promotes non- amyloidogenic APP processing in rats. SUVN-I1411030 did not enhance salivation when administered along with acetylcholine esterase inhibitors. SUVN-I1411030 was found to be safe when tested in hERG Patch clamp assay for assessing cardiotoxicity (IC50> 10 μM). SUVN-I1411030 was found to have a high margin of safety in acute toxicity studies. SUVN-I1411030 was found to have > 25 mg/mL solubility. Further detailed profiling of this compound is currently ongoing

Title: Improvement in translatable touchscreen tests of memory and attention with an M1 muscarinic positive allosteric modulator in rhesus monkeys

Authors: *H. S. LANGE[1], C. E. CANNON[2], J. DROTT[1], S. D. KUDUK[2], J. M. USLANER[1]; [1]Pharmacol., [2]Merck Res. Labs., West Point, PA

Abstract: Improved treatment for Alzheimer's disease (AD) is a significant unmet medical need given the continued rise in the number of patients and the substantial economic burden that the disease creates. The current standards of care, which are primarily acetylcholinesterase inhibitors (AChEIs), are hindered by gastrointestinal (GI) side effects due to their nonselective activation of muscarinic and nicotinic receptors. Recently, the M1 positive allosteric modulator PQCA (1-((4-cyano-4-(pyridine-2-yl)piperidin-1-yl)methyl-4-oxo-4 H-quinolizine-3-carboxylic acid) has been demonstrated to improve cognition in a variety of rodent and non-human primate cognition models without producing significant GI side effects. Here we describe the effect of PQCA and the AChEI donepezil on two clinically relevant and highly translatable touchscreen cognition tasks in NHPs, paired-associates learning (PAL) and the continuous performance task (CPT). Blockade of muscarinic signaling by scopolamine produced significant impairments in both PAL and CPT. PQCA and donepezil attenuated the scopolamine deficits in both tasks, and the action of these two compounds was similar in magnitude. In addition, the combination of subeffective doses of PQCA and donepezil enhanced PAL performance. These results suggest that M1 positive allosteric modulators have potential to reduce the cognitive deficits associated with Alzheimer's disease either as monotherapy or as an add-on to current standards of care.

Title: Scopolamine creates dose-dependent memory rather than sensorimotor impairment of latent learning in the water maze

Authors: *J. J. IZYGON, D. M. NGHIEM, M. M. HENCEROTH-CHOMIAK, D. J. MCGHIEY, R. TIJERINAR, M. F. MERIANO, P. GOYARZU, J. L. HAVENS, D. H. MALIN; HSH, Univ. of Houston Clear Lake, Houston, TX

Abstract: Most water maze studies model trial and error learning, as opposed to spatial learning by mere observation. Previous research in our laboratory, indicates that, with a revised procedure, highly efficient latent learning can be accomplished through direct placement of rats on the submerged water maze platform so that they can observe its location. This ability was almost entirely abolished by muscarinic cholinergic blockade with scopolamine thirty minutes before platform placement. A dose-dependence experiment compared the effects of i.p. injection of 1 mg/kg or 0.6 mg/kg of scopolamine HBr or saline alone. One-way ANOVA indicated a highly significant scopolamine dose effect on latency to swim back to the platform 5 minutes later, $p = .002$, and on accuracy of the rat's path to the platform relative to a direct route, $p = .001$. There was a significant negative linear trend of latency as a function of dose, $p = .05$ and a significant positive linear trend of accuracy as a function of dose, $p = .029$. To evaluate whether scopolamine's negative effects on performance were due to sensorimotor impairment, rats were tested for latency and accuracy of swimming to a non-submerged visible platform complete with a small flag. This eliminated any reliance on spatial memory. The subjects were 6 Long-Evans rats, who received the higher 1.0 mg/kg dose of scopolamine HBr on two days, alternating with two days receiving saline. It was found that rats performed almost identically after scopolamine or saline injection. They reached the visible platform in an average of 6.47 ± 1.61 (M ± SEM) seconds on days with saline injection, versus 5.74 ± 0.73 seconds on days with scopolamine injection. This difference was not significant, $p = .62$. After saline injection, they averaged $70.6\% \pm 6.5\%$ accuracy of swim trajectory as compared with $67.2\% \pm 5.4\%$ accuracy after scopolamine injection. This difference was also not significant, $p = .52$. These results suggests that muscarinic cholinergic blockade affects water maze latent learning, not through sensorimotor impairment, but through interference with spatial memory processes.

Title: Memory reconsolidation and scopolamine-induced amnesia modulated by guineensine in BALB/c mice

Authors: *I. C. REYNOSO-MORENO[1], A. N. ROSAS-ESCAREÑO[1], C. R. GUZMAN-PEREZ[1], M. E. FLORES-SOTO[2], J. M. VIVEROS-PAREDES[1];
[1]Univ. De Guadalajara (CUCEI), Guadalajara, Mexico; [2]Ctr. de Investigacion Biomedica de Occidente, Guadalajara, Mexico

Abstract: The high concentration of cannabinoid receptor type 1 (CB1) in the hippocampus, suggests that endocannabinoid system may play a role in learning and memory processes. Studies demonstrate that is critical for the encoding of emotional memory and for the extinction of fear-related memories. Also, studies have shown that the administration of CB1 agonists impairs memory and antagonists may improve. On the other hand, guineensine (present in *Piper nigrum)* was identified as inhibitor for endocannabinoid reuptake. In the cannabinoid tetrad test, guineensine dose-dependently induced cannabimimetic effects; shown strong catalepsy, hypothermia, reduced locomotion and analgesia. Therefore, the aim of this work was study if guineensine is able to modify acquisition or reconsolidation in the inhibitory avoidance test (hippocampal-dependent and fear-related memory paradigm). Also, we used scopolamine-induced amnesia for know if guineensine abolishes their effect. Due to that catalepsy and analgesia could interfere in mice performance, we used doses that not have this effects. The inhibitory avoidance test was carried in a box with light (500 lux), and dark compartments of equal size (20 x 20 cm). BALB/c mice (male, 22-25 g) were placed in the light side. For conditioning, when the mouse crossed over the dark side, it received a footshock (0.08 mA) for 10 s. For reconsolidation (48 h after), if crossed at the dark side no footshock was given. The retention trial was 24 h later. The crossover latency was recorded. Scopolamine (1 mg/kg, i.p.) or vehicle was administered 1 h before of acquisition trial, and guineensine (0.25 or 2.50 mg/kg, i.p.) or vehicle was administered 20 min before of reconsolidation trial. In resume, guineensine at 0.25 mg/kg decreased the crossover latency in reconsolidation and retention trial ($p<0.001$), therefore impairs the conditioning. At high dose (2.50 mg/kg), guineensine decreased the latency in retention trial ($p<0.001$), therefore impairs the reconsolidation. In the groups with scopolamine-induced amnesia, low dose of guineensine not have effect; however, at high dose, guineensine increased the crossover latency in reconsolidation ($p<0.001$) and retention trial ($p<0.05$), therefore abolishes the effect of scopolamine; this result must be better assayed

because anandamide could binding to nicotine receptors. In general, guineensine impairs acquisition memory process, in agree with other studies showing enhance anandamide levels and learning impair. It important to mention that studies with other inhibitor of uptake have presented improve of memory extinction; therefore, guineensine must be test in these assay.

Title: Evaluating putative deficit models in a hippocampal-dependent assay sensitive to task manipulations, aging and pharmacology

Authors: *R. GRAF[1], J. L. LONGO[2], Z. HUGHES[1];
[1]Dept. of Psychiatry & NeuroBehavioral Disorders, Neurosci. and Pain, Pfizer Inc., Cambridge, MA; [2]Northeastern Univ., Boston, MA

Abstract: Cognitive dysfunction is a key symptom of CNS disorders including schizophrenia and Alzheimer's disease. Currently, there are limited treatment options available that effectively improve cognitive deficits. Our research aimed to evaluate a rodent testing paradigm sensitive to cognitive disruptions as well as for detecting agents which restore cognitive function. Since patients with schizophrenia and Alzheimer's disease exhibit deficits in pattern separation, we established an assay to assess spatial learning, or pattern separation, in mice using touchscreen technology. The Location Discrimination Reversal (LD) task is a reward-based operant behavioral test that relies on the hippocampus, specifically the dentate gyrus to assess location memory by simultaneously displaying two identical stimuli in separate locations on a screen. The mice were trained to discriminate between the two illuminated images by pairing the correct response with a food reward; once learnt, the rule was then reversed. Three ways of impairing performance were evaluated. The first method involved reducing the discrimination index by decreasing the separation between the stimuli. There was separation dependent performance impairment as stimuli were presented closer together from intermediate (baseline) to minimum (hard) to adjacent (very hard) separations. The second method investigated whether the task was sensitive to age related cognitive decline by beginning training of mice when they were 11 months old. Compared to a younger cohort who began training in the same task at 3-4 months of

age, this cohort of aged mice required significantly more trials to reach criterion ($p<0.0001$). The final type of manipulation to cause a cognitive deficit was pharmacological intervention in adult mice. Mice were dosed with the muscarinic antagonist scopolamine (0.32 and 0.56 mg/kg, SC) or the NMDA antagonist, MK-801 (0.056 mg/kg, SC). Administration of scopolamine or MK-801 impaired performance which was evident in the exacerbation of the separation dependent deficit. In summary, here we demonstrated that performance in the LD task is sensitive to manipulations of task difficulty, age and pharmacological disruption. Work is ongoing to determine whether the cognitive deficits described in the LD task can be attenuated by compounds with cognitive enhancing properties.

Title: Blocking α7 nicotinic acetylcholine receptors improves specifically memory acquisition

Authors: *N. P. VAN GOETHEM[1], E. FEDELE[2], D. PUZZO[3], C. REBOSIO[2], W. GULISANO[3], A. PALMERI[3], L. P. WENNOGLE[4], Y. PENG[4], H. W. M. STEINBUSCH[1], J. PRICKAERTS[1];

Abstract: α7 nicotinic acetylcholine receptors (α7nAChRs) are ligand-gated ion channels expressed primarily in the brain. These receptors have been implicated in modulating cognitive functions like episodic memory and attention. Hence, α7nAChR agonists/modulators may be attractive drug candidates to improve cognition in Alzheimer's disease (AD) and schizophrenia. In the current study, the cognition enhancing properties of low dose administration of selective α7nAChR antagonists were investigated in rats as low doses of methyllycaconitine (MLA) have sporadically been reported to improve cognition in animals. Memory acquisition and consolidation processes were assessed separately with the object recognition task (ORT). The compounds used for these studies were MLA and Compound 7i. Interestingly, it was found that low doses of MLA and Compound 7i improved the acquisition, but not the consolidation processes of object recognition memory at a 24 h retention interval. Conversely, higher doses

impaired the memory performance at a shorter 1 h retention interval. In addition, the same compounds were studied in a model of neuronal plasticity, long-term potentiation (LTP). It was demonstrated that pre-tetanus low-dose administration of MLA or Compound 7i produced a longer lasting potentiation, whereas post-tetanus administration had no effect. Microdialysis studies showed that MLA administration substantially increased hippocampal glutamate efflux which has been found to be related to object memory processes. In summary, blocking α7nAChRs with low doses of selective antagonists improves specifically the memory acquisition process. While the main focus of the α7nAChR as a target for cognition enhancement lies on agonists and positive modulators, antagonism of these receptors at low doses might also prove to be a valuable tool for cognition enhancement in AD or schizophrenia.

Title: Effects of amnestic drugs on memory capacity in the rodent odor span task

Authors: M. MATHEWS, D. PANOZ-BROWN, A. PRICHARD, S. HESS, K. GOBENCIONG, J. COFFMAN, *J. GALIZIO;
Univ. North Carolina, Wilmington, NC

Abstract: Ketamine (NMDA antagonist), scopolamine (anticholinergic), zolpidem and flunitrazepam (positive allosteric $GABA_A$ modulators) have been associated with memory impairments in a variety of animal models. The present study used the odor span task to assess drug-induced deficits in working memory capacity in rats. The odor span task uses an incrementing non-match to sample procedure in which responses to a new olfactory stimulus result in reinforcement on each trial, while responses to previously presented stimuli are not reinforced. Responses were made by removing scented lids from cups presented in the arena. On each trial a novel stimulus was added, progressively incrementing the number of odors to remember (memory load). Six trials of a simple olfactory discrimination task, as a performance

control, were interspersed in each session to assess drug-induced impairments unrelated to working memory. dependent measures included number of consecutive correct responses prior to the first error (span), longest run of correct responses and overall accuracy. Rats were trained to a stability criterion prior to drug administration. Acute administration of all four compounds produced a dose dependent reduction in span, longest run and overall accuracy, but for ketamine, scopolamine, and zolpidem, this generally occurred only at doses in which performance on the simple discrimination control was also impaired. In contrast, acute flunitrazepam administration produced a dose dependent decrease in span, longest run and overall accuracy at doses that had no effect on the simple discrimination control. These results indicate that not all amnestic drugs produce selective deficits in the odor span task which may have a bearing on understanding the neurochemical basis of memory capacity.

Title: Methamphetamine-induced changes to monoamine neurotransmission and allocentric learning and memory in barren-housed adult rats

Authors: ***A. GUTIERREZ**[1,3], S. A. JABLONSKI[2], R. M. AMOS-KROOHS[4], A. A. BRAUN[2], M. T. WILLIAMS[2,3], C. V. VORHEES[2,3];

Abstract: Dopamine (DA) modulates brain regions known to be involved in learning and memory (L&M). The effects of methamphetamine (METH) on the dopaminergic system have been well characterized although the effects on allocentric spatial L&M have been unclear. Chronic stress can enhance or decrease cognitive performance depending on the intensity of the stressor. The current study investigated the effects of barren housing (BAR) on brain monoamines and L&M in METH-treated adult rats. Adult Sprague-Dawley males were housed

in standard housing (with bedding) or in BAR housing, consisting of a cage with no bedding and only a single paper towel. The animals continued to be housed this way for 3 weeks. At the 3-week point, blood was collected and the animals were treated with 10 mg/kg METH, 4 times at 2 h intervals. Temperatures were monitored throughout METH dosing. The animals were then allowed another 2 weeks to recover. At 2 weeks, one group of animals underwent behavioral testing in a 244 cm Morris water maze (MWM), while a second group had blood and brain tissue collected. Behavioral testing consisted of a day of straight channel, followed by an acquisition, reversal, shift, and cued phase. All phases, with the exception of the cued phase, consisted of 6 days of learning trials, and a one-day memory probe trial. The cued phase totaled 2 days. The second group of animals were sacrificed 2 weeks after METH treatment, blood was collected, and dorsal striatum (DS), nucleus accumbens (NAcc), and hippocampus (HIP) were collected. Monoamine levels were analyzed by HPLC-ECD. Glial fibrillary acidic protein (GFAP) expression was analyzed by western blotting. METH significantly increased temperatures during dosing. METH treatment produced behavioral deficits during the learning trials of all 3 phases. BAR animals performed better than standard-housed animals during the acquisition, but not reversal or shift phase. Reversal and shift, but not acquisition, probe trials were negatively affected by METH treatment. METH treatment significantly decreased DA and its metabolite, 3,4-dihydroxyphenylacetic acid (DOPAC) in the DS. A cage x drug interaction was detected for DOPAC levels in the DS (BAR increased DOPAC in saline animals). METH treatment also decreased levels of serotonin (5-HT) and its metabolite, 5-Hydroxyindoleacetic acid (5-HIAA) in the DS. Increases in expression of GFAP within the DS and the NAcc, but not the HIP, were detected. A cage x drug interaction was detected in the NAcc where BAR housing afforded protection against increased expression of GFAP in METH-treated animals. CORT levels at both time points and monoamine levels in the NAcc and HIP are currently being analyzed.

Title: GPR55 modulates procedural memory

Authors: *B. A. MARICHAL-CANCINO[1], A. SÁNCHEZ-FUENTES[1], M. MÉNDEZ-DÍAZ[1], A. E. RUIZ-CONTRERAS[2], Ó. PROSPÉRO-GARCÍA[1];
[1]Lab. De Cannabinoides, Fac. De Medicina, UNAM, Ciudad De México, Mexico; [2]Lab. de Neurogenómica Cognitiva, Facultad de Psicología, UNAM, Ciudad de México, Mexico

Abstract: GPR55 receptor is highly activated by several endocannabinoids. This receptor interacts functionally with CB1/CB2 receptors in different tissues; however, its functions in the Central Nervous System are practically unknown. Although GPR55 has been involved in bone dynamics, pain perception, vasomotor regulation and locomotor coordination, no systematic studies have analyzed its potential role in cognitive function regulation. As this receptor is widely expressed in the striatum, a brain structure that participates in procedural memory regulation, our aim was to analyze the role of striatal GPR55 on this type of memory. Therefore, we set up pharmacological experiments to evaluate the effect of striatal GPR55 stimulation/blockade on rat performance in a T-maze task. Wistar rats were trained to learn the strategy-1 (S1; reinforcer was in the east arm of a T-maze) during 5 sessions (1 session per day; 10 trials per session). This training was followed by 2 sessions to learn strategy-2 (S2; reinforcer was in the opposite arm) that implied the extinction of S1. Five min before each session, animals received bilateral intradorsolateral-striatum injections of Noladin-ether (3.1 nM; endogen agonist of GPR55 and CB_1), CID16020036 (5.6 nM; GPR55-antagonist), AM251 (5.6 nM; CB_1 -antagonist) or a combination of Noladin-ether with each antagonist. Noladin-ether impaired evocation on the second day of S1, inducing no other changes. However, while simultaneously blocking CB_1 (with AM251), Noladin-ether improved the acquisition and evocation of S1. In contrast, while simultaneously blocking GPR55 (with CID16020036), Noladin-ether weakened S1 acquisition and evocation. CID16020036 by itself hindered acquisition of both S1 and S2. AM251 by itself induced no significant changes in the task performance. Latency to reach arms from starting point was similar among groups, thus no motor coordination impairments interfered with this task. These results strongly suggest a role of GPR55 in procedural memory and constitute the first evidence indicating this receptor regulates cognitive processes.

Title: Increased learning rate in a visual discrimination and reversal learning task by chronic GPR6-antagonist treatment

Authors: *H. S. LINDGREN, P. HJØRRINGGAARD LARSEN, I. VESTERGAARD KLEWE;
Synaptic transmission *in vitro*, H.Lundbeck A/S, Valby, Denmark

Abstract: The constitutively active G-protein coupled receptor 6 (GPR6) is coupled to a stimulatory G-protein and increases the levels of cyclic AMP when activated. The receptor is predominantly expressed on striatopallidal medium sized spiny neurons but knowledge about its precise function is sparse. The importance of the striatum in various forms of rule learning and behavioural flexibility is however well documented and interestingly, GPR6 has been identified as a regulator of instrumental conditioning in mice, and genetically linked to reinforcement learning in humans. In this study, we investigated the effect of chronic GPR6-antagonist treatment on the acquisition of a visual discrimination task and reversal learning in an operant touchscreen system. Rats treated with the GPR6-antagonist learned the visual discrimination task more readily than the vehicle-treated controls with higher response accuracy during the three last days of treatment. In addition, the number of responses was overall higher in these rats compared to controls, which was speculated to reflect the increase in motor activity seen with this drug. During the reversal phase, both groups of rats reversed their behaviour and started responding to the previously non-rewarded image. However, the rats treated with the GPR6-antagonist were faster in learning the new contingencies and displayed higher response accuracy than the vehicle treated controls already after a few days of testing and remained better throughout the testing period. Initially, the number of responses was higher in the GPR6-treated rats, but this difference got smaller and diminished at the end of the testing period. The specific localisation of GPR6 to striatopallidal neurons were confirmed using *in situ* hybridisation. This study has shown that the GPR6-antagonism increases the learning rate of both a visual discrimination and reversal learning task in intact rats. Considering the nearly specific striatal expression of GPR6, drugs targeting this receptor may be beneficial in many neurological and psychiatric disorders, in which cognitive dysfunction of striatal origin is evident.

Title: Prelimbic cortex hyperactivation during fear memory consolidation or reconsolidation induces maladaptive behaviors outcomes in rats

Authors: *A. C. VANVOSSEN, C. A. J. STERN, M. A. M. PORTES, L. J. BERTOGLIO; Univ. Federal De Santa Catarina, Florianópolis, Brazil

Abstract: The activity of prelimbic (PL) cortex, a medial prefrontal cortex subregion, has been implicated in aversive memory consolidation and reconsolidation in rodents. The homolog human brain region of the rodent PL cortex is reported to be hyperactive in post-traumatic stress disorder (PTSD). Based on that, this study sought to investigate whether potentiating the PL cortex activity, through pharmacological glutamatergic NMDA receptor stimulation, during consolidation or reconsolidation of a contextual fear memory would induce fear generalization, a feature of PTSD involving an inability to restrict freezing to the appropriate context. In Experiment 1, male Wistar rats were fear conditioned to the context A and immediately after that received a bilateral infusion of vehicle or NMDA (30-300 pmol in 0.2 µl per hemisphere) into PL cortex. On the following days, they were re-exposed to the paired context A (Test A) and exposed to a neutral and unpaired context B (Test B). In any case, freezing behavior was measured as an index of fear memory. During Test A, all groups presented a comparable amount of freezing time, but animals infused intra-PL with 100 pmol of NMDA expressed significantly more freezing than controls during Test B (42 ± 6 vs. 15 ± 5%), indicating fear generalization. In Experiment 2, to corroborate that fear memory generalization was due to a consolidation potentiation, rats were subjected to a weaker fear conditioning and immediately after that received a bilateral infusion of vehicle or NMDA 100 pmol into PL cortex. During Test A, PL-stimulated group expressed significantly more freezing than controls (57 ± 10 vs. 30 ± 6%), indicating a potentiation of the memory consolidation, without any changes in Test B (8 ± 4 vs. 6 ± 2%). In Experiment 3, rats were submitted to a fear extinction session one day after fear conditioning. PL-stimulated group was less prone to fear extinction (69 ± 3 vs. 34 ± 9%), another PTSD-related feature. In Experiment 4, PL-stimulated group showed a more persistent contextual fear memory in Test A performed 28 d later (64 ± 5 vs. 43 ± 8%). In Experiment 5, rats were fear conditioned to the context A and had the memory reactivated by a brief re-exposure to the paired context on the next day. Immediately after that, they received a bilateral infusion of vehicle or NMDA into PL cortex. PL-stimulated group during memory

reconsolidation expressed significantly more freezing than controls during Test B (47 ± 7 vs. 17 ± 5%). Altogether, present results suggest that hyperactivity of the PL cortex is able to potentiate the consolidation and reconsolidation of recent and remote fear memories, with generation of maladaptive behavioral outcomes associated with PTSD.

Title: Effects of optogenetic stimulation of the rat lateral and ventrolateral periaqueductal gray on fear behaviour and fear learning

Authors: *N. ASSAREH, G. P. MCNALLY;
Sch. of Psychology,, Univ. of New South Wales, Sydney, Australia

Abstract: The midbrain periaqueductal gray is important for the expression of species-specific defense responses to threat and danger as well as for learning about such threat and danger via Pavlovian conditioning. We used adenonassociated viral vectors to express ChR2 or eNpHr3.0 in rat lateral or ventrolateral periaqueductal gray (PAG) neurons to examine the effects of optogenetic excitation and inhibition of PAG on expression of defensive behaviour and Pavlovian fear conditioning. When studying expression of defensive behaviour, lateral PAG (lPAG) ChR2 excitation caused pronounced and robust activity bursts, similar to those observed following foot shock. These bursts had very short onset latencies (< 25ms), were stimulation bound, and were dependent on the frequency (1 - 20 Hz) as well as intensity of stimulation. There was evidence for adaptation to these effects so that with repeated stimulation, the activity burst was replaced by the species-typical defense response of freezing. eNpHr3.0 inhibition of lPAG had few observable effects on behaviour. ChR2 excitation of ventrolateral PAG (vlPAG) caused expression of the species-typical defense response of freezing. Unlike lPAG, these behavioural effects were not time locked to stimulation, so that freezing emerged slowly (2 - 3 s) following stimulation onset and persisted seconds to minutes following stimulation offset, and were not obviously linked to stimulation frequency or intensity. eNpHr3.0 vlPAG inhibition had

few observable effects on behaviour. In contrast, during fear conditioning, eNpHr3.0 lPAG inhibition limited to the time of footshock delivery impaired the acquisition of fear learning whereas eNpHr3.0 vlPAG inhibition limited to the time of footshock delivery augmented the acquisition of fear. Taken together, these findings suggest that lPAG is critical to the adaptive responding to and learning about unexpected aversive events whereas vlPAG is critical to the adaptive responding to and learning about expected aversive events.

Title: Neural correlates of fear in rats foraging for food and encountering a 'predatory' threat

Authors: *E. KIM[1], M.-S. KONG[1], S. PARK[3,4], M. PARK[3,4], S. J. Y. MIZUMORI[1,2], J. CHO[3,4], J. J. KIM[1,2];

Abstract: Fear serves protective functions in animals and humans by influencing daily behaviors to reduce exposures to threats in their ecological niches. By using an ecologically-relevant "approach food-avoid predator" conflict paradigm (Choi and Kim 2010), we recently reported that a looming predatory robot induced remapping of hippocampal place fields as the animals advanced toward the vicinity of the threat and were unsuccessful in procuring food, but not when they were around the safety of the nest (Kim et al., 2015). These behavioral and neurophysiological effects were prevented by lesioning the amygdala. How amygdalar neurons respond to the immenient threat to regulate foraging decisions, however, remains unknown. Given that the amygdala is reciprocally connected with the medial prefrontal cortex (mPFC), a structure also implicated in fear regulation, we employed simultaneous single unit recordings to

investigate how cells in the basolateral amygdala (BLA) and mPFC may signal fear in foraging rats. To do so, hunger-motivated rats (85% normal body weight), implanted with tetrode arrays in the BLA and mPFC ipsilaterally, underwent successive stages of nest habituation, foraging baseline, and robot testing. Tetrodes were gradually advanced towards their target structures as the rats exited their nest in search of food pellets placed in a large open field. The robot testing consisted of 'pre-robot,' 'robot,' and 'post-robot' recording sessions. We found that both the BLA and mPFC neurons exhibited increased and/or decreased firing when the rats entered the foraging area and encountered a looming robot from distant. Specifically, the mPFC neurons showed more persistent firing than the BLA neurons. The differential time course of responses by BLA and mPFC neurons suggest that these structures make different contributions to foraging decision in the presence of a predatory threat.

Title: Stimulus-specific enhanced contextual fear learning following lateral fluid percussion experimental traumatic brain injury

Authors: *A. N. HOFFMAN[1,2], J. LAM[1], Y. CAI[2], C. C. GIZA[2], D. A. HOVDA[2], M. S. FANSELOW[1];
[1]Psychology, [2]Brain Injury Res. Center, Neurosurg., UCLA, Los Angeles, CA

Abstract: Traumatic brain injury (TBI) is a silent epidemic and is labeled the signature injury of troops in recent combat operations, a population that are often exposed to stressful stimuli and emotional trauma. While TBI is typically known to impair learning and memory for neutral events, traumatic fear memories are enhanced after TBI, consistent with increased prevalence of comorbid TBI and post-traumatic stress disorder (PTSD). Changes in sensitivity to sensory stimuli are common after TBI, and might influence the encoding of traumatic events. Our lab has shown enhanced contextual fear after lateral fluid percussion injury (LFPI) when fear conditioned after injury with white noise cues paired with footshocks (Reger et al., *Biol. Psychiatry*, 2012). In the current study we show that compared to sham, LFPI did not impact acquisition, context, or cued fear when fear conditioned with low frequency (2800Hz), pure tones. Given that white noise encompasses a greater frequency range, we hypothesize that LFPI enhances contextual fear to white noise-signaled conditioning due to injury-induced altered sensory processing. In a second experiment, LFPI or sham rats were pre-exposed to white noise trials, then were fear conditioned and tested for contextual and cued fear on subsequent days. Interestingly, LFPI rats showed elevated freezing to the white noise (16.8% vs. 4.2%, $p<0.001$) and context (32.6% vs. 7.1%, $p<0.001$) during the pre-exposure session, and during baseline the next day (6.9% vs. 1.2%, $p=0.035$), suggesting that LFPI rats conditioned to white noise alone. Furthermore, LFPI rats displayed enhanced contextual fear in the days after conditioning (day 1 freezing: 83.1% vs. 56.6%, $p=0.001$). These data provide implications for altered sensory processing after TBI, where otherwise neutral stimuli may adopt aversive properties and impact encoding of traumatic memories.

Title: Differential involvement of cortical areas in associative memory formation and retrieval in three versions of cued fear conditioning task in mice

Authors: *O. I. IVASHKINA[1,2], K. TOROPOVA[1,2], M. ROSHCHINA[1,2], T. KUNITSYNA[1,2], N. VOROBYEVA[1], K. ANOKHIN[1,2,3,4];

Abstract: Associative learning is a fundamental mechanism for experience-dependent modification of the cerebral cortex. Though synaptic mechanisms of associative conditioning in the cerebral cortex have been thoroughly studied, much less is known about its representation at the level of global neuronal populations. In the present study, we compared mouse behavior in three versions of classical fear conditioning task and imaged c-Fos activity in several associative and sensory cortices after memory acquisition and retrieval. First, we studied a classical cued fear conditioning to the auditory conditional stimulus (CS). We found that association of the tone CS with the footshock resulted in activation of the ventral part of the secondary auditory cortex, while retrieval of memory in response to the auditory CS produced preferential activation of prelimbic, infralimbic and parietal associative cortices. Next, we used a compound fear conditioning, where CS consisted of the auditory (tone, T) and visual (blinking light, L) components. Mice successfully associated the compound CS with the footshock and displayed freezing response both to the entire compound CS and to its separate T and L components. Acquisition of association between the compound CS and the footshock specifically involved the prelimbic and frontal associative cortices. Retrieval of memory by the entire compound cue resulted in specific activation of the prelimbic, parietal, primary visual, secondary visual and auditory cortex, whereas retrieval by one of the components of the compound CS did not activate the parietal cortex. Finally, we developed a new model of associative conditioning with pre-exposure facilitation by adding an auditory cue to the context pre-exposure learning session. Mice received three tone stimuli in a novel neutral context and three days later were briefly (5 sec) exposed to the same context with the auditory CS followed by the footshock. In the retrieval session, mice were presented with the tone CS in a novel context. Mice that received both the initial tone pre-exposure and the 5 sec tone CS successfully associated the tone with the footshock. Thus, our data suggest that mice are able to form complex associations in different versions of the classical fear conditioning task. We also showed that the compound associative memory engages additional sensory and associative cortical areas compared to the traditional single cue fear conditioning. Moreover, acquisition and retrieval of the associative fear memory engages distinct patterns of cortical activity in mice.

Title: Activity-dependent structural plasticity after fear conditioning in amygdala and auditory cortex pyramidal neurons

Authors: *T. GRUENE[1], K. FLICK[1], S. RENDALL[1,2], J. GRAY[2], R. SHANSKY[1];
[1]Northeastern Univ., Boston, MA; [2]Genet., Harvard Med. Sch., Boston, MA

Abstract: The brain is highly plastic and undergoes changes in response to many experiences. Learning especially can induce structural remodeling of dendritic spines, which is thought to relate to memory formation. Pavlovian auditory fear conditioning has been widely used to study neural processes underlying learning and memory, and involves recruitment of the medial prefrontal cortex, hippocampus, amygdala and auditory association areas. Past research has found dendritic spine changes after fear conditioning in several of these structures. But, due to heterogeneity of cells within brain structures and limitations of traditional neuroanatomical techniques, it is unclear if all cells included in analyses were actually involved in fear learning, even if known circuits are isolated. In this study, we employed a novel approach to analyze structural plasticity explicitly in neurons activated by fear conditioning. We used male and female Arc-dVenus transgenic mice, which express the Venus fluorophore driven by the activity-related Arc promoter, to identify neurons that were active during fear conditioning. All mice underwent auditory fear conditioning in custom built home cages to reduce noise in Arc expression and structural plasticity induced by handling. We then targeted fluorescent microinjections to Arc+ and neighboring Arc- neurons in the basolateral area of the amygdala (BLA) and auditory association cortex (TeA). Dendritic segments were imaged in 3D using a confocal microscope and automated spine analysis was performed. In the BLA, Arc+ neurons had reduced thin and mushroom spine densities compared to Arc- neurons. This effect was present in both males and females. In the TeA, however, differences between Arc+ and Arc- neurons were not uniform across all animals. To look for additional structural differences, spine head diameters were analyzed. Overall, this study adds to our understanding of how learning affects structural plasticity, and represents a methodological advance in the ways we can directly relate structural changes to learning-related neural activity. While we did not observe sex-differences in dendritic spine changes in the BLA and TeA, future studies will need to explore if sex-differences exist in other brain regions involved in fear conditioning.

Title: Amygdala is essential for hippocampal place cells to encode a distance gradient of fear in foraging rats

Authors: ***M.-S. KONG**[1], E. KIM[1], M. PARK[2,3], S. PARK[2,3], J. CHO[2,3], J. J. KIM[1,4];
[1]Dept. of Psychology, Univ. of Washington, Seattle, WA; [2]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [3]Korea Univ. of Sci. and Technol., Daejeon, Korea, Republic of; [4]Program in Neurobio. & Behavior, Seattle, WA

Abstract: Fear is an adaptive mechanism evolved to guide behaviors that help maximize survival while minimizing exposure to risk. Our laboratory has recently developed a relatively simple semi-naturalistic preparation to investigate the rat's foraging behavior when confronted with an artificial predator (assembled from LEGO Mindstorms robotic kit) programmed to surge toward the animals seeking food (Choi and Kim, 2010). Our initial work revealed that while the rats were unable to acquire food pellets placed distal from the safety of the nest (i.e., near the predatory robot), they were able to secure pellets placed nearby the nest. This suggests that fear significantly reduced the distance the rats will travel to intercept food and that the animals formed a spatial gradient of fear or defensive distance from the source of threat. Very recently, we reported that the hippocampal place cells exhibited differential activity patterns during the foraging task (Kim et al, 2015). The surging robot induced transient remapping of place fields near the source of threat (i.e., distal to the nest), whereas those fields adjacent to or inside the nest were relatively stable. The present study investigated whether the transient remapping of distal place fields is in fact due to fear by recording place cells in rats where the robot was stationary and in amygdala-lesioned rats. A pixel-by-pixel correlation analysis indicated that with a stationary robot, hippocampal place cells were comparably stable in all foraging area. In amygdala-lesioned animals, the looming robot affected neither the foraging behavior nor the

stability of place fields in the distal area. These results indicate that the amygdalar signaling of fear evoked by the looming motion, and not the salience/novelty, of the robot influences the stability of hippocampal place cells as a function of threat distance in rats foraging for food.

Title: Fear conditioning using a two-tone discrimination paradigm: Potential use for chronic stress investigations

Authors: ***J. M. JUDD**, K. J. NISHIMURA, C. R. ARNETT, F. SANABRIA, C. D. CONRAD; Psychology, Arizona State Univ., Tempe, AZ

Abstract: In the laboratory, variations of fear conditioning are frequently used as a model of post-traumatic stress disorder, as it pertains to fear memory formation, extinction, and reconsolidation. In fear conditioning, pairing a neutral stimulus, such as tone (conditioned stimulus, CS), with an unconditioned stimulus (US) can eventually lead to the CS eliciting a freezing response. Freezing to the CS in the absence of the US is a conditioned response (CR), due to an association between the CS and the US. The amount of freezing to the tone alone can be used as an indicator of the strength of the fear memory. Typically in the stress and fear conditioning field, researchers use a between-subject design, in which one set of animals is used to investigate the CS/US paired outcome and another set is a control in which the CS is explicitly unpaired from the US. The unpaired group allows the researcher to determine whether the CR is associative or non-associative. Other conditioning paradigms use a within-subject design, which have the benefits of reducing subject number, lowering the inter-subject variability, and providing higher power. We determined if a within-subject design could be used in fear conditioning by employing a discriminative fear conditioning paradigm, in which animals were exposed to both a predictive tone (CS+) and a non-predictive tone (CS-). This method is a powerful way to target a specific fear memory and explore the effect a treatment would have on fear memory persistence. Male Sprague-Dawley rats were used. Fear conditioning consisted of a

training day (CS+ and CS-), reactivation 24-hrs later (one CS+ only), post-reactivation short-term memory (PR-STM 4 hrs later with CS+ and CS-) and post-reactivation long-term memory (PR-LTM, with CS+ and CS-) 24-hrs after reactivation. In the first study, we used variations of tone to optimize discrimination as follows: three tone sets (3 CS+ and 3CS-), 7kHz tone range (3kHz vs 10kHz), tone persistence (continuous vs pulses 100 ms on and 100 ms off). In the second study, modifications to the tones were as follows: five tone sets (5 CS+ and 5CS-), 12kHz tone range (3kHz vs. 15kHz), tone persistence (continuous vs 100 ms on and 200 ms off). Rats had difficulty maintaining discrimination across days with three sets of CS+/CS-. However, rats discriminated with five CS+/CS-, but extinguished quickly by PR-LTM. As part of a larger study, we plan to implement a five CS+/CS- training paradigm with three CS+/CS- during PR-STM and PR-LTM to investigate mechanisms of reconsolidation after chronic stress.

Title: The indirect pathway from entorhinal cortex to CA3 should be used during recall of hippocampal conjunctive representations

Authors: *F. B. KRASNE[1,2], M. S. FANSELOW[1,2,3], J. D. CUSHMAN[1];
[1]Dept Psychol, UCLA, Los Angeles, CA; [2]Brain Res. Inst., [3]Dept. of Psychiatry and Biobehavioral Sci., UCLA, La, CA

Abstract: It is widely believed that the hippocampus creates long-persisting representations of complex stimuli to which associations can be made. For example, during context fear conditioning the hippocampus creates a representation of the conjunction of a context's attributes to which fear becomes conditioned in the amygdala. There is consensus that representations are expressed within CA3 and that they are encoded as synaptic potentiation in CA3's system of recurrent collaterals. CA3 receives "direct" input from EC and "indirect" input from EC via dentate (DG). There is wide agreement that which CA3 cells will comprise a representation is determined by which DG cells are most excited by EC input during the representation's creation;

however, it has been argued that in order to prevent this selection process from being distorted by interference from the recurrent collaterals, DG-CA3 synapses must be overridingly effective. But, it is then argued that such strong DG-CA3 synapses preclude use of the indirect pathway for activation of the correct representation of a familiar context on subsequent recall occasions because input from the recurrent collaterals would be overshadowed by DG input (Treves and Rolls, 1992). However, we see no reason why DG-CA3 transmission should not simply be up-regulated during representation creation (see Krasne et al, 2015). We therefore investigated the relative merits of using only the direct, only the indirect, or various balances of the two pathways to CA3 during recall, using a computational model of hippocampal function (BACON, Krasne et al, 2015). Consistent with theoretical expectations, the indirect pathway alone provides better recall than the direct alone, but both together are best. Moreover, to be helpful, the direct pathway must be quite weak; the distal location of direct path inputs in the biological hippocampus is consistent with this. We therefore believe that computational considerations should not be used to discount a major role for the indirect pathway in recall.

Title: Modulating innate fear based on visual stimulus by a novel subcortical pathway in mice

Authors: ***N. LIU**, P. WEI, X. LIU, Y. TANG, Y. LIU, Z. ZHOU, L. WANG;
Shenzhen Inst. of Advanced Technology, Chines, Guandong, China

Abstract: The innate ability of animals to respond to life-threatening stimuli is essential for survival. These stimuli activate modular brain circuits consisting of phylogenetically ancient subcortical structures, however, details regarding the circuitry mechanisms responsible for processing innate threat stimuli remain to be elucidated. Here,we investigate the circuitry underlying innate defensive behaviors elicited by predator-like visual stimuli in mice. Our results demonstrate that neurons in the superior colliculus (SC) are essential for a variety of acute and persistent defensive responses to overhead looming stimuli, and phasic optogenetic activation of these neurons or their terminals projecting to lateral posterior thalamic nucleus (LP), a non-canonical polymodal sensory relay, is sufficient to elicit similar defensive behaviors, such as unlearned long lasting freezing, followed by sustained avoidance and anxiety-like behavior. Using trans-synaptic tracing in conjunction with *in vivo* electrophysiology experiments, we figured out a di-synaptic circuit from SC through LP to the lateral amygdala (LA), and inhibition of the amygdala blocked the full range of defensive responses. Taken together, Our results revealed a novel SC-LP-LA subcortical pathway that conveys visual threat information, leading to innate, fear-related defensive behaviors.

Title: Dissociation of the medial and lateral habenula in the expression of unconditioned defensive behavior

Authors: *B. A. PELLMAN[1], E. KIM[1], Y. RAO[1], J. J. KIM[1,2];
[1]Dept. of Psychology, [2]Program in Neurosci., Univ. of Washington, Seattle, WA

Abstract: Both the medial and lateral habenula (MHb and LHb, respectively) have been implicated in processing information about aversive events in the environment (Viswanath et al., 2014). Neurons in the LHb increase activity when an animal is presented with an unexpected aversive stimulus, such as the absence of an expected reward or the presence of punishment (Matsumoto & Hikosaka, 2009). Correspondingly, lesions/inactivations of the LHb impair avoidance learning and memory while its stimulation enhances avoidance learning (Pobbe & Zangrossi, 2008; Stamatakis & Stuber, 2012). While less is known about the functions of the MHb, some evidence suggests that it may play an opposing role to the LHb (Bjartmer et al., 2010; Viswanath et al., 2014). The present study compared the roles of the LHb and MHb in rats utilizing an ethologically-relevant 'approach food-avoid predator' paradigm and classical fear conditioning to assess both unconditioned defensive behaviors and conditioned fear responses. Rats received either electrolytic lesions to the LHb or MHb or sham lesions. They were then trained over 4 days in an elongated open field to retrieve grain pellets at increasing distances from a safe 'nest' area to which they had previously been habituated. Subsequently, a LEGO® Mindstorms® robot shaped like an alligator and programmed to surge forward and snap its 'jaws' when rats approached the pellets was placed opposite of the 'nest' area, and the rats attempted to retrieve the pellets while avoiding the predator-like robot (cf., Choi & Kim, 2010). After testing with the robot on days 1, 2 and 9, rats underwent auditory fear conditioning and freezing to the tone and context were assessed independently 24 h later. Lesions of the MHb impaired the ability of rats to obtain the pellet across all distances relative to sham controls, whereas LHb lesions reduced the time rats took to obtain the pellet at farther distances relative to sham controls. Thus, MHb-lesioned animals showed sustained heightened fear across all three days of exposure to the robot while LHb-lesioned animals exhibited reduced fear and faster habituation to the false threat of the robot compared to sham control animals. In contrast, there were no differences between groups during the acquisition or expression of fear conditioning to the tone or context. These results seem to suggest that the MHb and LHb play opposing roles in unconditioned avoidance responses but are not critical for the acquisition or expression of conditioned freezing.

Title: Behavioral, neuroanatomical, neuroendocrine and neurochemical features of the expression phase of fear conditioning to a light-CS

Authors: *A. R. OLIVEIRA[1,2], A. E. REIMER[3,2], L. ALBRECHET-SOUZA[2,4], F. M. C. V. REIS[3,2], M. C. CARVALHO[3,2], M. L. BRANDÃO[3,2];

Abstract: The Pavlovian fear conditioning is one of the most common paradigms used to study the biological basis of emotion, as well as of learning and memory. Considering the complexity of defensive response expression, several interactions between diverse stress mediators acting in distinct brain structures may be required for optimal performance in front of aversive conditioned stimuli (CS). In this direction, the mesolimbic dopamine (DA) pathway is being demonstrated to have an important role in states of fear and anxiety. On the other hand, the activation of the hypothalamic-pituitary-adrenocortical (HPA) axis, reflected by an increase in plasma corticosterone in rodents, has been considered a key part of the stress reaction. In previous studies, we showed that corticosterone upregulates the dopaminergic neurotransmission in the ventral tegmental area (VTA)-basolateral amygdala (BLA) pathway, which facilitates the expression of conditioned fear responses. In the present study, we aimed to expand the characterization of the expression phase of fear conditioning using a light-CS. For this, separate groups of animals were submitted to one training session in which they were exposed to 10 non-paired presentations of light and footshocks (control group) or 10 pairings of light and footshocks (conditioned group). Twenty-four hours after training, animals were subjected to 10 presentations of light during a test session that lasted 20 minutes, in a different cage from that used during the training session. An additional group of animals that did not pass by the training or testing sessions was also used (no stress group). The parameters monitored included the conditioned freezing response, the distribution of Fos protein in the VTA and amygdala, the plasma concentrations of corticosterone, and the tissue content of DA and metabolites in the amygdala. Rats previously subjected to paired presentations of light and footshocks exhibited a robust increase in the time spent freezing compared with controls. Light-CS also promoted a significant increase in the number of Fos-positive cells in the VTA, but not in the amygdala. A general increased plasma corticosterone concentration was associated with exposure to the conditioned fear protocol. No differences in DA, DOPAC or HVA concentrations in the amygdala were observed after exposure to light-CS in conditioned group compared to control.

Although more investigation is needed to clarify this field, the data obtained in the present work bring additional evidence to the notion that a complex interaction of stress mediators acting in different brain areas play a role in the expression of conditioned fear to a light-CS.

Title: Chemogenetic inhibition of the ventromedial prefrontal cortex increases fear generalization and impairs fear extinction

Authors: *Z. T. PENNINGTON, J. Z. AVERSHAL, A. S. ANDERSON, M. S. FANSELOW; Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Post-traumatic stress disorder is associated with both structural and functional changes in the ventromedial prefrontal cortex (vmPFC). Evidence indicates that the vmPFC is important in mediating the extinction of responses to feared stimuli, suggesting that these anomalies may be responsible for the pervasiveness of symptoms. Nevertheless, both human and rodent studies suggest that the vmPFC is also integral to reducing fear to stimuli similar to those that have been paired with an aversive event (i.e. fear generalization), a behavioral phenomenon that is also clinically relevant. The present work was undertaken as a foray into parsing the contribution of the vmPFC to fear extinction and fear generalization. Designer receptors exclusively activated by designer drugs (DREADDs) were used to inhibit the infralimbic subregion (IL) of the rat vmPFC while animals were tested for the acquisition, generalization, and extinction of a fear memory. Subsequently, anxiety in response to IL inhibition was assessed in an open field. Although IL inhibition did not alter the acquisition of a fear memory, it did result in greater freezing to a novel context following fear conditioning, indicative of heightened fear generalization. Additionally, IL inhibition during extinction training resulted in subsequently poorer recall of the extinction memory when animals were tested drug free. Notably, inhibition of the IL neither altered the total distance traveled nor the time spent in the center of an open field, suggesting that IL inhibition does not reduce locomotor activity or induce anxiety. Using transient chemogenetic

inhibition, these findings replicate the findings that the IL is important for both fear generalization and fear extinction. Future studies aim to use both pathway- and temporally-specific manipulations to understand how dysfunction of the vmPFC alters these processes.

Title: Serotonin, affective biases and prefrontal control

Authors: *H. E. DEN OUDEN[1], D. E. M. GEURTS[2], K. SCHMIDT[3], N. D. DAW[4], R. COOLS[1];
[1]Donders Inst. for Brain, Cognition and Behaviour, [2]Dept. of Psychiatry, Radboud Univ., Nijmegen, Netherlands; [3]Dept. of Psychiatry, Oxford Univ., Oxford, United Kingdom; [4]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Serotonin (5HT) is implicated in both aversive processing[1,2] and behavioral inhibition[3], with evidence showing that a reduction in 5HT disinhibits behavior in the face of expected punishments[4,5]. Indeed a popular recent idea is that 5HT has a specific role in tying aversive Pavlovian influences to instrumental inhibition[6-9]. To test this idea, we pitted the Pavlovian and instrumental control systems against each other, by varying instrumental demands while keeping the Pavlovian value of the cue constant. We manipulated 5HT levels using tryptophan depletion in 50 participants who performed this task in the fMRI scanner (randomised double blind within-subject design). On each trial, a cue informed subjects whether they were playing for a reward (versus neutral) or punishment, consisting of primary reinforcers in the form of lemonade vs. a bitter solution. They chose to respond (Go) or not (NoGo), in order to get the desired outcome. As expected, participants showed a strong Pavlovian bias: they were both faster and more likely to make a Go response when playing to get a reward than to avoid punishment.

There were, surprisingly, no behavioural effects of lowering 5HT levels. However, we observed a striking difference in their neural responses. In the control condition the dorsolateral prefrontal cortex showed an increased response when participants made a Pavlovian 'incongruent' (Go2avoid or NoGo2win) response, compared to making a congruent response. This is line with previous findings that the degree of frontal response to incongruent cues predicts our ability to suppress the Pavlovian bias [10]. However, when 5HT levels were lowered, this prefrontal response was abolished. This effect was independent of cue valence. Thus, while people were equally capable of making the incongruent response, we speculate that less prefrontal control was required to override the Pavlovian bias. This finding supports our idea that 5HT is particularly important in implementing automatic affective biases responding. 1 Graeff FG, Guimaraes FS, De Andrade TG & Deakin JF (1996) *Pharmacology, biochemistry, and behavior* 2 Deakin JF & Graeff FG (1991) *J Psychopharmacology* 3 Soubrie P (1986) *Behavioral and Brain Sciences* 4 Crockett MJ, Clark L, Apergis-Schoute AM, Morein-Zamir S & Robbins TW (2012) *Neuropsychopharmacology* 5 Crockett MJ, Clark L & Robbins TW (2009) *J Neuroscience* 6 Boureau YL & Dayan P (2011) *Neuropsychopharmacology* 7 Cools R, Nakamura K & Daw ND (2011) *Neuropsychopharmacology* 8 Dayan, P. & Huys, Q. Title: Opioidergic modulation of cost-benefit decision making of AA rats in rat Casino-model

Authors: *V. OINIO[1,2], P. BÄCKSTRÖM[2], J. UHARI-VÄÄNÄNEN[1], A. RAASMAJA[1], K. KIIANMAA[2], P. PIEPPONEN[1];
[1]Univ. of Helsinki, Helsinki, Finland; [2]Natl. institute for health and welfare, Helsinki, Finland

Abstract: Co-morbidity with gambling disorder (DSM-5) and substance abuse disorders, especially alcohol use is well documented and might share same neuronal pathways including opioidergic systems. Aim of the study was to study cost-benefit decision making of alcohol-preferring AA (Alko Alcohol) rats and whether it can be modulated by opioidergic agents. We developed the Casino-model of rodent gambling, which resembles the situation when gamblers go to casino over and over again despite knowing the fact that casino "always wins". The model is based on operant probabilistic discounting i.e. devaluing a reinforcer by decreasing the probability of obtaining it and eventually stabilizing the probability to level where single high rewards can be received by expense of many smaller, but in long run, more profitable rewards. Male alcohol preferring AA rats were trained to self-administer sucrose pellets (45 mg) in a two-lever choice task. One lever was designated as SS-lever ("Small-Sure") which delivered one sucrose pellet always at probability of 100% and other was designated as LL-lever ("Large-Lucky") which delivered three sucrose pellets at decreasing probabilities (100%, 50%, 33% and 25%). Duration of one session was 24 trials (called "credits") or 30 minutes. First the rats were taught to make rational decisions based on one versus three sugar pellet rewards (probability for receiving both 100 %). Rats that could not perform rational decision making behavior were disqualified. After rational behavior was reached the probability for obtaining pellets from LL-lever was decreased over time to a probability level of 25 % (Casino-level), thus at the Casino-level by choosing the LL-lever the rats received calculatory only 0.75 pellets by each credit. The effects of morphine (n=12) and naltrexone (n=11) were examined at the Casino-level. Both drugs were administered s.c. at two different doses (0.3 mg/kg and 1.0 mg/kg). Morphine decreased AA rats LL-lever choices significantly compared to vehicle in dose dependent manner. Morphine had no effect on played "credits" or time spend to consume these. Naltrexone had no significant effects to lever choices but had trend to decrease amount of played "credits" and increased significantly the time that rats spend to consume these. Results indicate that reward guided cost-benefit decision making can be modulated by opioidergic agents, especially with alcohol preferring AA rat strain.

Title: Content analysis of dreams induced by an alleged oneirogenic plant: Calea zacatechichi

Authors: *A. ROSALES-LAGARDE[1], L. MAYAGOITIA[2], J. GONZÁLEZ[3], J. DÍAZ[4]; [1]Inst. de Ciencias de la Salud, Área Académica de Gerontología, CONACYT-UAEH, Tilcuautla, Mexico; [2]Inst. Nacional de Psiquiatría Ramón de la Fuente, DF, Mexico; [3]Univ. Autónoma del Estado de Morelos, Cuernavaca, Mexico; [4]Univ. Nacional Autónoma de México, DF, Mexico

Abstract: Calea zacatechichi (Asteraceae), a shrub employed in traditional mexican medicine has been used as appetizer, antipyretic, antidiarrhetic and cholagogue. Considered to be in non-controlled studies oneirogenic and cognodsyleptic, it rarely produces hallucinations. A double blind counterbalanced repeated measures experimental design to evaluate physiological, behavioral and psychological effects of zacatechichi appeared in 1986. Evidence in that paper pointed to an increase on frequency and colorfulness of dreams with the methanol extract, but most dreams measured by the number of lines written in the report were shorter than 5 lines. A content analysis with Hall and Van de Castle scales was undertaken to further explore the detailed complexity of short dreams considering RT tasks and subsequent night dreams. College and graduate students free from drugs or pathological or neurological antecedents (3 women and a man) gave their written consent. From the leaves and stem of the plant, hexane and methanol were used to obtain two extracts. Placebo (PL), hexane (H) or methanol (M) capsules (30 mg/Kg and 86 mg/Kg, respectively) were administered in a double blind random procedure an hour before subjects performed RT tasks while physiological measures were simultaneously recorded. All sessions began at noon and 7 days elapsed at least between sessions. Ad hoc questionnaires were used to collect dreams after the experimental tasks and after that night. For each dream and condition, word count was obtained and its content analyzed and categorized in characters, settings, actions, emotions, interactions, modifiers, temporal and negative scales and statistical analysis were carried out with real and incongruent categories. Interrater reliability by two blind judges was 95%. Mean for each category was calculated and results were submitted to the non-parametric Friedman tests. Only characters between PL and M and settings among PL and M; H and M conditions, reached significance. In two subjects word count as well as number of dreams were especially greater with the extracts. Real content was also near of reaching significant results and incongruent content was found in 36.3% of the M dream reports. C. zacatechichi during naps has been reported to increase stage 1 and awakenings, while REM sleep stage decreases. The Hall and Van de Castle method seems useful for the analysis of shorter dreams induced by oneirogenic extracts. Oneiric experience with the administration of C. zacatechichi

while performing RT tasks and during the subsequent night appears to be short, colorful, includes characters and settings and tends to have real content.

Title: Role of serotonin in the motivational control of behavior: a pharmacological challenge in humans

Authors: ***N. BORDERIES**[1], R. LEBOUC[1], F. MEYNIEL[2], J.-C. CORVOL[1], F. VINCKIER[1], M. PESSIGLIONE[1];
[1]Brain and Spine Inst., PARIS, France; [2]Neurospin, Gif sur Yvettes, France

Abstract: Serotonin signaling in the brain is an important system for the motivation of behavior. It has been associated in particular with aversive processing, impulsivity and inhibitory control. It is also the target of the most prescribed antidepressant drugs, such as citalopram (a serotonin reuptake inhibitor). However, we still lack a mechanistic understanding that would articulate the role of serotonin in various motivational processes such as effort production, decision making and instrumental learning We conducted a randomized, cross-over, double-blind, placebo-controlled experiment in which a group of healthy subjects were administered an acute dose of citalopram while they were tested on a comprehensive battery of motivational tasks. Significant effects of citalopram included a reduced sensitivity to monetary incentives in effort production (force task) and a consistent reduced willingness to accept effort or punishment costs in order to get rewards (choice task). These two effects can be explained by a common down-regulation of positive expectations in the cost-benefit calculation that determines the intensity and orientation of behavior. These results suggest a role for serotonin in motivational control that is in line with the alleged opponency to dopamine, which has been shown to amplify reward sensitivity in similar tasks. This might also explain the affective blunting of appetitive expectations that has been observed in depressed patients treated with serotoninergic medication.

Abstract: Motivational valence influences behavioural activation in a seemingly Pavlovian manner, such that a reward context promotes activation and a punishment context promotes inhibition. Both human and animal research has shown that dopamine modulates these affective biases. In this study we aimed to assess whether i) dopamine-induced changes in affective biases should be understood as altered action execution (activation/inhibition) or as altered learning (credit assignment), and ii) how these effects depend on individual differences in measures predictive of baseline dopamine function. We tested 102 participants once after placebo and once after administration of the dopamine/noradrenalin transporter blocker methylphenidate (MPH). MPH-induced changes were predicted by individual differences in working memory (WM) capacity; MPH strengthened the Pavlovian biases proportional to WM capacity. These changes were explained by altered global activation/inhibition rather than credit assignment. In this poster session, I will discuss the differential influence of MPH on affective biases and instrumental

learning, and thereby emphasise the importance of taking into account individual differences when understanding the effects of methylphenidate.

Title: The effects of stress on effort-based decision making: evidence from one model

Authors: *E. E. HART, A. STOLYAROVA, T. R. MINOR, A. IZQUIERDO;
UCLA, Los Angeles, CA

Abstract: In order to survive, animals and humans must conduct cost-benefit analyses wherein the cost of emitting a reward-seeking action is weighed against the value of its reward. Common costs of reward-seeking actions include time, risk, and effort. Effort-based decision-making has been modeled in rodents with effort requirements ranging from physical to attentional, with the former as most studied. Stress affects performance in several tests of cognition and decision-making ranging from altered memory formation (Sun & Alkon, 2014) in humans and impaired reversal learning in rodents (Campeau et al. 2011). Recent reports show effects of stress in an operant task assessing effort (Shafiei et al. 2012) and alterations in cognitive flexibility following exposure to a rat model of post-traumatic stress disorder (George et al. 2015). It is well established that effortful choices (and effort discounting) is mediated by dopamine signaling (Salamone & Correa 2012, Denk et al. 2005), which is also impacted by stress (Arnsten, 2000). Moreover, brain regions affected by stress (e.g. mPFC, BLA, NAc) are also implicated in effort. However, the effects and mechanisms of stress on effort-based decision making have not been extensively studied. For these reasons, we investigated effort-based decision making on a maze task with three possible courses of action, each associated with different effort requirements and reward magnitudes. Behavioral testing was conducted in a standard eight-arm radial maze. Four arms were permanently blocked, leaving a start arm and three choice arms. One arm of the maze was randomly designated as a low-effort/reward arm (LER, 1/2 cereal loop), another as a medium-effort/reward arm (MER, 1 cereal loop), and a third as a high-effort/reward arm (HER, 2 cereal loops). The arm containing low reward was unimpeded by a barrier, but to obtain a medium or high reward, rats were required to climb a 20 or 30 cm barrier, respectively. Male S-

D rats (n=12) received pretraining on this task before being administered shock (100, 1.0 mA tail shocks, 60s variable interval, 8s variable duration). Testing took place 24 hours after stress and had no effect on the pattern of HER, MER, and LER choices. In a control task where each reward magnitude choice had the same low effort requirement, rats did not show a preference for the high-reward magnitude option, suggesting augmented habitual control of choice behavior. Taken together, these data suggest that effort costs and habits may interact in controlling choice behavior. Further research will examine the effects of stress in other tests of effort in addition to brain mechanisms including adenosine, dopamine and acetylcholine signaling.

Title: Methylphenidate alters decision making about cognitive control

Authors: ***M. I. FROBOSE**[1], J. C. SWART[1], J. L. COOK[2], D. E. M. GEURTS[1], S. J. FALLON[3], H. E. M. DEN OUDEN[1], R. COOLS[1,4];
[1]Donders Ctr. for Cognitive Neuroimaging, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]City Univ. London, London, United Kingdom; [3]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [4]Dept. of Psychiatry, Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Methylphenidate is frequently prescribed for ADHD, but is also taken by healthy adults for cognitive enhancement (Maher, 2008). Elucidating the neurocognitive consequences of methylphenidate is a key scientific puzzle, given that estimates of the proportion of healthy students and academics using drugs like methylphenidate off-label range between 4% and 16% (Farah et al., 2004). Pharmacologically, methylphenidate has been found to be a potent blocker of the dopamine transporter (DAT(Ritz et al., 1987, Gatley et al., 1999), leading to increased dopamine and noradrenaline in prefrontal cortex (Berridge et al., 2006) and striatal areas (Volkow et al., 2001). Optimal catcholamine levels in the prefrontal cortex are necessary for efficient cognitive control (Brozoski et al., 1979; Berridge and Arnsten, 2012). However, the mechanisms underlying these effects are unclear. We build on recent insights that reconceptualize cognitive control as a cost-benefit decision (Shenhav et al., 2013; Westbrook and

Braver, 2015) and asked whether methylphenidate altered decision making about cognitive control. Specifically, we employed a demand selection task, developed by Kool et al (2010) to assess the degree to which subjects avoid a mentally effortful task, involving frequent task-switching. A double-blind, placebo-controlled, within-subject design was employed, where 100 healthy adults were administered placebo on one day and methylphenidate (20 mg, oral) on another. In keeping with our hypothesis, results revealed significant effects of methylphenidate on demand selection. Notable, we could isolate these effects only because we took into account individual differences in baseline working memory capacity, which is suggested to correspond with individual differences in baseline levels of striatal dopamine synthesis capacity (Cools et al., 2008). Demand avoidance was decreased in subjects with low working memory capacity, consistent with its cognitive enhancing effects in ADHD (Berridge and Arnsten, 2015). By contrast, methylphenidate increased demand avoidance in subjects with high working memory capacity, thus impeaching its cognitive enhancing potential in healthy, high-functioning healthy volunteers. Together these data demonstrate that methylphenidate alters cognitive control, by modulating decision making about cognitive control, in a baseline-dependent manner. This result concurs with current knowledge about (striatal) dopamine's role in cost-benefit decision making.

Title: Action initiation shapes mesolimbic dopamine encoding of future rewards

Authors: E. C. J. SYED[1], L. L. GRIMA[2], P. J. MAGILL[1], P. BROWN[1], *M. E. WALTON[3]; [1]MRC Brain Network Dynamics Unit, [2]Dept. of Exptl. Psychology, [3]Univ. of Oxford, Oxford, United Kingdom

Abstract: It is widely held from electrophysiological and electrochemical studies that dopamine signalling encodes predictions of future rewards and such predictions are regularly used to drive

behaviour. Moreover, manipulations of mesolimbic dopamine demonstrate that dopaminergic transmission is not only required to drive behavioural responses to incentive cues but can also facilitate action initiation. However, to date, the precise relationship between cue-elicited dopamine release, reward prediction, response choice and movement remains ambiguous. To investigate this issue, we used fast-scan cyclic voltammetry to monitor dopamine release in the nucleus accumbens core (NAcc) while animals performed variants of a task that required them either to initiate or withhold an action to gain reward. Following an initial response, a cue instructed the animals either to maintain their position (No-Go) or to disengage and press a lever (Go). Rats learned to perform this task with high accuracy across conditions, responding rapidly on Go trials and refraining from responding for > 2s on No-Go trials. Dopamine levels rapidly increased after cue presentation on correctly performed Go trials, the signals evolving rapidly as animals progressed through a sequence of discrete actions to gain reward. By contrast, no such change was observed on trials where a response was withheld until a response was made to collect the reward. Importantly, it was not the case that all actions resulted in dopamine release: dopamine levels on erroneously performed Go or No-Go trials also failed to elicit any change in dopamine even during or after a movement was made. Together, these results indicate that dopamine release in this region is contingent upon correct action initiation and not just reward prediction.

Title: Phasic dopamine release in the nucleus accumbens shell encodes the individual difference in impulsive decision making

Authors: ***X. XIE**, L. WILSON, B. GUZIK, C. LEE, L. QI, K. BLANTON, L. SOMBERS; Chem., North Carolina State Univ., Raleigh, NC

Abstract: High impulsivity is associated with vulnerability to cocaine relapse and treatment failure in cocaine addicts. Remarkably, impulsivity can be elicited by chronic cocaine administration, given that passive chronic cocaine exposure regimens enhance impulsivity in laboratory animals, using the delay discounting paradigm. However, little is known about the neural mechanisms underlying this behavior phenomenon. To this end, rats were surgically implanted a carbon fiber micro-electrode into the nucleus accumbens (NAC) shell region. Following recovery from surgery, rats received once daily delay discounting task training session in a standard operant conditioning chamber. The training session involved three types of contingencies (30 trials each) intermixed within 90 total trials. The presentation of these reward contingencies allowed animals to fully learn the predictive associations of the cue lights and the reward contingencies (i.e. one sucrose pellet immediately delivered or two sucrose pellets delivered after 2s delay period). Animals were trained on the task for at least 10 sessions to achieve stable performance, and electrochemical recordings of dopamine transients in the NAC shell were conducted during the first day and last day of training. Our results have shown that there is an individual difference in the preference of large delayed reward across the group of rats. Given that phasic dopamine release from the ventral tegmental area (VTA) into the NAC encodes reward delay and reward magnitude, we hypothesize that the choice reward contingency will be positively correlated with the magnitude of cue-evoked dopamine release in the NAC during the performance of impulsive decision making task. This line of study will help understand the neural mechanisms of impulsive decision making, and have the potential to provide novel insight into the cocaine addiction prevention and treatment.

Title: Evaluating the role of striatal dopamine D2, glutamate mGluR5, and adenosine A2a receptor interactions in a rat model of risky decision-making

Authors: C. M. GOBIN[1], C. A. ORSINI[2], B. SETLOW[2], *M. SCHWENDT[1];
[1]Psychology, [2]Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: Abnormal risky decision-making is a common feature in many psychiatric disorders, including addiction and ADHD, in which it may worsen prognosis and complicate treatment. Using a rodent model of risky decision-making, we have previously shown that decreased expression of dopamine D2 receptor (D2R) mRNA in the striatum is associated with elevated risky choice, and further, that administration of D2R agonists reduces risky choice. However, prolonged administration of D2R agonists may not be the most optimal treatment for abnormal risky decision-making, as it may produce a variety of side-effects, or even paradoxically promote risky choice in susceptible subjects. Since in the striatum, glutamate mGluR5 and adenosine A2a receptors display inhibitory synergistic control over D2R function, blockade of mGluR5 and/or A2a receptors may provide an alternative to dopaminergic treatments for maladaptive risk-taking behavior. In the current study we used a rat model of risky decision-making to investigate (1) whether the expression of A2a, mGluR5, and D2 receptors in specific striatal subregions correlates with risk-taking behavior, and (2) whether mGluR5 and A2a antagonists attenuate risk-taking or potentiate the effects of D2 agonists on risk-taking. In the risky decision-making task, rats made discrete-trial choices between two response levers, one which resulted in delivery of a small, “safe” food reward, and the other which resulted in delivery of a large, “risky” food reward accompanied by a variable probability of a mild footshock. Following characterization of performance in this task, rats were left undisturbed in their home cages for 1 week, followed by sacrifice and removal of brain tissue for immunoblotting analysis. Initial data from the dorsal striatum indicate the presence of a positive correlation between risk-taking (percent choice of the large, risky reward) and A2a receptor expression, and a negative correlation between risk-taking and Galpha-i protein expression. Ongoing studies are aimed at further characterization of D2-mGluR5-A2a functional synergism in the striatum in relation to risky decision-making behavior.

Lab., Woods Hole, MA

Abstract: Major advances in cell biology and neuroscience have been made possible by new imaging instrumentation and the concomitant development of appropriate probes. Optical and electron based imaging instruments extend detection capabilities to the nanoscale level, but new nanoscale probes are needed to take advantage of the increased resolution. Graphene dots (GDs), 0D nanostructures of sp2 C in the 2-20 nm size range, show intrinsic fluorescence due to quantum confinement, surface defects, and edge structures and have attracted tremendous attention for their potential in cellular sensing and imaging. However, that potential has not been realized. A strategy to enhance the fluorescence quantum yield of GDs is by plasmonic interaction with metallic nanoparticles, most typically silver or gold. The proximity of a metallic nanoparticle to a fluorophore increases the local electromagnetic radiation intensity and the probability of spontaneously emitted photons. Therefore, the fluorescence of GDs can be increased by direct contact with metallic nanoparticles, in this case, silver nanoparticles. In our study, the silver-nanoparticle-augmented GDs show the utility of the silver-graphene dots (Ag-GDs) as a nanoscale imaging probe. Three-dimensional correlative imaging shows internally localized clusters of Ag-GDs within the somas and axons of spinal motor neurons following retrograde neural tract-tracing. New nanoscale imaging probes such as the one described here are needed to overcome the challenges of new optical and electron based imaging technologies and to take advantage of the increased resolution they provide. Title: Visualization of myelin during development using black gold two

Authors: *R. A. DEYO[1], M. D. ALLEN[2], K. J. NELSON[2];
[1]Psychology, [2]Chem., Winona State Univ., Winona, MN

Abstract: Our goal was to create a histological atlas of myelin in the developing mouse brain for use in the study of disorders associated with abnormal myelination. The problem has been that myelin stains tend to be unreliable, of poor quality and can be difficult to use. Black-Gold II is a halogen gold phosphate complex with improved myelin staining properties relative to earlier Black-Gold and gold chloride methods (Schmued et al., *Brain Res*, 2008,1229: 210-7). In this study we used Black Gold II staining to track the development of myelin from the perinatal period through late adolescence in the C57BL6J mouse. All procedures followed the policies of the Society for Neuroscience for the use of animals in neuroscience research and the project was approved by the WSU IACUC. Male and female C57BL6J mice were removed from their litters on day 5, 10, 15, 20, 25, 28, or 60 post-partum and their brains were removed and fixed in 3% buffered formalin for at least 10 days prior to thin-sectioning at 40 microns. Sections were obtained in both the coronal and sagittal planes. Tissues were mounted on gelatin-subbed slides and stored at 4 c until stained. Animals from each age group were counterbalanced in each staining run to ensure that staining variables were kept to a minimum. The staining protocol followed that of Schmued et al. (2008). After staining and coverslipping, the slides were photographed and the resulting images were analyzed using NIH image-J software to determine the density of myelin staining. Myelin was visible at all ages, albeit faintly in ages younger than day 15 postpartum (see Figure 1). Myelin staining appears to peak by day 28 in C57BL6J male mice. These data demonstrate that the Black-Gold II stain can be used effectively to study postnatal myelination in mice and should prove to be a useful tool for the study of developmental disorders associated with abnormal myelination.

Title: Coherent quantum control in fluorescent dyes and caged neurotransmitter compounds by femtosecond pulse shaping

Authors: *E. D. ARK[1,2,3], S. YOU[3,4], H. TU[3], S. A. BOPPART[1,2,3,4];
[1]Electrical and Computer Engin., [2]Col. of Med., [3]Beckman Inst. for Advanced Sci. and Technol., [4]Bioengineering, Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Caged neurotransmitter compounds and fluorescent dyes have been fundamental tools in the optical control and imaging of neural networks. In particular, multi-photon events with the use of pulsed laser sources have been favored for their reduced scattering and phototoxicity in tissue, as well as for the tighter spatiotemporal localization of transition events. The use of multiple optical stimulation or recording probes simultaneously would open the way to greater flexibility in experimental design. Unfortunately, due to factors such as the heterogeneity of the chemical environment in biological samples, there is a great deal of broadening of the absorption and emission spectra of these molecules. As a result, the use of multiple probes simultaneously often runs a significant risk of cross-excitation, even in the case of large separation in peak

sensitivities. The field of coherent control is concerned with exploiting quantum interference to guide a quantum system into a desired state. One way to achieve this is through the use of ultrafast pulse shaping to control the temporal profile of an applied electromagnetic field on time scales of the order of femtoseconds. Coherent control has been shown to afford experimenters the ability to alter the probability of multi-photon transition events by exclusively altering the spectral phase function of light, while leaving the spectral composition of the light intact. This leads to the possibility of improving the selectivity with which multiple optical probes present simultaneously within a sample can be activated by a shared light source. However, there has yet to be a systematic exploration of the potential contrast enhancement between pairs of probes that such techniques can achieve. Here, we use a supercontinuum-generating photonic crystal fiber (NL-1050-NEG-1, NKT Photonics) pumped by a Yb:KYW laser (1040 nm center wavelength, 80 MHz repetition rate, HighQ) as a broadband, high-intensity, pulsed light source spanning 723 nm to 1300 nm, whose spectral phase function is modified by the use of a 640 pixel femtosecond pulse shaper (MIIPSBox 640, Biophotonics Solutions Inc.). We show results for multi-photon fluorescence as well as mass spectrometry analysis of photolysis products of multi-photon uncaging with varying temporal pulse profiles in several commonly used dyes and caged compounds.

Title: Zinpyr-1 in flash frozen tissue can be used to show increased Zn fluorescence in the dentate gyrus and CA3 region of the hippocampus

Authors: *S. L. LIPPI, D. D. CERRI, J. M. FLINN;
Psychology, George Mason Univ., Fairfax, VA

Abstract: Zinc (Zn) is an essential element for development and biochemical processes including cell proliferation, enzymatic integration, and cellular communication. Although a majority of Zn within the body is bound through metalloproteins, metalloenzymes, and protein complexes, loosely bound or “free” Zn2+ can be detected through the use of fluorescent sensors including those in the Zinpyr family (Woodroofe, Masalha, Barnes, Frederickson, & Lippard, 2004). Although much research with Zn probes is conducted either in cell culture or *in vivo*,

Zinpyr-1 (ZP-1) can be applied histologically to freshly cut frozen brain tissue and analyzed in brain regions implicated in Zn signaling, such as the amygdala and the hippocampus (Frederickson & Bush, 2001). Zinpyr-1, a fluorescein-based sensor for Zn2+ (Woodroofe, et al., 2004) that stains bouton-Zn, was chosen for its membrane permeability, bright fluorescence, high Zn2+ affinity, and ideal excitation properties (Walkup, Burdette, Lippard, & Tsien, 2000). We have recently modified a standard protocol for ZP-1 staining in order to apply it to our histological studies. A 1mM stock solution of ZP-1 (Santa Cruz Biotechnology, Inc.) was made in DMSO and a working solution of 40μM was made through 0.9% saline. Brains from four-month old Sprague-Dawley rats were sliced coronally at 20μm on a Leica CM3050 S cryostat and placed on positively charged slides. Slices were exposed to ZP-1 for 30 minutes and then the ZP-1 was tilted off. Imaging was completed using an Olympus BX51 fluorescence microscope equipped with a fluorescein isothiocyanate (FITC) cube, and mercury burner. The FITC cube matched the recommended ZP-1 excitation and emission wavelengths of 490 nm and 530 nm, respectively. 1.25x and 2x objectives were used to capture images for further analysis through ImageJ (NIH). In agreement with previous research (Ketterman & Li, 2008) the hilus of the dentate gyrus and CA3 region exhibited the highest levels of fluorescence in the hippocampus.

Title: Degeneration and normal neuron staining method to aid in quantitative analysis

Authors: ***B. TIPTON**, C. J. ZURHELLEN, H. T. YORK, J. A. BAUN, R. C. SWITZER, III; Lab., Neurosci. Associates, Knoxville, TN

Abstract: The Amino Cupric Silver (ACS) stain of deOlmos reveals neurons in the degenerative (disintegrating) state in the brain and spinal cord. These neurons stain intensely black, while normal neurons do not take up the stain. To assess the degree or the amount of degeneration, a numbered score (0,1,2,3,4, with 4 being highest level of degeneration) is usually assigned. Here we describe a more quantitative means for this type of evaluation that can be achieved by applying a second stain ‘over’ the ACS stain. The antibody NeuN reveals a marker expressed in all normal neurons over 2 weeks old. When combining the ACS stain with NeuN IHC on the same tissue, degenerative neurons stained with the ACS protocol can be counted against “live”

neurons that stain positive for NeuN. Using imaging software (FIJI) the numbers of degenerating (black) neuron and NeuN positive (brown) neurons can be determined for any given region of interest. Using 'batch processing' methods, captured images are pre-processed using Adobe Photoshop to make them more amenable for image analysis. Further batch processing using brightness, contrast, selection and thresholding tools, black degenerating neurons and brown "live" neurons are isolated for quantification using the 'particle analysis' tool in FIJI (Image J). Although this method does not replace quantitative determinations provided by the more time consuming and expensive Stereologic analysis, it does provide a numeric index of observables rather than a subjective assessment.

Title: Development of novel sensors for autophagosome

Authors: Y.-K. LEE[1], Y.-W. JUN[2], J.-A. LEE[1], *D.-J. JANG[3];
[1]Biol. Sci. and Biotech., Hannam Univ., Daejeon, Korea, Republic of; [2]Ecological Sci., Kyungpook Natl. Univ., Sangju, Korea, Republic of; [3]Kyungpook Natl. Univ., Sangju-si/gyeongsangbuk-Do, Korea, Republic of

Abstract: Autophagy,referred to as macroautophagy, is the intracellular bulky degradation pathwayin lysosome. Formation or degradation of autophagosome, a hallmark of autophagy, is critical for autophagic process. Therefore, monitoring of autophagosome is essential for autophagy research. However, so far, expression of GFP/RFP-LC3 is only way to detect autophagosome in living cells, which has the limitations due to overexpression of LC3. Here, we tried to develop new probes for autophagosome by monitoring endogenous LC3 using LC3-interacting region (LIR) motifs. To selectively detect LC3 in autophagosome embrane, a smallpeptide from *Aplysia* phosphodiesterase 4 (ApPDE4) short-form, which was necessary but not sufficient for membrane localization alone, was combined with a LIR motif from FYCO1. Newly generated probes could detect RFP-LC3-positive autophagosome in RFP-LC3

overexpressed MEF cells and cultured cortical neurons. Under starvation or rapamycin treatment, these probes could efficiently detect endogenous LC3-positive vacuoles in wild-type MEF but not in *atg5-/-* MEF cells, raising the possibility that these new probes might be used as specific markers for tracking endogenous LC3 positive autophagic vacuoles in living cells. We are currently modifying the newly generated probes to improve monitoring endogenous autophagosomes more efficiently in living cells.

Title: Infrared diffraction phase microscopy for nanoscale imaging of live brain slices

Authors: ***E. MIN**[1,2], S. KIM[1], L. MA[3,1], W. JUNG[2,4], Y. WANG[1], G. POPESCU[1], C. BEST-POPESCU[1];
[1]Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of; [3]Zhejiang Normal Univ., Jinhua, China; [4]Ctr. for Soft and Living Matter, Inst. of Basic Sci., Ulsan, Korea, Republic of

Abstract: Neuroimaging over broad spatial scales, molecule to organ, is key for answering fundamental questions about the connectivity of the brain. Histochemical stains and fluorescent labels remain the gold standard for differentiating various neuronal structures in the brain tissue. When imaging live cells and brain slices, fluorescent tags are often limited by photoxicity and photobleaching. Recently, label-free imaging has been considered as key for in neuroimaging. Therefore, optical imaging methods such as optical coherence tomography, optical projection tomography, spatial light interference microscopy (SLIM, Kim et al., Nature Photonics 2014, Mir et al., Sci. Rep. 2014), and diffraction phase microscopy (DPM, Park et al., PNAS 2010) that operate with intrinsic contrast has been introduced as valuable tools for neuroscience. DPM is particularly used to visualize neuronal network in wide field and detect fast nanoscale

fluctuations in cell membranes, due to its advantage of high speed and sensitivity. However, conventional DPM has been used with visible light mainly for thin specimens (e.g., single cell layers). As a result, penetration depth in thick tissue is limited due to visible light being scattered strongly. Here, we report on a new *label-free* approach for studying live brain slices with nanoscale sensitivity to morphology and dynamics. In order to push the applicability of DPM's label-free, nanoscale imaging to thick tissues, we developed a new instrument that uses common-path interferometry with near-infrared (NIR) light. Since the scattering mean free path of NIR is longer than that of visible light, we achieve a longer penetration depth without significant loss of transverse resolution. With NIR DPM, we demonstrate, for the first time to our knowledge, quantitative phase imaging of live mouse brain slices.

Title: A DNA based method for highly multiplexed and super-resolution imaging of neurons

Authors: *Y. WANG[1,2], S. S. AGASTI[1], N. DONOGHUE[1], R. JUNGMANN[3], P. YIN[1]; [1]Harvard Wyss Inst., Brookline, MA; [2]Program of Biol. and Biomed. Science, Harvard Med. Sch., Boston, MA; [3]Max Plank Inst. of Biochem. and LMU, Munich, Germany

Abstract: Fluorescence microscopy combined with various immunostaining methods allows us to visualize neurons directly. However, conventional fluorescence microscopy has limited capabilities in terms of resolving fine structural detail (i.e. low resolution) and multiplexed detection (i.e. ~4 targets in the same sample). This limits our ability to map key protein networks at high spatial resolution, for example, protein-protein interaction in individual synapses. Here, we describe a DNA based imaging method, named as Exchange-PAINT (Point Accumulation for Imaging in Nanoscale Topography), which offers high multiplexing power (>10x) and super-resolution (~10nm). Using Exchange-PAINT, we demonstrate here, for the first time, 8-target

super-resolution imaging in neurons. Additionally, by tuning the DNA length, Exchange-PAINT was adapted to a fast and robust multiplexed diffraction limited imaging. A 10-target image in neuron was achieved as fast as one hour. Exchange-PAINT utilizes transient binding properties of short DNA oligos (9nt) to achieve super-resolution in a highly multiplexed fashion. Specifically, fluorophore-conjugated DNA strands (i.e. imager Strand) transiently hybridize to the immobilized DNA docking strands on antibodies to accomplish the stochastic fluorescence blinking required for localization-based super-resolution microscopy. Importantly, since imager strands are not stably bound to their targets, they can be easily washed away using PBS. Orthogonal imager strands can therefore be sequentially applied to image an potentially infinite number of target proteins. Unlike other multiplexed immunostaining methods (e.g. array tomography), Exchange-PAINT allows each antibodies to be applied to the sample at the same time, thus dramatically reducing the total time required to perform such an experiment. To demonstrate the ability of Exchange-PAINT for super-resolution imaging, we selected 8 targets from neuron and astrocytes, of which 4 targets (alpha-tubulin, acetyl-tubulin, vimentin and Tom20) are structural proteins whereas the other 4 targets (bassoon, synapsin, gephyrin and vgat) are synaptic proteins. To adapt Exchange-PAINT for diffraction limited imaging, we increase the DNA length to 10nt and exposure time of cameras to a few second to capture all the binding events within a single frame of the image. We achieved diffraction limited imaging of 10 targets in neuron culture using a spinning disc microscope.

Abstract: Characterization of tissue by fluorescence microscopy is typically constrained by available excitation/emission channels, and consequently only a handful of markers can be simultaneously probed while retaining the spatial integrity of the tissue context. We have developed an approach to circumvent this problem using iterative rounds of staining, imaging and dye deactivation for molecular tissue characterization in cancer (Gerdes, 2013). In this work, we have extended the approach to brain tissue, allowing overlapping localization of dozens of cellular, structural and pathological markers. We validated more than 50 commercial antibodies against neuronal and immune markers as direct dye conjugates compatible with our process, and developed image processing and analysis algorithms for cellular and tissue analyses. Image processing includes multi-round image registration using DAPI-stained nuclei as tissue fiducials, correction of illumination non-uniformity, and removal of remaining autofluorescence signal by subtraction of paired images prior to staining. Image analysis employs a modular algorithm toolkit, allowing segmentation of channels, either singly or in combination, and quantification of signal intensity across all marker channels at the level of single cells, compartments or tissue structures. To demonstrate the potential of this approach, we conducted a 25-marker study of affected and non-affected brain regions from 9 Alzheimer's disease cases (Figure 1) and 4 non-AD controls, both in whole section and tissue array formats. Resulting images were segmented and quantitated for neurons and for microglia, enabling identification of cell subclasses via clustering of the expression profiles. This approach allows for thorough molecular, morphologic and spatial characterization of cell subclasses in relationship to each other and to pathological tissue features, and should be useful for the study of normative cell taxonomy and of molecular mechanisms in neurodegenerative disease. Title: Supernova systems enable high intensity single-cell labeling and labeled cell-specific gene-manipulation

Authors: *W. LUO[1,2], H. MIZUNO[1,2], R. IWATA[1,2], S. NAKAZAWA[1,2], T. IWASATO[1,2]; [1]Natl. Inst. of Genet., Mishima, Japan; [2]Dept. of Genet., Grad. Univ. for Advanced Studies (SOKENDAI), Mishima, Japan

Abstract: Methods that enable high intensity labeling of single cells and labeled cell-specific gene manipulation (e.g. knockout, knockdown, overexpression) are valuable for understanding cellular and molecular mechanisms responsible for development and function of the mammalian brains. For this purpose, we developed vector systems termed “Supernova”, which synergistically use the tTA/TRE expression system and site-directed recombination system (e.g. Cre/loxP) to enhance the expression of genes of interest only in a sparse population of cells. We recently reported the first version of Supernova method (Mizuno et al., Neuron 2014), in which

red fluorescent protein (RFP) was highly expressed in a small subset of cortical neurons by *in utero* electroporation (IUE)-mediated transfection of a Cre/loxP-based Supernova vector set. The whole cellular morphology including individual dendritic spines and axons were clearly visualized. RFP-labeled cell-specific gene knockout was also achieved when floxed mice were transfected. Combined with two-photon *in vivo* imaging, we successfully observed the dynamics of dendritic refinement of individual wild-type and mutant neurons in layer 4 of the neonatal mouse cortex (Mizuno et al., Neuron 2014). Here, we expanded the Supernova system in several aspects. First, we constructed Supernova vector sets that use different types of fluorescent proteins (e.g. GFP, CFP, GCaMPs, fluorescence proteins fused with subcellular localization signals). Second, we demonstrated that multiple genes can be co-expressed in individual cells. Third, we showed that other types of site-specific recombination systems (e.g. flpe/FRT, Dre/Rox) can also be used. Forth and finally, we showed that Supernova systems can be used for RNA interference. By expressing shRNA-based Supernova vectors in two distinct reporter mouse lines, we showed that expression of endogenous genes was suppressed. Thus, the Supernova systems provide powerful tools in various aspects of neuroscience, for elucidation of the neural properties and gene functions in single cell levels.

Title: Combined structured-illumination with localization-based super-resolution microscopy

Authors: H. LI, X. JIN, Y. LIANG, S. LI, G. WEN, *H. JIA;
Brain Res. Instrument Innovation Ctr., Suzhou Inst. of Biomed. Engin. and Technol., Jiangsu, China

Abstract: Single Molecule localization based super-resolution microscopy methods, known as Photoactivated localization microscopy (PALM) and Stochastic Optical Reconstruction Microscopy (STORM), has gained much interests in biology due to its high spatial resolution down to 10 nm whilst using moderate laser power. However, its application to study the

dynamics process in live cells is limited by its slow image acquisition process. On the other hand, Structured Illumination Microscopy (SIM) can obtain video-rate imaging speed with worse spatial resolution. These limitation can be overcome by combining these two techniques together. Here, we describe an newly developed microscope system with such combination. Rapid physiological signals in live cells can be fist observed in the SIM mode, subsequently, small regions of interested can be selected for further high-resolution imaging with STORM mode.

Title: Wedge-based approach for simultaneous multichannel microscopy

Authors: S. H. CHUNG[1,3], *C. V. GABEL[2];
[1]Boston Univ. Sch. of Med., Boston University, MA; [2]Dept. of Physiol. and Biophysics, Boston Univ. Sch. of Med., Boston, MA; [3]Physical Sci. Inc, Andover, MA

Abstract: Multichannel (i.e., multicolor) microscopy is becoming increasingly relevant to many research areas; however, limitations to conventional approaches prevent full technique utilization. Our approach for simultaneous multichannel microscopy separates channels by a fundamentally different mechanism, leading to many advantages. The figure shows a schematic representation of a two-channel approach. Multiple sample fluorophores absorb multichannel excitation. Multichannel fluorescent emission passes through the dichroic and side-by-side emission filters, separating into parallel heterochromatic beamlets, which are the two channels. Wedges deflect the beamlets in opposite directions. The microscope tube lens images the channels on separate locations on the CCD for simultaneous observation. For typical CCD and tube lens focal lengths, the wedge angle is small, and chromatic dispersion negligible. The use of wedges rather than mirrors yields significant improvements in simplicity and user-friendliness

because errors propagate through mirror reflection different than wedge prism deflection. An error in mirror orientation changes both incident and reflected light angles, producing twice the error in the reflected beam direction. In contrast, for our wedges the error in the refracted beam direction is the error in wedge orientation multiplied by 0.0002, so wedge orientation errors have little impact on deflected beam direction. Thus, the use of wedges significantly reduces the need for precise alignment. This allows users to place our device in the standard filter wheel without complex installation and alignment. Our device is about 1/3rd the cost of existing commercial devices. We have developed multiple device prototypes and imaged *in vivo* neuronal calcium transients, with results comparable to a conventional dual-view device. In addition, we employed a four-channel device to efficiently image Brainbow samples. In summary, our simple, user-friendly, and inexpensive device allows single-channel microscopes to perform simultaneous multichannel microscopy.

Abstract: Understanding the connectivity of neuronal circuits with cellular resolution is paramount for uncovering the principles governing brain network organization and functional architecture. This complex circuitry is assembled using diverse populations of neurons. Recent advances provide handles to genetically target specific subsets of neurons and systematically trace their projections across the brain. We developed a custom dual color Oblique Plane Tomography (dcOPT) platform based on Digital Scanned Laser Light Sheet Microscopy (DLSM), in which the illumination and detection paths are oriented obliquely (45°) with respect to the tissue surface. dcOPT is an automated whole-brain imaging technique that uses the principle of DLSM where the sample is illuminated with a scanned micrometer thin laser beam to generate a planar light sheet and images are acquired by a fluorescence wide-field microscope placed perpendicular to the illumination path. The oblique orientation allows for imaging the brain surface to ~500 μm depth in an XY raster pattern. Once the raster scan is completed, the brain is translated to an integrated vibratome to section the imaged top 450 μm tissue morsel. The raster scan and automated sectioning is repeated iteratively to obtain whole brain coverage. Since tissue scattering limits the light penetration depth of light and increases imaging time, we further modified and optimized the CUBIC protocol for clearing brains (~ 10 days). The current instrument configuration represents a significant advance compared to previous reports, allowing the whole cleared adult mouse brain be imaged within ~10 hrs at 0.7 X 0.7 X 5 μm voxel resolution in 2,500,000 tiles with overlapping regions for image registration and reconstruction. For mapping and tracing neuronal projections of brains, we developed a custom atlas that warps onto the Allen Reference Atlas. We are using dcOPT to trace input and output projections from defined cell types of neocortex and piriform cortex. First, we present examples of single cell labeling of virally induced supragranular Chandelier cells, an enigmatic cell type that provides powerful inhibition at axon initial segment of pyramidal neurons. Second, via similar approaches, we characterize the projections patterns of subsets of supragranular pyramidal

neurons across the brain. These strategies enrich our understanding of cortical structure and connectivity and suggest roles for the subtypes of pyramids in information processing.

Abstract: Advances in high-resolution 3D microscopy have enabled the investigation of subcellular microstructures in biological specimens. For higher resolution imaging of whole organs or even whole animals, an increasing number of techniques are relying on physical sectioning [1]. However, the physical sectioning imaging process is not without error. Common errors include imaging artifacts due to vibration of the knife (chatter), illumination irregularities, and obstruction due to debris generated from the sectioning process. However, these problems are not widely recognized and thus solutions are scarce. In this abstract, we present our effort to characterize, detect, and correct imaging error due to the sectioning process in the Knife-Edge Scanning Microscope (KESM) developed in our laboratory (Fig 1). KESM can image on the order of 1 cm^3 at sub-micrometer resolution (0.7 um lateral, 1.0 um axial) [2]. We present (1) methods to characterize the vibration of the knife using accelerometers, and correlating that with imaging artifacts due to chatter, (2) controlling low-amplitude, high-frequency vibration of the knife using piezoelectric oscillators to reduce chatter, and (3) imaging error detection and alert system [3] based on image change-detection. We applied these techniques to image whole

zebrafish embryos (Nissl-stained, Fig 2), and to detect errors automatically in our Nissl whole mouse brain data. Imaging and analysis results will be reported (Fig 3).

Abstract: Scanning tissue samples at sub-micrometer resolution can help bridge the gap between slow but highly detailed electron microscopy and fast but less informative MR imaging. The imaging technique, Knife-Edge Scanning Microscopy (KESM) [1], allows us to scan a tissue block at high speed with sub-cellular level resolution. We implemented a scanning microscope powered by KESM and digitized a wide variety of organs [2]. However, the instrument had a few critical issues. The complex design required users to have extensive knowledge of machining and optics. This hindered its application as a shared-use instrument for research. Manual intervention for fixing operational problems caused misalignments in the imaging module. Remounting the tissue resulted in further misalignment as well as registration issues. We present the Internet Enabled RObotic Microscope (IEROM), the second generation of the microscope powered by KESM that solves the aforementioned problems. Advantages of the IEROM include 1/3 cost and ease of shared operation with a login based web interface control. The imaging module has been upgraded to use precision angle brackets to maintain the orientation required for line scan imaging. Magnetically pre-loaded kinematic sample holder helps rapid sample changes and easier user interface. Other improvements include illumination changes, higher sensitivity of line scan camera with a responsivity of more than 6 times that of original design and better positioning mechanics reduced scanner size to ¼ that of the original. The data resulting from the robust instrument, shared on an open virtual microscope platform, is expected to accelerate discovery in neuroscience. References: [1] Mayerich, D., Abbott, L. Title: Labeling and mapping memory traces in intact mouse brains of control and disease states

Authors: *I. PAVLOVA[1,3], S. C. SHIPLEY[1], R. HEN[2,3], C. A. DENNY[2,3];
[2]Psychiatry, [1]Columbia Univ., New York, NY; [3]Integrative Neurosci., Res. Fndn. for Mental Hygiene, Inc., New York, NY

Abstract: Visualizing behaviorally-evoked neural activity maps in intact mouse brains is essential in studying circuit-based mechanisms underlying learning and memory. Here, we compare methods for obtaining whole brain maps of markers for neural activity during memory encoding and/or memory retrieval based on intact tissue clearing, immunolabeling or endogenous transgenic expression of fluorophores, and automated microscopy imaging and analysis. Specifically, we utilized an ArcCreERT2 transgenic mouse model that allows for the indelible labeling of neurons that encode individual memory traces and outline a protocol based on organic solvent clearing and immunolabeling for markers, such as: eYFP, c-Fos and Arc. We also outline a method for the automatic microscopic imaging. In summary, we demonstrate that these methods allows for uniform labeling of memory traces across the brain in less than 18 days and present whole brain maps of memory traces in normal mice and mouse models of disease states.

Title: Rabies virus vector with improved transgene expression level for transsynaptic tracing

Authors: *Y. SOTA, S. OHARA, S. SATO, K. ITO, K.-I. TSUTSUI, T. IIJIMA;
Div.Sys Neurosci., Grad Sch.Life Sci.,Tohoku Univ., Miyagi, Japan

Abstract: Recombinant viral vectors that can cross synapses and can strongly express foreign genes are useful for investigating the organization of neural circuits. We have previously developed a recombinant rabies virus (RV) vector based on an attenuated HEP-Flury strain in which the CVS strain glycoprotein (CVSG) takes the place of the HEP-Flury strain glycoprotein (HEPG). This vector (rHEP5.0-CVSG) can be used as a transsynaptic tracer because it selectively infects neurons and propagates between synaptically connected neurons in a retrograde direction. Its relatively low level of transgene expression, however, makes immunohistochemical staining necessary if one wants to visualize the morphological features of the infected neurons. This vector therefore isn't suitable for use with marker proteins that cannot be immunostained. To develop a recombinant RV vector with a high level of transgene expression, in this study we focused on two viral proteins: RNA polymerase (L) and glycoprotein (G). We first attempted to increase the expression of the L gene because increased L-gene expression level is known to enhance viral mRNA transcription. An L-gene-enhanced RV vector (rHEP5.0-CVSGctL) was constructed by shortening the intergenic region between G and L gene from 24-nucleotide to 2-nucleotide. Next, we modified the G of the RV. We recently reported that the expression of the G gene also has an influence on the transgene expression level of the RV vector. To enhance the interaction of the CVS-derived G with the matrix protein of HEP-Flury strain, we constructed a G-modified RV vector (rHEP5.0-CVSG-HEPGCD) by replacing the cytoplasmic domain of CVSG with that of HEPG. These modifications improved the transgene expression level of the RV vector, which was examined by measuring the mRFP fluorescence intensity expressed by the vector. To further evaluate the usability of this RV vector, we constructed an RV vector that expresses a genetically encoded fluorescent timer (FT). The FT was an mCherry-derived monomeric variant that changed its fluorescence from blue to red over time. By using this high-transgene-expression RV vector, we succeeded in visualizing the infected neurons with the FT fluorescence *in vivo* without any staining. Furthermore, the primary infected neurons could be distinguished from the secondary infected neurons by the difference of the fluorescence wavelength. We expect this improved RV vector to be useful in revealing the hierarchical connectivity of the central nervous system.

Title: Differential collateral patterns of sensory corticofugal projection neurons revealed by target-specific AAV2/1-mediated retrograde tagging

Authors: *B. ZINGG[1], L. MESIK[2], X.-Y. JI[2], H. TAO[2], L. ZHANG[2];
[1]Neurosci. Grad. Program, USC, Los Angeles, CA; [2]Zilkha Neurogenetic Institute, USC, Los Angeles, CA

Abstract: Projection neurons form long range connections that give rise to large-scale networks in the brain. In the cortex, neuronal populations with distinct laminar distributions form specific connections with cortical and subcortical targets. The degree to which these populations overlap in their targeting--or represent independent output channels--is uncertain, as is their functional contribution to cortical processing. Currently, experimental access to these cell groups is hindered by a limited number of transgenic mouse lines and the feasibility of optogenetically manipulating axonal target terminals. Furthermore, viruses currently available for retrograde labeling of projection neurons have limited functional use due to toxicity or inefficiency. Here we present a method for accessing projection neuron subtypes using two commercially available adeno-associated viruses (AAVs). This method allows for the selective labeling of neurons defined by their projection target and reveals all additional collateral targets for the population. Using this approach we find that different corticofugal populations in primary auditory or visual cortex exhibit partially overlapping, yet distinct, collateralization profiles. Moreover, this method may provide a means for long term, non-toxic, retrograde expression of opsins or calcium indicators for use in functional studies in these projection-defined neurons.

Title: Novel strategy for studying the circuit organization of globus pallidus in cell type and projection specific manner

Authors: V. LILASCHAROEN, S. SHIN, D. KNOWLAND, *B. LIM;
Biol. Sci., UCSD, La Jolla, CA

Abstract: The brain is an enormous network consists of numerous neuronal cell types, which are organized into distinct elaborate circuits that give rise to such a diverse array of functions. Understanding how these neural circuits underlie perception, cognition and behavior is a major goal of neuroscience research. The extreme complexity of the brain is one of the main difficulties that hinder our understanding of the organization of these circuits and how the dysregulation of circuits contributes to psychiatric illness. Recent advances in circuit tracing have provided powerful tools that reveal extensive information about the neural circuitry. However, thus far, no viral tracer has proven potent enough to allow a robust, long-lasting retrograde expression of transgenes without inducing cytotoxicity. Because even neighboring neurons of the same cell type differ in their connectivity and functions, a new method is required to achieve both cell-type- and projection-specific delivery of transgene via retrograde infection. Here we present a new viral strategy that allows long-term expression of transgenes including optogenetic tools and neural activity sensors in a cell-type- and projection-specific manner. We developed a novel viral vector based on the rabies glycoprotein-pseudotyped equine infectious anemia virus (EIAV), which has been proven successful to infect neurons retrogradely. We genetically engineered this EIAV vector to express site-specific recombinase including Flp, Dre and VCre in a Cre-dependent manner. Together with adeno-associated virus (AAV) expressing transgenes such as fluorescent markers, opsins, and genetically encoded calcium indicators in a Flp-, Dre- or VCre-dependent manner, we are able to deliver these transgenes in a specific population within the same cell type of neuron that projects to an area of interest. We will demonstrate the application of this strategy by dissecting the circuit of the external segment of the globus pallidus (GPe). GPe is one of the major nuclei of the basal ganglia that involves in motor learning, habit formation and is thought to contribute prominently to basal ganglia dysfunction in Parkinson's diseases. In fact, GPe is the one of major targets for deep brain stimulation for alleviating dyskinesia, dystonia, and symptoms of PD. However, the anatomical organization of GPe circuitry including cell types, efferent and afferent connections and their roles in pathological symptoms have not been fully addressed. By using this strategy, together with transgenic mice, we will be able to delineate the inputs and outputs relationship and projection-specific roles of different distinct neuronal cell types of GPe.

Title: Using the G-deficient recombinant rabies virus to study multi-synaptic fronto-cerebellar circuitry

Authors: *P. A. ZAMUDIO-BULCOCK, J. J. WOODWARD;
Med. Univ. of South Carolina, Charleston, SC

Abstract: The envelope protein G (RG)-deficient rabies virus (RVΔG) was developed to trace monosynaptically connected neuronal circuits. But, its efficiency at labeling fine dendrite structures, and its low neurotoxicity (i.e. unchanged electrophysiological properties in infected neurons), also makes it an attractive candidate for morphological and functional studies of neuronal connectivity. In these viral vectors, the RG coding sequence is replaced with that of a reporter protein such as mCherry that permits infected cells to be visualized. In addition, the virus has the envelope glycoprotein from the avian sarcoma and leucosis virus (EnvA) that is not recognized by mammalian neurons. Thus, infection and generation of new viral particles is limited to cells expressing RG and the receptor for EnvA, receptor Tumor Virus A (TVA), that can be provided by using AAV expression vectors. Source cells infected with all components result in effective monosynaptic labeling of connected neurons. Since AAV viruses do not undergo significant retrograde or transynaptic transport, the newly generated RVΔG in the connected neuron cannot cross another synapse. In these studies, we surmounted this restriction via AAV delivery of RG in a relay region between the frontal cortex and the cerebellum, thus permitting an additional monosynaptic crossing of the RVΔG. This allowed us to identify individual neurons within the frontal cortex that sent disynaptic projections into the cerebellar cortex (CBC) via the pons (PN). First, AAV viruses containing RG and TVA were injected into CBC L7; and GFP- labeled AAV-RG was delivered into the PN. These viruses were allowed to express for 2 weeks. Subsequently, RVΔG-EnvA was injected into CBC L7, using the same coordinates where the TVA and RG AAVs had been injected. After 10 days, slices were prepared and analyzed for RVΔG - mCherry fluorescence. The CBC L7 received dense monosynaptic projections from the rostral portion of the PN and the caudal portion of the inferior olive. In the medial portion of the PN there was an overlap between RG-AAV and RVΔG expression, where source cells expressing both viruses were identified. Consequently, RVΔG-expressing neurons were found in layer V of the frontal cortex, predominantly in the motor centers, M1 and M2. Together with results from preliminary studies of dendrite morphology and electrophysiological recordings, these studies indicate that RVΔG can be used to study

anatomical, morphological and functional properties of fronto-cerebellar connections. Supported by T32 AA007474, R37 AA009986 and P50 AA010761.

Title: Facilitating the adoption of oxygen partial pressure imaging with two-photon microscopy

Authors: *S. SAKADZIC[1], T. V. ESIPOVA[2], S. A. VINOGRADOV[2], D. A. BOAS[1];
[1]Massachusetts Gen. Hosp., Charlestown, MA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The assessment of brain oxygenation on the microscopic level has the potential to transform our understanding of important clinical problems, such as stroke, Alzheimer's disease, dementia, chronic hypertension, and brain cancer, facilitating the development of new therapies and helping to improve clinical imaging and treatment protocols. Until now, no technology has been capable of microscopic oxygen imaging in the brain with high spatial and temporal resolution. Over the past several years we have developed a method, termed two-photon phosphorescence lifetime microscopy of oxygen (2PLM), which has the unique capability of fulfilling this niche. This is the only imaging method that allows high resolution mapping of brain oxygenation in real time. 2PLM of oxygen is a combination of state-of-the-art two-photon enhanced phosphorescent probes and a unique variant of two-photon laser scanning microscopy -

both of which are not presently available commercially. The transformative power of 2PLM of oxygen has been demonstrated in several high-impact publications [1-7], producing great interest in the neuroscience community. We are aiming to set up a self-sustaining resource that will promote widespread use of the two-photon oxygen imaging technology, making this new powerful method available to a broad group of neuroscience researchers. 1. Title: Trans-cellular activation of transcription for visualization of neural circuits

Authors: ***J. BONKOWSKY**, J. GAO, M. KEEFE, T. STEVENSON;
Dept. of Pediatrics, Univ. of Utah Sch. of Med., Salt Lake City, UT

Abstract: Visualization and manipulation of neural circuitry has remained a vexing problem in neuroscience. Our goal is to translate and implement a novel methodology, trans-cellular

activation of transcription (TCAT), to both genetically label cell-cell interactions, as well as to induce gene expression in interacting cells to assemble a functional circuit map of connectivity during development. TCAT is based on components from the receptor/ligand pair of Notch/Delta. Upon ligand binding to receptor, the intracellular domain of Notch is cleaved and translocates to the nucleus. We replaced the intracellular domain of Notch with the yeast transcriptional activator Gal4, so that we can express transgenes at the Gal4-binding site UAS. For TCAT we used the homologs LAG-2 (Delta) and LIN-12 (Notch) from the nematode *C. elegans* to prevent cross-reactivity with the endogenous zebrafish proteins. We overcame species-incompatibility of the protease cleavage reaction necessary for TCAT by developing a chimeric system: receptor-ligand binding specificity is maintained using *C. elegans* LAG-2 and LIN-12 binding domains, but with substitution of the zebrafish Delta and Notch signal sequences and transmembrane domains. In proof-of-principle experiments, we found that chimeric LAG-2/Delta tagged with red fluorescent protein (LADR) and LIN-12/Notch (LINch) activates transcription in different cell types in transient injections. To demonstrate the wide applicability of TCAT for a range of biological questions we have generated constructs expressing LINch or LADR in different cell types including retinal ganglion cells, dermal progenitor cells, epidermal cells, and in different neuron sub-types. TCAT can be used to drive expression of any desired gene; the method allows both labeling and manipulation in a variety of biological systems. We anticipate that TCAT may represent a significant technical innovation for mapping and understanding brain circuits in zebrafish and other vertebrate systems.

Title: Mapping of posterior cerebellum to thalamic and neocortical targets using herpesvirus-based anterograde tracers and large-scale tissue clearing

Authors: T. J. PISANO[1], T. K. WEIGEL[1], E. A. ENGEL[1], S. DEIVASIGAMANI[1], L. A. LYNCH[1], L. W. ENQUIST[1], *S. S.-H. WANG[2];
[1]Neurosci. Inst. and Dept. of Mol. Biol., [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: The cerebellum sends information to specific targets throughout the brain using closed loops as a major structural motif, in which a given cerebellar region shares reciprocal connections with specific target regions throughout the neocortex. However, this topographic relationship has been poorly characterized, in part because pathways in both directions are polysynaptic. To trace ascending cerebellum-to-neocortex pathways, we used H129 strains of herpes simplex virus 1 (HSV1-H129), which cross synapses and move largely anterogradely (Wojaczynski et al., 2014. Brain Structure and Function. 1-26). We made injections of HSV-H129 (2.8x104 to 5.6x104 PFUs) at a range of locations in lobule VI. Coinjection with Cholera Toxin B revealed that injection sites were 0.45-1.5 mm wide. After injection of HSV1-H129 768 (CMV-Brainbow 1.0L), we sectioned the brain after 3-5 days and found dTomato expression in thalamic and cortical regions. We found expression in two regions known to be required for cognitive flexibility, the parafascicular nucleus of thalamus (Brown et al., 2010. J. Neurosci. 3043:14390-14398) and the anterior cingulate cortex. Patterns of maximal expression varied across animals, indicating the potential to map projection topography. We are now using iDISCO (Renier et al., 2014. Cell. 159.4:896-910) to clear volumes of tissue, and imaging with a light-sheet fluorescence microscope. After clearing, HSV-labeled neurons visualized by immunohistochemistry are bright enough to allow detection throughout the entire mediolateral depth of a sagittally cut half brain, a distance of 4 mm. This approach opens the possibility to reconstruct cerebello-thalamo-neocortical projection patterns on large scales without need for tissue sectioning. We are now combining these methods with Cre-based recombination to label specific routes, such as paths that pass through dopaminergic neurons.

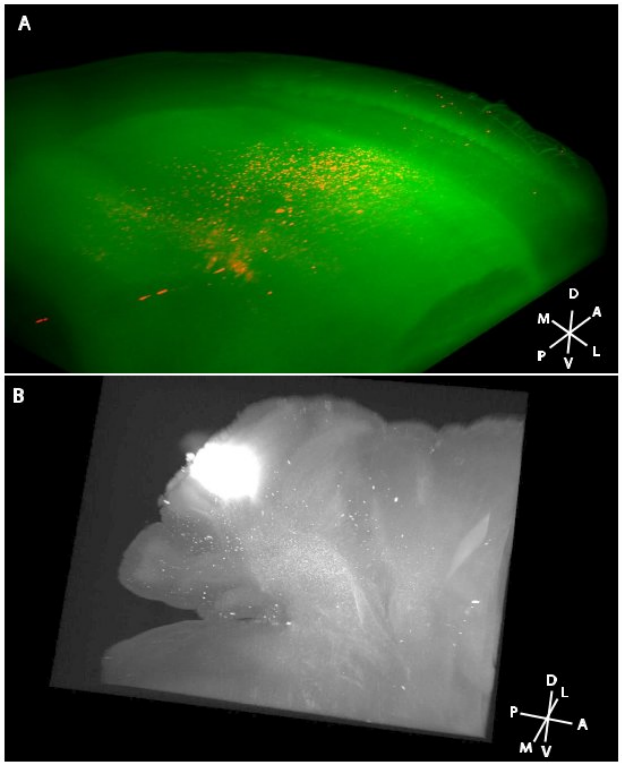

Figure: Labeling of neurons in iDISCO-cleared tissue after injection of HSV-H129-Brainbow 1.0L. (A) Neocortex. Red dots indicate dTomato-positive neurons. The green image indicates autofluorescence. (B) Injection site in cerebellum lobule VI, labeled with CTB.

Title: *In vitro* patterning of neural circuits at single cell resolution via optical tweezers

Authors: *B. POLAT[1], S. BAY[2], G. OZTURK[1];
[1]Regenerative and Restorative Med. Res. Ctr. (REMER), Istanbul Medipol Univ., Istanbul, Turkey; [2]Mol. Biol. and Genet., Gebze Tech. Univ., Kocaeli, Turkey

Abstract: Optical tweezers trap and manipulate microscopic objects via highly focused laser beam.With simple adjustments this tool can be facilitated in cell culture for various experimental

purposes. Good examples to these can be combining cells, delivering packed agents to cells and to recreating neuronal networks with intended topology and hierarchy. In this study we used optical tweezers as a simple and effective tool to trap and carry large primary neurons in designated patterns for long term monitoring of network structure and function. For this purpose, dorsal root ganglia cells were dissociated and neurons were selectively isolated via gradient centrifuge technique among a mixed cell population. Dorsal ganglia neurons are large and heavy by nature which makes them hard to pick up and manipulate once they settle down. So islands of thin silicon elastomere layers were produced to avoid the quick adhesion of neurons to the petri dish. This delayed the unwanted adherence up to 1 hour and gave us sufficient time for cell manipulation. Freshly prepared 50 cells per 5µl were plated onto the non adhesive silicone island, and cells were trapped and carried to the laminin coated network area. The optical tweezer tool facilitated a 1W continious wave diode laser of 1064 nm wavelength via a high numerical apperture, low magnification water immersion objective (**32x/0.85**) for laser tweezing. As a result, cells up to 30 µm diameter were succesfully carried up to 600 um distance. About 75% power was sufficient for glass surface while the silicone coated area called for power adjustment up to 85%. Once the cells were trapped they were moved via a joystick system which enabled movement of the trap in three axis (x, y and z). The manipulation took place in an on-stage incubator and was captured via a CCD camera. Our study shows that via application of coating, selection of highly transmittable objective and facilitation of IR laser very large primary cells can be trapped and manipulated without the need of any handle beads and with no observable damage to survival. 30 µm diameter is the largest size the literatur holds to our knowledge This system can be used in cell culture for various experimental applications such as building micro-circuits of few cells for studies of network structure and function.

Abstract: Behavioral demands require that the brain generate highly stereotyped output when executing skilled actions while at the same time retaining the flexibility to switch between different tasks and learn new actions. How do neural circuits deal with these conflicting requirements for stability and flexibility over long timescales? Addressing this question requires tracking the activity of neuronal populations continuously over weeks and months in naturally behaving animals. Such experiments face significant technical challenges, including processing vast amounts of neural and behavioral data. We present an automated solution that overcomes these challenges, making it near effortless to continuously record and analyze neural activity in freely behaving rats over several months as the animals engage in normal daily activities and perform prescribed motor tasks in their home-cages. A key aspect of the system is a novel spike-sorting algorithm that allows for automatic identification and tracking of single units in terabyte-sized datasets even when units have non-stationary waveforms. We used our system to continuously record activity in large populations of single neurons in motor cortex, striatum, and thalamus. In conjunction with the neural recordings, high-resolution behavioral data was acquired using high-speed cameras and head-mounted 3-axis accelerometers. The behavioral data, in conjunction with local field potentials, were used to identify epochs of sleep, rest, grooming, feeding, and to track and quantify movement kinematics during the execution of a skilled motor sequence task. We found that firing rates and correlation structure in neuronal populations were stable across many days, even as they varied substantially across different behavioral states in a single day. Additionally, motor representations of skilled behaviors were found to be stable at the single unit level over month-long timescales. Our results demonstrate that neural circuits can maintain distinct task representations with remarkable long-term stability at the level of single neurons.

Title: Dexterous robotic manipulation of alert adult fruit flies for high-content experimentation

Authors: ***J. SAVALL**[1,2], E. HO[1,4], C. HUANG[1], J. R. MAXEY[1], M. J. SCHNITZER[1,2,3]; [1]Clark Ctr., [2]Howard Hughes Med. Inst., [3]CNC Program, Stanford Univ., Stanford, CA; [4]Ctr. for Intelligent Signal and Imaging Res., Universiti Teknologi Petronas, Perak, Malaysia

Abstract: The fruit fly, *Drosophila* melanogaster, is widely used in research, but manual handling is often an experimental bottleneck. Here we present a dexterous high-speed robot that enables automated, high-content assessments of fly attributes and behavior. The robot can track and grab an alert fly's thorax, translate and rotate the picked fly, assess its phenotype and behavior, micro-dissect or release it, and rapidly interrogate multiple flies sequentially for diverse usages. By combining these elementary maneuvers, we used robotic handling to test flies' odor-evoked locomotor responses, sort flies by sex, dissect the cuticle to allow fluorescence imaging of neural activity, and quantitatively analyze body morphology through machine vision algorithms. Future, innovative usages of the robotic platform will likely exploit its capability for automated, quantitative measurement, the resulting statistical power that permits fine discriminations of fly morphology or active behavior, or the capacity to gently manipulate un-anesthetized flies in ways that humans cannot. Fast, automatic determination of fly sex provides the crucial ingredient for robotic establishment of fly matings, one of the most important in fly genetics. The robot can also perform many other analyses, handling tasks and surgical maneuvers for which humans lack the requisite dexterity or measurement precision. The capacity to catch and release individual flies will also allow novel time-lapse experiments involving automated, repeated examinations of individual flies' phenotypes across days or weeks. Overall, the robot has a tireless capacity for precise manipulations, is economical and readily scalable to multiple units, and thereby establishes a sophisticated technology platform for screening individual flies based on computerized appraisals of complex characteristics and behavioral responses.

Title: How to build a powerful, flexible, and user-friendly light sheet microscope

Authors: *C. J. GREER[1], T. HOLY[2];
[1]Washington Univ. In St. Louis, Saint Louis, MO; [2]Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Neuroscience laboratories are rapidly adopting light sheet microscopy as a tool to study neural circuits. The chief advantage of the technique is that thousands of neurons may be imaged at high speed with minimal photobleaching both *in vitro* and *in vivo*. Continuing improvements in fluorescent calcium indicators, voltage indicators, and optogenetic actuators are allowing neuroscientists to study physiology at an unprecedented scale. Yet light sheet microscopy is currently out-of-reach for many neuroscience laboratories: commercial microscopes are expensive, and building a microscope is challenging without optical expertise. In order make light microscopy more accessible, laboratories have begun to open-source the technology. I will contribute to this effort by presenting the design and assembly of a recently completed light sheet microscope to be shared by the neuroscience community in our institution. Our microscope uses the Objective Coupled Planar Illumination (OCPI) design. The system is capable of simultaneous two-color imaging and >5Hz scan rate through an entire larval zebrafish brain at cellular resolution. A second inverted brightfield microscope allows the user to more easily navigate the sample and to position electrodes for combining imaging with electrophysiology. Our design is also modular: users can easily switch between an axial scan mode and a horizontal scan mode that is more suitable for scanning along the cortical surface. Users are also free to remove the stage and replace it with custom equipment such as a spherical treadmill for mouse experiments. These features combine to result in a light sheet microscope that is at once powerful, flexible, and user-friendly.

Title: High-throughput screening and receptor binding reveal enzyme and GPCR targets as binding sites for a new PET tracer - D-deprenyl

Authors: A. A. LESNIAK[1], M. AARNIO[2], A. JONSSON[1], T. NORBERG[1], *F. J. NYBERG[1], T. GORDH[2];
[1]Uppsala Univ., Uppsala, Sweden; [2]Dept. of Surgical Sciences, Anaesthesiology and Intensive Care, Uppsala Univ. Hosp., Uppsala, Sweden

Abstract: Introduction and aim: D-deprenyl – an enantiomer of seligiline is a useful PET tracer for visualization of inflammatory processes. PET studies showed that peripheral D-deprenyl uptake is remarkably pronounced in patients suffering from chronic rheumatoid arthritis or musculoskeletal pain. High uptake points towards an existence of a yet non-characterized inflammation-specific binding site. Thus, the aim of our study was to identify the binding site for D-deprenyl via 1) commercial high-throughput screening towards 165 G-protein coupled receptors and 84 enzymes and 2) [H^3]D-deprenyl receptor binding analysis in rodent mitochondrial membrane and human inflamed synovial membrane preparations. **Methods**: D-deprenyl activity towards GPCR targets was assessed in CHO-K1 EDG1 β-arrestin EFC cell line with the PathHunter™ technique. Enzyme inhibition was assayed in the EnzymeProfiling™ screening panel. Binding studies with selective GPCR agonists and enzyme inhibitors at newly identified targets were performed in rat mitochondrial and human inflamed synovium preparations. **Results:** Our investigation revealed that D-deprenyl inhibits MAO-B, MAO-A and ACE activity by 99%, 55% and 70%, respectively. Binding studies confirmed a submicromolar [H^3]D-deprenyl competition with a selective MAO-B inhibitor seligiline, but not with the selective MAO-A inhibitor pirlindole mesylate. No evident hits among GPCR targets were identified. However, attention was drawn towards the histamine HRH1 and HRH3 receptors to which D-deprenyl showed a 20% and 42% antagonistic activity. **Discussion and conclusions:** MAO-B surfaced as a putative candidate target for D-deprenyl binding both in the mitochondrial and synovial membrane. Higher D-deprenyl uptake was documented in the CNS in activated astrocytes, non-secreting pituitary adenomas and at peripheral sites where MAO-B is overexpressed. Moreover, MAO-B expression is also present in the periphery in brown adipose tissue, fibroblasts and myocytes. Whereas, ACE inhibition by D-deprenyl could hamper down-regulation of transcription factors preventing ROS-mediated cartilage damage in animal models suggesting its role in inflammatory response.

Title: Maximization of brain manganese uptake for PET/MRI in neurological applications

Authors: *C. M. LEWIS[1], S. A. GRAVES[1], R. HERNANDEZ[1], I. SMIT-OISTAD[2], R. J. NICKLES[1], M. E. MEYERAND[3], M. SUZUKI[2];
[1]Med. Physics, [2]Comparative Biosci., [3]Biomed. Engin., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Manganese-enhanced MRI (MEMRI) has applications in anatomical and functional studies in rodents. The production of the PET isotope ^{52}Mn ($t_{1/2}$=5.6 days) has called interest to Mn-based PET/MRI and the possibility of ^{52}Mn PET in humans. Our group recently established proof of concept for tracking transplanted stem cells in the rat brain using Mn-based PET and MRI. Although the uptake and efflux of bulk doses of Mn^{2+} in the rodent brain are well established, the biodistribution of ^{52}Mn has yet to be thoroughly investigated. In this work, we study the uptake and retention of Mn^{2+} and ^{52}Mn in the rat brain with the aim of optimizing protocols for *in vivo* Mn-based PET/MRI. We first studied uptake of Mn^{2+} by observing R_1 relaxation rate (=1/T_1 relaxation time) with MRI. Female Sprague-Dawley rats (N=3 per group) were imaged prior to Mn delivery and over the course of two weeks following tail vein infusion of 30, 45, or 60 mg/kg $MnCl_2$. R_1 enhancement was observed at all time points and doses following $MnCl_2$ infusion. The greatest R_1 increase in the striatum of 84% was observed at the maximum dose 48 hours after contrast delivery. Despite high inter-subject variability in MRI contrast, a trend of increased R_1 enhancement at higher doses was observed. We next aimed to understand the dynamics of ^{52}Mn delivered both at tracer doses and supplemented with $MnCl_2$ at an MRI-appropriate dose. ^{52}Mn was diluted either in saline or in $MnCl_2$ solution then delivered by tail vein infusion at a dose of 2 mCi/kg. Brains were excised at days 1 and 2 post-contrast

(N=3 per group) and activity uptake was measured via gamma counting. A significant increase in brain activity of over 125% was observed in subjects delivered ^{52}Mn in saline (average 0.105%ID/g) compared to those delivered ^{52}Mn in $MnCl_2$ (average 0.044%ID/g). Three subjects underwent *in vivo* PET/CT over the course of 1 week beginning immediately following infusion of either no-carrier-added ^{52}Mn (N=2) or ^{52}Mn supplemented with bulk doses of $MnCl_2$ (N=1). It was found that the maximum brain-averaged uptake of 0.22%ID/g was reached by infusing no-carrier-added ^{52}Mn in saline and imaging the subject approximately 4 hours following infusion. These data lay the groundwork for Mn-based PET/MRI imaging protocols in rodent neurological applications. We observed reduced ^{52}Mn uptake in the brain when supplemented with bulk $MnCl_2$, which is an important consideration for designing *in vivo* PET/MRI imaging protocols. Importantly, *in vivo* PET imaging revealed low but detectable brain uptake of ^{52}Mn.

Title: Development of a PET tracer that targets amyloid β oligomers (AβOs)

Authors: *K. L. VIOLA[1], T.-T. CHANG[3,4], E. N. CLINE[1], E. CHUNG[5], M. DYKSTRA[3,4], B. MERRIFIELD[3,4], A. PECK[3,4], A. L. QIN[1], C. VALDEZ[1], H. J. WEISS[1], L. R. ZIESKE[6], W. L. KLEIN[1,2];

Abstract: The introduction of PET probes for amyloid plaques has shown that molecular imaging can be an important tool for Alzheimer's drug development. It is known, however, that amyloid plaques are not present in the earliest stages of the disease, and they no longer appear to

be the instigating cause of nerve cell damage. Probes for alternative markers, especially for the earliest stages of AD, are needed for effective disease intervention and management. Studies over the last 15 years indicate that pathogenic amyloid beta oligomers (AβOs) may be a more appropriate biomarker. AβOs cause the synapse failure regarded as responsible for AD memory loss, can be linked to major aspects of AD pathology, and appear early in the disease (Viola & Klein, 2015, Acta Neuropathol, 129(2):183-206). Antibody localization has been found to show a clear separation of AβOs from ThioS-positive plaques. These AβO-antibodies, when coupled to a magnetic nanostructure (NU4MNS), have been used experimentally to obtain an AD-relevant MRI signal (Viola et al, 2015, Nat Nanotechnol, 10(1):91-8). Because PET is more sensitive, an analogous antibody-based PET probe would be expected to be useful for earlier detection. Initial experiments have used the 5xFAD transgenic mice. AβOs in these animals begin to accumulate before the onset of memory dysfunction, as shown by histochemistry and an ultra-sensitive Erenna®-based assay (research use only). Initial tests of our antibody-based PET probe, NU4PET, were designed to determine if it can cross the blood-brain barrier and provide a disease specific signal. Virtually no signal was found in controls (rows 2-4: IgGPET in 5XFAD mice; NU4PET & IgGPET in wild type littermates). However, as predicted, in 5XFAD mice injected with NU4PET, brains were found to exhibit robust PET signals (top row).

Title: *In vivo* magnetic resonance imaging of neurotransmitter reuptake

Authors: *A. HAI, L. X. CAI, T. LEE, V. S. LELYVELD, A. P. JASANOFF;
Biol. Engin., MIT, Cambridge, MA

Abstract: Molecular imaging of dynamic processes in the brain is highly challenging and currently relies on modalities such as positron emission tomography (PET) which offers high specificity but relatively low temporal and spatial resolution and requires the use of radio-labeled ligands. We present the use of a novel protein-based serotonin binding MRI sensor for the detection of serotonin reuptake kinetics *in vivo*. Brain injection of the sensor with and without serotonin into the striatum of anesthetized rats, demonstrates a clear difference in MRI signal kinetics as a result of unbinding of serotonin from the sensor. Systemic injection of the serotonin transporter inhibitor (SSRI) fluoxetine blocks reuptake and reverses the MRI signal increase. Spatial maps of serotonin reuptake in conjunction with kinetic modeling allow for the first time to explore neurotransmitter transport and inhibition by anti-depressant drugs using MRI.

Title: Cobalt zinc ferrite nanoparticles - a suitable tool for magnetic cell labeling

Authors: *P. JENDELOVA[1], B. NOVOTNA[1], K. TURNOVCOVA[1], M. VEVERKA[2], P. ZVATORA[2], V. HERYNEK[3], Y. BAGRYANTSEVA[1], E. SYKOVA[1];

Abstract: Objectives To monitor the fate of transplanted cells within an organism, several non-invasive techniques have been introduced, including magnetic resonance imaging (MRI) of cells labeled with a contrast agent prior to grafting. Our previous study demonstrated a severe oxidative injury to lipids, proteins and the DNA of human bone marrow mesenchymal stem cells as a result of their labeling with superparamagnetic iron oxide nanoparticles. In searching for new contrast agents and magnetic cell labels, we prepared and tested a contrast agent based not only on Fe, but also on Co and Zn [cobalt zinc ferrite Co0.5Zn0.5Fe2O4+γ (CZF)] with a core encapsulated by amorphous silica. Methods Rat mesenchymal stem cells (MSCs) were labeled for 48 hour with 3 different concentrations of CZF particles, containing 7.5ug CZF/ml, 15ug CZF/ml and 75ug CZF/ml. Cell viability was assessed by trypan blue exclusion, and PI/Annexin V labeling was used to estimate the percentages of viable and dying cells. Cell proliferation was measured using a xCELLigence Real Time Cell Analyzer. To evaluate the genotoxicity of CZF nanoparticles, MSCs were labeled with all three concentrations of nanoparticles and then assessed for oxidative damage to their DNA (comet assay). MSCs labeled with CZF nanoparticles were differentiated into osteo-, chondro- and adipogenic phenotypes in appropriate differentiation media. Relaxivity was measured by a 20MHz Bruker Minispec relaxometer for the two lower concentrations only. The amount of Fe, Co and Zn in the cells was analyzed by the ICP/MS method. Results The two lower concentrations did not affect cell viability, while the highest concentration slowed down cell proliferation. Only the highest CZF dose increased DNA strand breaks (5.5x) and oxidative DNA damage (17x) above the control levels, while no obvious genotoxic effect was noticed in cells labeled with the two lower CZF doses. Differentiation into adipo-, osteo- and chondrogenic phenotypes was not affected by cell labeling at all. The relaxation rate of a cell suspension labeled at a concentration of 7.5ug CZF/ml was 0.85 s-1/million cells/ml, while the rate of cells labeled at a concentration of 15ug CZF/ml reached 1.55 s-1/million cells/ml and 1000 cells were visible as hypointense signal in rat brain. The average amount of magnetic ions inside one cell was 2.77 pg Co, 10.19 pg Fe and 4.28 pg Zn for a CZF concentration of 7.5ug CZF/ml and 6.35 pg Co, 27.97 pg Fe and 6.01pg Zn for a concentration of 15ugCZF/ml. Conclusions Concerning their safety for biomedical applications and their

suitability for MR tracking, CZF particles represent a very promising contrast agent suitable for cell labeling.

Title: 4-D wearable photoacoustic tomography for non-invasive imaging of cerebral hemodynamics in behaving rats

Authors: *J. TANG[1], J. ZHOU[2], P. CARNEY[2], H. JIANG[1];
[1]Biomed. Engin., [2]Dept. of Pediatrics, Univ. of Florida, Gainesville, FL

Abstract: We present a non-invasive wearable photoacoustic tomography (wPAT) system for 4-D imaging of cerebral hemodynamics in behaving rats. The 2nd generation wPAT system (2nd-G-wPAT) has 3 layers of transducer arrays, and has a size of 20 mm in height and 44 mm in diameter, and a weight of ~12 g (excluding cabling). It solved the vision occlusion problem that encountered in the previous design, and can obtain 3 layers' whole brain cross-sectional images within 0.3 s with an X-Y plane lateral resolution of 228 μm. The 2nd-G-wPAT's imaging ability has been demonstrated through a series of rat experiments, including hyperoxia functional imaging, PTZ-induced generalized seizure, 4-AP induced focused seizure, decision-making when challenged with cold/warm water, and emotional test by adding companion during experiment. The cerebral hemodynamic changes were successfully captured by the 2nd-G-wPAT in all testing experiments. Our studies suggest that this 4-D wAPT has the potential to be used in a wide range of behaving animal studies involving cerebral oxygen saturation monitoring, brain metabolism rate detection, visual learning/rewarding, behavior and cognition study, emotions,

stress, and brain disorders. It, therefore, may become a powerful tool for the neuroscience community.

Title: Quantitative tissue analysis with infrared imaging technology

Authors: *S. EATON[1,2], E. CUMYN[2,3], D. KING[2], R. KLINE[2], S. CARPANINI[2], J. DE POZO[3], R. BARRON[2], T. M. WISHART[2,4];

Abstract: Immunohistochemistry (IHC) is a key technique in the neurobiologists tool box used to identify specific antigens in order to characterise protein distribution and relative abundance within histological samples. Capture of images can be time consuming and their analysis can prove inherently difficult to quantify. Typically, quantification requires sophisticated software or complex normalisation parameters. Conventional fluorophores are not necessarily linear in their expression profiles and non-fluorescent methodologies, including diaminobenzine (DAB) label deposition, are not truly directly proportional to the expression of the targeted protein therefore IHC results are considered semi-quantitative. Recent advances in imaging using infrared (IR) "tags", with an appropriate scanner, provides an alternative system where the linear nature of the IR fluorophore emittance enables realistic Quantitative Fluorescence Immunohistochemistry (QFIHC) with little background. Furthermore, such a system allows entire tissue sections to be scanned yielding accurate area and protein abundance measurements from swiftly acquired tissue images. Here, we demonstrate that image capture and analysis using IR scanning technology produces comparable area based quantification to those obtained from a Hamamatsu Nanozoomer-XR slide scanner combined with ImageJ analysis. We demonstrate the scanners capacity for dual target visualisation within tissue sections. Additionally, we compare the distribution of two well-characterised proteins labelled using traditional biotin/streptavidin complex in conjunction with DAB or modern IR tagged secondary antibodies and conclude that IR based IHC produces images of comparable quality to that seen with DAB-labelled sections captured with light microscopy at X20 magnification regardless of upstream tissue processing methodology. Furthermore, by comparison with quantitative fluorescent western blotting (QFWB) data from microdissected brain regions we demonstrate that IR based relative protein abundance QFIHC measurements are an accurate reflection of tissue sample abundance. Thus, we suggest that IR based QFIHC employing an Odyssey scanner from LI-COR provides an alternative method of rapid low resolution imaging of whole brain sections for the production of reliable and accurate quantitative data.

Title: Atlas of forgotten dimensions: creating a metallome for epilepsy and beyond

Authors: *E. L. OHAYON[1,2], A. LAM[1,2];
[1]The Green Neurosci. Lab., Neurolinx Res. Inst., San Diego, CA; [2]Univ. of Toronto Epilepsy Res. Program, Toronto, ON, Canada

Abstract: Current efforts at uncovering "omes", in rough order of scale, have focused on the brain genome, proteome and, most recently, the connectome. However, a more fundamental aspect of the brain -- the elemental makeup at the atomic level -- is often overlooked. In this study we use synchrotron-based x-ray fluorescence imaging (SXRF) and other complementary techniques to map the spatial distribution of brain metals at resolutions of up to 1 micron with even higher resolutions on the horizon. Our dataset thus begins at 4D, reflecting the three spatial dimensions with the co-localization of metals constituting a fourth. We also implicitly add a temporal dimension by studying metals at different stages of development afforded through iPSCs, post-surgical and postmortem tissue studies. Samples include epilepsy tissue (post-surgical) as well as typical and Williams Syndrome (iPSCs and postmortem). We describe how the data is being prepared for an online open metal atlas. We also illustrate how the availability of this metallome could be essential for identifying new (i) biomarkers (ii) mechanisms and (iii) clinical therapies. Finally, we describe how the data may even help connect to an "ome" at the very other end of spatial scales, namely the "exposome" and consider how it may aid in environmental exposure assessment in neural tissue. (Atlas hosted at: http://greenneuro.org/atlas/).

Title: A small-molecule approach to the detection of aromatase activity in gonadal and non-gonadal tissues

Authors: *D. S. MCCARTHY[1], L. REMAGE-HEALEY[2,3], J. J. CHAMBERS[3,1];
[1]Dept. of Chem., [2]Dept. of Psycological and Brain Sci., [3]Dept. of Neurosci. and Behavior, Univ. of Massachusetts, Amherst, MA

Abstract: The goal of our current research is to develop a small molecule that can report on the activity of aromatase in tissue lysate and intact tissue including neural structures. To accomplish this, we have designed a novel, non-steroidal fluorogenic molecule that behaves as a substrate for aromatase, a cytochrome P450, family 19, subfamily A, polypeptide. Inspired by the structure of the native substrate, testosterone, our coumarin based small molecule is designed to undergo the same stepwise aromatization organic mechanism, thus converting an alpha, beta-unsaturated ketone into an aromatic ring that is in conjugation with the coumarin fluorophore. The effect of aromatization is to extend the pi-electron system of the fluorophore and to red-shift the emission wavelength of the coumarin. Analysis with tandem mass spectrometry of samples from *in vitro* experiments utilizing our substrate and gonadal tissue (zebra finch ovary) or sham treatments has indicated that we are able to convert the substrate into the aromatized product when active aromatase is present. These data, along with synthetic strategies, future designs, and fluorescence data will be presented and discussed.

Title: Visualizing neurite ultrastructure by electron cryotomography of cultured neurons

Authors: *M. T. SWULIUS, S. WEAVER, G. JENSEN;
Biol., Caltech, Pasadena, CA

Abstract: Electron Cryotomography (ECT) provides 3D molecular-resolution images of hydrated cells, allowing unprecedented preservation of cellular structure and macromolecular complexes in the cytoplasm. Here we use ECT to study the neurite morphology, organelles, cytoskeleton and cytoplasmic environment of axons and dendrites in cultured rat hippocampal neurons. We examine the *in vivo* structure of microtubules, neurofilaments and actin networks, as well as a cortical network of fine filamentous proteins situated near the membrane of dendrites. Subtomogram averaging is used to identify TriC chaperone complexes in the cytoplasm, and the formation of TriC clusters and their spatial relationship to polysomes in the cytoplasm is examined. The future of neuronal imaging by ECT and its potential to further investigate the dynamic molecular architecture of neurons will be discussed.

Title: A novel miniature multimodal imaging system to simultaneously monitor and measure brain ion fluxes, blood flow and oxygenation during seizure-like events in non-anesthetized freely behaving rats

Authors: *M. A. JEFFREY[1], D. RINGUETTE[2], I. SIGAL[2], R. GAD[2], P. CARLEN[1], O. LEVI[2];

[1]Fundamental Neurobio., Toronto Western Res. Inst., Toronto, ON, Canada; [2]Dept. of Electrical and Computer Engin., Inst. of Biomaterials and Biomed. Engin., Toronto, ON, Canada

Abstract: The spatiotemporal relationships between ion flux, blood oxygenation and blood flow are not well understood with respect to seieizures/ epileptogenesis. Robust quantitative measures of excitability, ion flux and vascular dynamics have not been possible due to the following technical limitations: 1) 1) Spatial resolution of local field potential measures is limited to the tips of electrodes;; 2) 2) When measuring ionic activity with fluorescent dyes, 3) Laser Doppler imaging systems are relatively large, and their imaging of blood flow is limited by low spatial resolution; 3) 4) Anesthetics alter brain excitability, inflammation, and blood flow. To address these challenges we designed a novel multimodal optical imaging system suitable for chronic studies. The system uses a fast camera and verticalcavity laserVCSEL sources, imaging through a cranial window with a large FOV. The system measures blood flow with using LCSI, oxygenation with IOSI, and ion flux using fluorescence. Anesthetized and ratsRats are injected with PTZgiven acute injections of low doses of pentylenetetrazol to induce a spectrum of seizure-like events. Measures are made in the presence and absence of anticonvulsant and gap-junction blocking drugs with differing effects on calcium and potassium comductance. A single bipolar stainless steel electrode in the sensorimotor cortex records the concomitant reference EEG signal. Quantitative measures from our recordings used to demonstrate the efficacy of our imaging system in assessing the simultaneous spatiotemporal dynamics of ion flux and hemodynamics. Correlation of dynamic calcium and potassium flux with blood flow/oxygenation is particularly of interest, since these fluxes are altered during epileptogenesis and ictogenesis. This imaging system allows us , for the first time, to study relationships and interactions between seizures-like events, blood flow/w and oxygenation, and ion flux with very high spatiotemporal fidelity. It could,, have major implications in the diagnosis and treatment of neurological disorders.

Title: Do trace metals levels differ in cases of refractory epilepsy? Insights from synchrotron x-ray fluorescence studies of human resected tissue

Authors: *A. LAM[1,2], S. WEBB[3], B. D. KOCAR[3], T. A. VALIANTE[4], P. L. CARLEN[4], E. L. OHAYON[1,2];
[1]Green Neurosci. Lab., Neurolinx Res. Inst., San Diego, CA; [2]Univ. of Toronto Epilepsy Res. Program, Univ. of Toronto, Toronto, ON, Canada; [3]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA; [4]Toronto Western Res. Inst., Toronto, ON, Canada

Abstract: Changes in biological processes dependent on trace metals (e.g., iron, zinc, copper, chromium, selenium, etc.) have been linked to epilepsy. The extent to which the metals themselves play a role is unclear due to the limitations in current techniques that result in the loss of structural information in order to detect metals levels in samples. We have previously described our advancements in synchrotron x-ray fluorescence (SXRF) imaging of human brain tissue which enables researchers to attain spatial information (e.g., in terms of colocalized distribution of metals), as well as the quantification of metals within user-defined areas. We have shown that SXRF is sufficiently sensitive to detect trace metal concentrations in cell cultures, postmortem and surgically resected tissue. In addition, SXRF enables us to co-register our metal maps to known substructures in the hippocampus and cortex. Here we examine differences between resected brain tissue recovered from minimally invasive epilepsy surgery to treat individuals with medically refractory epilepsy. Differences were observed between cortical and hippocampal tissue in copper and zinc levels in some, but not all individuals. These results suggest a potential subgroup of medically intractable epilepsies involving copper.

Title: Is the direction of Granger causal influence the same as the direction of information flow?

Authors: *P. VENKATESH, P. GROVER;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Granger causality and, more recently, Directed Information, have shown potential as measures of directed ``causal influence". Of late, many works have interpreted this direction of causal influence as being the direction of ``information flow" through neural pathways. We ask whether this interpretation is always correct by testing it on simple feedback models from communications theory. What, precisely, do we mean by information flow, and how is it different from causal influence? Causal influence, here, is simply a result of measures such as Granger causality. We think of information flow, on the other hand, in the more abstract sense of different parts of the brain sending messages to each other. If we consider just two parts of the brain as comprising a communication system, then it is of neuroscientific importance to understand which region is sending messages to the other, i.e., where did the information arrive first, and where did it thereafter go? Today, Granger causality and directed information are commonly used to infer this direction of information flow. We claim, using results motivated by information theory, that Granger causality *cannot* always correctly identify the direction of information flow (the direction in which the message is being passed). Our counterexamples are based on simple feedback systems where a transmitter communicates to a receiver using a well-known information theoretic strategy pioneered by Schalkwijk and Kailath in 1966. In these examples, the ``ground truth" for the direction of information flow is known by construction: from the transmitter to the receiver. We consider the case of communicating both a non-time-varying, as well as a time-varying message, using auto-regressive models (that are widely used to represent Local Field Potentials) for the latter. We show that for reasonable values of model parameters, even for this two-node problem, the direction of information flow can be opposite to the direction indicated by Granger causality and Directed Information. We believe that this interpretation only becomes more questionable for larger networks. We conclude that one needs to exercise care in interpreting the direction of Granger causal influence as the direction of information flow.

Title: Calibration of extracellular spike models of monosynaptic dynamics using intracellular recordings

Authors: *J. PLATKIEWICZ[1], D. F. ENGLISH[2], E. STARK[2,3,4], P. P. QUILICHINI[5], G. BUZSÁKI[2], A. AMARASINGHAM[1];
[1]Dept. of Mathematics, The City Col. of New York, The City Univ. of New York, New York, NY; [2]Neurosci. institute, Sch. of Med., New York Univ., New York, NY; [3]Dept. of Physiol. and Pharmacology, Sackler Fac. of Med., [4]Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv, Israel; [5]Inst. de Neurosciences des Systemes, Aix Marseille Univ., Marseille, France

Abstract: Synaptic connectivity has been identified from large datasets of extracellular spikes in the freely moving rat, using cross-correlation-type statistics (Barthó et al, 2004; Fujisawa et al, 2008). There are, however, numerous concerns regarding the analysis: spikes are an impoverished representation of a cell's membrane activity; cell detection and identification result from numerous indirect inferences; detecting synaptic connectivity from a cross-correlogram observation is an ill-posed problem. Motivated by these issues, we aimed at testing the spike train model used in (Fujisawa et al, 2008) on more direct measurements of cellular firing behavior. For that, we examined paired intracellular-extracellular recordings in anesthetized rats (Quilichini et al, 2010), and freely moving mice (English et al, 2014). First, we developed predictions about membrane potential fluctuations based on the spike train model. For this purpose, we used simple biophysical spiking models, whose parameters were adjusted to the intracellular data, and simple synapse models. Second, we tested these predictions on the paired intracellular-extracellular recordings. This work provides an attempt to reconcile spike train and biophysical models in the same framework, with the purpose of detecting and identifying more systematically synaptic connectivity under *in vivo* conditions. In particular, we highlight how the parameters extracted from extracellular data relate to biophysical parameters, typically estimated from intracellular data.

Title: Reliability of multi-site functional connectivity

Authors: *S. M. NOBLE[1], D. SCHEINOST[2], R. T. CONSTABLE[3], T. D. CANNON[4];
[1]Interdepartmental Neurosci. Program, [2]Diagnos. Radiology, [3]Diagnos. Radiology, Neurosurg., [4]Psychology, Yale Univ., New Haven, CT

Abstract: Functional magnetic resonance imaging (fMRI) connectivity maps are often combined or compared across multiple fMRI scanning sites to improve analytical power, but the validity of pooling multi-site data given scanner-related variability remains under-investigated. The reliability of connectivity across sites was assessed using a sample from the North American Prodrome Longitudinal Study (NAPLS) comprising healthy subjects (n = 8 subjects) who were each scanned at every site in the NAPLS consortium (n = 8 sites) on two consecutive days. The brain was parcellated into functional subunits using a 278-node functional connectivity atlas. Two measures of connectivity were investigated: whole brain voxel-wise connectivity, as measured by the intrinsic connectivity distribution (ICD), and standard seed connectivity relative to network hubs (i.e., PCC, motor cortex, thalamus). Mean reliability of ICD was found to be excellent across sites and days (mean generalizability ICC = 0.7809). Mean reliability of connectivity between network hubs and the whole brain was found to be fair (mean ICC = 0.55). Seed connectivity maps were further subdivided into subnetworks evidencing excellent reliability (ICC > 0.74) and networks evidencing poor reliability (ICC < 0.4). Subnetworks evidencing excellent reliability contained edges highly consistent with previously classified networks (e.g., the PCC - mPFC edge in the default mode network). Subnetworks evidencing poor reliability often contained edges outside of recognized networks and distributed throughout the brain (e.g., a PCC - left putamen edge). These results suggest that future multi-site connectivity studies involving edges outside of previously classified networks warrant further

investigation to address issues of poor reliability; these issues may be attributable to some combination of intrinsic factors, e.g., weak connectivity, and multi-site effects.

Title: A novel re-referencing method for ERP based brain-computer interfaces

Authors: ***M.-K. KIM**;
UNIST, Ulsan, Korea, Republic of

Abstract: Scalp electroencephalography (EEG) is one of the brain signal measurements, which is widely used in the development of brain-computer interfaces (BCIs) not only for patients with tetraplegia but also as applications for the able-bodied. Especially, an event-related potential (ERP) based BCI is a technology known to yield high accuracy and information transfer rate. Still, some users cannot achieve reliable BCI performance due to inability to generate fine ERP waveforms. The ERPs contain time-locked features elicited by an external stimulus, and factors that have direct negative influences such as artifacts can be overcome by either multi-trial averaging or adopting various de-noising methods. However, there are reports of another factor that has an indirect influence on the generation of ERPs: phase-resetting from the thalamocortical oscillations (TOs) known to be associated with the EEG pacemaker. The influences of the TOs are task dependent. Particularly, changes of alpha activity in the TOs are affected by visual stimuli and observed in the occipital area. Thus, ERPs measured during a visual task may be seen as a mixture of activities associated with visual information from occipital areas as well as various cognitive functions from many other areas. Under such a hypothesis, we suggest a new re-referencing method that enables detection of clearer ERPs by subtracting TO-related visual components from EEG measurements in each channel location. The TO-related visual components were estimated using the first principal component of the

multiple occipital channels (O1, O2, and Oz). For evaluation, we conducted an experiment in twenty healthy volunteers who performed a visual oddball task with flickers designed to simulate an online TV channel selection scenario using a P300-based BCI. Online performance was compared among four methods: no re-referencing, Laplacian filter, common averaging, and the proposed re-referencing method. The proposed method allowed acquisition of more pronounced ERP waveforms and also yielded superior online BCI performance than other methods: the overall accuracy was 75 ±14.7% for the proposed method, 55±18.1% for the Laplacian filter, 52±13.9% for the common averaging and 51±14.7% without re-referencing, respectively. The result suggests that the proposed method to re-reference EEG signal could help obtain improved ERPs in visual tasks. While this study limited its scope to task-dependent re-referencing for ERP based BCIs, our future focus will be the development of a more generalizable task-independent re-referencing method.

Title: Experimental validation of hierarchical Bayesian diffuse optical tomography algorithm for human brain function studies

Authors: *O. YAMASHITA[1], T. SHIMOKAWA[1], R. AISU[1,2], T. AMITA[3], Y. INOUE[3], M. SATO[1];

Abstract: The multi-channel continuous wave near infrared spectroscopy (NIRS) is used to investigate human brain functions. However lack of ability to specify activity location on brain anatomy is one of big issues to interpret activity spatial patterns. Diffuse optical tomography (DOT) is an emerging technology for improving the spatial resolution and spatial specificity of conventional multi-channel near infrared spectroscopy by means of high density measurement and image reconstruction algorithm. Although any DOT algorithm has the ability to reconstruct

scalp and cortical hemodynamics changes in their respective layers, which are the two main contributors of NIRS measurement, no DOT algorithm has been proposed to achieve accurate separation of these changes. Previously we have proposed a hierarchical Bayesian DOT algorithm in which the distinct nature of scalp and cortical hemodynamics changes is modeled and verified its performance with phantom experiment, computer simulation and human experimental data of one subject (Shimokawa et al. 2013, Yamashita et al. 2014). Here we extend the previous human case study to multi-subject and multi-task study to show validity of the algorithm to wider population and task conditions. We measured brain activities during right hand movement, right index finger movement and no right hand movement from 12 subjects using high-density NIRS and fMRI in two different sessions. DOT reconstruction performance is quantified with localization error (LE), area under curves (AUC) and spatial pattern similarity (SS) using fMRI activity maps as ground-truth. Median LE, AUC and SS for hand and finger conditions were about 6 and 8 mm, 0.86 and 0.84, 0.62 and 0.42, respectively. AUC and SS of our algorithm were significantly better than those of the standard DOT algorithm (depth-compensation minimum norm algorithm). In no-movement condition, our method successfully reconstructed no activity while the standard method showed some spurious activities. In conclusion, this study showed feasibility of our algorithm for wider subject population and wider task conditions and superiority to the standard DOT algorithm.

Title: Performance of an adaptive interictal spike detection algorithm

Authors: ***S. MEISENHELTER**[1], P. C. HORAK[2], A. CONNOLLY[2], B. JOBST[2];
[1]Neurol., Geisel Sch. of Med. At Dartmouth, Lebanon, NH; [2]Geisel Sch. of Med. at Dartmouth, Hanover, NH

Abstract: The identification of epileptiform activity and recording artifacts is crucial for the analysis of electrocorticography (ECoG) data. For the study of human brain activity, for clinical

diagnostics, and for the study of epilepsy, it is desirable to detect and classify spikes and other epilepsy related signals automatically. For many scientific studies, the removal of these waveforms is an indispensable pre-processing step. In humans, effective algorithms for the automatic detection and classification of epileptiform activity remain elusive partially due to the difficulty in defining the characteristics of an interictal spike. The morphology of interictal spikes varies considerably between patients. However, epileptiform activity is usually consistent within patients, suggesting that spike detection strategies that incorporate a patient-specific learning phase would be capable of lower error rates. Currently, the detection of interictal spikes and other epileptiform activity in clinical ECoG data is almost always carried out manually by trained neurologists. This introduces considerable variability in the accuracy of spike detection from reviewer to reviewer. The problem is further complicated by the lack of a consensus among neurologists on the features which define a spike. Discrepancies in review are explained by subjective variance between neuologists. In this study, we demonstrate a clustering based interictal spike detection algorithm. This algorithm improves upon an earlier method of creating patient-specific pattern matching templates by clustering the results of a generic pattern matching analysis (Nonclerq et al., 2010). This method was extended by expanding the generic pattern matching step and the clustering method. Further analysis examined the improvements in detection performance brought about by comparing signals from multiple electrodes in spike detection. This improved algorithm was evaluated using hippocampal ECoG recordings from epilepsy patients.

Title: Understanding the impact of drugs of abuse and behavioral training using novel peptidomic assays

Authors: ***B. SOUTHEY**[1], X. CHEN[2], P. A. MORRIS[1], A. E. MAKI[1], P. E. GOLD[4], S. L. RODRIGUEZ ZAS[3], J. V. SWEEDLER[2];
[2]Chem., [3]Animal Sci., [1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [4]Dept. of Biol., Syracuse Univ., Syracuse, NY

Abstract: A microdialysis peptidomic experiment was conducted on 11 adult male Sprague Dawley rats to characterize the impact of drugs of abuse and behavioral training on endogenous peptides in the hippocampus as well as peptide release as monitored via *in vivo* micro-dialysis. Rats were subcutaneously injected with either saline or morphine (5 mg/kg) and were then trained or untrained on a spontaneous alternation. Peptides were extracted from each rat and analyzed using an 11 Tesla linear trap quadruple Fourier Transform Mass Spectrometer. The resulting tandem mass spectra were annotated using ProSight PTM. Spectral counting is a label-free semi-quantitative proteomics method that measures peptide abundance as the number of times a peptide is identified in tandem mass spectrometry spectra. This count data can only take zero and whole positive numbers. Furthermore, zero inflation (where there are a large number of zero counts than would be expected) can occur because not all peptides are detected in all samples. Generalized linear models are used to analysis discrete variables and address the problems associated with zero-inflation and overdispersion. Using a false discovery rate adjusted ProSight PTM p-value threshold of 0.0001, 1482 peptides including post-translational modifications were detected across all samples. The most frequent proteins included: polyubiquitin-B (768 peptides detected), thymosin beta-4 (173 peptides detected) and fibroblast growth factor (137 peptides detected). Peptide spectral counts were analysis using Poisson, zero-inflated, hurdle and truncated Poisson models as well as the Negative Binomial counterparts. The analysis of multiple models with different distributional assumptions identified many cases where the significant differences was due to the failure of a particular model to account for the zero-inflation and/or any overdispersion. For example, a polyubiquitin-B peptide exhibited a highly significant effect ($P < 0.001$) in models without overdispersion; however the same peptide only exhibited marginally significant differences (P-value < 0.1) using models with overdispersion. Significantly differential abundant peptides included: a SMG1 phosphatidylinositol 3-kinase-related kinase peptide that was 12 times more abundant with morphine than saline ($P<0.05$) and two thymosin beta-4 peptides were approximately 2.2 times more frequent with training than without training ($P<0.05$). These results exhibit the combination of proteomics and statistical methods for effective analysis of neuroscience experiments.

Title: Dynamic estimation of human brain's receptive fields with confidence intervals

Authors: *S. AKRAM, J. Z. SIMON, B. BABADI;
Univ. of Maryland, College Park, MD

Abstract: One of the most important problems in computational neuroscience is to characterize the brain function using neural activity recorded from the brain in response to sensory inputs with statistical confidence. Most of existing estimation techniques, such as those based on reverse correlation, exhibit two main limitations: first, they are unable to produce dynamic estimates on par with the sampling resolution of neural data, and second, they often require heavy averaging across time as well as multiple trials in order to construct statistical confidence intervals for a precise interpretation of data. In this study, we address the above-mentioned issues for estimating auditory temporal receptive fields (TRF) as a parametric computational model for selective auditory attention in competing-speaker environments. In this case the TRF, which describes the way in which the neural response encodes an acoustic envelope, can be described mathematically as a sparse kernel, which regresses auditory MEG data with respect to the envelopes of the speech streams. We develop an efficient estimation technique by exploiting the sparsity of the TRF and adopting an l1-regularized least squares (SPARLS) estimator. This technique is capable of producing dynamic TRF estimates as well as confidence intervals at sampling resolution from single-trial MEG data. We evaluate the performance of our proposed estimator using evoked MEG responses from the human brain in an auditory attention experiment with two competing speakers. In the experiment, subjects are asked to stay attended to a target speaker for the first half of each trial (~ 30 seconds) and switch their attention to the masker speaker for the rest of the trial. The TRFs are estimated dynamically over time using the proposed technique, which reveal a precise characterization of the modulation of M50 and M100 evoked responses with respect to the attentional state of the subject at multi-second resolution.

Title: Resting state fMRI identification of communicating sub-regions in the human medial temporal lobe

Authors: *R. SANCHEZ ROMERO[1], J. D. RAMSEY[1], J. C. LIANG[2], C. GLYMOUR[1]; [1]Philosophy, Carnegie Mellon Univ., Pittsburgh, PA; [2]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Introduction: Connectivity analyses depend on building ROIs signals as averages of individual voxels. This average implies a loss of functional and anatomical information about sub-regions of voxels that drive high-level ROI connectivity. To recover this information, we present a statistical search method that analyze voxelwise conditional independence relations to identify sub-regions of voxels within a pair of effectively connected larger ROIs that are responsible for exchanging signals between those ROIs. We illustrate the method for rs-fMRI of medial temporal lobe (mtl) of a single human subject. Methods: High-resolution rs-fMRI of a single subject, 10 min scan, TR=1160ms, voxel size=2.4x2.4x2mm. ROIs in the mtl were defined manually according to procedures of the Preston Lab. at U.Texas at Austin. ROIs were defined for subiculum, CA1, CA23DG, entorhinal, perirhinal and parahippocampal cortex. To avoid high dimensionality statistics we concatenated ten sessions and applied our method to the concatenated dataset. Our method tests the independence of each pair of voxels, one from each of a pair of ROIs, R1, R2, that are directly causally connected, conditional on all voxels in any other ROIs that according to the given causal graph may influence voxels in both R1 and R2. For a voxel v in R1, the number of voxels in R2 that are found to be significantly associated with v is counted. This number is the R2 connection number for v in R1. Similarly for the R1 connection number for v in R2. The connection numbers of all the voxels in R1 and R2 are aggregated and partitioned into 2 sets using k-means. One set corresponds to highly connected voxels and the other to voxels with low or no connections in the R1-R2 pair. Locations of the voxels in the highly connected set yield the R1-R2 communication sub-region. This procedure is repeated for each pair of ROIs that are causally connected. We consider as the given causal graph the well-known medial temporal lobe structural connectivity circuitry. Results: We recovered sub-regions within larger ROIs of entorhinal cortex, CA1, CA23DG and subiculum. The sub-regions show robust spatial coherence and are in agreement with previous tractography-based structural connectivity results. We also tested our method on a simulated incorrect co-registration case that may arise when multiple scans are concatenated, and recovered sub-regions qualitatively similar to those obtained when simulated scans were correctly co-registered. Conclusions: Resolution of ROIs into voxelwise communication sub-regions allows us to recover important functional and anatomical information that bring us closer to understand the causal role of neural complexes.

Title: 3-D tract-based regression analysis of white matter abnormalities in Alzheimer's disease

Authors: ***Y. JIN**[1,3], C. HUANG[2], D. SHEN[1], H. ZHU[2], P. M. THOMPSON[3]; [1]Radiology, [2]Biostatistics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Neurol., USC, Los Angeles, CA

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disease that causes cognitive decline and affects millions of people worldwide. Diffusion weighted imaging (DWI) is an effective non-invasive method to yield information on white matter (WM) tract abnormalities caused by AD. Unlike traditional studies using the regional average measures or statistics from the "skeleton" of the WM, we examined the AD effects on the reconstructed 3-D profiles of major WM tracts. We analyzed baseline DWI data from 200 participants from the ADNI database (mean age: 73.2+/-7.5 SD; 116M/84F), consisting of 49 normal elderly people (NC), 111 with mild cognitive impairment (MCI), and 40 AD patients. Whole-brain tractography was performed. We manually constructed five WM tract atlases and applied a multi-atlas label fusion algorithm to extract 18 major WM tracts per subject. Next, we implemented a point-wise matching scheme to match fiber points across the population. Finally, we conducted a multivariate varying coefficient model to characterize the association between diffusion properties of tracts, such as fractional anisotropy (FA) and mean diffusivity (MD), and diagnostic status, with age and sex as covariates. Pointwise regression analysis was performed. Fig. 1 shows the 3-D MD profiles of three tracts affected by AD, the left and right cingulum and fornix, for groupwise comparisons. Each point's color represents the significance of difference between two groups based on the false discovery rate (FDR) corrected p-values (thresholded at 0.05). Comparing NC vs. MCI shows little difference in MD values in both cingulum tracts. As the disease progresses, the posterior portion demonstrates greater difference. Multiple regions in the fimbria and body of the fornix show degeneration even at the MCI stage and it spreads to the entire tract at the AD stage. The MD values of the AD group in all three tracts are higher. The 3-

D FA profiles between groups show less difference than those of MD, so MD may be a better measure for detecting AD and provide additional information on the etiology of the disease.

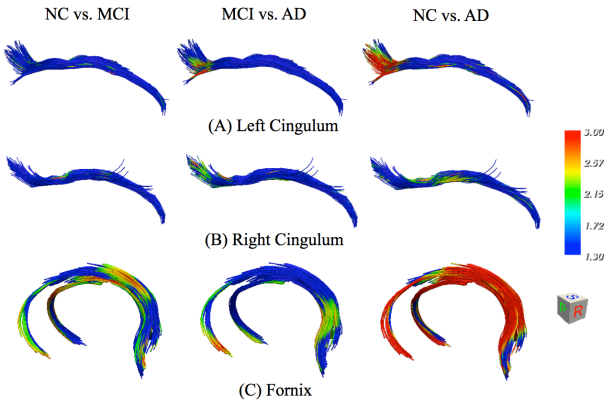

Fig. 1. 3-D tract profiles of left/right cingulum and fornix reveal difference in MD values among groupwise comparisons within the three diagnostic groups. The $-\log_{10}$ p-values are shown corresponding to the color bars. Results are FDR corrected across all points on each tract tested, thesholded between 1.3 (p=0.05) and 3 (p=0.001). Redder colors show greater group differences. The viewing direction is marked in the cube on the right (R-Right, P-Posterior, S-Superior).

Title: Methods to remove motion artifact in resting state multi-echo fMRI data

Authors: *J. D. POWER[1], M. PLITT[2], P. KUNDU[3], P. BANDETTINI[2], A. MARTIN[2]; [1]Lab. of Brain and Cognition, NIMH, Natl. Inst. For Mental Hlth., Bethesda, MD; [2]NIMH, Bethesda, MD; [3]Mount Sinai Hosp., NYC, NY

Abstract: The study of correlations and dynamics among resting state fMRI timeseries is increasingly influential in cognitive neuroscience and clinical studies. fMRI timeseries partially and indirectly reflect neural activity, but they are also prominently influenced by multiple kinds of artifactual factors. Removing or at least minimizing these artifactual influences on fMRI signals is of clear importance for drawing accurate inferences from such data. Over the last five years it has become apparent that some lifespan and clinical resting state fMRI effects can be attributed to unremoved motion artifact. New approaches and better validation of existing

approaches are needed to establish the validity of resting state findings. Recently, several groups have begun collecting “multi-echo” fMRI data in the hope that such data can be more thoroughly denoised than traditional “single-echo” fMRI data. Here, we examine 89 “multi-echo” datasets for evidence of motion artifact. These data are obtained from typical adults using sequences already described (Kundu et al., 2013) and are analyzed following procedures and logic outlined in (Power et al., 2015) and (Kundu et al., 2013). Motion artifact is present in the raw data and its properties are similar to those reported in prior studies. Multi-echo independent component analysis (ME-ICA), when applied to these data, removes some but not all influences of motion. After ME-ICA, global artifactual influences remain that are clearly artifact. An additional novel procedure, termed “godec”, is introduced to separate these more global signals from sparser signals. After removing the more global signals, motion dependence in the data is reduced to nearly undetectable levels (Figure 1). Although further demonstrations of the technique in other datasets are warranted, ME-ICA+godec appears to be a promising method of removing motion-dependent properties from resting state fMRI data.

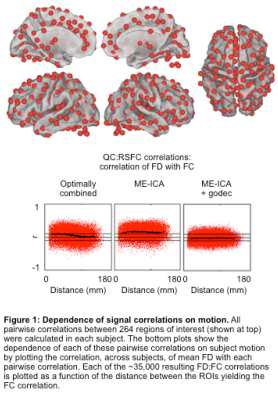

Figure 1: Dependence of signal correlations on motion. All pairwise correlations between 264 regions of interest (shown at top) were calculated in each subject. The bottom plots show the dependence of each of these pairwise correlations on subject motion by plotting the correlation, across subjects, of mean FD with each pairwise correlation. Each of the ~35,000 resulting FD:FC correlations is plotted as a function of the distance between the ROIs yielding the FC correlation.

Title: Scalable human EEG: Task-motivated alignment of volitional behaviors reduces variability and enables population neurophysiology

Authors: *T. A. NICK, L. M. BERMAN, A. Z. BARNEHAMA;
Neurosci., DAQRI, Los Angeles, CA

Abstract: Human studies are difficult to control, leading to a heavy focus on time- and labor-intensive clinic and laboratory studies. These studies have illuminated numerous robust biological processes that can be studied using brief recordings of human subjects that may be stressed, uncomfortable, and unmotivated. However, behavioral and physiological processes that shift in response to the laboratory environment or that vary with daily or longer cycles according to biological pressures and rhythms are less well understood. We have developed a set of feedback tasks on mobile devices that, in concert with our wearable electroencephalography (EEG) headband, encourage users to actively participate in field studies through instant reinforcement using sensory cues that are derived from real-time analysis of behavior. A cloud analytics pipeline and database were built to provide longitudinal reports to users. We mined these de-identified data to compare tasks with associated behaviors and neural activity from >8,000 recording sessions and >600 unique users. Here we report that at least two behaviors, facial muscle activity and eye blinks, appear to be shaped by mobile application tasks (Percent time with muscle activity, positive-reinforcing task vs all others [Wilcoxon signed rank with N = 524 users]: $p < 3e-16$; Eye Blinks, gaze fixation vs a neutral task [Wilcoxon with N = 460 users]: $p < 7e-14$). This shaping occurred in users with little or no instruction on how to use the EEG headband or the mobile app, suggesting that this technology is easily scalable. Further, variation in these behaviors during a gaze fixation task was less than during a neutral task (Flinger-Killeen, $p < 0.002$ for each behavior). Next, we examined whether we could observe neural activity patterns in the data despite no exclusion or segregation of subjects based on age, gender, race, or other trait. We focused on a gaze fixation task that discourages eye blinks (see above). We found changes in brain oscillation that previously have been quantified only under highly controlled laboratory conditions with limited subject diversity (e.g., Cummings et al, 2000). Our preliminary data suggest that task-motivated alignment (TMA) of user behavior mimics laboratory control and enables scalable monitoring of diurnal neural activity patterns. For example, theta increased during the day (morning vs evening; Flinger-Killeen, $p = 0.19$; paired t-test with N = 107 users: $p < 0.027$). Therefore, TMA could provide a mechanism for decreasing behavioral variability and enhancing experimental control in human field studies, enabling scalability of clinical trials, research studies, and user-tailored feedback.

Title: Predicting quality of life and functional independency after stroke using supervised machine learning

Authors: M. BRANSCHEIDT[1], B. ZENKO[2], J. CERNY[1], *A. R. LUFT[1], C. GLOBAS[3]; [1]Univ. Zurich, Zurich, Switzerland; [2]Dept. of Knowledge Technologies, Jozef Stefan Inst., Ljubljana, Slovenia; [3]Univ. of Zurich, Zurich, Switzerland

Abstract: Prediction of stroke specific health outcome is essential but complex. With higher long-term survival there is rising interest for multidimensional assessment tools that reflect the impact of stroke on various aspects of life and for more accurate long-term prognostic models. The availability of high volume data sets is promising in this regard but poses new requirements to analyzing methods. We aimed to identify predictors for stroke specific quality of life evaluated by the Stroke Impact Scale (SIS) and for functional independence evaluated by the Extended Barthel index (EBI) using a machine learning approach. Clinical, neuropsychological and imaging data of 79 stroke patients (mean age 63.7 ±15.7, 29 females) from the Zürich Registry of Rehabilitation Outcomes were prospectively collected in the acute stage, at discharge from hospital and one year after stroke. Supervised machine learning with a decision tree algorithm was used 1) to describe the predictive value of 15 variables for the two outcome measures (SIS and EBI) and 2) to describe the impact of 14 variables at 12 months on SIS and EBI. Regarding the parameters collected in the acute stage, age, modified Rankin Scale (mRS) and the National Institute of Health Stroke scale (NIHSS) scores at discharge from hospital predicted SIS outcome (correlation coefficient 0.72). At 12 months the variables correlating with SIS outcome were mRS, NIHSS, Becks depression index (BDI), neglect and Berg balance scale (BBS) (correlation coefficient 0.85); BBS showing the highest relative predictive weight. For the prediction of the EBI outcome, we found different variable associations for two patient groups depending on mRS at discharge: for patients with mRS $\leq$3 the predictive variables were BMI, Fugl-Meyer-Assessment for the upper extremity (FM-UE), Early Rehabilitation Barthel Index (ERBI), NIHSS and mRS; for patients with mRS $\geq$ 4, NIHSS was not predictive for the later

functional outcome and ERBI and BMI had a higher main contribution compared to patients with lower mRS at discharge (correlation coefficient 0.63). At 12 months EBI scores correlated with BBS and the modified Ashworth scale (MAS) (correlation coefficient 0.74), again with BBS having a markedly higher main contribution. Machine learning using a decision tree algorithm can create complex but easy to interpret predictive models for functional independence and quality of life after stroke. These next-generation analytics might be particularly advantageous to elucidate the complex interactions between variables and multidimensional outcome measures that are increasingly applied in stroke rehabilitation.

Title: Explicit modelling of the hemodynamic response in linking cognitive computational models to fMRI data

Authors: *G. DE HOLLANDER[1], S. D. BROWN[3], B. U. FORSTMANN[2];
[2]Psychology, [1]Univ. of Amsterdam, Amsterdam, Netherlands; [3]Fac. of Sci. and Information Technology, Sch. of Psychology, Univ. of Newcastle, Newcastle, Australia

Abstract: The past 10 years have seen a surge of studies that try to link computational, formal models of cognition, rooted in behavioral fields such as mathematical psychology and reinforcement learning, to neural measurements in humans. This is usually done with fMRI and has been called “model-based neuroimaging”. The model-based neuroimaging approach provides a way of increasing sensitivity to neural representations of latent cognitive processes and variables, such as evidence accumulation and stimulus-value. It also offers a way of testing the possible implementations of models of cognition. These models are usually validated in pure behavioral data, but say little about their implementation in the human brain. By far the most popular approach in model-based neuroscience is the regression-approach: a general linear model (GLM) is set up that includes a regressor corresponding to an estimated parameter of the model, convolved with a canonical hemodynamic response function. The GLM is fit to all voxel

timecourses in the brain, searching for brain areas where functional activity correlates with the parameter-of-interest as estimated by the cognitive model. This model is simplistic, because it assumes that the correlate of the parameter-of-interest in the BOLD-signal is nothing more than a linearly scaled canonical hemodynamic response function. Simple plots of the raw HRF signal during a speed-accuracy-tradeoff task in relevant areas show that not only the height of the response, but also the onset-to-peak and dispersion are modulated by the experimental manipulation. Here, we propose a joint-modeling-approach, where multiple aspects of the shape of the HRF are jointly estimated with the cognitive model using Markov Chain Monte Carlo sampling in a Bayesian setting. We applied the approach to fMRI data in a speed-accuracy-tradeoff task and show that it increases sensitivity while providing insight in the role of cortico-basal ganglia networks during speeded decision making

Title: Automatic sulcal labeling and quantitative pattern analysis in the fetuses with brain malformations

Authors: *K. IM[1,4], A. GUIMARAES[5], Y. KIM[1], B. GAGOSKI[1,4], C. ROLLINS[4,2], E. YANG[4,3], P. GRANT[1,4];

Abstract: Defects in neurodevelopmental associated with many brain disorders result in disrupted global patterns of sulcal folding, which may emerge in early fetal life. For an advanced analysis of early sulcal folding development, this study aims to automatically label early primary sulci and investigate their patterns from T2 weighted MRI in 10 normal fetuses (21 – 28 weeks gestational age) and 6 fetuses with brain abnormalities (20 – 30 weeks). Fetal head motion in the raw image was corrected and isotropic high-resolution image volumes (0.75 × 0.75 × 0.75 [mm]) were reconstructed. Cortical plate area was semi-automatically segmented and 3D inner cortical plate surface was reconstructed using the isosurface function. Sulcal catchment basins were

identified on the cortical plate surface and previously published 9 fetal brain templates (23 – 31 weeks) were also used and processed as a reference for sulcal labeling and pattern analysis. We automatically labeled the sulcal basins and simultaneously quantified the global sulcal pattern similarities to the templates for individual fetal brains by matching with the templates using multivariate geometric features (relative 3D position, normalized surface area, and mean sulcal depth) and their inter-sulcal relationships and the prior knowledge of the spatio-temporal sulcal patterns. The sulcal pattern similarities to the normal templates were statistically compared between normal and abnormal fetuses using the Mann-Whitney *U* test. Our quantitative method optimized for the fetal brain showed the high accuracy and reliability of the automatic labeling and revealed significantly reduced sulcal pattern similarities to the normal templates in the fetal group with brain abnormalities, compared to the normal group (similarity to the template in the left, normal [mean ± SD]: 0.821 ± 0.018, abnormal: 0.754 ± 0.037 [$p < 0.001$], right, normal: 0.812 ± 0.022, abnormal: 0.762 ± 0.065 [$p = 0.039$]). Furthermore, it showed higher sensitivity in detecting individual's abnormality than qualitative fetal MRI assessment and reported abnormal sulcal pattern that might be compensatory or secondary to other brain abnormalities, but not qualitatively perceived. This study provides the potential to perform various regional analyses following sulcal labeling and to catch early signs of abnormal cortical growth from individual fetal brains.

Title: Quantitative analysis of sleep neural dynamics

Authors: ***M. J. PRERAU**[1], M. T. BIANCHI[2], P. L. PURDON[1];
[1]Anesthesia, Critical Care, and Pain Med., Massachusetts Gen. Hosp., Charlestown, MA;
[2]Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Sleep is a continuous, dynamic process involving the complex interaction of cortical and sub-cortical networks within the brain, which operate on multiple time scales. Study of the

sleep electroencephalogram (EEG) is therefore an ideal, natural means of simultaneously observing the correlates of activity from numerous brain regions. While the past 50 years have seen extraordinary advances in our understanding of the physiological mechanisms underlying sleep, current analyses still rely heavily on sleep staging, a subjective process using visual inspection to discretize sleep into semantically-defined stages (e.g. Wake, REM, NREM 1-3) using 30-second epochs. The activity within these stages is assumed to be stationary, with instantaneous transitions between them. As a consequence, sleep staging greatly oversimplifies the true signal dynamics and thus does not fall in line with the observed evolution of the data. We develop novel computational techniques to capture the full dynamic nature of the sleep EEG, thereby more accurately representing our knowledge of the underlying neurophysiology, while providing a robust statistical framework for characterizing sleep.

Title: Reciprocal couplings and their modes in eye contact

Authors: *R. LEE;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Eye contact recruits multiple brain processes. Some of them are reciprocal, while others are non-reciprocal. With dyadic fMRI (dfMRI) [1], many of these interactive processes can be identified in a data-driven approach, and entwinement between reciprocal and non-reciprocal responses can be untwined by the dual logic theory (DLT) [2]. The fusion of dfMRI and DLT results in a cerebral coordinate for reciprocal interaction (CCRI). In this study, 19 dyadic datasets for eye contact are decomposed by group ICA [3]. The independent components (IC) with dyadic responses and eye-contact rhythm are selected and projected to the CCRI, and yield reciprocal coupling modes [2]. Each coupling mode is parcellated by anatomical structures based on Harvard-Oxford atlas in FSL. The activated parts of the parcellations are served as regions-of-interest (ROI) to extract the average time series from each dyadic dataset. For each dataset, correlations between all the time series are calculated, but only the correlations with

p<0.05 are selected. For all 19 datasets, the average correlations are selected by z-test with 95% chance and threshold 0.1, which become the connectivity of the given mode. Currently ten coupling modes are identified. Two of the ten modes are illustrated in Fig. 1 where a & b are their IC, and c & d are their connectivity. In Fig. 1 c & d, the right and left side labels are for right and left side subjects, upper and lower part labels are for the exogenous and endogenous systems. For the 1st mode in Fig. 1c, left subjects' brainstem is coupled with right subjects' postcenter gyrus (POG), and the exogenous coupling emerges to endogenous precuneus. For the 2nd mode in Fig. 1 d, left subjects' pallidum is coupled with right subjects' POG, and the exogenous coupling emerges to endogenous angular gyrus. The reciprocal coupling modes reveal the parallel processes during dyadic interaction. It set forth an approach to analyze social interaction. [1] Lee RF, et al (2012): Magn Reson Med 68(4):1087-96. Title: Mapping subcortical shape heritability to empower genetic association studies

Authors: *B. GUTMAN[1], N. JAHANSHAD[2], P. K. DOUGLAS[3], P. M. THOMPSON[2]; [1]Inst. for Neuroimaging and Informatics, IGC - Univ. of Southern California, Marina Del Rey, CA; [2]Imaging Genet. Ctr., USC, Los Angeles, CA; [3]Neurol., Univ. California Los Angeles, Los Angeles, CA

Abstract: Imaging Genetics is the study of genetic associations with imaging biomarkers. Its relevance to our understanding of the brain has been demonstrated recently [1]. In a number of previous imaging genetics studies, subcortical regional volumes have been traditionally used as the standard image-derived measures. While reducing the multiple comparisons burden to a manageable size, this approach overlooks subtleties of sub-regional shape differences. In this work, we choose instead to analyze the entire shape complex of the basal ganglia and limbic system at a fine scale. We present a multi-cohort shape heritability study, extending the fast spherical demons registration to subcortical shapes via medial modeling. A multi-channel demons registration based on vector spherical harmonics is applied to medial and curvature features, while controlling for metric distortion [2]. We registered and compared seven subcortical structures of 1480 twins and siblings from the Queensland Twin Imaging Study and Human Connectome Project: Thalamus, Caudate, Putamen, Pallidum, Hippocampus, Amygdala, and Nucleus Accumbens. Radial distance and tensor-based morphometry (TBM) features were found to be highly heritable throughout the entire basal ganglia and limbic system. Surface maps reveal subtle variation in heritability across functionally distinct parts of each structure. Medial Demons reveals more significantly heritable regions than two previously described surface registration methods. This approach may help to prioritize features and measures for genome-wide association studies. 1.Hibar DP, et al.: Common genetic variants influence human subcortical brain structures. Title: Distributed anatomical substrates identified by pattern classification predict cortical excitability and inhibition

Authors: *E. DAYAN[1], V. LÓPEZ-ALONSO[2], S.-L. LIEW[3], L. G. COHEN[4];
[1]Human Cortical Physiol. Section, NINDS/NIH, Bethesda, MD; [2]Univ. of A Coruña, A Coruña, Spain; [3]USC, Los Angeles, CA; [4]NINDS, NIH, Bethesda, MD

Abstract: Motor evoked potentials (MEPs), elicited by single-pulses of transcranial magnetic stimulation (TMS) over the primary motor cortex, are a well-regarded measure of cortical excitability. Similarly, short interval intracortical inhibition (SICI), elicited by paired-pulse TMS, is widely used as a protocol for measuring cortical inhibition. These two TMS protocols have been highly instrumental in probing the physiological characteristics of the central nervous system, and are often used to quantify plastic changes induced by noninvasive brain stimulation techniques such as transcranial direct current stimulation. Still, MEPs and SICIs clearly differ among subjects, and the origins of this variability remain poorly understood, often being attributed to spontaneous and transient factors such as fluctuations in corticospinal excitability. Here, we evaluated whether inter-individual variability in MEPs and SICIs may also originate from more stable factors like individual variability in brain structure. High resolution structural magnetic resonance imaging scans were collected in a group (n=25) of healthy volunteers for whom- in a separate session-TMS with single and paired pulses was administered to record MEPs and SICIs respectively. Support vector machine (SVM) pattern classification was then used to train a classifier to distinguish between subjects who had lower and higher MEPs and SICIs, based on their segmented gray-matter images. Testing of the classifier's performance revealed that distributed patterns of gray-matter volume, extending beyond motor regions allowed for an accurate and significant classification of MEP and SICI amplitudes. These results suggest that variability in TMS-elicited cortical excitability and inhibition may partially originate from subjects' brain anatomy.

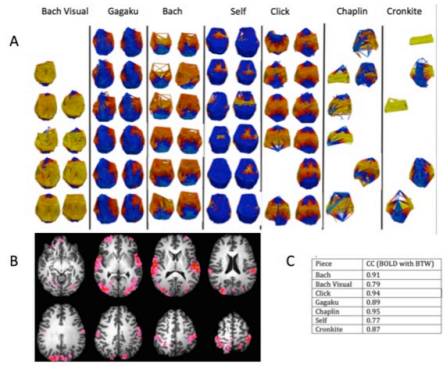
Title: Correlation between bold activation and centrality in fmri connectivity when listening to music

Authors: *C. KARMONIK[1,2], J. ANDERSON[1], A. BRANDT[3], F. BROOKS[2], J. FRAZIER[2]; [1]Houston Methodist Res. Inst., Houston, TX; [2]Ctr. for Performing Arts Med., Houston Methodist Hosp., Houston, TX; [3]Shepard Sch. of Music, Houston, TX

Abstract: Background: Listening to familiar music has recently been reported to induce beneficial changes during stroke recovery concurrently with increase of cortical thickness. To foster a better understanding of the neural correlates when listening to different music genres, fMRI BOLD activation from listening to different music genres was correlated with functional connectivity. Materials and Methods: Twelve healthy volunteers listened to seven different auditory pieces, two unfamiliar pieces (Bach invention #1, classical Japanese opera, Gagaku), one with visual guidance (Bach), one self-selected piece and three language pieces (African click language, emotional speech, Chaplin, and unemotional textbook reading, Cronkite). BOLD activation maps were derived and functional connectivity maps were created using a graph theoretical approach from which betweenness (BTW) was calculated as centrality measure. Centrality maps were built for individual subjects and averaged in Talairach space. Results: Distinct different BOLD activation maps and functional connectivity patterns were obtained for each audio piece but consistent amongst all subjects (figure 1). Bach and click language pieces exhibited more regions with increased blood flow during the listening periods as compared to the resting periods. This was reversed for Japanese opera and self-selected pieces. For both Chaplin and Cronkite textbook passages, activation was distinctively less and variable between the listening and resting period. Group-averaged maps correlated strongly and statistical significantly ($p<0.05$) for BOLD and BTW patterns (figure 1). Conclusion: Dynamic changes in fMRI connectivity are induced by listening to different music genres and spoken language. Strength of BOLD activation coincided with a centrality measure that identifies voxels with large influence on the transfer of information through the fMRI connectivity network.



Piece	CC (BOLD with BTW)
Bach	0.91
Bach Visual	0.79
Click	0.94
Gagaku	0.89
Chaplin	0.95
Self	0.77
Cronkite	0.87

Title: Acceptable values of similarity coefficients in neuroanatomical labeling of MRI

Authors: *A. J. WORTH[1], J. A. TOURVILLE[2];
[1]Neuromorphometrics, Inc., Somerville, MA; [2]Dept. of Speech, Language, and Hearing Sci., Boston Univ., Boston, MA

Abstract: The delineation of neuroanatomy in magnetic resonance brain scans (known as segmentation, labeling or tracing) is commonly validated by comparison with a manually created gold standard. This is done using spatial overlap statistics such as the Dice index and Jaccard coefficient. We examine published similarity values for particular anatomical regions to

determine what is generally acceptable and compare this with results obtained by manually labeling repeat scans of 20 subjects. Each subject was scanned twice separated by some time and both scans were labeled independently. MRI brain scans were obtained from the "reliability" set in the Open Access Series of Imaging Studies (OASIS). A single highly trained technician used custom software “NVM” to create closed borders around regions with isointensity contours and editing. Labeling was performed using protocols that precisely define the landmarks, borders and methods for delineating anatomical regions. “SegMentor” scripts helped assure accuracy and documented adherence to the labeling protocols by imbedding them into the software. 72 regions comprehensively covered the brain including: cerebral and cerebellar gray and white matter, ventricles, brain stem, accumbens, amygdala, caudate, hippocampus, pallidum, putamen, and thalamus according to the “General Segmentation” protocol defined by the MGH Center for Morphometric Analysis, and the cortex was parcellated into 51 units based on 36 sulci according to the BrainColor protocol. An anatomist with years of labeling experience checked all results and the technician made corrections as necessary. We demonstrate that manual results can have the best possible overlap metrics, but only after spending a sufficient (and many would say excessive) amount of effort. The similarity coefficients we present thus represent a kind of upper bound on what is currently attainable. Similarity values occur over a range because specific anatomical regions have differing amounts of anatomical variation and are affected differently by scanning artifacts: some regions are harder to label than others because the boundaries are less apparent. Manual methods have the advantage that anything that can be seen by the human visual system can be labeled. But manual labeling is tedious, requires a lot of expertise, and can have errors due to fatigue and variation in the application of the labeling protocol. Automated methods require less human time/cost but fail on unfamiliar anatomy and need to be checked and corrected. We conclude with an argument as to why an optimal system involves interactive automation: a combination of algorithms along with manual checks and corrections.

Title: Real-time activity recognition graphical front-end display with semi-supervised labeling assistance

Authors: *I. RABKINA, L. L. NOGUEIRA, M. V. ALBERT;
Loyola Univ. Chicago, Chicago, IL

Abstract: Activity recognition is a valuable tool for both diagnosing motor impairments and measuring response to therapeutic interventions. We have developed a graphical user interface for interactively displaying activity recognition results in real-time. The system also provides off-line navigation and visualization of recorded sensor data, and assists in activity labeling using a semi-supervised machine learning approach. Traditionally, the primary means of evaluating activity recognition algorithms is through the relatively slow process of off-line analysis of pre-recorded data. The goal of this system is to provide real-time feedback to researchers and clinicians about the behavior of advanced activity recognition algorithms. Sensor readings including accelerations, torques, and magnetic field strength are collected using a wireless motion sensor worn on the waist (Shimmer3). The data is communicated via low-power Bluetooth to a client device which transmits it to a MySQL database in the cloud. If a trained activity recognition algorithm is provided, the system renders the sensor signals and inferred activity in real-time using a traditional client-side front-end architecture (JavaScript/jQuery/Flot). Using our system, data can also be labeled directly for use in training and validating recognition models. Uniquely, An iterative supervised learning approach is used to provide labeling suggestions which are updated as the user labels additional data. For this labeling, we use regularized logistic regression on a standard set of signal processing features used in activity recognition. Using the automatic labeling suggestions, real-time interactive demonstration, and off-line review, this system can help any lab streamline activity recognition algorithm training, validation, and acceptance; this can lead to better activity recognition for future personal, research, or clinical use.

Title: Crosscorrelation analysis of prewhitened human connectome resting-state fMRI data: Interhemispheric effects in pre- and post-central areas

Authors: *P. S. CHRISTOVA, A. P. GEORGOPOULOS;
Dept Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: We used public, resting-state fMRI data of the NIH Blueprint Human Connectome Project (HCP; www.humanconnectome.org) to investigate the interactions between left and right pre-and post-central areas in 10 healthy right-handed subjects (2 mm isometric spatial resolution; temporal resolution = 0.72 sec; ~2,000 vertices per area above). For that purpose, first, we prewhitened the individual fMRI time series of each vertex using a (15,1,1) ARIMA model (Christova et al., True associations between resting fMRI time series based on innovations. J Neural Eng 8:046025, 2011) to obtain practically white noise innovations (residuals). We then calculated the crosscorrelation (CC) function (±30 lags = 21.6 s) between all innovations of left/right vertices in pre- and post-central areas (~4,000,000 crosscorrelograms per subject per area). Finally, we identified the lag where the absolute maximum CC occurred, retained the signed CC value, and transformed it to z = arctanh(CC) to normalize its distribution. We found the following. In 9 out 10 subjects, the left precentral cortex exerted a negative effect on the right one, as evidenced by a highly significantly lower mean z (across 30 lags) in the Left-to-Right half of the crosscorrelogram. In contrast, the right precentral cortex exerted a positive effect on the left one, as evidenced by a highly significantly higher mean z (across 30 lags) in the Right-to-Left half of the crosscorrelogram ($p < 0.001$, for all effects, t-test). (The direction of these effects was reversed in 1 subject.) The same highly significant effects were observed for the postcentral areas. These results demonstrate orderly interhemispheric interactions between pre-and post-central cortices that point to a negative feedback mechanism, probably serving to maintain a stable equilibrium.

Title: An automated tool for parcellating human visual cortex in individual subjects based on functional imaging data

Authors: *N. C. BENSON[1], K. KAY[2], J. WINAWER[1];
[1]Dept. of Psychology, New York Univ., New York, NY; [2]Psychology, Washington Univ., Saint Louis, MO

Abstract: One of the first tasks in the analysis of many neuroimaging experiments is the parcellation of the cortical surface into functional regions of interest (ROIs) based on experimental localizers, for example the labeling of V1, V2, and V3 based on retinotopic mapping data or the identification of the fusiform face area (FFA) based on cortical responses to faces. This task is time-consuming and prone to human bias; additionally, its difficulty increases as imaging resolution increases, as localizer experiments become more complex, and in cases where ROI boundaries are highly variable between subjects. Particularly in the case of large datasets, such as the Human Connectome Project (HCP), drawing individual ROIs by hand for hundreds of subjects represents a significant expense. These difficulties often lead researchers to rely on cortically aligned group-average data to represent or define ROIs despite poor alignment in many cortical areas. In order to compare results across laboratories and across subject populations (disease vs. control, children vs. adults, etc), it is essential to have well-justified and reproducible methods for defining ROIs in individual subjects. We have automated the process of labeling individual-subject ROIs by registering localizer data to simple boundary or map models projected onto the cortical surface. Our method allows researchers to incorporate group-average data into the labeling process as a prior while also respecting the functional data from the individual subjects. Moreover, multiple ROIs can be simultaneously defined in a template and jointly fit. We demonstrate this method first by labeling areas V1-V3 in 19 subjects with retinotopic mapping data. When V1-V3 maps were automatically defined using only half of the retinotopic data, the remaining eccentricity and polar angle values were predicted with a median absolute error of 0.7° and 20.3°, respectively. We then examine the face, place, body, and object data from 494 subjects in the HCP500 working-memory experiment and quantify the accuracy of fits to individual ROIs for faces, places, bodies, and objects based on automatically labeling. The ROIs are fit to individual brains in a large dataset despite the variation in cortical activation patterns between subjects. The use of a prior from a large set of group data makes the algorithm robust to noise in the individual functional data, while at the same time, incorporating the individual data allows the researcher to capture individual variations in ROIs. The tool and source code will be made publicly available. Because the tool is automated, it facilitates reproducible computation across studies and laboratories.

Title: Intrinsic connectivity between auditory and motor networks: Is it associated with sensory suppression during overt speaking?

Authors: ***V. G. VAN DE VEN**[1], L. WALDORP[2], I. CHRISTOFFELS[3], J. VAN DEN BOSCH[4], A. WALTHER[5], M. J. NAUMER[6];
[1]Fac. of Psychology and Neuroscience, Maastricht Univ., Maastricht, Netherlands; [2]Univ. of Amsterdam, Amsterdam, Netherlands; [3]Ctr. of Expertise for Vocational Educ., 's Hertogenbosch, Netherlands; [4]Univ. of Washington, Seattle, WA; [5]Cognition and Brain Sci. Unit, Cambridge, United Kingdom; [6]Goethe Univ., Frankfurt am Main, Germany

Abstract: During speaking, auditory cortex (AC) activity may be suppressed as the result of an internal copy of motor commands that is sent to sensory areas (efference copy). Recent incidental reports of auditory-motor functional connectivity during resting states suggest that sensory-motor interactions may occur before and beyond motor planning states. It is unknown if intrinsic sensory-motor connectivity is associated with task-related sensory suppression. In this study, we investigated this issue of auditory-motor connectivity during resting states and during overt speaking in two parts. In the first part, we used bilateral AC in a seed-based analysis to assess functional connectivity in resting state FMRI data of four independent studies. We found that AC was significantly connected to supplementary motor area (SMA) and dorsal anterior cingulate cortex, medial thalamic nuclei, right inferior frontal gyrus and sensorimotor cortical areas. In the second part, we investigated FMRI timeseries of two overt speaking studies with superimposed pink noise to mask speech feedback. AC-seeded functional connectivity of the fixation periods between task blocks showed similar results to the resting state studies. We then correlated the functional connectivity coefficients of fixation in non-auditory areas to task-based sensory suppression in bilateral AC. We found that stronger AC-SMA connectivity during fixation was associated with stronger sensory suppression in AC across individuals. These findings suggest that the intrinsic functional architecture of the human brain includes ongoing auditory-motor coupling, and that this intrinsic connectivity may contribute to task-based sensory suppression.

Abstract: Deriving structural connectivity using diffusion-weighted imaging (DWI-SC) methods has become especially popular across both the basic and clinical neurosciences. However, direct empirical validation of DWI-SC derived *in vivo* with SC derived using the current "gold standard" invasive tract tracing (TT-SC) technique is lacking, and a recent study that used DWI to estimate SC in macaques *ex vivo* has suggested that the neuroimaging technique may be severely limited (Thomas et al., 2014; but see Azadbakht et al 2015). In this study, we estimated SC using DWI and directly compared it to SC derived from invasive tracer studies. DWI data were collected using a Siemens 7T scanner from two macaque monkeys under light anaesthesia. Probabilistic tractography was performed for two parcellations: a single-hemisphere parcellation matching that reported in a recent comprehensive tracer study (Markov et al., 2014), and a whole-brain parcellation with SC derived from the CoCoMac database of tracer studies (Stephan et al., 2001). When curvature thresholds were set to recommended values (~80 deg), accuracy (proportion of correctly detected connections) was high for the single-hemisphere parcellation (.745) and better than the whole-brain parcellation (.517). Consistent with previous reports on probabilistic tractography, an ROC analysis revealed high sensitivity (.895) but low specificity (.173). Sensitivity dropped with increasing tract length and decreasing tract capacity, suggesting that DWI is limited in its detection of long and small tracts. Sensitivity and specificity, however,

were optimal at lower curvature thresholds (~65 deg), and tractography results were better matched to TT-SC when the weakest one-third of DWI-SC was discarded. Importantly, the topological features of the DWI-derived network mimicked that of the TT-derived one. Node degree was highly correlated between the two networks ($r = 0.6$, $p < 0.001$), and high-degree hubs identified in the DWI network were the same as those identified in the TT network. Moreover, the community structure of the two networks was highly overlapping, suggesting that the global topology of the macaque connectome is well captured by DWI techniques. Together, these data suggest that DWI is a valuable tool for understanding large-scale structural networks.

Title: Mixed effects for large datasets

Authors: *D. M. NIELSON[1], P. B. SEDERBERG[2];
[2]Psychology, [1]Ohio State Univ., Columbus, OH

Abstract: Mixed effects models provide significant advantages in sensitivity and flexibility over typical statistical approaches to neural data analysis, but mass univariate application of mixed effects models to large neural datasets is computationally intensive. Threshold free cluster enhancement also provides a significant increase in sensitivity, but requires computationally-intensive permutation-based significance testing. Not surprisingly, the combination of mixed effects models with threshold free cluster enhancement and nonparametric permutation-based significance testing is currently completely impractical. Our mixed effects for large datasets (MELD) method combines the power of linear mixed effect regression with multivariate approaches for maximizing variance in the dimensions of interest. When evaluated on simulated data and with publically available fMRI data, MELD is more sensitive than standard techniques, such as element-wise general linear models followed by cluster correction.

Title: Man vs. machine: improving physical activity tracking in the presence of deceptive human behavior

Authors: *S. SAEB[1], K. KORDING[2], D. MOHR[3];
[2]Dept. of Physical Med. and Rehabil., [3]Dept. of Preventive Med., [1]Northwestern Univ., Chicago, IL

Abstract: Human activity tracking systems are intended to be used with normal, expected behavior. For example, tracking systems do not expect that humans will walk on their hands. As a result, people can trick activity trackers by performing any behavior that generates similar tracking results. For example, one can make a smartphone-based pedometer detect 'walking' or 'running' by simply shaking the phone with one's hands while sitting. In this study, we asked (1) to what extent users are capable of deceiving activity tracking systems, and (2) if these systems can be improved to detect deceptive behavior by using training data from intentionally deceptive behavior. To answer these questions, we asked 15 participants to try to deceive a phone-based activity classifier by making it detect 'walking' while they were seated, and making it detect 'sitting' while they were walking. The participants continuously received feedback about the detected activity, and were free to carry and move the phone in any way they preferred. If they succeeded in deceiving the classifier, we used their motion data (accelerometer and gyroscope sensors) to retrain the classifier, and asked them to challenge it again. Importantly, participants had to adapt after each retraining since the classifier learned about their previous deceptive behavior. The experiment continued until they could no longer deceive the classifier. We found that some participants were not able to deceive the classifier at all, while others succeeded in up to 5 rounds of retraining. We next asked whether a classifier trained on one individual's deceptive behavior improved the predictions of other individuals. Classifiers trained on normal activity data predicted true behavior (i.e., not the intended deception) with an accuracy of ~38%, while training on only one participant's deceptive behavior improved accuracy to ~62%. Interestingly, this improvement was not affected by whether the training samples were from a successful participant with multiple retraining sessions or unsuccessful ones with only one session. An implication of this study is that activity tracking systems can be significantly improved by including deceptive activity data from even a few individuals.

Title: The integrated pain quantification index (IPQI): a novel multi-domain index for measuring pain

Authors: *J. A. SHETAKE[1], S. LIN[2], N. MEKELBOBROV[2], J. NORTH[3], L. KAPURAL[3], M. WALLACE[4], E. GRIGSBY[5];
[1]Boston Scientific Neuromodulation, Santa Clarita, CA; [2]Boston Scientific Neuromodulation, Valencia, CA; [3]Carolinas Pain Inst. and Ctr. for Clin. Res., Salem, NC; [4]Ctr. for Pain Medicine, Univ. of California, San Diego, San diego, CA; [5]Napa Pain Inst., napa, CA

Abstract: Multi-site pain, including anatomical distribution, continuousness, and regional intensities, is a key challenge in neurostimulation treatment where pain relief depends heavily on capturing nerve fibers with highly diverse anatomical accessibility. We undertook the Multiple Areas of Pain (MAP) study to estimate the prevalence of multi-site pain in the spinal cord stimulator (SCS)-eligible pain patient population and to develop a quantitative and clinically relevant measure which captures the various aspects of multi-site pain in a single index. In this paper, we will present the methodological details of the Integrated Pain Quantification Index (IPQI), and its development and validation. The Multiple Areas of Pain (MAP) study is a multi-center epidemiological study of multi-site pain in the SCS-eligible, chronic pain patient population. The study included a total of 828 US subjects enrolled across 14 clinical sites. Patients were provided with body map drawings to capture the following 4 key dimensions of multi-site pain: distribution, continuousness, local average intensities, and local peak intensities. Each was collected at high resolution, for each one of 47 regions of the body. Principal Component Analysis (PCA) was used to assign relative weights to each component for its contribution to the index. Each subject's 47 regional IPQI scores were calculated and finally the overall IPQI score was calculated as the sum across all regions. The IPQI provides a single score ranging from 0-100, with 0 corresponding to no pain anywhere on the body and 100 corresponding to pain everywhere on the body at maximum intensities and at all times. Finally, validation assessments were collected across multiple health domains, including pain quality (McGill), disability (Oswestry, PDI), quality of life (EQ-5D-5L), depression (CES-D), anxiety (GAD-7), and productivity (WPAI:SHP), to validate the IPQI against well-established measures. The IPQI exhibited statistically robust behavior across all four of its component variables, and

can therefore be used as a single stand-in measure for all four assessments. Strong correlation was observed with multiple well-established assessments across several health-domains, validating the clinical relevance of this index. In light of the potential importance of multi-site pain for SCS patients, a comprehensive and robust measure is needed. The IPQI is a new measure that captures 4 keys dimensions of multi-site pain in a single score. This index is well-suited for characterizing the prevalence of multi-site pain in SCS patients, and is recommended as an analytical tool in future studies.

Title: Skellify: a machine learning tool for classifying depression using DTI-based white matter skeletons

Authors: J. BENOIT[1], M. BROWN[1], A. GREENSHAW[1], S. DURSUN[1], *R. RAMASUBBU[2]; [1]Univ. of Alberta, Edmonton, AB, Canada; [2]Psychiatry/Clinical Neurosciences, Univ. of Calgary, Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Background: Machine learning approaches are increasingly being used in the development of diagnostic and prognostic tools for Major Depressive Disorder (MDD). Differences in brain white matter shown by Diffusion Tensor Imaging (DTI) scans may serve as a proxy for MDD symptom severity. Here, machine learning methods were applied to DTI scans to examine the diagnostic accuracy of white matter integrity in predicting MDD symptom severity. Methods: Participants were fifty two medication-free patients with DSM-IV-defined MDD, and eighteen healthy controls. MDD patients were divided by tertile based on Hamilton Rating Scale for Depression (HRSD) scores: mild to moderate depression (HRSD 14-19, n= 16), severe depression (HRSD 20-23, n= 19), and very severe depression (HRSD ≥ 24, n= 17). DTI scans were analyzed using the TBSS (Tract-Based Spatial Statistics) modules of the FMRIB Software Library (FSL) 5.0. This allowed for creation of an alignment-invariant map of the brain's white matter. These white matter maps were then used to train a linear SVM classifier to differentiate control from MDD patient scans, and differentiate HRSD tertiles. Results: Classification of DTI data using linear SVM showed statistically significant diagnostic classification of MDD and HC (AUROC 0.67) and in two HRSD tertiles vs. controls (AUROCs: mild to moderate, 0.67; severe 0.68), and in two comparisons within HRSD tertiles (AUROCs: mild-to-moderate vs. very severe, 0.64; severe vs. very severe, 0.68). Conclusions: Using TBSS-based white matter maps, the machine learning classifier achieved statistically significant classification of two MDD severities vs controls and two MDD severity comparisons, but there was no added value in diagnostic accuracy in the classification of MDD based on severity of symptoms.

Title: Reproducibility and sensitivity analysis of MEG source current estimation

Authors: *Y. TAKEDA, D. LI, N. HIROE, M.-A. SATO, O. YAMASHITA;
ATR Neural Information Analysis Labs., Kyoto, Japan

Abstract: Source current estimation from MEG data is an ill-posed problem that requires prior assumption about brain activity. The reliability of estimated currents has been evaluated using simulated data with known true currents. For real MEG data, however, it is difficult to evaluate the reliability because true currents are unknown. Examining reproducibility across recording sessions could be a way to evaluate the reliability. However, it is not sufficient because imposing the strong prior assumption may increase the reproducibility. In this study, we propose a measure that combines the reproducibility and task sensitivity to evaluate the reliability of source currents estimated from real MEG data. For each vertex, this measure evaluates how large the difference of estimated currents across tasks is compared to the difference of estimated currents across sessions. We applied this measure to source currents estimated from MEG data during viewing motion stimuli. In two separate days, we conducted the same MEG experiment using visual motion stimuli at 0, 3.5, 7.0, 14 deg/sec. To obtain prior information about brain activity, we also conducted a fMRI experiment. From the MEG data, we estimated source currents in three ways: Variational Bayesian Multimodal EncephaloGraphy (VBMEG) with fMRI prior, VBMEG with uniform prior, and linearly constrained minimum variance (LCMV) beamformer. Our measure shows higher values for the source currents estimated by VBMEG with fMRI prior than those estimated by VBMEG with uniform prior and LCMV, indicating that using fMRI prior increase the reproducibility and sensitivity of the estimated source currents. From real MEG data, therefore, our measure confirms the validity of using fMRI prior in source current estimation.

Title: Multi-connection pattern analysis (MCPA): multivariate discriminant analysis of functional connectivity between neural populations

Authors: *Y. LI[1,3,2], A. S. GHUMAN[3,4];
[1]Ctr. for the Neural Basis of Cognition, [2]Program in Neural Computation, Carnegie Mellon Univ., Pittsburgh, PA; [3]Dept. of Neurolog. Surgery, [4]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: How neural populations and interacting neural circuits encode information is a central question in neuroscience. Pattern classification methods from modern statistics and machine learning, such as multivariate pattern analysis (MVPA), have gained popularity in recent years for decoding the information content contained in neuroimaging and multiunit data. These methods allow one to go beyond examining the involvement of a population in a particular neural process and infer the representational content of the population activity. However, current MVPA methods do not allow one to assess the discriminant information encoded in the pattern of functional connections between different neural populations. Furthermore, traditional methods for assessing functional connectivity only allow one to examine differences in the degree of coupling across conditions and not the information carried by the pattern of interregional connections. Here we propose a method termed Multi-Connection Pattern Analysis (MCPA) to extract the discriminant information about cognitive states solely from the shared activity between neural populations from two brain areas. First, canonical correlation analysis (CCA) was used to learn the transformation of the activity between two populations. A classifier was then trained based on the patterns of interaction corresponding to different cognitive conditions. Simulation results showed that MCPA could successfully detect the information contained in the functional connectivity patterns across a wide range of simulated data types covering the normal range of neuroimaging and intracranial data from a variety of modalities. We then used MCPA to analyze intracranial EEG data recorded from human occipital face area (OFA) and fusiform face area (FFA) during a visual face processing task. The results demonstrated that the interaction between OFA and FFA contained category-level information about faces in an early time window (0-200 ms after stimulus onset), and information about which face the participant was viewing in a later window (after 200 ms). The timecourse of this interaction is consistent with a previous neural decoding study based on event related potential signals within only FFA, suggesting that face categorization and recognition relies on reciprocal OFA-FFA interactions. Here we present a novel tool that uses multivariate interactions between neural populations to decode representational content contained in the coupled activity of distributed, interacting neural circuits.

Sch. of Med., St. Louis, MO; [9]Le Bonheur Children's Hosp., The Univ. of Tennessee, Memphis, TN

Abstract: The Human Connectome Project (HCP) aims at exploring and mapping consistently the anatomical and functional brain networks as well as their functional principles, their relation to behaviour and the role of the underlying genetic factors that regulate them. In the context of the HCP in the recent years, a large amount of high quality data from different modalities has been acquired. In terms of neuroimaging, Magnetic Resonance Imaging (sMRI, fMRI, DTI) has been used to study the topology of anatomical and functional connections with high-spatial resolution. Magnetoencephalography(MEG) has been used to study the dynamics of activity in and between frequency bands due to its very high temporal resolution. Most importantly this data in raw, preprocessed and processed formats is available to the whole community. In this work we present all the MEG analysis pipeline protocols and results that are disseminated to the scientific community from the HCP. In the HCP, MEG data was acquired during Resting State and 3 different Task experimental paradigms, aiming to reveal the functional networks of Motor Control, Working Memory and Language Processing. While during the Task experiments both evoked and induced activity are modulated by the characteristics of the exogenous stimulation, in the Resting State brain activity is intrinsically modulated. Accordingly, MEG data from Resting and Task experiments has different characteristics and this means that also different analysis approaches are better suited for these two types of paradigms. In both cases we investigate

connectivity in different frequency bands and in different time epochs in the source space using the preprocessed MEG data. The main connectivity metrics employed are band-limited power correlation and imaginary coherence metrics. These connectomes are produced in CIFTI format and can be handled through the Connectome Workbench, so that MEG connectomes can be related to the fMRI and DTI processed data of the HCP. In fact, the cortical sheet representation of the source space allows for comparison between different modalities by means of parcellation scheme. Pipelines released are mainly automatic and can be used to reproduce the results already released to HCP users, to process HCP data with different settings or to analyze different data. To our knowledge, this is the first time that a complete and unified set of processing tools, able to provide the user with a variety of frequency resolved MEG connectomes at different time and spatial scales, together with a large sample of already processed subjects have been delivered to the scientific community.

Title: Assessing the influence of color scales on data interpretation in neuroimaging - a comparative empirical study

Authors: ***M. CHRISTEN**[1], P. BRUGGER[3], S. I. FABRIKANT[2];
[2]Dept. of Geography, [1]Univ. of Zurich, Zurich, Switzerland; [3]Dept. of Neurol., Univ. Hosp. Zurich, Zurich, Switzerland

Abstract: Objective: The visualization of complex data routinely relies on mapping data to a color space in order to display, for example, activity changes in functional neuroimaging. However, empirical research on how the mapping of data onto color space influences data interpretation is sparse. We empirically assessed the effect of using different color scales (rainbow, heated body, color-intensity change, red-white-blue) and the influence of image background (white/black) on the interpretation of data in neuroscience (imaging brain activity from normal brains to locked-in state, minimally conscious state, vegetative state up to brain

death) and in geography (depictions of environmental sustainability models in a country that match the employed brain state descriptions). Methods: The study used a between-group-design with pair-matched subjects regarding age, gender and imaging expertise (neuroimaging experts, geo-visualization experts, lay people; n=134 per group) where one out of eight conditions per paradigm (brain state, sustainability state) has been presented randomly to a single subject using a web-based survey. Additional question assessed issues like professional experience and image production practice. Results: We hypothesized that domain experts would be least influenced by a particular color scale when interpreting the depicted data, such as determining whether an image faithfully conveys the fact that a person is brain dead. We measured interpretation variability by taking the total mean over all conditions for a single state as reference and then by determining the distribution of differences per condition and group. Contrary to our hypothesis we found that neuroimaging experts' image interpretations were more strongly influenced by changes in color scales in both the neuroscience data and geo-data conditions, compared to the other participant groups. This interpretation difference was significant for neuroscience data depictions. We also found that trust in the visualized data depends on the valence of the depicted theme, for example, whether a healthy brain or non-healthy brain state is depicted. Interestingly, data depictions representing a negative state (i.e., brain death or "ecological death") are considered significantly more trustworthy if the image background is black. Conclusions: Given the importance of neuroimages and imaging software for conveying results in neuroscience, in particular in the public discourse, the study points to the need of generating increased awareness on the potential influence of data visualization methods on data interpretation, in particular also amongst the domain experts themselves.

Title: Asymmetry of neuronal migration pathways in developing human fetal brains

Authors: *Y. MIYAZAKI[1], J. W. SONG[2], E. TAKAHASHI[3];
[1]Dept. of Neurobio., Sch. of Medicine, Chiba Univ., Chiba, Japan; [2]Dept. of Radiology, Yale Univ. Sch. of Med., New Haven, CT; [3]Div. of Newborn Medicine, Dept. of Med., Boston Children's Hospital, Harvard Med. Sch., Boston, MA

Abstract: The radial glial pathway and ganglionic eminence (GE) are two major neuronal migration streams in humans, and have been investigated by histological assessment. However, due to limitations inherent to microscopic studies, only small regions can be investigated through histological assessment alone, and little evidence is available about their three dimensional fiber pathways throughout the entire brain. Therefore, we imaged and analyzed whole human brain radial pathways and the GE structure using high angular resolution diffusion MR imaging (HARDI) tractography. In this study, we imaged ten intact fixed fetal cerebral (17 gestational weeks (GW), 18 GW, 19 GW, three 20 GW, three 21 GW and 22 GW) and eight intact *in vivo* newborn cerebral (two 30 GW, 34 GW, 35 GW and four 40 GW). We statistically compared the GE and radial pathways in the left side and the right side of the brain, as well as radial pathways in the anterior and posterior regions of the brain. Two age groups (equal or younger than 22 GW and older than 22 GW) were separately analyzed to minimize confounding factors from the difference between *ex vivo* and *in vivo* imaging. The volume of radial pathways in the left hemisphere was significantly larger than that of the right hemisphere in the specimens equal or younger than 22 GW. The volume of posterior radial pathways was also larger than that of the anterior pathways. In contrast, no significant differences were observed in ages older than 22 GW. Moreover, our study did not identify any significant differences related to GE pathways. These results suggest that the two neuronal migration pathways regress in differential manners, and the duration of radial neuronal migration varies depending on brain regions, potentially allowing regionally various amounts of excitatory and inhibitory neurons migrate along the radial pathways.

Title: Brain transfer for the analysis of cortical data

Authors: H. LOMBAERT[1], M. J. ARCARO[2], *S. KASTNER[3], N. AYACHE[1];
[1]Inria Sophia-Antipolis, Valbonne, France; [2]Princeton Neurosci. Inst., Princeton Univ., PRINCETON, NJ; [3]Ctr. for Stdy of Brain, Mind & Behav, Dept Psychol, PRINCETON, NJ

Abstract: The cerebral cortex is the largest part of the human brain and is critical for a variety of sensory, cognitive, and motor functions. Though the functional and anatomical organization of cortex are related, the complexity and variability of the folds makes comparisons across individuals challenging. Neuroimaging often requires accurate algorithms for matching cortices. Efficient mathematical frameworks are consequently sought for analyzing data on inflated cortical surfaces, and for transfering corresponding anatomical and functional maps between subjects. Standard methods typically rely on anatomical features, including sulcal depth, to drive the alignment across individuals (Fischl et al. 1999). Recent methods can align subjects based on the similarity of neural activity patterns (Conroy et al. 2013). These present approaches typically treat each task separately and can be computationally expensive, requiring several hours to process a single subject. Here, we propose Brain Transfer, a spectral shape framework that provides fast point matching with confidence regions, and transfers of functional maps, within minutes of computation. Spectral methods have the advantage of capturing the underlying intrinsic geometry of shapes. We improved over previous spectral approaches by addressing the instabilities of geometrical harmonics (Lombaert et al. 2013). The improved normalization is key to process and analyze functional data on matched cortices. More precisely, our contributions consist of (1) the optimization of a spectral transformation matrix, which combines both, surface correspondence and normalization of geometrical harmonics, and (2) a localized spectral decomposition of functional data, via focused harmonics. This spectral transfer provides a robust formulation for spectral methods and naturally handles sign changes as well as differences across Laplacian eigenvectors. The novel focused harmonics capture the essentials of the intrinsic geometrical properties in a confidence area, and form a basis for reconstructing the shape of cortical surfaces and functional maps across subjects. Thus, Brain Transfer enables the transfer of functional data across interchangeable cortical surfaces, accounts for localized confidence, and gives a new way to perform statistics on surfaces. When matching cortical surfaces based on sulcal depth, we achieve similar accuracy in a fraction of the time compared to spherical-based methods. We outperform standard spherical-based methods when matching functional data within the visual cortex.

Abstract: The formation of transient networks in response to external stimuli or as a reflection of internal cognitive processes is a hallmark of human brain function. However, in the past twenty years, task-based fMRI studies have primarily focused on signal amplitude changes or connectivity related to a few selected nodes. Shifting focus away from signal amplitudes or constraining connectivity patterns of a few selected nodes, we propose an alternative view on fMRI data analysis by considering large-scale, task-induced synchronization networks. Networks consist of nodes and edges connecting them, where nodes in our method correspond to voxels in fMRI data, and the weight of an edge between any two voxels is determined via task-induced changes in dynamic synchronization between their respective times series. Based on these definitions, we developed a new data analysis algorithm that is designed to identify time series of voxels in an fMRI image that collectively synchronize in response to a task. At the heart of our approach is the concept of spatially localized and task-induced edge density motivating us to call this algorithm "TED" (Task induced Edge Density). In short, TED identifies edges in a brain network that differentially respond in unison to a task onset and that occur in dense packs of edges with similar responses to tasks. We found TED to be a very strong marker for dynamic network formation that easily lends itself to statistical analysis using large scale statistical approaches such as the local false discovery rate (local fdr). A major advantage of TED compared to other network-based methods is that it does not require a presegmentation of the data for dimensionality reduction as it can handle large networks consisting of tens of thousands of voxels. Because its conceptual basis is task-induced synchronization it does not depend on a

hemodynamic response model. We applied TED to task-based fMRI data provided by the Human Connectome Project focusing on the motor, social recognition and working memory tasks. In all cases, TED identified several task-specific, large-scale patterns of synchronization. We conclude that the new TED method provides us with an entirely new window into the immense complexity of human brain function.

Title: Heartbeat evokes electrical potential in human insular and cingulate cortex

Authors: *H. PARK, O. BLANKE;
École Polytechnique Fédérale De Lausanne, Lausanne, Switzerland

Abstract: Neural processing associated with interoceptive signals underlies maintenance of homeostasis and also could impact cognitive functions such as emotion, memory, and perception. Neural response associated with heartbeat could be investigated by analyzing heartbeat evoked potential (HEP). HEP has been associated with heartbeat awareness ability, pain perception, empathy, and visual perception. However, two important questions are still unanswered in the HEP literature. First, there is no direct evidence showing HEP is truly 'evoked' neural activity rather than reflecting mere heart cycle related artifact such as cardiac field artifact or pulse artifact. Second, cortical and subcortical source of HEP is still unknown. Although a recent ECoG study showed HEP can be measured from the somatosensory cortex, it is missing whether HEP can be directly recorded in the alleged interoceptive cortex, such as insula and cingulate cortex. To answer these questions, we analyzed HEP using subdural strip electrodes including both insula and cingulate cortex location from 2 epileptic patients while patients were lying in the bed without any experimental task. In order to test whether HEP is truly evoked neural response, we analyzed inter-trial coherence (ITC) of HEP. On both patients, we observed transient increase of ITC at 6 Hz around 200ms after the onset of R-peak from electrodes place in the insula and cingulate cortex. Across 2 patients 35% of tested electrodes showed significant ITC increase after the onset of R-peak. Our findings represent a compelling evidence that HEP reflects truly 'evoked' neural activity, and is not an electrophysiological

artifact associated with the heart cycle related activity. Indeed the finding of transient increase of ITC selectively after the onset of R-peak indicates heartbeat evokes transient neural activity from specific brain areas. Furthermore increased ITC was mainly observed in alleged interoceptive cortex such as insula and cingulate cortex. This finding reveals that insula and cingulate cortex in humans processes neural activity associated with visceral interoceptive signals as shown in animal studies.

Title: Estimating whole brain connectivity dynamics using spectral clustering

Authors: *I. CRIBBEN;
Finance and Statistical Analysis, Alberta Sch. of Business, Edmonton, AB, Canada

Abstract: A great challenge in neuroscience is reconstructing and understanding the dynamic manner in which brain regions interact with one another in both task-based and resting-state brain imaging studies. To understand precisely how such complex brain networks evolve under varying experimental and/or behavioral conditions could have a major impact on our comprehension of the functional organization of the brain. Recently, the use of graphical models for estimating the functional connectivity or brain networks has become increasingly popular. In most functional magnetic resonance imaging (fMRI) studies, the networks between brain regions are assumed to remain fixed or static over the course of the experiment. However, there is now more evidence that the network or functional connectivity is changing over time even when the subjects are at rest. In this work, we first introduce a novel time-varying statistical method that dynamically clusters brain regions or voxels by their functional connectivity. This new method allows for situations where the number of brain regions is greater than the number of time points in the experimental time course ($n < p$). Hence, this method promises to offer deeper insight into the mechanisms of the brain as it can be used for the dynamic modelling of a very large number

of voxels or brain regions. We also propose a new nonparametric method for estimating time varying graphical structures, or networks between brain regions, that allows for both smoothly changing graphs over time and also abrupt changes in the brain network structure. The method is very flexible as there is no a priori assumption on where the changes occur. This new method has a major advantage over moving window-type methods as we do not have to choose the window length. We apply both new methods to simulated data and to a resting-state fMRI data set. For the fMRI data set, participants are instructed to rest in the scanner for 9.5 min, with the instruction to keep their eyes open for the duration of the scan. The individual time series data are bandpass-filtered and motion corrected. The voxel time courses at white-matter and CSF locations are submitted to a Principal Components Analysis and, together with the motion parameters, we use all components with an eigenvalue > 1 as independent variables in a subsequent nuisance regression. Each voxel's time series is residualized with respect to those independent variables. The residual time series images are then smoothed with an isotropic Gaussian kernel (FWHM=6mm). We apply the Automated Anatomic Atlas Labeling to the adjusted voxel-wise time series and produce time series for 116 ROIs for each subject.

Title: Some overlooked properties of cross-validated classification and the implications for hypothesis testing in life science data

Authors: *H. JAMALABADI[1,2,3], S. ALIZADEH[1,2,3], M. SCHÖNAUER[1,3,4], C. LEIBOLD[5,3], S. GAIS[1,3,4];

Abstract: Recently, multivariate pattern classification (MVPC) has come into widespread use in various neuroscience areas for decoding and hypothesis testing. However, although it is often used as a replacement of parametric statistics, its behavior is not well understood and is often used without a clear understanding of its intricacies.To investigate reliability of applying MVPC for hypothesis testing purposes, we explored the properties of cross-validated classification in low sample size, low effect size data (LSS-LES) data, which is typical in the life sciences.To describe the distribution of classification results we usedan analytical approach and simulations when systematically varying sample size, effect size, and number of cross-validation folds in a cross-validated classification scheme. For our simulations we used synthetically generated as well as real EEG data. The recorded EEG data comprises event related potentials (ERP) elicited by two kinds of visual stimuli in a visual learning task. We show that cross-validated MVPC behaves unexpectedly in LSS-LES data: correct classification rates (CCRs) are non-binomially and asymmetrically distributed in case of no or low effect size. Distributions exhibit strong skewness and a high probability for classification rates below what should be expected from chance classification. In the one-dimensional case, we analytically prove that below-chance classification rates must occur in cross-validationin LSS-LES data, because of the dependency between subsample means. The skewed distribution of classification rates has strong implications when using MVPC for hypothesis testing. It can lead to far below-chance classification rates as well as to a higher number of spuriously high CCRs than expected. In particular, below-chance outcomes must not be discarded as experimental failures or outliers, but regarded as part of the expected distribution of results. Our analyses also warrant the conclusion that CCRs do not reflect the size of the effect under investigation nor the classifier's sensitivity. We conclude that effect sizes should be reported in terms of significance levels and estimated using randomization tests. Sensitivity of the classifier should be reported in terms of statistical power. Finally, in simulations, we show that cross-validation procedures using a low number of folds, e.g. 2-fold, are generally more sensitive, i.e. have higher significance, than those obtained using a higher number of folds, even though the average CCRs are often considerably lower.

Title: Revised minimum variance beamformer weights for functional brain imaging data analysis

Abstract: Adaptive minimum variance beamformers are widely used source-localization analysis tools for functional magnetoencephalography (MEG) and electroencephalography (EEG) brain imaging data. When the target brain activity presents itself in the form of spatially localized responses, the procedure usually involves two steps. First, positions and orientations of the sources of interest are determined. Second, the filter weights are calculated and source time courses reconstructed. This last step is the focus of the current study. Despite different approaches utilized at the source localization stage, basic expressions for the weights have the same form, dictated by the minimum variance condition. These classic expressions involve covariance matrix of the measured field, which includes contributions from both the sources of interest and the noise background. In this study, we present analytical evidence that the weights used in conventional beamformer analysis could alternatively be obtained, if full covariance is replaced with the noise covariance, provided the target lead fields exactly match the lead fields of the true sources. In practice, however, localization and modeling errors are always present and certain mismatch is inevitable. We show that such mismatch results in partial suppression of the true sources because by design the beamformer tries to cancel interference to the target. To avoid this effect, the “alternative” weights constructed using the noise covariance matrix should be

used. Our analytical results demonstrate that such weights provide in many situations better reconstruction quality than the traditional ones. We further demonstrate in simulations and in human MEG measurements that alternative weights a) yield better source-level signal-noise ratio (SNR) and more accurately reconstructed waveforms b) provide more precise estimates of inter-source correlations c) decrease adverse effects of the source correlations on the beamformer performance for commonly used single-source beamformers. Most importantly, using the alternative weights comes at no additional computational cost, as the weights expressions remain essentially the same, while the scientific outcome is poised to increase by improving source-based analysis and connectivity dynamics of functional EEG and MEG data.

Title: Towards a complete volumetric assessment of the human memory circuit: Segmentation of medial temporal lobe, and subicular cortices on high-resolution 3T images

Authors: *R. S. AMARAL, JR[1,2], J. WINTERBURN[1,6], J. PRUESSNER[3], M. CHAKRAVARTY[1,2,4,5];
[1]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [2]Integrated Program in Neurosci., [3]McGill Ctr. for Studies in Aging, [4]Dept. of Psychiatry, [5]Dept. of Biomed. Engin., McGill Univ.,

Abstract: INTRODUCTION The human memory circuit begins with inputs to the perirhinal cortex (PRC), and parahippocampal cortex (PHC). Incoming information is re-routed to the entorhinal cortex (ERC) before entering the hippocampus (HC) via the perforant pathway. From the HC, white matter projections lead out of the medial temporal lobe (MTL) via the fornix to higher cortical regions. Our aim was to create a detailed, anatomically-accurate protocol for the segmentation of all MTL and subicular cortices on magnetic resonance (MR) images that would also complement our previous HC subfield and white matter atlases. METHODS T1- and T2-weighted high-resolution MR images were acquired for 5 healthy controls (mean age=37 years; 0.3 mm isotropic voxel dimensions) on a 3T GE scanner. Manual tracing was completed using MINC Display while employing a tri-planar segmentation approach. In addition, 3D reconstructions were used to aid segmentation in areas of obscurity. Given the inherent homogeneity present along the grey matter of the MTL cortices, reliable definitions based on contrast differences were relatively nonexistent. Therefore, the use of geometric borders adhering to the underlying anatomy were employed where possible. Multiple print, MR, and histological atlases, as well as existing publications outlining MTL anatomy were used in protocol development. RESULTS The present segmentation protocol identifies the PRC, ERC and PHC in their full anterior to posterior extent. The protocol also enables identification of both the presubiculum and parasubiculum and is tailored to compliment both the Winterburn et al. (2015) HC subfield atlas, and the Amaral et al. (in prep) extra-HC white matter atlas (See Figure 1 for protocol details). CONCLUSION Here we present a comprehensive and anatomically accurate protocol for the volumetric assessment of the MTL and subicular cortices. Given its close fit with the other available protocols from our group, their combined use can enable a more in-depth volumetric characterization of the memory circuit in various populations and disease states.

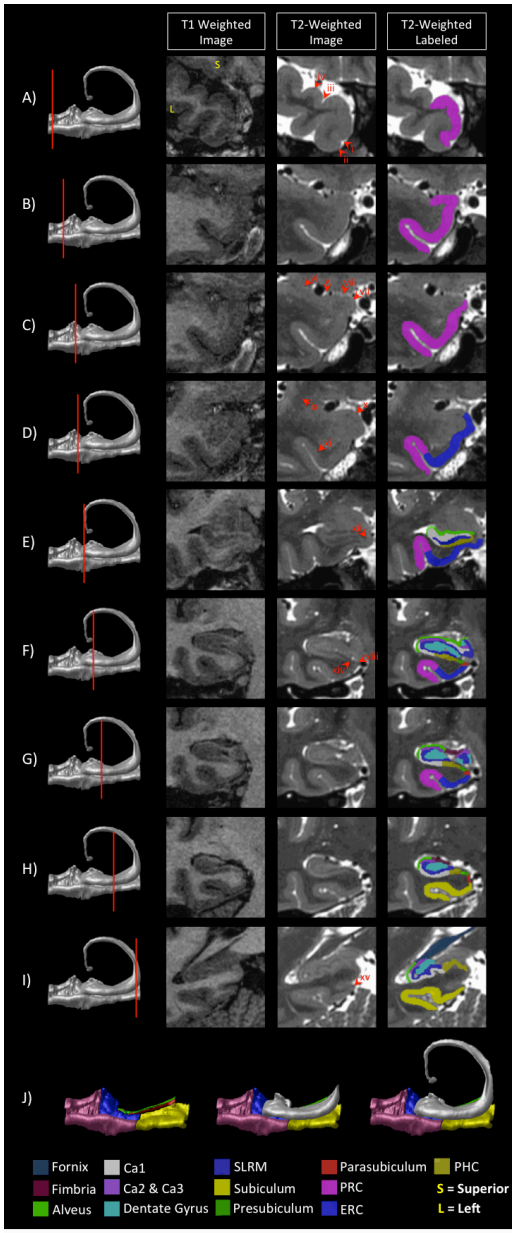

Figure 1. Sample of segmentation protocol for left medial temporal lobe (MTL) cortices. Rows A-I depict coronal sections of T1 and T2-weighted images. An additional column includes completed MTL tracings on T2-weighted images with both the Winterburn et al. (2013) subfield and Amaral et al. (in prep) hippocampal white matter atlases overlaid. 3D renderings depict the level at which each coronal slice occurs within the sagittal length of the MTL (red line). **A:** Depicts a coronal section through the anterior extremity of the MTL. Tracing of the perirhinal cortex (PRC) begins at the first slice which the collateral sulcus is visible (i). In these slices and subsequent, the inferolateral border of the PRC is the elbow of where the grey matter of the collateral sulcus comes to meet the inferotemporal cortex (ii). The hyperintense signal of the grey matter ribbon is followed superiorly until the fundus of the temporopolar sulcus (iii). The grey matter of the gyrus of Schwalbe (iv) is not included as PRC. **B:** Row depicts tracing protocol anterior sections through the MTL. The same inferomedial and superiomedial borders are maintained. At this point the fundus of the collateral sulcus typically begins to increase in depth and the temporopolar sulcus begins to stretch and subsequently takes a flattened appearance. **C:** At more posterior sections of the MTL, the limen insulae begins to form (v) as the grey matter ribbons of the planum porale and the piriform cortex begin to merge (vi). Here the the superior boundary of the PRC incudes all gray matter until the elbow of the uncus (vii) prior to the sulcus semiannularis (viii). **D:** Row depicts coronal section at the level of the frontal temporal junction (FTJ). As soon as the FTJ appears (ix) the entorhinal cortex (ERC) begins to be traced. The superior border of the ERC follows the same demarcation as the PRC in pervious slices (x). The inferior border of the ERC extends half way down to the fundus of the collateral sulcus (xi) and borders the PRC. The inferiolateral border of the PRC remains the same. **E:** Row depicts coronal sections at the level of the extreme anterior head of the hippocampus. The same inferior and superior boundaries for the PRC and ERC remain. Here, the ERC extends superiorly half way up the uncus (xii). **F:** Row depicts level of the middle hippocampal head. Once the grey matter ribbon of the ERC rises to meet the subiculum of the hippocampus the presubiculum and parasubiculum are traced. First, a line is placed at the bend of the hippocampal gyrus where the uncual sulcus opens to meet the cerebrospinal fluid of the lateral ventricle (xiii). The existing curve is intersected into two parts. The presubiculum extends superiorly half way up the bend (xiv) to reach the subiculum, while the parasubiculum extends inferiorly half way down the bend to meet the ERC. **G:** Posterior slices through the hippocampal head depicting a disappearing uncus. Moving more posteriorly, segmentation of the ERC, PRC and the pre/parasubiculum maintain the same rules. **H:** Coronal slice through the body of the hippocampus. Once the uncus disappears from the medial area adjacent to the hippocampal head, the PRC and ERC are no longer traced. Instead the entire cortex is traced as parahippocampal cortex (PHC; following the same inferiolateral and superiomedial borders as before). **I:** Coronal section through the level of the hippocampal tail. Tracing guidelines for the PHC remain the same, however, the medial extent terminates just prior to the opening of the anterior calcarine sulcus (xv). **J:** 3D reconstruction of MTL segmentation protocol product, followed by MTL atlas overlaid with Winterburn et al. (2013) subfield segmentation and Amaral et al. (in prep) hippocampal white matter atlas.

Title: Decoding continuous EEG signals during sleep using an ensemble of support vector machines

Authors: *S. ALIZADEH[1,2,3], M. SCHÖNAUER[1,3,4], H. JAMALABADI[1,2,3], S. GAIS[1,4,3]; [1]Med. Psychology and Behavioral Neurobio., [2]IMPRS for Cognitive and Systems Neurosci., Univ. of Tuebingen, Tuebingen, Germany; [3]Bernstein Ctr. for Computat. Neurosci., [4]Psychology, Ludwig-Maximilians-Universität München, München, Germany

Abstract: Recent advances in multivariate pattern classification (MVPC) methods have made it possible to investigate covert cognitive processes in continuous brain activity. These methods can help to determine whether specific information is present in electroencephalography (EEG) without requiring precise hypothesis about localization and timing of the signal, assumption of statistical normality, or arbitrary significance thresholds. In this study, we employed MVPC to see whether human sleep EEG contains any information about what has been learned before sleep. This is of particular interest because animal and human imaging studies support the hypothesis that the brain reprocesses previously learned information during sleep (Wilson and McNaughton, 1994; Peigneux et al., 2004). It should therefore be possible to distinguish between EEG recordings from nights that were preceded by different learning situations. To detect such replay activity, we had 32 subjects learn pictures either of faces or of houses before an 8-h period of nighttime sleep. Brain activity was recorded with high-density EEG during a whole night of sleep. Our goal was to determine based on electrical brain activity during sleep what type of images (face/house) participants had viewed in the previous learning session. However, the large variability of EEG recordings from different subjects, high dimensionality of the recorded data (128 channels, 1 KHz sampling rate) and low sample size (32 subjects), posed specific problems for conventional MVPC algorithms. To address these problems, we developed a stepwise classification procedure based on a chain of linear support vector machine (SVM) classifiers. The main idea was to use the spatial and temporal features in two successive stages that could serve as a feature reduction method and at the same time increase the signal-to-noise ratio. We

find significant and generalizable learning-related processing in the EEG in all sleep stages, which occurs during specific time windows (2 and 5 hours after sleep onset) and which also correlates with later recall performance. We track the reprocessing in both rapid eye movement (REM) and non-REM (NREM) sleep but its spatial distribution over the scalp and its frequency composition differ between NREM and REM sleep. Interestingly, reprocessing in both sleep stages is cyclic in nature, and may be timed to windows of maximal synaptic efficacy. We showed that it is possible to classify long continuous EEG data recorded from sleep. Our proposed algorithm not only could be used to decode the content of sleep EEG but also to localize brain spatiotemporal electrical activity during sleep.

Title: SumLog and order statistics for group-fMRI analysis

Authors: *S. PAMILO, M. SEPPÄ;
Dept. of Neurosci. and Biomed. Engin., Aalto Universtiy, Espoo, Finland

Abstract: Introduction Parametric statistical tests, traditionally used in fMRI data analysis, rely on several assumptions that might not hold, such as normality of the underlying data. Violation of the assumptions may lead to biased inferences. In contrast, non-parametric approaches, such as the permutation test, make only minimal assumptions but are often computationally more expensive. We present order statistics and SumLog, a new, computationally efficient, non-parametric method, for group-fMRI analysis. **Methods** *Order statistics and SumLog* The voxel values (e.g. correlation or general linear model beta values) are sorted within subject and replaced by their ordinal numbers, which are then transformed into standard uniform variables. For *n*th order statistics, these standard uniform values are then ordered across subjects and the *n*th largest value is picked for each voxel. For SumLog, the

standard uniform variables are log-transformed and summed over subjects for each voxel. The values in the resulting single volume can be compared against theoretical thresholds from the beta (for order statistics) or gamma (for SumLog) distribution. *Simulation* We used a simulated 2D data set to test the performance of SumLog and order statistics, and to compare them with t-test and permutation test. Each subject's data comprised a 128 x 128 pixel image with a 100-point time course for each pixel. A source with one-period sinusoid time course was located at the center of the image. Subject count, noise level, co-registration accuracy, extent of spatial smoothing, and the between-subject variance in signal strength were varied. **Results** For most of the tested parameter combinations, the receiver operating characteristics (ROC) curve of SumLog was superior to the others. In general, SumLog gave equally many or more true positives than the other methods. The performances of the t-test and permutation test decreased drastically when the location of the active area varied across subjects. SumLog was over 6 000 times faster to compute than the permutation test. **Conclusions** SumLog was more resilient to noise and variability in signal location and strength than the other methods. It performed well even without smoothing and with low number of subjects (under 20). Compared with the permutation approach, SumLog was computationally much more efficient.

Title: Reconstruction of target velocity for overt/covert visual pursuit by using cortical currents estimated from MEG data

Authors: *K.-I. MORISHIGE[1,2], N. HIROE[2], M.-A. SATO[2], M. KAWATO[3];
[1]Toyama Prefectural Univ., Toyama, Japan; [2]ATR Neural Information Analysis Labs., Kyoto, Japan; [3]ATR Brain Information Communication Res. Lab. Group, Kyoto, Japan

Abstract: The mechanism of prediction is necessary for realizing human smooth pursuit eye movements. Some cortical regions are well known for contributing to realize it, but it is not clear yet how the brain represents the spatial-temporal information for the eye movements. To answer such question, we measured MEG data during overt/covert pursuit tasks. Subjects were required to overtly or covertly pursue the target motion, that moves in the horizontal plane. Target motions were sinusoidal, and their frequencies were 0.5Hz and 0.8Hz. The cortical currents were estimated using a hierarchical Bayesian MEG inverse method (VBMEG), and investigated the spatial-temporal pattern of the currents. The measurement of MEG signals is contaminated by large magnetic artifacts stemming from eye movements, heart-beats, and so on. These artifacts can be of orders of magnitude larger than those of typical brain signals, thus making cortical current estimation extremely difficult. In order to remove the eye and heart-beat artifacts, we used extra-dipole method, which is based on hierarchical Bayesian method and simultaneously estimates the cortical and extra-brain source currents while placing dipoles not only on cortical surfaces but also on extra-brain sources. We calculated the current intensities from the estimated mean cortical currents during all tasks. The current intensities were increased in the cortical regions of the lateral occipital temporal cortex (LOTC), the intraparietal cortex (IPC), the precentral cortex (PreCC), and the medial superior frontal cortex (MSFC). These areas are related to the saccadic and smooth pursuit eye movements, and also activated when subjects orient their attention to visually target motion and pursue it covertly within their visual fields. The estimated cortical currents exhibited reasonable spatial-temporal patterns. We reconstructed the target velocities from the estimated cortical currents using a sparse regression method. Test datasets demonstrated a high similarity and an adequate fit between true and reconstructed target velocities (Pearson correlation coefficients: [overt 0.5 Hz] 0.95±0.01, [overt 0.8 Hz] 0.96±0.01, [covert 0.5 Hz] 0.87±0.06, [covert 0.8 Hz] 0.89±0.05; Goodness-of-fit: [overt 0.5 Hz] 0.76±0.07, [overt 0.8 Hz] 0.78±0.04, [covert 0.5 Hz] 0.33±0.09, [covert 0.8 Hz] 0.38±0.14), and weight values were mainly distributed on the LOTC. These results indicated that this cortical area plays a major role for realizing overt/covert pursuit tasks to represent the spatial-temporal information of the target velocities.

Title: Visualization of bicoherence for real-time signal processing and its practical application

Authors: ***K.-H. CHOI**, J. KIM, S. CHO, M. KIM, Y. SHIN, O. KWON, S.-Y. KANG, S. YEON, Y. RYU;
Korea Inst. of Oriental Med., Daejeon, Korea, Republic of

Abstract: In this thesis, a novel signal processing tool is introduced which is visualization of bicoherence. The bicoherence is a measure for quantifying the extent of phase coupling in a signal and generally utilized for analyzing electroencephalogram in depth of anesthesia area. Although the bicoherence is a powerful measurement method, it is hard for human to catch the implicit meaning of that especially in case of real-time analysis. Here we visualized the bicoherence by a color. The method is following: 1) divide frequency range into two; 2) R(red) value is taken by bicoherence of F1~F2, F1~F2 be G(green) value, and F2~F2 be B(blue) value; 3) all value is averaged and normalized. As a result, we archive colors as the number of channels. To verify the efficiency of the proposed tool, we analyzed 64 channel electroencephalogram data. The experiment was for ensuring the effects on somatic nervous system caused by the acupuncture stimulation. The analysis by tool showed a trend that the colors obtained are lowered after manual acupuncture stimulation. The physiological significance of bicoherence index is not yet clarified. However, the contribution of the proposed tool is that it help to find out the meaning visually without further complex analysis. In the foreseeable future, this tool can be utilized in various real-time signal processing fields.

Abstract: Recent studies have shown it is possible to decode cognitive states from fMRI data. Decoding cognitive states could be useful for training and therapy applications by providing information about the participant's decision-making process. To overcome the low BOLD signal-to-noise ratio in standard neuroscientific experiments, block averaging is typically employed. However, the subject is not likely to switch between cognitive states in a simple block structure during a training or therapy exercise. Instead, we treat the series of cognitive states as a hidden Markov model (HMM) with the fMRI data as the observable variables. **Methods:** The forward algorithm can efficiently determine the most likely hidden state (X_t) given the sequence of observed variables (Y_1 to Y_t) in a HMM. We present a modified forward algorithm where we calculate $P(Y_t \mid X_t)$ by applying Baye's rule to a neural network (NN) approximation of $P(X_t \mid Y_t)$ and a Gaussian approximation of $P(Y_t)$. We tested our modified forward algorithm on a block-structured stimulus design so that we could compare it with block averaging. Subjects (N = 5 ,,2 sessions each) passively viewed a realistic virtual environment with animated characters. The number of characters varied (1—6) in a 15-s block structure. 12 blocks were presented in each run, and 4—6 runs were presented in each session. Whole-brain fMRI data was collected on a 3T scanner with 2.5-mm cubic voxels and TR=2.5 s, using 2x GRAPPA acceleration. The modified forward algorithm was applied to the fMRI data to decode the number of characters. NNs were also trained on the fMRI data and block averaged data for comparison. **Results:** For all subjects and all sessions, the modified forward algorithm shows a significant increase in decoding accuracy over simple block averaging and baseline NN performance. **Discussion:** The modified forward algorithm significantly outperforms simple block averaging without imposing a block structure on the stimulus. This allows for improved decoding accuracy of cognitive states during more natural tasks and potentially during training and therapy exercises.

Title: Mapping dorsal and ventral caudate in humans

Authors: *H. HUANG[1], N. SCHWAB[2], J. JONES[2], J. TANNER[2], C. PRICE[2], M. DING[1]; [1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Dept. of Clin. & Hlth. Psychology, Univ. of Florida, Gainesville, FL

Abstract: Caudate nuclei are subcortical gray matter structures that can be divided into dorsal and ventral regions based on associated connectivity and functions. Autopsy and lesion studies suggest that the dorsal region is associated with executive functions such as working memory and reasoning, while the ventral region is implicated in moresomatic symptoms. Novel processing approaches may help to improve the mapping of caudate ventral/dorsal boundaries. The goal of this work is to examine whether resting-state fMRI data can be used to validly differentiate dorsal from ventral regions. We recorded resting state fMRI data from 56 non-demented old adults (age: 69.07±5.92 years; MMSE/MOCA: 26.07±2.68) who also completed cognitive testing for working memory (WMS-III Letter Number Sequencing, Digit Span), reasoning, pain (Brief Pain Inventory), and fatigue (BFI). To segment dorsal and ventral regions, we generated caudate voxels whole brain correlation maps. A K-means clustering analysis with K=2 yielded a dorsal caudate map and a ventral caudate map consistent with anatomically determined dorsal/ventral parcellation. We then applied functional connectivity analysis to examine the hypothesized dorsal/ventral caudate-cortex interaction patterns and expected dissociations between dorsal/ventral caudate functions by correlating caudate-cortex functional connectivity with neuropsychological test scores. Results identified dorsal caudate-cortex functional connectivity positively associated with working memory index and fluid reasoning scores, while ventral caudate-cortex functional connectivity associated with pain, fatigue severity, and anxiety. This study demonstrates the validity of fMRI methods for segmenting dorsal and ventral regions with the caudate nucleus in non-demented older adults.

Title: Attenuation correction of PET data in hybrid MR/PET scanners: Performance of CT-based versus template-based approaches

Authors: E. ROTA KOPS[1], *H. HAUTZEL[2], G. ANTOCH[3], C. LERCHE[1], H.-W. MÜLLER[4], N. J. SHAH[1];

Fac., Düsseldorf, Düsseldorf, Germany; [4]Dept. of Nuclear Med., Heinrich-Heine-University Düsseldorf, Med. Fac., Düsseldorf, Germany

Abstract: Aim: Attenuation correction (AC) of cerebral PET is a pre-requisite to achieve semi-quantitative or quantitative data. In PET/CT scanners the CT data are used for this purpose. However, AC in hybrid MR/PET scanners remains challenging. One way to overcome this are template-based attenuation maps (AMTmpl) derived by PET transmission scans using rotating 68-Ge/68-Ga sources. Here, we aim to compare the template-based and CT-based AC methods and the impact of these different methods on reconstructed PET images of the brain. Methods: 11 subjects underwent 18FDG MR/PET imaging and a whole head CT scan at the same day. The CT images were transformed to CT-based attenuation maps and filtered with 3 mm (AMCT3mm; resembling MR/PET resolution) and 9 mm (AMCT9mm; resembling AMTmpl resolution) filter width. The AMCT3mm served as reference. Comparisons between the attenuation maps were performed by using Dice coefficients D and by calculating true positive, true negative and false negative voxels. The 18FDG MR/PET emission data were reconstructed with the three AMs, then scaled to standardized uptake values (SUVs) and normalized to the MNI brain for using the AAL-VOI Atlas analysis. Correlation plots with regression equation, coefficients of determination R2 and relative differences (RD) between AMCT3mm and the other two AMs were derived. Results: As compared to AMCT3mm 91.8±2.4 % voxels were true positive for AMCT9mm (Dbone 0.82±0.04; Dsoft tissue 0.94±0.02; Dair 0.95±0.00) and 79.2±7.5 % for AMTmpl (Dbone 0.63±0.08; Dsoft tissue 0.83±0.08 and Dair 0.79±0.04). A misclassification of bone as soft tissue and vice versa was evident in both comparisons. The correlation plots of all VOIs in all patients revealed an R2mean of 0.992 for AMCT9mm and an R2mean of 0.964 for AMTmpl. For AMCT9mm an RDmean of 1.33±0.95 % (min=-0.12 %, max=2.85 %) and for AMTmpl an RDmean of 0.32±2.89 % (min=-4.74 %, max=5.43 %) were found. Conclusions: The template-based AC method shows considerable differences in comparison to the higher resolution CT-based AM with respect to the Dice coefficients, in particular in the classification of bone and soft tissue. While the resulting overall difference after

reconstruction of the 18FDG PET data remains small in some VOIs SUVs were under- or overestimated up to 5%.

Title: Information theory reveals neural correlates of predictions - a magnetoencephalography study

Authors: *A. BRODSKI[1], I. ÖZDEMIR[1], G.-F. PAASCH[1], J. LIZIER[2], M. WIBRAL[1]; [1]Goethe Univ., Frankfurt Am Main, Germany; [2]The Univ. of Sydney, Sydney, Australia

Abstract: The theory that “predictive coding” is a fundamental functional principle of the brain has become increasingly popular in neuroscience. It suggests that the brain exploits information from context and memory for generating predictions in order to anticipate the incoming sensory evidence. Although this concept has been strengthened in many theoretical studies during the last decade, neurophysiological evidence for prediction signals in the brain remains rare. This is closely related to the fact that associating neural signals with prediction signals has not been easily possible. To solve this problem we suggest to identify prediction signals based on their predictability: Typically, predictions have to be maintained as the brain will not know when they are needed. If content is maintained and if there is a neural coding of this content then maintenance of predictions means that at least some property of the past signal should also predict the future signal. This predictability can be measured by an information-theoretic measure called active information storage (AIS), which quantifies the amount of stored information used for computation of the next processing step. We tested the ability of AIS to identify brain signals that are more predictable under specific task instructions. For this purpose subjects were presented with degraded pictures of faces and houses combined with task instructions alternating in 7 min blocks ("face or not?” or “house or not?”) in a discrimination

task during MEG recordings. This aimed at inducing predictions maintained for several minutes at distinct brain areas, supposed to be represented in more predictable brain signals for face or house instructions, respectively. We analysed 478 potential brain areas of 42 subjects in the prestimulus interval of the discrimination task and found higher AIS values in the inferior temporal gyrus/FFA and V1 when subjects maintained face information in memory. Thus, we demonstrate that the instruction to detect faces leads to higher AIS values in well-known face processing areas in the brain. This is in line with the assumption that face predictions are maintained in these areas. Spectral analysis at the identified brain areas revealed increased power in the beta frequency band when subjects were instructed to identify faces. Notably, beta frequencies have been linked to the representation of predictions in recent neurophysiological accounts of predictive coding. Thus, our results not only strongly indicate that AIS is an useful tool to analyse predictions in the brain, they also provide evidence for the assumption that neural activity in beta frequencies is related to the maintenance of predictions.
