Abstract: Autism spectrum disorders (ASDs), a group of debilitating neurodevelopmental disorders, currently affect 1% of the world population. The number of children affected by an ASD has grown at an alarming rate, with a current U.S. diagnosis of 1 in 45 births. Despite this, no cure exists. Epidemiological studies report an association between maternal infection and development of ASD in children, regardless of the pathogenic species. ASD patients and genetic animal models show immune dysfunction and abnormalities in the numbers and morphology of microglia, the brain's innate immune cells that are critical for normal neurodevelopment. However, the precise changes in microglial homeostatic functions and their effects on neuropathophysiology remain unknown. We hypothesize that maternal immune activation (MIA) abnormally programs fetal microglia, thereby impairing their neurogenic and pruning functions and leading to detrimental effects on brain connectivity thought to be responsible for cognitive and behavioral deficits in ASD. We performed longitudinal behavioral, morphological and neurophysiological evaluations and microglial RNA-expression profiling studies of an MIA mouse model using the innate immunity ligand polyinosinic:polycytidylic acid. MIA offspring displayed core symptoms of ASD (social/communication deficits; repetitive and hyperactive behaviors). Microglia in MIA adult offspring displayed alterations in specific homeostatic genes, sustained impairment of pruning-related dendritic spine interactions, and increased distal branching complexity, which were associated with increased spine density and neuronal hyper-

excitability in prefrontal layer V cortical neurons. Postnatal pharmacological microglia replenishment using a specific colony stimulating factor -1 (CSF1)-receptor inhibitor corrected repetitive behavior and social interaction deficits, and reduced neuronal excitability in the MIA cohort. However, only a portion of genes was normalized in replenished microglia 18 days after depletion. These data describe specific microglial gene expression and morphological aberrations resulting from insults during embryonic development, and their restoration by postnatal microglia replenishment. This suggests that targeting specific microglial genes may be a viable therapeutic approach for pharmacological intervention in ASD.

Title: A comparison of microglial distribution in embryonic primate and rodent using multiple immunofluorescence histochemistry

Authors: ***N. BARGER**[1], C. WEIDENTHALER[2], S. C. NOCTOR[2];
[1]Univ. of California, Davis - MIND Inst., Sacramento, CA; [2]Univ. of California, Davis, Davis, CA

Abstract: Microglia, the resident immune cells of the nervous system, have recently become recognized for their participation in normal developmental processes in addition to their traditional immune functions. We have previously shown that manipulating microglial numbers impacts embryonic neurodevelopmental programs in mammals, indicating that they regulate critical aspects of neurodevelopment. We have also found evidence of similar function in a broad array of mammals, suggesting that these functions are conserved. However, the distribution of microglia in the developing cortex is not uniform across species. We have noted that microglial distribution in macaque monkeys at mid-gestation is more heterogeneous than in rats at a similar stage of development. We will present data that augment our prior findings by systematically assessing microglial distribution throughout the rostrocaudal extent of the developing cortex in cross-sectional profiles of prenatal rhesus macaques and Sprague Dawley rats, targeting a longer

developmental period. We have developed a multiple immunofluorescence staining protocol that allows for the visualization of microglial distribution, with antibodies to Iba1, relative to markers commonly used to differentiate the ventricular from the subventricular zone, Pax6 and Tbr2, respectively. We labeled tissue from multiple rostrocaudal levels in prenatal macaque neocortex and in rats from embryonic days 15-21. Species differences in distribution of microglia are assessed using confocal and wide-field florescence microscopy. Addressing variation across species in this way can provide novel translational information important for developing experimental models of neurodevelopmental disorders.

Title: Infiltrating monocytes promote brain inflammation, contribute to breakdown of the blood-brain barrier, and exacerbate neuronal damage after status epilepticus

Authors: ***N. H. VARVEL**[1], J. NEHER[2], A. BOSCH[2], W. WANG[1], R. RANSOHOFF[3], R. MILLER[4], R. DINGLEDINE[1];

Abstract: The generalized seizures of status epilepticus (SE) induce a succession of molecular and cellular events producing cognitive deficits and can culminate in the development of epilepsy. Known early events include opening of the blood brain barrier and astrocytosis accompanied by activation of brain-resident microglia. Whereas circulating monocytes do not

infiltrate the healthy CNS, monocytes can enter the brain in response to injury and contribute to the neuroimmune response. We examined the cellular components of innate immune inflammation in the days following pilocarpine SE by discriminating microglia versus brain-infiltrating monocytes. CCR2+ monocytes invade brain tissue between one and three days after SE. The initial cellular sources of the chemokine CCL2, a ligand for CCR2, included perivascular macrophages and microglia. *Ccr2* knockout mice displayed reduced monocyte recruitment into brain and decreased hippocampal induction of the pro-inflammatory cytokine IL-1β after SE, but the induction of IL-6, TNFα, CCL2, and iNOS was not different between *Ccr2* sufficient and knockout animals. Surprisingly, the induction of the pro-inflammatory cytokine IL-1β was greater in FACS-isolated microglia (referenced to microglia in saline-treated control mice) than in brain-invading monocytes (referenced to blood monocytes from saline-treated control mice), when assessed four days after SE. Importantly, preventing monocyte recruitment accelerated weight regain, attenuated neuronal damage in the hippocampus, and reduced blood-brain barrier leakage as assessed four days after SE by serum-derived albumin in the cortex. Our findings identify brain-infiltrating monocytes as a myeloid cell subclass that contributes to neuroinflammation, deterioration of the blood-brain barrier, and morbidity after SE. Inhibiting brain invasion of CCR2+ monocytes could represent a viable method for alleviating several deleterious consequences of SE.

Abstract: Microglia are innate immune cells of the brain. We have studied a subpopulation of microglia, called satellite microglia. This cell type is defined by a close morphological soma-to-soma association with a neuron, indicative of a direct functional interaction. Indeed, ultrastructural analysis revealed closely attached plasma membranes of satellite microglia and neurons. However, we found no apparent morphological specializations of the contact and biocytin injection into satellite microglia showed no dye-coupling with the apposed neuron or any other cell. Likewise, evoked local field potentials or action potentials and postsynaptic potentials of the associated neuron did not lead to any transmembrane currents or non-capacitive changes in the membrane potential of the satellite microglia in the cortex and hippocampus. Both satellite and non-satellite microglia, however, showed spontaneous transient membrane depolarizations which were not correlated with neuronal activity. These events could be divided into fast-rising and slow-rising depolarisations, which showed different characteristics in satellite and non-satellite microglia. Fast-rising and slow-rising potentials differed with regard to voltage dependence. The frequency of these events was not affected by the application of tetrodotoxin, but the fast-rising event frequency decreased after application of GABA. We conclude that microglia show spontaneous electrical activity that is uncorrelated with the activity of adjacent neurons.

Title: Functional investigation of microglia involvement in the maturation of synapses during postnatal development of the somatosensory neocortex

Authors: *C.-A. M. MOSSER;
INSERM U1128, Paris, France

Abstract: Microglial cells, the only immune cells permanently residing in the central nervous system (CNS), have been classically studied in pathological contexts. However, recent evidence revealed that these cells also actively participate to the normal CNS development by regulating developmental apoptosis, neuronal survival, and by pruning inappropriate synapses. Moreover, we previously demonstrated that reciprocal interactions between neurons and microglia are essential for functional maturation of thalamocortical excitatory synapses. During the first postnatal week, microglial cells are recruited at sites of maturating synapses in the mouse somatosensory barrel cortex by a mechanism involving the neuronal chemokine fractalkine and its microglial receptor CX3CR1. Furthermore, CX3CR1 deficiency affects the functional maturation of postsynaptic glutamate receptors at excitatory thalamocortical synapses. Besides the increasingly investigated interactions between microglia and developing excitatory synapses, little is known on the role of these immune cells on the maturation of inhibitory synapses**.** We therefore aimed at investigating whether microglial cells influence the functional development of inhibitory synapses in the somatosensory cortex. Using patch-clamp recordings of layer IV neurons of the barrel cortex, we first compared the evolution of spontaneous (sIPSCs) and miniature (mIPSCs) inhibitory postsynaptic currents in wild type (WT) and CX3CR1 deficient (KO) mice from P5 to P12. We observed that the frequency of sIPSCs and mIPSCs increased similarly in WT and CX3CR1 KO mice during this developmental window. There was no difference either in the mean amplitude of sIPSCs and of mIPSCs between WT and CX3CR1 KO mice. However, the amplitude distribution of sIPSCs, but not that of mIPSCs, differed between the two genotypes. In addition, the decay time constant of mIPSCs was significantly slower in CX3CR1 KO than in WT mice and this difference was already observed as early as P5 when the first IPSCs could be recorded. These results suggest that CX3CR1 deficiency impairs the functional expression of synaptic $GABA_A$ receptors at very early stages of synaptogenesis. To further explore the roles of microglia in the maturation of cortical inhibitory synaptic networks, we currently investigate the consequences of depleting microglia at early postnatal days as well as those of activating these immune cells during embryonic development.

Abstract: Microglia, the resident macrophages of the central nervous system, continuously sense their environment to control brain homeostasis in physiological conditions and are able to quickly adapt to inflammation and injury. These cells colonize the brain during early embryonic development and persist throughout life. While much is known about microglia physiology in the adult, we still have limited information on the developmental phases and factors that regulate their differentiation during brain development. Here, we used transcriptomic analyses to delineate specific stages of microglia differentiation during embryogenesis and early life. We identified and validated embryonic microglia markers that are up-regulated during this developmental time period and potentially mediate specific functions in brain wiring. In spite of showing specific profiles, embryonic microglia expressed the main components of its "sensome" very early on. Consistently, embryonic microglia was affected by the absence of microbiota in germ free (GF) animals. Indeed, while brain patterning and morphogenesis were not affected in embryonic GF animals, microglia density in the neocortex, the preoptic area and the striatum was increased with altered morphology. By comparing control and GF embryonic microglia, we highlighted pathways dysregulated by the absence of microbiota (*i.e.* nurture) as compared to those that are not changed in GF animals (*i.e.* nature). Our study reveals that from embryonic stage to later on, microglia follows discrete developmental steps coordinated by intrinsic developmental programs and microbiota-derived environmental signals.

Title: Sex differences in microglial and fast-spiking interneuron maturation in mice and in human disease

Authors: *R. HANAMSAGAR[1], M. ALTER[2], C. BLOCK[3], H. SULLIVAN[3], J. BOLTON[4], S. BILBO[1];
[1]Duke Univ. Med. Ctr., Durham, NC; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Duke Univ., Durham, NC; [4]Univ. of California, Irvine, Irvine, CA

Abstract: Many neurological disorders have a clear sex difference associated with their incidence or outcome such as autism, depression and schizophrenia. Several of these diseases also have a major immune-component associated with their pathophysiology, including over activation of microglia (MG). MG are increasingly implicated in normal brain development and are involved in functions such as cytokine release and synaptic pruning. Furthermore, MG modulate fast-spiking (FS) interneuron maturation and migration during normal development. FS interneurons, specifically those that express the maturation marker parvalbumin (PV), are critical for synaptic inhibition; any disruptions in the development or migration of this population are implicated in several neuropsychiatric disorders including autism. Hence, changes in MG maturation could potentially impact neuronal migration and connectivity, resulting in increased susceptibility to development of neurological disorders. However, little is known about how MG impact specific populations of neurons during development, in health or disease, or if there are sex differences in these processes. We performed whole transcriptome analysis on MG isolated from hippocampus of male and female mice at different developmental time points, calculated maturity indices (IDX) based on global gene expression patterns and found that not only does MG maturity increase with development, there is a striking sex difference in this IDX - adult female MG are more mature than male MG at baseline. When IDX was quantified for mouse fast-spiking (FS) interneurons using transcriptome datasets obtained from publically available literature, it was found that FS-interneuron maturation also increases with development. Interestingly, when the indices were applied to datasets obtained from human clinical studies such as Alzheimer's disease and Autism, it was found that in the diseased state, the relationship between MG maturity and FS-interneuron cell maturity displayed a steep inverse slope that was significantly different from the controls. This suggests that increased MG maturation, that takes place during diseased state, can result in exacerbated decrease in FS-interneuron maturity.

Similarly, systemic injection of lipopolysaccharide in mice accelerated transcriptional maturity in male but not female MG, and inverted the association with PV expression as seen in human disease. These data suggest that males may be more vulnerable to developmental disorders such as autism based on sex differences in microglial maturation and its impact on FS cell development in response to immune activation.

Title: Microglia and astroglia phenotype in a neuron specific - A_{2A} receptor overexpression model with age-like alterations.

Authors: ***J. E. COELHO**[1], I. MARQUES-MORGADO[1], M. BADER[2], D. BLUM[3], L. V. LOPES[1];
[1]Faculdade de Medicina da Univ. de Lisboa, Inst. De Medicina Mol., Lisbon, Portugal; [2]Max-Delbrück-Center for Mol. Med., Berlin, Germany; [3]Alzheimer & Tauopathies, Inserm URM-S1172, Univ. de Lille, Lille, France

Abstract: Upregulation of A_{2A} receptors in hippocampal and cortical brain regions is a common feature following brain insult and in Alzheimer's disease (AD). Previous work in our lab has shown this effect is accompanied by memory and synaptic plasticity impairment and structural changes, namely dendritic retraction (Batalha et al., 2013, Mol. Psychiatry). Little is known on the mechanism involved in this $A_{2A}R$ upsurge, although various studies suggest that this upregulation is an early-aging phenotype and may be instrumental in driving neurodegeneration. To address this issue we have generated a transgenic rat model with a postnatal neuronal-specific overexpression of human $A_{2A}R$ under the control of the CaMKII promoter [Tg(CAMKII-$hA_{2A}R$)]. These animals display age-like alterations in hippocampal function, with cognitive, synaptic and molecular impairments that are reversed upon $A_{2A}R$ blockade. (Batalha et al., 2013, Mol. Psychiatry; Temido-Ferreira et al., 2015, SFN). The aim of the present work was to clarify and characterize the phenotype of microglia and astroglia in these animals to evaluate the involvement of different cellular subsets in the $A_{2A}R$ neuronal dysregulation. We assessed glial

density, reactivity and morphology in Tg(CaMKII-hA_{2A}R) as compared to WT littermates. Along with a significant increase of the microglial marker Iba1 in the hippocampus (n=7; $P<0.05$), we found significant morphological differences in microglial cells of CA1 area of the hippocampus of transgenic animals: a decrease in the area of cellular influence; process retraction and acquisition of a more elongated cellular shape (n=2-3; $P<0.05$). The total number of microglia cells did not differ between WT and Tg animals. A significant decrease in GFAP protein was found in the hippocampus of Tg animals (n=7; $P<0.05$), which did not correlate with morphological changes neither in the length nor branching of astrocytic processes in CA1 area. These data reveal that A_{2A}R overexpression in forebrain neurons is sufficient to drive significant changes in glial cell function, inducing a primed state of microglia - triggering morphological alterations that resemble early states of activation process - and an asthenic phenotype of astrocytes. This suggests that the pathological process of A_{2A}R dysregulation derives from a synergy of synaptic and glial dysfunction, mimicking features of hippocampal aging. **Funding**: FCT- PTDC/BIM-MEC/4778/2014; LVL is an Investigator FCT, JEC is an FCT fellow (SFRH/BPD/87647/2012).

Title: The role of microglia and their CX3CR1 signaling in olfactory bulb neurogenesis

Authors: *R. RESHEF[1], E. KUDRAYAVISTKAYA[2], H. SHANI[2], N. RIMMERMAN[1], A. MIZRAHI[2], R. YIRMIYA[1];
[1]Dept. of Psychology, The Hebrew Univ., Jerusalem, Israel; [2]Dept. of Neurobiology, The Hebrew Univ., Jerusalem, Israel

Abstract: Microglia are known to play important roles in brain development and plasticity, but their roles in development and maturation of synapses on adult-born neurons remains unknown. To elucidate the role of microglia in neurogenesis, we labeled newborn granule neurons (GNs)

migrating to the olfactory bulb (OB) in microglia-depleted mice (induced by CSF-1 receptor inhibition) and CX3CR1 deficient ($CX3CR1^{-/-}$) mice, by injecting a tdTomato-expressing lentivirus. 28 days later we imaged infected maturing OB GNs using 2-photon microscopy, followed by immunohistochemical examination of their spine density and size. Our data shows that microglia-depleted and $CX3CR1^{-/-}$ mice had a significant reduction in spine density. Moreover, $CX3CR1^{-/-}$ mice had smaller spine heads. Time-lapse data indicated that microglia depletion and CX3CR1 deficiency caused stabilization of synaptic turnover in maturing GNs, as fewer dendritic spines were formed and lost over 24h. These morphological changes were found to have functional significance as *in vivo* calcium imaging showed enhanced responses to odors of mitral cells, which are normally inhibited by GNs. RNA-Seq analysis indicated that the morphological changes in the two experimental models were associated with different molecular mechanisms, including the complement and cytokines transcriptional programs in microglial depletion, and MHC-I, wnt and interferon transcriptional programs in CX3CR1 deficiency. Our findings indicate that microglia are involved in normal development, maturation and plasticity of adult-born OB neurons, with functional implications to the OB output.

Title: Sex differences in microglia number and activation in the developing rat brain

Authors: *A. TURANO, J. LAWRENCE, J. SCHWARZ;
Univ. of Delaware, Newark, DE

Abstract: Microglia are the resident immune cells of the brain. During development, microglial progenitor cells migrate and infiltrate into the nervous system from the periphery. This period of migration and infiltration is critical to the maturation of the developing brain. Microglia in the developing brain are quite distinct from microglia in the adult brain as they have a round, amoeboid shape with short, thick processes and they produce elevated levels of cytokines and chemokines imperative for many processes of normal brain development. Activation of microglia in the developing brain, via neonatal infection or immune activation, can often lead to

long-term neuronal and cognitive dysfunction. Furthermore, microglial activation is associated with multiple neurodevelopmental disorders including autism, ADHD, schizophrenia, and cerebral palsy - disorders also known or suspected to have immune etiologies. All of these disorders exhibit a strong sex bias in males. We have previously seen that male rats have significantly more microglia in the developing hippocampus, cortex and amygdala than female rats on postnatal day 4 (P4) (Schwarz et al. J. Neurochem., 2012). It is possible that this difference is mediated by the surge of testosterone occurring in males during masculinization of the brain (Lenz et al. J. Neurosci., 2013). More so, females do not show the same vulnerability that males show to infection at P4 (Bilbo et al. J. Neuroimmune Pharmacol., 2011). Given these rodent data and well-known human epidemiological data, we hypothesize that male rat pups will be more vulnerable to an immune challenge during the critical period in which microglia are infiltrating the nervous system. To test this hypothesis, we treated male and female rat pups with a mild *E.coli* infection on P4 and observed the presence of activated microglia in the developing hippocampus. Also, using an *in vitro* method, we treated isolated sex-specific microglia cultures from the hippocampus of male and female rat pups with a mild lipopolysaccharide (LPS) challenge on P4 and examined whether immature microglial cells exhibit a sex-specific response to immune activation. Lastly, sex-specific microglia cultures from the hippocampus of male and female rat pups were treated with testosterone on P0 and P1 and then treated with LPS on P4. Cultures were analyzed for inflammatory gene expression to determine whether immature microglial cells exhibit a sex-specific response to immune activation and whether this is mediated by the early surge in testosterone that occurs around birth. Title: The distinct effects of prenatal stress on microglia morphologies in adult and embryonic brain and mediation by interleukin 6

Authors: *S. B. GUMUSOGLU[1,3], R. S. FINE[3], S. J. MURRAY[3], M. E. DAILEY[2], H. E. STEVENS[4,3];
[2]Dept. of Biol. Sci., [1]Univ. of Iowa, Iowa City, IA; [3]Yale Child Study Ctr., Yale Univ., New Haven, CT; [4]Univ. of Iowa Carver Col. of Med., Iowa City, IA

Abstract: Background: Microglia are widely understood as the brain's immune cells, responsible for pathogenic defense but also other functions including regulation of synapses and progenitor number. Like other cells in the brain, microglia function may be developmentally regulated. Microglia can also be functionally altered in circumstances of infection and/or stress. Prenatal stress (PS) occurs very early in development and can increase offspring risk for altered neurodevelopmental and psychiatric phenotypes. Microglia may play a dynamic role in the persistent effects of PS across neurodevelopment. Here, we sought to elucidate the effects of PS on microglia in the prenatal and postnatal brain. By targeting one potential mediator of PS effects, maternal interleukin 6 (IL-6), we found that distinct microglia changes in embryonic and adult brain after PS may in fact be linked. A better understanding of stress-induced microglial changes across neurodevelopment may elucidate mechanisms for prevention and intervention in psychiatric disorders.
Method: CD-1 mouse dams were either maintained as controls or restraint stressed three times daily. Some dams were also injected IP with anti-IL-6 neutralizing antibody or vehicle 15-20 minutes before restraint for the last week of gestation. Offspring cortices were analyzed for microglia density and morphology along a spectrum at embryonic day 14 (E14) or at postnatal day 90 (P90). A third cohort of control dams received IL-6 injections three times daily with offspring examined at E14. Microglia morphology in embryonic brain explants were also examined via live confocal microscopy.
Results: While adult microglia displayed more ramified features across the microglia morphological spectrum, embryonic microglia occupied only its most amoeboid end. PS offspring showed increased densities of ramified microglia at P90 but, surprisingly, also showed increased densities of multivacuolated, amoeboid-like microglia at E14. PS effects on microglia appeared to be in part mediated by IL-6:IL-6 provoked the same changes at E14, and anti-IL-6 prevented morphological changes at both E14 and P90. Live imaging microscopy confirmed the presence of a dynamic microglia morphological spectrum at E14, as microglia shift from more ramified (i.e. multiple spines) to less ramified, before becoming amoeboid or multivacuolated.
Conclusions: These findings suggest that PS exposure, perhaps through IL-6 mechanisms, disrupts the normal developmental trajectory of microglia in the brain. Furthermore, pre- and post-natal microglia may serve different roles, particularly in response to stress, as evidenced by distinct morphologies.

Title: Use of multiple sub-threshold glutamate stimuli to monitor brain cell calcium dynamics in cultures with decreasing microgial and astrocyte content

Authors: *K. C. ST MARTHE[1], C. N. POOLE[1], M. GRAGSTON[2], N. NGUYEN[1], T. PIEHLER[3], L. PIEHLER[3], M. A. DECOSTER[1];
[1]Biomed. Engin., Louisiana Tech. Univ., Ruston, LA; [2]Mechanical Engin., Univ. of Tennessee, Knoxville, TN; [3]US Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: Recent work identifies astrocytes and microglia as active elements of the brain, maintaining numerous homeostatic functions. Disturbances in these functions result in development of neuropathologies, including effects in neuroinflammation, traumatic brain injury, and different stages of brain tumors. Astrocytes and microglia in the central nervous system (CNS) contribute to homeostasis for dynamic second messengers in the CNS, including intracellular calcium concentration ($[Ca^{2+}]_i$). We hypothesized that altering glial density in primary rat cortical brain cell cultures could shape network $[Ca^{2+}]_i$ responses after multiple stimuli with subthreshold (nM), concentrations of the neurotransmitter glutamate (GLU). We used antimitotic agents, 10 micromolar (uM) cytosine arabinoside, or 5-fluorodeoxyuridine (FdU) at 1-4 uM, to inhibit proliferating glia. After developing for 14-21 days in vitro to establish network connections and to modify glial content with antimitotics, cells were stimulated with 250, 500, and/or 750 nM GLU and $[Ca^{2+}]_i$ dynamics measured using digital imaging microscopy with the fluorescent Ca^{2+} indicator fluo3-AM. GLU stimuli were determined to be subthreshold and non-toxic, since once added, GLU was not washed from the culture well, and $[Ca^{2+}]_i$ returned back to baseline levels. For both AraC and FdU, responses to multiple GLU stimuli were consistent: cultures high in glia (no antimitotics), resulted in transient, non-synchronized $[Ca^{2+}]_i$ dynamics after GLU stimuli. In contrast, cultures depleted of glia showed synchronized, more sustained $[Ca^{2+}]_i$ elevations. Quantum dot- and 2 micron fluorescent bead- uptake was used to identify phagocytic microglia, the expression marker glial fibrillary acidic protein used for astrocytes, and microtubule-associated protein-2 used for neurons. Since Hui et al. (2016) have recently described the importance of FdU concentration in

mediating the effects of neuroinflammation by altering glial content in cultures, we varied the concentration of FdU in our studies using 1, 2, or 4 uM before GLU stimulus. Our results support the hypothesis of a tight concentration gradient for effective FdU treatment, as our most dynamic $[Ca^{2+}]_i$ results after GLU stimulus occurred after 1 uM FdU, which along with controls, had 8-fold higher bead uptake than 2 and 4 uM FdU conditions. Higher concentrations of FdU (2 or 4 uM) resulted in overall decreases in all cellular responses to GLU stimulus, although a variety of cell morphologies were intact. Thus $[Ca^{2+}]_i$ network dynamics can be shaped by controlling glial cell density, revealing information processing by the system in response to multiple GLU stimuli.

Title: Role of the complement receptor C3aR in excitotoxicity-induced neuropathology

Authors: *H. LIAN[1], X. LI[2];
[1]Zhejiang Univ. Sch. of Med., Zhejiang, China; [2]Zhejiang Univ. Sch. of Med., Hangzhou, China

Abstract: Excitotoxicity participates in the pathology development of many neurological diseases. Inflammation caused by glial activation is now recognized not only as a consequence but also a contributor to excitotoxicity-induced neuropathology. Complement system is an essential conservative inflammation-regulatory pathway activated in patient brains of many neurological diseases. As an important downstream receptor for complement activation, C3aR has been shown to regulate synaptic function and neuronal excitability. By using pharmacological and genetic manipulation of C3aR activity in vivo and in vitro, we'll dissect out how complement signaling through C3aR activation mediates pathophysiology caused by excitotoxicity.

Title: Role of anti-oxidant supplementation on developing cerebellum of rats exposed to sodium arsenite ($NaAsO_2$)

Authors: *P. DHAR[1], P. KUMAR[2], P. KAUSHAL[2];
[2]Anat., [1]All India Inst. of Med. Sci., New Delhi, India

Abstract: Background:
Millions of people across the globe are exposed to inorganic arsenic (*iAs*). Ground water contaminated with *iAs* and soil dust are the major environmental sources of exposure to *iAs*. Higher incidence of cancer has been reported in exposed populations. Gestational and early postnatal exposure to *iAs* in animal models has been associated with structural and functional alterations. Oxidative stress has been suggested as one of the important factors underlying *iAs* induced adverse effects.
Aim: To determine the role of anti-oxidant supplementation on rat cerebellum following sodium arsenite ($NaAsO_2$) exposure during early postnatal period.
Methods:
Pregnant Wistar rats (18-19 days gestation) were housed under controlled laboratory conditions. The day of delivery of pups was considered as postnatal day zero (PND 0). The pups from different litter groups were randomly assigned to control and experimental groups such as normal controls and vehicle controls (receiving distilled water, ethanol and (DMSO), *iAs* ($NaAsO_2$) alone treated, *iAs*+ALA and *iAs*+Curcumin treated. The test substances ($NaAsO_2$ alone and $NaAsO_2$ $NaAsO_2$along with ALA/Curcumin) were administered by intraperitoneal route from PND 1 to 21 to experimental groups where as the control groups were given no treatment or received only the vehicle. During this period behavioral tests were carried out and, the animals were sacrificed on PND22. The cerebellar tissue obtained from perfusion fixed animals (n=6/group) was processed for immunohistochemical localization of various proteins and fresh tissue was used for Western blot analysis.
Results:
The behavioral tests showed functional deficits with context to cerebellar functions in *iAs* alone treated group and a substantial recovery in ALA/Curcumin supplemented groups. Also, IHC expression of proteins associated with dendritic and axonal growth (MAP2 and Tau), synaptogenesis (Syp and PSD95) and myelination (MBP) showed downregulation in *iAs* alone treated groups where as co-administration of ALA or Curcumin along with *iAs* resulted in significant upregulation in expression of these proteins.

Conclusions:
Exposure to *iAs* during early postnatal period resulted in adverse effects on the developing cerebellum. However, substantial recovery observed in antioxidant-supplemented groups is suggestive of the potential of ALA and Curcumin in ameliorating *iAs* induced developmental neurotoxicity to a certain extent.

Title: Running enhances structural maturity of young adult-born dentate granule cells in mouse hippocampus

Authors: *S. T. LUBEJKO[1], N. SAH[1], C. VIVAR[2], H. VAN PRAAG[1];
[1]Neuroplasticity and Behavior Unit, Lab. of Neurosciences, Natl. Inst. On Aging, Baltimore, MD; [2]Dept. of Physiology, Biophysics, and Neurosci., Ctr. for Res. and Advanced Studies of the Natl. Polytechnic Inst., Mexico City, Mexico

Abstract: The dentate gyrus (DG) of the mammalian hippocampus is one of two brain regions in which new neurons are continuously integrated throughout adult life. Voluntary running has been shown to increase hippocampal neurogenesis and performance on hippocampal-related behavioral tasks in rodent models. Additionally, running has been demonstrated to boost dendritic morphological maturity and structure in adult-born DG granule cells. Adult-born cells require weeks to differentiate, integrate, and mature in the granule cell layer of the DG; however, less is known about the structure and function of these neurons and the possible effects of running within the first week after cellular division. To determine the exercise effects on neurogenesis and the morphology of very young seven-day-old neurons in the adult DG, we stereotactically injected a retroviral vector expressing green fluorescent protein (GFP) in the DG of 5-week-old C57Bl/6 male mice housed in standard cages or with unlimited access to running

wheels. In addition, animals received three days of intraperitoneal bromodeoxyuridine (BrdU) injections for a systemic quantification of dividing cells. Quantification of $BrdU^+$ cells showed that running animals exhibited a significant increase in proliferation in the DG after seven days compared to controls. Furthermore, one-week-old neurons located in the dorsal aspect of the DG already display structural plasticity in response to running conditions. Retrovirus-infected cells from running animals showed increases in multiple aspects of fine morphology such as soma size and dendritic branching. Our results indicate that a short duration of voluntary exercise modifies the structure of one-week-old adult-born neurons, potentially allowing for more functional connections within their neural circuits.

Title: Developmental influence of stress and fluoxetine on the oxytocinergic system in the california mouse (Peromyscus californicus)

Authors: *J. CRUZ, S. PETERSON, E. A. BECKER;
St. Joseph's Univ., Philadelphia, PA

Abstract: A recent unprecedented increase in antidepressant use among pregnant and lactating mothers has caused concern among researchers and clinicians over the safety of this practice for developing offspring. Infants may be exposed to antidepressants, as selective serotonin reuptake inhibitors (SSRIs) cross the placental barrier and the ductal epithelium of mothers. Researchers, prescribing physicians and mothers alike must carefully weigh the potentially detrimental effects of perinatal stress on offspring development against the risks associated with early SSRI exposure. Previous research has indicated that SSRI exposure results in altered social behavior of the offspring later in life. Although mounting evidence suggests a significant impact on offspring development, the neural mechanisms through which SSRI exposure in development affects these social behaviors has not been fully characterized. Because oxytocin (OT) is sensitive to serotonergic insult early in development and is involved in social behaviors, it is a reasonable

candidate. We used the California mouse (*Peromyscus californicus*) to investigate the interaction between maternal stress and SSRI exposure on developing offspring. We exposed offspring prenatally to a stress condition (no stress/ stress) and a postnatal fluoxetine condition (control/fluoxetine) and examined oxytocin (OT) at a multiple sites of the brain (SON & PVN). At PND 120, offspring were sacrificed and brains were preserved for immunocytochemical analyses. Preliminary data has revealed a significant decrease in OT-ir staining in the stressed/fluoxetine groups compared to the stressed/no fluoxetine group and the no stress/fluoxetine group. Our preliminary data further implicates developmental fluoxetine as harmful to normal neural outcomes later in life.

Title: Early postnatal lipopolysaccharide exposure leads to enhanced neurogenesis and impaired communicative functions in rats

Authors: *Y. PANG[1,2], X. DAI[2], A. ROLLER[2], K. CARTER[2], I. PAUL[2], A. BHATT[2], R. LIN[2], L.-W. FAN[2];

Abstract: Perinatal infection is a well-identified risk factor for a number of neurodevelopmental disorders with neurobehavioral impairments, including the white matter injury (WMI) and Autism Spectrum Disorders (ASD). The underlying mechanisms by which early life inflammatory events cause aberrant neural, cytoarchitectural, and network organization, reflecting neurobehavioral dysfunction, remain elusive. This study is aimed to investigate how systemic lipopolysaccharide (LPS)-induced neuroinflammation affects microglia phenotypes and early neural developmental events in rats. We show here that LPS exposure at early postnatal age leads to a robust microglia activation which is characterized with mixed microglial proinflammatory (M1) and anti-inflammatory (M2)-like phenotypes. More specifically, we found that microglial M1 markers iNOS and MHC-II were induced at relatively low levels in a

regionally restrict manner, whereas M2 markers CD206 and TGFβ were upregulated in a sub-set of activated microglia in multiple white and gray matter structures. This M2-biased microglia polarization was associated with a markedly decrease in natural occurring apoptosis, but increase in cell proliferation in the subventricular zone (SVZ) and the dentate gyrus (DG) of hippocampus. LPS exposure also leads to a significant increase in oligodendrocyte lineage population without causing discernible hypermyelination. Moreover, LPS-exposed rats exhibited significant impairment in communicative and cognitive functions. These findings suggest a possible role of a M2-like microglial activation in abnormal neural development underlying ASD-like behavioral impairments in the current animal model.

Title: Regional distribution and cellular colocalization of KCC2 in ferret neocortex

Authors: ***F. T. DJANKPA**[1], M. CHATTERJEE[3], S. L. JULIANO[2];
[1]Program in Neurosciences, [2]Dept. of Anat. Physiol. and Genetics-Program in Neurosciences, Uniformed Services Univ. of the Hlth. Scienc, Bethesda, MD; [3]Anat. Physiol. and Genet., USUHS, Bethesda, MD

Abstract: KCC2 plays several important roles in the development of the cerebral cortex that range from neuronal migration to maturation and differentiation. KCC2 is an ion channel protein also known as a potassium/chloride co-transporter. This protein modulates neuronal chloride homeostasis by influencing the switch of GABA polarity from depolarizing in young neurons to hyperpolarizing in mature neurons. Although the developmental regulation and regional distribution of KCC2 has been described in rodents, little information describes the distribution and regional localization of KCC2 in ferrets, which are the smallest mammals with a gyrencephalic brain. In addition, very few reports in any species describe the developmental cellular distribution of KCC2 in the cerebral cortex. As an ion channel protein, we do not know whether KCC2 is expressed in a large cohort of neurons or in a selective phenotype. We describe here the expression pattern of KCC2 during development, the regional distribution, subcellular

localization and cellular colocalization with neuronal markers in ferret cortex. KCC2 is strongly expressed in the subplate at P0 and P7, which reorganizes to a subtle laminar pattern at P14 as the neocortical layers develop. In the adult, however, KCC2 has a homogenous distribution throughout the cortical thickness. In younger brains (P0, P7), KCC2 immunoreactivity occurs in the cytoplasm of neurons, while by P14, KCC2 appears in a pattern apparently surrounding cells or in their processes. Subcellular localization by separating cytoplasmic and membrane fractions shows that KCC2 remains in the membrane fraction of neocortical samples. We also found that KCC2 colocalizes with multiple neuronal markers including TUJ1 and MAP2 and the presumptive inhibitory markers parvalbumin and calretinin in both young and mature neocortex. We also know from previous studies that administration of the toxin methylazoxymethanol (MAM) to pregnant ferrets results in an upregulation of KCC2 in the cerebral cortex of the offspring. This increase is reflected in a number of functional and structural consequences (e.g. Abbah and Juliano 2015). We also see histologic alterations in the distribution of KCC2 after MAM treatment that reflects the increased KCC2 levels and altered laminar organization. In an organotypic culture model, cells migrating away from the ganglionic eminence show reduced speed when treated with agents that increase KCC2. Our findings indicate that the action of KCC2 in ferret cortex is likely to change focus as the animal develops and may influence the activities of both excitatory and inhibitory neurons.

Title: Role of metabolic and nutritional status in programming cognition by early-life stress: potential for peripheral interventions using fatty acids

Authors: *K.-Y. YAM[1], E. NANINCK[1], L. SCHIPPER[2], S. LA FLEUR[3], A. GREFHORST[4], A. OOSTING[2], E. VAN DER BEEK[2], P. LUCASSEN[1], A. KOROSI[1];
[1]Structural and Functional Plasticity of the Nervous Syst., Swammerdam Inst. For Life Sci., Amsterdam, Netherlands; [2]Nutricia Res. – Danone Nutricia Early Life Nutr., Utrecht, Netherlands; [3]Dept. of Endocrinol. and Metabolism, Academic Med. Ctr., Amsterdam, Netherlands; [4]Dept. of Intrnl. Medicine, Erasmus Univ. Med. Ctr., Rotterdam, Netherlands

Abstract: Early-life stress (ES) is associated with cognitive deficits in adulthood. Mechanisms underlying such programming remain elusive and the role of metabolism and nutrition are

largely ignored in this context. Importantly, leptin, the metabolic hormone secreted from white adipose tissues (WATs), and essential fatty acids (FAs) play key roles in brain development. Imbalances in circulating leptin as well as in FAs early in life are also associated with cognitive impairments in later life. We therefore studied if; i) ES affects metabolic and nutritional status, both centrally and peripherally, ii) early dietary intervention with a reduced linoleic acid (LA) to α-linoleic acid (ALA) ratio prevents these ES-induced cognitive impairments, and if iii) modulations of hippocampal neurogenesis might mediate effects of this diet.We used a chronic ES mouse model in which C57/BL6j dams are housed with limited nesting/bedding material from postnatal day (P) P2-P9, resulting in cognitive decline in adulthood. Dietary intervention consisted of subjecting mice to a diet equal in total FAs, but either containing a low (1) or high (15) LA/ALA ratio between P2-P46. Cognitive performance was assessed using object recognition, object location and morris water maze tasks and neuronal survival determined by BrdU+ immunocytochemistry. Chronic ES resulted in; i) lasting reductions in WAT weight, circulating leptin levels and WAT *Lep* mRNA expression, together indicating an ES-induced programming of WAT function. In addition, ES did not affect hippocampal leptin receptor (*Lepr*) mRNA expression, but interestingly, upregulated *Lepr* expression in the choroid plexus, indicating a compensation for the peripheral changes. Moreover, ES leads to increased omega-6-to-3 FA ratio in the hippocampus, while it was decreased in livers of ES mice early in life. In addition, ii) low LA/ALA diet early in life prevented the ES-induced cognitive impairments in all three behavioral tasks. And iii) this diet prevented the reduction of adult born neuron survival caused by ES, suggesting that the beneficial effects of the diet may, at least partly, be mediated by preserving the neurogenic capacity in the ES-exposed offspring. Further characterization of the lasting effects of ES and FAs diet on nutritional status in peripheral and central organs are currently under investigation. These results highlight for the first time the relevance of body-to-brain signaling by leptin, and the potential of dietary intervention with LA/ALA in programming the brain by ES. This creates exciting innovative and non-invasive opportunities to prevent the ES-induced cognitive impairments.

Title: Maternal melatonin deprivation during pregnancy and lactation impairs spatial reference and working memory in adult rats

Authors: *L. C. TEIXEIRA[1], A. V. MACHADO-NILS[2], F. G. AMARAL[1], G. F. XAVIER[2], J. CIPOLLA NETO[1];
[1]Physiol. and Biophysics, [2]Physiol., Univ. of Sao Paulo, São Paulo, Brazil

Abstract: Maternal melatonin plays a role in providing photoperiodic information to the fetus and by that influencing the regulation and timing of internal rhythms of the offspring and their preparation for extrauterine life. Maternal melatonin deprivation during prenatal and early postnatal has negative health consequences for the offspring that continue into adulthood (e.g. altered energy metabolism). There is a paucity of data examining the effects of maternal melatonin suppression on cognitive function of offspring. The present study examined the spatial memory of adult offspring born to pinealectomizeddams. Female Wistar rats were submitted to pinealectomy (PINX) or SHAM surgery (CTL). The PINX rats were divided into two groups and received either melatonin (PINX+MEL) or vehicle (PINX). After 4 weeks the rats were allowed to mate and received the treatment until lactation's end. Adult male offspringwere trained in water maze. Probe test was performed 24 hr after training.Two days after probe test, working memory training was conducted.Preliminary data show that maternal melatonin deprivation during pregnancy and lactation disrupts both spatial reference and working memory; these results may be related to changes in neurogenesis in the hippocampus. Importantly, these impairments were reversed by maternal melatonin replacement.

Title: Hippocampal neuronal loss and impaired neurogenesis following repeated closed-head concussive impacts

Authors: *D. A. PETERSON[1], S. G. CHIREN[1], E. REISENBIGLER[1], N. JAMNIA[2], N. KAPECKI[3], G. DEJOSEPH[2], J. H. URBAN[2], R. A. MARR[3], G. E. STUTZMANN[3], D. A. KOZLOWSKI[4];
[1]Ctr. for Stem Cell & Regenerative Med., [2]Dept. of Physiol. and Biophysics, [3]Dept. of Neurosci., Rosalind Franklin Univ. Med. Sci., North Chicago, IL; [4]Biol. Sci., DePaul Univ., Chicago, IL

Abstract: Head impact and/or acceleration-deceleration can produce traumatic brain injury (TBI) that can be categorized as severe or mild, with concussions categorized typically as mild TBI. There is emerging evidence that the accumulation of concussive injuries, frequently encountered in sports or combat, contributes to the development of chronic traumatic encephalopathy (CTE). To assess the sequence of degenerative and regenerative responses following repeated concussions, we utilized a closed-head model of controlled cortical impact to deliver injury to rats. All procedures were approved by IACUC. Young adult Long Evans rats received a sham procedure (anesthetic) or the addition of impact on the surface of the head by a modified Leica CCI device at a location overlying the sensorimotor cortex. Experimental groups received a single impact or three successive impacts separated by 48 hour intervals. After 30 days, animals were deeply anesthetized, transcardially perfused, and the brains were collected and sectioned at 40 μm. There was no evidence of skull fracture and no macroscopic deformation of the cerebral cortex underlying the impacted skull. Closed head impact produced neuronal disorganization in the underlying cerebral cortex and the volume of cerebral cortex and corpus callosum was reduced in experimental groups. Hippocampal volume was also reduced and we investigated further the effect of impact on this more distant structure. Repeated concussive impact produced no noticeable alteration in Iba1+ microglial or Olig2+ oligodendrocyte progenitor cell populations in the hippocampus. However, repeat concussion produced astrocytic (GFAP+) hypertrophy throughout the hippocampus that was pronounced at the hippocampal fissure. The population of DCX+ neuroblasts was reduced in the dentate gyrus following repeat concussions with more severe loss in the buried blade of the dentate gyrus. Repeated concussion also resulted in neuronal (NeuN+) loss in Area CA1. Despite the distance of the hippocampus from impact, repeated mild impact results in an injury response, reduced neurogenesis, and neuronal loss in the hippocampus. Thus repeated concussion may contribute to long-term disruption of hippocampal circuitry.

Title: Early-age running enhances activity of adult-born dentate granule neurons following learning

Authors: O. SHEVTSOVA[1], Y. TAN[1], C. M. MERKLEY[1], G. WINOCUR[2], *M. WOJTOWICZ[1];
[1]Dept Physiol, Univ. Toronto, Toronto, ON, Canada; [2]Baycrest Inst., Toronto, ON, Canada

Abstract: We have shown previously that early-age running enhances survival of adult-born hippocampal neurons later in life. This effect may be a contributing factor to cognitive reserve (Merkley et al., 2014, Front. Neurosci.). In this study we are addressing the hypothesis that enhanced neuronal survival is a significant factor in improving functionality of dentate granule neurons in learning tasks. One group of young, 1 month old rats was given free access to running wheels for 6 weeks and another group was housed in standard laboratory cages. After this period the running animals were returned to standard cages. After 4 months all rats were trained on a contextual fear conditioning task and, 2 weeks later, tested for memory of the contextual fear response. The testing was done on the same context as well as similar and very different contexts to provide information on the quality of memories. A group of non-tested animals was used as controls. Neurogenesis was measured with standard immunohistochemical procedures using endogenous markers Ki67, DCX and NeuN. These static measures of neurogenesis did not provide any evidence for differences between early runners and non-runners. Cell activity was measured using the expression of c-fos at 90 minutes following the memory test. Neuronal survival was measured at 5 weeks following injections of a mitotic marker CldU. The overall expression of activity marker c-fos was enhanced 4-5 fold in the dentate gyrus of the tested vs. non-tested animals suggesting significant involvement of dentate gyrus in learning. However, there was no effect on overall c-fos expression due to early running. In contrast, the % expression of c-fos in CldU-labeled cells was significantly increased in early runners vs. non-runners. These preliminary results show enhanced functional status of adult-born dentate granule neurons in comparison to developmentally-born neurons and their preferential activity in animals that were exposed to early-age running. With respect to previously published studies this work provides further support for involvement of adult-born neurons in neurogenic and functional

cognitive reserve.

Title: Adult neurogenesis in the dentate gyrus is regulated by α7 nAChR activation.

Authors: *S. L. OTTO, J. L. YAKEL;
Neurobio. Lab. - Ion Channel Physiol. Group, Natl. Inst. of Envrn. Hlth. Sci., Research Triangle Park, NC

Abstract: Hippocampal adult neurogenesis is a life-long process whereby neural stem cells located in the subgranular zone of the mammalian dentate gyrus divide, differentiate, mature and integrate in the local circuitry. Our overall objective is to determine how cholinergic input affects the generation of new granule cells, and whether these changes impact learning and memory. A hallmark of neurodegenerative disorders is impaired adult neurogenesis. Alzheimer's disease shows both loss of cholinergic innervation and impairment of neurogenesis. The dentate gyrus receives cholinergic input from the basal forebrain, a source of signaling that may impact adult neurogenesis. Cholinergic receptors could contribute a counterbalanced set of signals to modulate neurogenesis. Here we focus on the α7 nicotinic acetylcholine receptors (nAChRs), considered important in maturation of granular cells in the dentate gyrus and expressed on cells in the subgranular zone. α7 nAChRs are highly expressed in neonates and then decline until reaching adult levels. Though environmental factors as diverse as exercise and solitude have been shown to have an effect on adult neurogenesis, extant literature conflicts as to possible cholinergic effects. Little is known of the possible mechanism(s) through which cholinergic signaling may act. To better understand adult neurogenesis in the dentate gyrus, we use a nestinCrERT2 mouse that permits the labeling of nestin^{+} neural stem cells. Using this model we show that expression of nestin^{+} neural stem cells in global α7 nAChR knock-out (KO) mice is significantly decreased. In addition, in organotypic cell culture, adding MLA (a selective antagonist of the α7 nAChR) caused a decline in the quantity of nestin^{+} cells. To further study

the mechanism involved we are quantifying nestin^{+} cells from organotypic cultures treated with PNU-120596, an α7 nAChR positive allosteric modulator, and choline. One possible explanation of the decline in nestin^{+} cells is that maturation of adult born granule cells is delayed, resulting in overall loss of neurons as they fail to integrate in a timely fashion. This may result in a compensatory increased neurogenesis, decreasing the neural stem cell pool. To investigate this we are using EdU to birthdate adult born granule cells as well as quantifying immature granule cells present in α7 nAChR KO or wild-type mice. We are also investigating whether pattern separation, a function of adult neurogenesis, is affected in α7 nAChR KO mice with reduced nestin stem cell expression. Ongoing research is using an AChRα7 fl/fl mouse to determine which cells are most responsible for the loss of nestin^{+} cells seen in a global α7 nAChR KO.

Title: Reversible developmental stasis in response to nutrient availability in Xenopus laevis CNS.

Authors: *C. K. THOMPSON, C. R. MCKEOWN, H. T. CLINE;
The Scripps Res. Inst., La Jolla, CA

Abstract: Many organisms are confronted with intermittent nutrient availability, but the mechanisms used to cope with such fluctuations during development are not well understood. This is particularly true of the brain, the development and function of which is energy intensive. Here we examine the effects of nutrient restriction and availability on development of the visual system in Xenopus laevis tadpoles. During the first five-seven days of development, Xenopus tadpoles draw their nutrients from internal yolk stores in the gut, however upon depletion of these nutrients animals must forage for food in their environment. By altering access to external

nutrients starting when yolk is depleted, we have defined a period of reversible stasis during tadpole development. We demonstrate that nutrient restriction (NR) results a decrease in overall growth of the animals, a failure to progress through developmental stages, and a decrease in volume of the optic tectum. During NR, neural progenitors virtually cease neuronal proliferation, but tadpoles swim and behave normally. Delayed feeding following NR increases neural progenitor cell proliferation in the tectum by more than 10 fold relative to NR tadpoles, with the number of proliferating cells equaling that of fed counterparts after a week of supplemental feeding. The delayed feeding paradigm also rescued the NR-induced body length and tectal volume deficits, and partially rescued the delayed progression through developmental stages. We determined that tadpoles can recover from developmental stasis if food is provided at any point within the first 8 days of NR. Food availability restores neural progenitor cell proliferation in the tectum and rescues NR-induced developmental deficits. After 8 days of NR, however, access to food fails to increase cell proliferation. These results show that development of the brain in tadpoles is acutely sensitive to fluctuations in nutrient availability and that NR induces stasis of developmental processes, from which animals can recover if food becomes available within a critical window.

Title: Loss of the sulfate transporter Slc13a4 alters behavior and neurogenesis in adult mice

Authors: *Z. ZHANG[1], M. PIPER[1], P. DAWSON[2], D. SIMMONS[1];
[1]SBMS, the Univ. of Queensland, Brisbane, Australia; [2]Mater Res. Inst., Brisbane, Australia

Abstract: Sulfate conjugation (sulfonation) of molecules is essential for a diverse array of physiological processes. In the brain, sulfonation is a critical step in modulating the functions of extracellular matrix molecules, which in turn regulate adult neurogenesis. SLC13A4 is a sodium-dependent sulfate transporter which is primarily expressed both in the placenta, and by the choroid plexus of the brain. Our previous work has shown that deletion of *Slc13a4* causes severe fetal abnormalities and death in mice. Interestingly, we also found that $Slc13a4^{+/-}$ female mice lost a significant number of pups after birth compared with $Slc13a4^{+/+}$ females, regardless of pup

genotype, suggesting that *Slc13a4*$^{+/-}$female mice may have deficits in maternal behavior. Indeed, pregnant *Slc13a4*$^{+/-}$ mothers took significantly longer to retrieve their pups in a test of maternal care behaviors. Behavioral tests, including open field, elevated plus maze, odor discrimination and home cage metabolic tests were then performed on non-pregnant female mice to investigate whether the loss of *Slc13a4* alleles causes abnormal behavior more generally. *Slc13a4*$^{+/-}$ and *Slc13a4*$^{-/-}$ mice were found to exhibit increased exploring behavior in a novel environment compared with *Slc13a4*$^{+/+}$ mice. Analysis of *Slc13a4* expression in choroid plexus during pregnancy identified a significant peak at gestational day 8.5, which is consistent with the peak in adult neurogenesis in the maternal subventricular zone (SVZ) during pregnancy. This coincidence suggested that *Slc13a4* might participate in the regulation of neurogenesis. Therefore BrdU injections were performed to track adult neurogenesis in non-pregnant *Slc13a4*$^{+/+}$, *Slc13a4*$^{+/-}$ and *Slc13a4*$^{-/-}$ mice. We found that both *Slc13a4*$^{+/-}$ and *Slc13a4*$^{-/-}$ mice displayed significantly increased cell proliferation in the neural stem cell niches. Intriguingly, no differences were found in BrdU labeled cell numbers within the olfactory bulb or molecular layer of dentate gyrus 28 days after final injection, indicating the extra cells born in the niches of *Slc13a4* mutant mice do not appear to integrate into their appropriate networks. Therefore, our recent work indicates that altered sulfate transport within the choroid plexus has important implications for both behavior and the regulation of adult neurogenesis.

Title: Neurons born during reactive neurogenesis activate to Morris water maze similarly between binge alcohol exposed and control rats

Authors: *C. R. GEIL, K. NIXON;
Univ. of Kentucky, Lexington, KY

Abstract: Excessive alcohol intake in alcohol use disorders results in neurodegeneration in corticolimbic regions including the hippocampus. In the hippocampus, deficits can recover with

abstinence, potentially due, in part, to reactive adult neurogenesis. Alcohol intoxication inhibits neural progenitor cell (NPC) proliferation and adult neurogenesis, effects that appear to contribute to neuronal loss. However, after 7 days of abstinence (T7) following a 4 day alcohol binge, striking increases in NPC proliferation result in increases in adult neurogenesis. Here, we investigate whether these new neurons are functionally activated (c-Fos) following a hippocampal-dependent task. Thus, we used a 4 day binge to model an AUD, bromodeoxyuridine (BrdU) to label proliferating cells on T7, and the Morris water maze (MWM) to activate hippocampal cells. Briefly, 21 adult male Sprague-Dawley rats were fed an ethanol (25% w/v) or isocaloric control diet via gavage every 8h for 4d with the ethanol dose titrated based on the rat's intoxication score (ethanol dose: 9.7 ± 0.2 g/kg/d, blood ethanol concentration: 401 ± 14 mg/dl). On T7, rats were injected with BrdU (100 mg/kg, i.p.) every 8h for 24h (3 injections). After 6 weeks (7 weeks post-binge) animals underwent 4d of MWM and 90 min following the last trial (i.e. 52d post-binge; T52), animals were transcardially perfused, brains were removed, post-fixed, and sectioned at 40 μm. Every 12th section was processed for fluorescent BrdU/c-Fos/NeuN immunohistochemistry to label cells that divided on T7, were recently activated, and mature neurons, respectively. In the dentate gyrus at T52, ethanol rats had a 2.9-fold increase in the number of BrdU+/NeuN+ cells compared to controls ($p=0.006$). Thus, more cells were labeled with BrdU on T7 and survived to T52. Next, the number of c-Fos+/NeuN+ cells were similar between ethanol and controls, as was the percentage of BrdU+ cells that were triple labeled for BrdU/c-Fos/NeuN. Therefore, a similar percentage of newborn neurons were activated following ethanol as in controls. Surprisingly, ethanol rats appeared to learn faster than controls in the MWM, the task used to induce c-Fos expression. Two-way repeated measures ANOVA revealed significant Diet x Day interactions for time to locate the platform, distance traveled to locate the platform, and swim speed ($p<0.05$). Post-hoc tests revealed that ethanol animals located the platform more quickly than controls on the first 2 days of testing ($p<0.05$). Therefore, increases in neurogenesis may contribute to improved performance in the MWM, but newborn cells were functionally activated at the same rate in ethanol-exposed and control rats.

Title: Effect of thyroxine on neurogenesis following galactic cosmic radiation

Authors: *L. R. VOSE, O. MIRY, K. R. GOPAUL, G. SUBAH, P. K. STANTON;
Cell Biol. and Anat., New York Med. Col., Valhalla, NY

Abstract: Simulated galactic cosmic radiation (GCR) impacts learning, memory, synaptic plasticity, neuronal physiology, and adult neurogenesis. Neurons, especially neural stem cells, are highly susceptible to damage, which may cause both subtle alterations in the function of mature neurons, and impair the ability of the brain to replace these cells. Thyroid hormone (TH) is required for normal neurogenesis, and hypothyroid humans and rodents exhibit decreased cognitive function and depression-like behavior which is rescued by TH supplementation. Additionally, high dose radiation to treat cancer causes hypothyroidism with negative cognitive effects. Hippocampal neurogenesis can be upregulated after neural insults such as cerebral ischemia. It is not known if there are compensatory mechanisms to upregulate neurogenesis after GCR exposure, or if these mechanisms can be tapped therapeutically to protect neurogenesis and cognition. Multiple studies have shown that rodent cognitive abilities are impaired 3 mo after GCR. Reduced neurogenesis is seen 6-9 mo post-GCR, and surviving hippocampal neurons show altered neurotransmitter release and receptor subunit composition 3-6 mo post-GCR. Previous data from our laboratory has found that, while impaired at earlier time points post-GCR, synaptic plasticity and spatial learning are enhanced 20 mo post-GCR. These data suggest both that GCR effects persist for the remainder of an animals' life span, and that the mammalian brain may have compensatory capabilities with the capacity to respond to GCR and GCR-induced impairments in neurogenesis and cognition by upregulating these processes. We hypothesize that TH supplementation could be a novel and effective therapeutic strategy to protect neurogenesis from GCR-induced impairment with an FDA approved compound (thyroxine). We treated C57BL/6 mice with TH for 1 week before and after GCR (^{28}Si, 0.5 or 1 Gy). Three months post-GCR, newborn hippocampal neurons were labeled with doublecortin (DCX). Preliminary data did not show changes in DCX+ cell number in irradiated mice, but did show marked differences in dendrite arborization. TH treatment appeared to have more effect on dendritic arborization than the number of DCX+ cells. Understanding the interactions between GCR and neurogenesis, their effects on cognition, mood, and executive function, and identifying neuroprotective strategies, will all be critical for rational assessment of long-term CNS risk and development of countermeasures for in-mission risks from GCR in long-duration space travel.

Title: DREADD-mediated activation of adult hippocampal progenitors: effects on neurogenesis and behavior

Authors: *M. MAHESHWARI[1], S. SHAH[1], S. PATI[1], A. RAWAT[1], J. CHELLIAH[2], V. A. VAIDYA[1];
[1]Tata Inst. of Fundamental Res., Mumbai, India; [2]Jawaharlal Nehru centre for Advanced Scientific Res., Bangalore, India

Abstract: Adult-born granule cells represent a unique form of hippocampal plasticity wherein new neurons are generated throughout the adult life of an organism. It is a multi-step process which involves proliferation of progenitors, differentiation, survival and integration into mature neurons of the hippocampal niche. A period of few weeks after birth of progenitors is marked by lowered threshold to stimulus and heightened excitability. About half of the dividing cells generated in the niche are targeted for cell death, and a lack of environmental experience or neuronal activity during this critical period is thought to play a key role in determining cell survival. While several studies provide a correlative link between the nature of neuronal activity within the neurogenic niche and progenitor turnover and survival, thus far this has not been directly examined. Further, the impact of changes in neuronal activity or calcium signaling within the neurogenic niche do not delineate effects that are cell-autonomous or niche-mediated. To directly address whether alteration in Gq-mediated signaling and downstream calcium-driven responses can modulate progenitor turnover, survival, and mood-related behavioural function we used pharmacogenetic strategies to regulate Gq-signaling in hippocampal progenitors. Using bigenic mouse models expressing Gq-DREADD (Designer Receptors Exclusively Activated by Designer Drugs) under the control of the Nestin-drivers we examined the consequences of DREADD-mediated activation on different aspects of neurogenesis and behavior. Following chronic activation, mice exhibited a significant increase in - number of proliferative cells, total number of immature neurons and complexity of dendritic morphology. In addition, we observed a time-dependent emergence of anxiolytic behaviour at 4-8 weeks following activation of hippocampal progenitors. These effects were age-dependent, observed in both juvenile and adult animals, but not in aged mice. Experiments are currently underway to characterize the specific stages of hippocampal neurogenesis that are sensitive to DREADD-mediated activation and to examine the consequences on hippocampal function using electrophysiological studies. Taken

together, these results provide evidence that Gq-signaling driven activation can drive robust proliferative effects in hippocampal progenitors and eventual behavioural modulation in an age-dependent manner. Also, it supports the notion that newborn neurons may exert specific effects on hippocampal networks and behaviour at a critical junctures during their maturation and integration into hippocampal neurocircuitry.

Title: Oxytocin stimulates hippocampal neurogenesis via oxytocin receptor expressed in CA3 pyramidal neurons in adult mice

Authors: *Y. LIN[1], C. CHEN[2], K. HSU[2];
[1]Inst. of Basic Med., Tainan, Taiwan; [2]Dept. of pharmacology, Tainan city, Taiwan

Abstract: Acute and repeated peripheral oxytocin (OXT) administration have been shown to increase hippocampal neurogenesis; however, the mechanisms underlying the action of OXT is still unclear. Here we show that OXT control adult neurogenesis through non-cell-autonomous mechanisms by OXT receptors (OXTR) expressed in CA3 pyramidal neurons. Using oxytocin receptor-Venus reporter mice, we found that OXTR is not expressed in the neural progenitor cells in the subgranular zone of the adult dentate gyrus, but is enriched in subpopulations of hippocampal CA2 and CA3 pyramidal neurons. Consistent with a function of OXT signaling in adult neurogenesis, conditional deletion of OXTR ($OXTR^{-/-}$) from excitatory neurons led to impaired differentiation, survival and maturation of newly generated dentate granule cells (DGCs). Retrograde neuronal tracing combined with immunocytochemistry revealed that the OXT neurons in the paraventricular nucleus project directly to the CA3 region of the hippocampus. In addition, bath application of OXT elicited a membrane depolarization and increased action potential firing in OXTR-expressing CA3 pyramidal neurons in slices from wild-type mice, which were completely abolished by OXTR deletion. Using adenoviral-mediated expression of engineered $G_{i/o}$-coupled human M4 (hM4Di) receptors, we observed that activation of hM4Di receptors with clozapine-*N*-oxide (CNO) reduced CA3 pyramidal neuronal activity and resulted in fewer newly DGCs in Floxed OXTR mice. Conversely, CNO-induced activation of G_q-coupled human M3 (hM3Dq) receptors restored adult neurogenesis in the DG of $OXTR^{-/-}$

mice. These results suggest that CA3 may regulate adult DG neurogenesis under basal conditions and OXT controls adult hippocampal neurogenesis via OXTR expressed in CA3 pyramidal neurons.

Title: Adult neurogenesis in a crustacean brain: Serotonin levels influence the integration of adoptively transferred immune cells into a neurogenic niche

Authors: J. L. BENTON, *B. S. BELTZ;
Neurosci. Program, Wellesley Col., Wellesley, MA

Abstract: Neurogenesis continues in the brains of adult decapod crustaceans and is regulated by serotonin levels. However, the 1st-generation neural precursors (neural stem cells), which reside in a neurogenic niche, are not self-renewing in crayfish (*Procambarus clarkii*) and must be replenished. Our previous studies indicate that the source of these neural precursors is the innate immune system. Semi-granular hemocytes, which are central players in innate defense mechanisms in crustaceans, have the capacity to become neural precursors that generate adult-born neurons. Following adoptive transfer of ethynyl-2'-deoxyuridine (EdU)-labeled hemocytes, these cells populate the neurogenic niche. After a 7-week survival time, EdU-labeled cells are located in brain clusters 9 and 10 where adult-born neurons differentiate, and express appropriate neurotransmitters. Recent experiments have shown that serotonin levels alter the outcomes of adoptive transfers. When EdU-labeled blood cells are transferred to recipient crayfish that are then exposed to serotonin (10^{-9} M), the proportion of EdU-labeled niche cells from the semi-granular cell lineage increases compared with control levels. In addition, the total numbers of cells that compose the niche rise. It also is known that serotonin stimulates the expression of astakine, a crustacean cytokine, which promotes the release of semi-granular cells. Further studies will therefore ask whether serotonin can influence the number of circulating semi-

granular hemocytes by regulating astakine levels, and also whether serotonin's effects on adoptive transfers and neurogenesis are mediated by this cytokine.

Title: Transient inhibition of neural stem cell proliferation during early life decreases adult dentate gyrus neurogenesis

Authors: *M. YOUSSEF, G. KIRSHENBAUM, V. KRISH, T. BRINER, E. D. LEONARDO, A. DRANOVSKY;
Columbia Univ. Med. Ctr., New York, NY

Abstract: Early life stress has been shown to increase vulnerability to psychiatric illness in adulthood. The hippocampal dentate gyrus (DG) is altered by stress and plays a role in stress regulation. The DG is also one of the two brain regions in which neural stem cells give rise to neurons throughout an animal's life, a process that is negatively regulated by stress. In this study, we sought to determine whether inhibition of neurogenesis during critical developmental periods is sufficient to permanently decrease DG neurogenesis. We used a pharmacogenetic approach to transiently target dividing neural stem cells for elimination by administering the drug valganciclovir to GFAP-Tk mice during periods sensitive to stress. We then assessed the Nestin neural stem cell lineage in adulthood. We found that suppression of cell proliferation during the early postnatal, but not the periadolescent period, led to fewer neurons from the Nestin lineage in adulthood, suggesting that the early postnatal intervention leads to a permanent reduction in neurogenesis. This study highlights the early postnatal period as a sensitive period during which perturbations in stem cell proliferation are sufficient to dictate the homeostatic set point for adult neurogenesis. It is intriguing to speculate that infantile neurogenesis serves as a cellular target for the enduring effects of stress.

Title: Effect of voluntary exercise on adult hippocampal neurogenesis in maternally separated rats

Authors: ***V. A. RUSSELL**[1], N. HARDCASTLE[2], L. MARAIS[2], D. LANG[2];
[2]Human Biol., [1]Univ. Cape Town, Cape Town, South Africa

Abstract: Maternal separation (MS) produces depression-like behaviour in animals. The underlying mechanisms are unknown. Evidence suggests that neurogenesis may be a key factor. Voluntary wheel running is a form of exercise that increases neurogenesis and decreases depression-like behaviour in a rat model. However, the role of neurogenesis in exercise-induced antidepressant effects is unknown. Ki-67, an endogenous marker of cell proliferation, was used to study the effect of exercise on neurogenesis in the MS rat model of depression. Briefly, on postnatal day (PND) 2, litters were culled to eight pups (with a minimum of two females and two males per litter to normalize dam behaviour towards pups) and randomly assigned to MS (n = 8) or non-MS (n = 10) groups. MS pups were separated from their dams for 3 h per day from PND2 to PND14. Non-MS pups were left with their dams. On PND21, pups were weaned and housed in groups of 4-5 rats per cage. From PND 54 - 74, rats were housed in single cages with attached running wheels. Exercised rats were housed in cages with free-running wheels and could exercise at will, while non-exercised rats were housed in cages with locked wheels. On PND 74, rats were perfused with 4% paraformaldehyde. The brain was removed from the skull, placed in 4 % paraformaldehyde for three hours and then dehydrated in 30 % sucrose solution for 3 - 5 days until the brain sank. Thereafter brains were sectioned with no more than two days between sinking, freezing and sectioning. Coronal sections containing the dorsal hippocampus (40 μm sections from approximately 6.96 to 5.52 mm anterior to the inter-aural line) and the ventral hippocampus (50 μm sections from 3.84 to 2.76 mm anterior to the inter-aural line) were collected. Every 5th section was submerged in 3 % Triton X-100 in phosphate-buffered saline for 1 hour prior to immunohistochemistry. Ki-67 and DCX were used to determine the number of mitotically active cells that were destined to become neurons. Voluntary exercise produced the

expected increase in neurogenesis in non-MS rats, evidenced by increased Ki-67/DCX cell counts relative to non-MS rats housed in cages with locked wheels. Consistent with depression being associated with impaired neurogenesis, MS rats that were allowed free access to running wheels had fewer Ki-67/DCX-labelled cells in the dentate gyrus of both dorsal and ventral hippocampus when compared to non-MS rats that were allowed to exercise voluntarily. This finding suggests that MS alters neurogenesis in adult life and attenuates the effect of exercise on neurogenesis in the hippocampus.

Title: Retinoic acid regulates neural stem & progenitor cell proliferation in the adult hippocampus

Authors: ***S. MISHRA**, J. SIEGENTHALER;
Univ. of Colorado ,Anschutz Med. Campus, Aurora, CO

Abstract: In the adult hippocampus, stem and progenitor cells (NSPCs) proliferate and differentiate to make new neurons which then integrate into functional neural circuits. Inhibition of NSPCs proliferation is associated with several neurodegenerative disorders. However, the mechanisms regulating NSPC proliferation are unclear.We are interested in understanding the role of meningeal derived signal Retinoic acid (RA) in regulating NSPC proliferation. To address this, we inhibited endogenous RA synthesis in adult mice using the drug disulfiram and examined NSPC proliferation in the hippocampus. After 3 days of treatment, disulfiram treated mice showed a decrease in total numbers of NSPCs. This decrease was not due to increased apoptosis as assessed by TUNEL assay. Instead we found decreased NSPC proliferation, as demonstrated by decreased number of total Edu+ cells in the dentate gyrus of disulfiram treated mice. To test if altered NSPC proliferation is due to direct effect of RA on NSPCs, adult hippocampal NSPCs were cultured in presence of RA and RA with pan-Retinoic acid Receptor (RAR) antagonist, which inhibits RA signaling. RA increased NSPC proliferation, an effect that was blocked with the pan-RAR antagonist. To test a possible mechanism of regulation of proliferation by RA, we determined if RA regulates vascular endothelial growth factor (VEGF) signaling in the adult hippocampus. VEGFs and their tyrosine kinase receptors (VEGFRs) are expressed by NSPCs in the adult hippocampus and are established, positive regulators of NSPC

proliferation. We find that hippocampal cell lysates from disulfiram treated mice showed substantially reduced VEGFA ligand protein levels as compared to control. To examine if upregulation of VEGF-A is a direct effect of RA on NSPCs, mouse adult hippocampal NSPCs were cultured in presence of RA and RA with pan-Retinoic acid Receptor (RAR) antagonist. RA increased VEGF-A protein levels and this expression was reduced when RA signaling was inhibited. We next investigated if the effect of RA on progenitor proliferation is mediated via increased VEGF-A synthesis by co-treating cells with RA and the VEGFR2 antagonist. When VEGF signaling was inhibited in presence of RA the proliferation index was equivalent to cells treated with VEGFR2 antagonist alone. This data suggests RA regulates progenitor proliferation through VEGFA/VEGFR2 signaling. Taken together, these results support the hypothesis that RA, a meningeal derived signal, activates proliferation via VEGFA/VEGFR2 signaling in NSPCs of the adult hippocampus.

Title: Prenatal diabetes affects the postnatal hippocampal neurogenesis, learning and memory: Role of neurotrophic factors

Authors: *N. A. AL-BAHOUH, M. S. RAO;
Dept. of Anat., Kuwait Univ., Jabriya, Kuwait

Abstract: Diabetes mellitus is a chronic metabolic endocrine disorder and it is characterized by abnormally high glucose levels in blood. Diabetes mellitus is associated with central nervous system alterations. Gestational diabetes mellitus is the impairment of glucose tolerance that can affect pregnant women who have high blood glucose levels during pregnancy. Previous studies have shown that gestational diabetes produces a number of complications involving CNS including a significant decrease in hippocampal neurogenesis, significant reduction in the pyramidal cell density in the CA1 and CA3 sub regions of the hippocampus in the rats born to the diabetic mother rats (Gestational diabetic rats). Objective of the experiment is to study the effects of prenatal streptozotocin induced diabetes on young postnatal rat learning and memory, hippocampal cell proliferation, dentate gyrus neurogenesis, levels of brain derived neurotropic

factor (BDNF) and vascular endothelial growth factor (VEGF) in the hippocampus. Pregnant rats were injected with streptozotocin (STZ, 60mg/kg) on gestational day10. Diabetes was confirmed in them by measuring the blood glucose level 48 hrs after STZ injection. Pups born to the STZ-injected mother were divided into two age groups [40 days (STZ-40) and 60 days (STZ-60)] Pus born to the normal control mother were also divided into two age groups [40days (NC-40) and 60days (NC-60)]. Learning and memory was tested in these rats on 31^{st}-37^{th} (NC-40, STZ-40) and 51st -57^{th} (NC-60, STZ-60) postnatal day. Rats in all groups were sacrificed after learning and memory test, brain was dissected and processed for immunostaining, western blot and ELIZA analysis. Results showed that both STZ-40 and STZ-60 had significantly poor memory retention, decreased cell proliferation, and decreased neurogenesis, less number of doublecortin positive neurons in the crest, supra-pyramidal blade and infra-pyramidal blade regions of dentate gyrus compared to NC-40 and NC-60 groups. Further BDNF and VEGF were found to be significantly decreased in hippocampal tissue in STZ-40 and STZ-60 groups compared to control groups. We conclude from these results that gestational diabetes leads to an adverse effects on off-springs. Gestational diabetes can lead to necrotic changes, including a significant decrease in stem cell proliferation and neurogenesis in the dentate gyrus of the hippocampus of the offspring. It can cause a significant impairment in memory retention and poor memory recalling.

Title: Emergence of doublecortin positive cells from astrocytes in the substantia nigra in response to transplantation of cells derived from pluripotent stem cells

Authors: D. M. ARZATE[1], M. GUERRA-CRESPO[2], *L. COVARRUBIAS[1];
[1]Inst. de Biotecnologia, UNAM, Cuernavaca, Morelos, Mexico; [2]Mol. Neuropathology, Inst. de Fisiología Celular, Ciudad de México, Mexico

Abstract: Neurogenesis in the substantia nigra (SN) has been a controversial issue. Using embryoid body (EB) cells as an indicator of a neurogenic environment in the adult brain, we

found that SN allows, possibly involving an induction mechanism, efficient EB cell differentiation into neurons, suggesting that the SN may contain a silent neurogenic niche. Accordingly, we observed many host doublecourtin positive (DCX+) cells near the transplant. The aim of this study was to characterize these putative neuroblasts. Some host dividing neural precursor cells (NPC) Sox2+ were detected between 1-6 days postransplantation (dpt). In agreement with the activation of NPCs due to transplantation of EB cells, host neurosphere-like aggregates were generated from host cells in the presence of Egf and Fgf2; these aggregates showed neural multipotency as neurons and astrocytes derived from them *in vitro*. The contralateral to the transplanted SN showed very few dividing cells, none Sox2+ or Nestin+ cells, and neurospheres could not be derived from its cells. However, continuous BrdU administration after transplantation showed that only a fraction (~8%) of the host DCX+ progeny at 15 dpt derived from dividing cells and few BrdU+, some NeuN+, cells survived up to 30 dpt. Interestingly, in addition to detecting an increased proportion of host GFAP+ expressing Nestin around the transplant (~50%), we detected 30-50% of DCX+ or PSA-NCAM+ cells expressing glial markers such as GFAP and S100β. In order to confirm that a large proportion of host putative neuroblasts originated from astrocytes, we used a lineage tracing strategy in which we transplanted EB cells to brains of GFAP-CreER;R26-lox-mTomato-pA-lox-mEGFP-pA double transgenic mice that two weeks earlier were treated with tamoxifen for broad CreER activation in astrocytes. Consistent with an astrocytic origin of DCX+ cells, we found many DCX+/EGFP+ cells surrounding the transplant. Preliminary data indicate that Fgf2 and VEGF, two proteins produced by EBs, are able to promote neurosphere formation and the emergence of DCX+ cells in the absence of EB cells. Together our data suggest that the adult SN has the ability to generate new neurons mainly from astrocytes by a dedifferentiation/transdifferentiation mechanism.

Title: Age-related changes on hippocampal neurogenesis and mnemonic discrimination of similar objects and locations

Authors: S. ABDEL MALEK, S. SHARMA, R. DE, Y. E. WEN, A. N. S. CHOWDHURY, *E. SATVAT;
Sch. of Publ. Hlth. & Hlth. Systems, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Adult hippocampal neurogenesis appears to be critical for pattern separation. Aging is associated with suppressed adult hippocampal neurogenesis but exercise and environmental enrichment stimulate it. The aim of our study is to investigate whether age-related suppressed adult hippocampal neurogenesis is associated with deficits in tasks designed to assess pattern separation and whether exercise or an enriched environment can reverse such deficits. We started with a water maze training that showed learning deficit in middle aged rats (8 months) in comparison to young rats (2 months). At this age however, there was no difference between the two groups in the probe test and the reversal training. The middle aged rats were then randomized into exercise, environmental enrichment or standard housing conditions. Young rats stayed in standard housing condition. All the rats received 50 mg/kg BrdU injections per day for the first 6 days. After 3 months, rats underwent a second water maze training followed by a reversal training and a significant difference between the old and the young group was found only during reversal training. Three months later, rat's ability to discriminate between very different objects as well as their ability to discriminate between highly similar objects were examined. With 5-hour delay interval, only the young group and the old-enriched group were able to comparably discriminate the two very different objects. With the same delay interval and highly similar objects none of the groups were able to discriminate familiar object from highly similar yet novel object. Next, rats underwent a spontaneous location recognition task. Regardless of the degree of separation, none of the groups discriminated between the novel and the familiar locations at either 1- or 5-hour delay intervals between the sample phase and the choice phase. Finally, when old and young rats were 18 and 12 months of age, respectively, a delayed nonmatching to place radial arm water maze task was performed to evaluate spatial pattern separation. Older rats showed impairment in the task only when the separation between the sample and choice arms were small. Interestingly, both exercise and environmental enrichment protected older rats from this deficit. Brain tissues were collected and are being analyzed for functional neurogenesis.

Title: Ankyrin-G interacts with X-linked intellectual disability-associated deubiquitinase Usp9X to regulate spine maintenance

Authors: *S. YOON, K. MYCZEK, P. PENZES;
Northwestern Univ., Chicago, IL

Abstract: Recent genome-wide association studies and whole-exome sequencing have shown that ANK3 (encoding Ankyrin-G, AnkG) is a risk gene for multiple neuropsychiatric disorders, such as bipolar disorder, autism spectrum disorder, intellectual disability and schizophrenia. Here, we identified a novel AnkG interacting partner, Usp9X (ubiquitin specific peptidase 9, X-linked), using the yeast two-hybrid system. Usp9X mutations are associated with X-linked intellectual disability (XLID) in humans, and Usp9X protein is known to regulate neurite outgrowth and synaptic growth during the early stages of development. We observed that the expression of AnkG and Usp9X highly overlaps in the cerebral cortex and hippocampus. At the cellular level, both proteins co-expresses mostly on the soma and dendritic area, and interact in co-immunoprecipitates from brain homogenates. Co-immunoprecipitation with deletion mutants of AnkG and Usp9X demonstrates that Usp9X binds to the 24 ankyrin repeats and regulatory domains of AnkG. Knockdown of Usp9X in cultured cortical neurons decreases the intensity of AnkG in the soma and dendrites and impairs spine maintenance. These data implicate Usp9X in spine morphogenesis through regulating AnkG protein levels and suggest that deubiquitination is a potential mechanism of synapse maintenance, which, when abnormal, could contribute to pathogenesis.

Title: CNTNAP2 paracrine signaling by ectodomain shedding

Authors: *M. D. MARTIN-DE-SAAVEDRA[1], O. VAREA[1], R. GAO[1], B. P. SPIELMAN[1], K. J. KOPEIKINA[1], K. MYCZEK[1], E. A. HALL[2], J. N. SAVAS[2], P. PENZES[1];
[1]Physiol., [2]Neurol., Northwestern Univ., Chicago, IL

Abstract: The *CNTNAP2* gene is a risk factor for a complex range of phenotypes whose shared common features are intellectual disability, seizures, language impairments and autism spectrum disorder. *CNTNAP2* encodes the CNTNAP2 or Caspr2 transmembrane protein which belongs to the neurexin superfamily. CNTNAP2 KO mice showed repetitive/restrictive behaviors, impaired communication and decreased social interaction. However, little is known about how CNTNAP2 contributes to the physiopathology of neurodevelopmental disorders. We and others have recently shown that CNTNAP2 is present at spiny synapses in excitatory cortical neurons, and is required for correct trafficking of GluA1 subunits of AMPA receptors and spine maintenance. We therefore set out to investigate its functions at synapses using a wide range of imaging techniques (including confocal and super resolution imaging), biochemistry and mass spectroscopy. We found that CNTNAP2 undergoes activity-dependent ectodomain shedding mediated by matrix metalloproteases. Using structured illumination microscopy we determined the subcellular sites of Cntnap2 ectodomain shedding. Incubation with Cntnap2 ectodomain promotes morphological and functional changes in cortical neurons. Proteomics analysis has identified novel candidate binding partners of CNTNAP2 ectodomain. Taken together, our findings can provide new insight into the role of CNTNAP2 at synapses and in the pathogenesis of neurodevelopmental disorders.

Title: Regulation of cortical gabaergic interneuron function by the mental disorder susceptibility molecule cntnap2

Authors: *R. GAO, A. MELENDEZ, S. YOON, M. D. SAAVEDRA, M. FORREST, P. PENZES;
Physiol., Northwestern Univ. Dept. of Physiol., Chicago, IL

Abstract: While complex neuropsychiatric disorders have equally complicated genetic etiologies, recent research revealed common disruptions of individual genes across multiple diseases, suggesting similar pathological mechanisms. For example, several genetic studies have established contactin-associated protein-like 2 (CNTNAP2) as a risk gene in mental disorders such as autism spectrum disorders, schizophrenia, epilepsy, and intellectual disability. Studying the function of CNTNAP2, therefore, can lead to unprecedented insight into shared susceptibility pathways of mental diseases. CNTNAP2 is a member of the neurexin superfamily, is highly expressed in the brain, and clusters potassium channels in the axon's juxtaparanodes. However, its function outside of the axon is less explored. Recent studies of *CNTNAP2* knock-out mice revealed not only behavioral abnormalities and epileptic seizures, but also reductions of cortical interneurons and abnormal neuronal synchrony (Peñagarikano et al., 2011). In addition, CNTNAP2 knockdown in primary neuronal culture resulted in the reduction of both excitatory and inhibitory transmission (Anderson et al., 2012).Taken together, these data implicate CNTNAP2 in controlling E/I balance and behavior, possibly through cortical interneuron function. Indeed, epilepsy - an E/I imbalance disorder - is a common core phenotype of many human subjects with *CNTNAP2* disruption (Rodenas-Cuadrado et al., 2014). However, mechanistic studies verifying this hypothesis have not yet been established. To this end, we used a wide array of techniques including yeast-2-hybrid screening, confocal and high resolution imaging, biochemistry, primary neuronal culture, and *in vivo* models, to dissect CNTNAP2's role in cortical interneuron function and to uncover novel interaction candidates involved with this process.

Title: A synaptic role of FKBP5, a genetic risk factor for stress-related psychiatric disorders.

Authors: *K. MYCZEK[1], I. OZSAN[1], H. YAMAZAKI[2], M. MARTIN-DE-SAAVEDRA[1], P. PENZES[1];
[1]Northwestern Univ., Chicago, IL; [2]Gunma Univ., Maebashi, Japan

Abstract: The development of psychiatric disorders, such as depression, post-traumatic stress-disorder, and bipolar disorder has been shown to be associated with alterations in neuronal structure and function, particularly in the cerebral cortex. While recent large scale clinical genomics studies have identified genetic risk factors for psychiatric disorders, the functional analysis of these risk genes and their encoded proteins is the next major challenge. Among these, FKBP5, encoding FK506 binding protein, is a prominent genetic risk factor for stress-related mood and anxiety disorders, including depression and post-traumatic stress-disorder. However, the mechanisms by which FKBP5 contributes to disease pathogenesis are not well understood. While a role for FKBP5 as a glucocorticoid receptor co-chaperone has been studied, additional mechanisms in the brain remain under investigated. We hypothesized that FKBP5 may also function at synapses, sites relevant for the pathogenesis of psychiatric disorders. By utilizing an *in vitro* model of stress and primary rodent cortical cultures we have found independent effects of stress and FKBP5 on neuronal morphology. Furthermore, our super-resolution microscopy and live cell imaging techniques have revealed a unique synaptic role of FKBP5. Further studies investigating the molecular pathways involved in FKBP5-mediated synaptic processes can provide insight into disease pathogenesis and may lead to novel therapeutic strategies.

Title: Kalirin proteins display differential localization in dendritic spines and regulate spine morphology and trafficking of NR2B-containing glutamate receptors

Authors: T. A. RUSSELL, K. R. SMITH, K. J. KOPEIKINA, *P. PENZES;
Dept Physio, Nothwestern Univ. Feinberg Sch. Med., Chicago, IL

Abstract: Kalirin proteins are guanine nucleotide exchange factors that are essential for dendritic spine maintenance and function in forebrain pyramidal neurons, and have been shown to be linked to psychiatric disorders including schizophrenia. The three most abundant kalirin isoforms, kalirin-7, -9, and -12, have various combinations of protein-protein interaction and enzymatic domains, which have been shown to afford them distinct localizations and functions in developing cultured cortical neurons. However, he subcellular localizations of individual kalirin isoforms in mature neurons have not been ascertained. Here we used structured illumination microscopy to examine the nanoscale level distribution of kalirin proteins in dendritic spine compartments, and correlated the presence and levels of immunoreactive nanodomains with spine morphology. The majority of spines analyzed contained kalirin-7 and/or kalirin-12, but not kalirin-9, and the presence and levels of all three isoforms were associated with larger spines. We then chose to characterize the relative distributions of individual kalirin isoforms and the NMDA receptor subunit NR2B, since kalirin-7 and kalirin-12 have been shown to interact with NR2B, *KALRN* knockout mice have dysregulated NR2B expression during development, and like *Kalrn*, the gene encoding this subunit has been linked to psychiatric disorders. Interestingly, the presence of kalirin-12 in the spine neck appeared to preclude the presence of NR2B in spines, and was associated with smaller spines than those without kalirin-12 in the neck. Overexpression and shRNA- mediated knockdown of kalirin-12 confirmed the role of this isoform in regulating trafficking of NR2B- containing NMDA receptors to spine heads. Taken together, these data establish a heretofore unknown mechanism by which kalirin proteins regulate spine structural plasticity and glutamate receptor signaling.

Title: Role of 190 kDa Ankyrin-G palmitoylation in spine and dendrite maintenance

Authors: *N. H. PIGUEL[1], K. R. SMITH[2], P. PENZES[1];
[1]Northwestern Univ., Chicago, IL; [2]Univ. of Bristol, Bristol, United Kingdom

Abstract: Common and rare variants in the ANK3 gene, encoding the ankyrin-G protein, have been associated with bipolar disorder, schizophrenia and autism. Ankyrin-G has been studied extensively in the axon initial segment, where 480 kDa and 270 kDa isoforms stabilized and compartmentalized several proteins such as sodium channels. Furthermore, those ankyrin-G isoforms can bind EB1 and EB3 proteins and seem to have a unique role in the axon involving EB3 and tubulin organization. Recent evidence implicates glutamatergic synapses as key pathogenic sites in psychiatric disorders. Our previous work showed 190 kDa ankyrin-G can form nanodomains in dendritic spines and specifically regulated AMPA stability and activity-dependent spine enlargement. Here, we provide evidence than ankyrin190 kDa is present in a complex with the NMDA receptors, another major actor in dendritic spines implicated in psychiatric disorders, and can stabilize this receptor through a palmitoylation site. We also illustrate that ankyrin-G can affect tubulin dynamics in dendrites and that these functions are critical for dendrite and spine maintenance.

Title: The epilepsy and intellectual disability-related gene tbc1d24 encodes a novel synaptic protein that regulates dendritic spine morphogenesis in neuron

Authors: L. LIN[1], Q. LYU[1], E. FEI[2], N. Y. IP[2], *K.-O. LAI[1];
[1]Sch. of Biomed. Sci., The Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong

Abstract: The majority of excitatory synapses are located on dendritic spines of the postsynaptic neuron. Spine formation and turnover is considered as an important mechanism underlying brain development as well as learning and memory. Several missense mutations of the human *tbc1d24* gene have been associated with epilepsy and intellectual disability. However, the physiological role of the TBC1D24 protein remains largely unexplored. Here we report an essential role of TBC1D24 in regulating the density and morphology of dendritic spines in hippocampal neurons. We found that TBC1D24 protein was enriched in the synaptic plasma membrane fraction of adult mouse brains. Immunocytochemistry further revealed that TBC1D24 was present in close proximity to dendritic spines and the postsynaptic scaffold protein PSD-95. Notably, the expression of TBC1D24 in hippocampal neurons was bi-directionally regulated in response to elevation and blockade of neuronal activity. Using short-hairpin RNA (shRNA) to knock down its expression in mature hippocampal neurons, we demonstrated that the maintenance of dendritic spines critically depends on TBC1D24. Moreover, the small GTPase ARF6 was identified as the downstream mediator of TBC1D24 in the regulation of spine morphogenesis. These findings suggest that TBC1D24 is involved in activity-dependent spine morphogenesis in the postsynaptic neuron, and defects in spine development might contribute to the pathophysiology of intellectual disability in individuals harboring the loss-of-function gene mutations.

Title: A potential role of NMDA receptor-dependent expression of Striatin-4 in dendritic spine maturation

Authors: *L.-Y. LO, L. LIN, Q. LYU, K.-O. LAI;
Sch. of Biomed. Sci., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Most excitatory synapses are located in dendritic spines of the postsynaptic neuron. Spines exist with various shapes: the immatures spines, such as the short and stubby spines or the long and thin filopodia, do not possess a distinct spine head. In contrast, the mature spines appear as mushroom-shaped with large heads, or thin spines with elongated necks and small heads. Spine maturation requires local dendritic synthesis of new proteins in response to ongoing synaptic activity. Dysregulated dendritic mRNA trafficking and local protein synthesis can lead to altered spine morphology in neurodevelopmental disorders such as Fragile-X syndrome and autism. Nonetheless, the molecular mechanism underlying activity-dependent spine maturation is not fully understood. Striatin-4 (also called Zinedin) was identified in recent transcriptomic studies as one of the mRNA transcripts present in hippocampal neuropil and a putative cargo of the RNA-binding protein FMRP. Stiratin-4 belongs to the striatin family which serves as scaffold protein for signal transduction. Interestingly, some of the striatin-interacting proteins, such as mammalian STE20-like protein kinase 3 (MST3) and cortactin-binding protein 2 (CTTNBP2), are encoded by autism risk genes. Despite previous studies demonstrating Striatin-4 enrichment in dendritic spines, the function of Striatin-4 in neuron remains unknown. Here we found that Striatin-4 mRNA and protein expression in cortical and hippocampal neurons was regulated by neuronal activity and NMDA receptors. Notably, Striatin-4 was preferentially expressed in mature dendritic spines, and its down-regulation by NMDA receptor antagonist APV was accompanied with a switch of mature spines to stubby spines and filopodia. Knockdown of striatin-4 in hippocampal neurons by shRNA led to the loss of mature spines and increased proportions of stubby spines and filopodia, therefore mimicked the spine phenotypes after NMDA receptor blockade. Taken together, these findings suggest that NMDA receptor-dependent synthesis of striatin-4 is crucial for the maturation of dendritic spines in hippocampal neurons.

Title: Role of IQSEC3 in inhibitory synapse formation

Authors: H. KANG[1,2], D. PARK[1,2], S. JEON[3], J. KO[3], *J. UM[1,2];
[2]BK21 PLUS Project for Med. Sci., [1]Yonsei Univ. Col. of Med., Seoul, Korea, Republic of;
[3]Dept. of Biochem., Yonsei Univ., Seoul, Korea, Republic of

Abstract: Gephyrin is a central scaffold protein that mediates development, function and plasticity of mammalian inhibitory synapses by interacting with various inhibitory synaptic proteins. Here, we show that IQSEC3, a guanine nucleotide exchange factor (GEF) for ARF6, directly interacts with gephyrin, an interaction that is critical for the inhibitory synapse localization of IQSEC3. Overexpression of IQSEC3 increases inhibitory, but not excitatory, synapse density in a GEF activity-dependent manner. Conversely, knockdown (KD) of IQSEC3 decreases size of gephyrin cluster without altering gephyin puncta density. Collectively, these data reveal that IQSEC3 acts together with gephyrin to regulate inhibitory synapse development.

Title: Spines require normal DISC1 function during development of their parent dendritic branch

Authors: *A. M. DE HAAN, N. R. HARDINGHAM, K. FOX;
Cardiff Univ., Cardiff, United Kingdom

Abstract: Disrupted-In-Schizophrenia 1 (DISC1) is known to play an important role in brain development and is implicated in mental disorders such as schizophrenia and autism. We investigated effects of disrupting DISC1 using a transgenic mouse with a dominant negative

fragment of the DISC1 c-terminal (DISC1cc), which can be activated via tamoxifen injection. DISC1cc is then active for 6-48 hours only, allowing a narrow time window of effect to be studied.

Activation of the mutant protein at postnatal day 7 (P7) results in schizophrenia-related phenotypes (Li et al., 2007) and a loss of LTP and experience dependent plasticity in layer 2/3 (L2/3) of adult barrel cortex (Greenhill et al., 2015). Disruption at P28 has no effect on experience dependent plasticity, suggesting a critical period for the development of plasticity itself (Greenhill et al., 2015).

Disruption at P7 was found to specifically affect 2nd and 3rd order basal dendrites, which corresponds to the age at which these dendritic segments largely develop. These dendrites showed lower spine density and had fewer mushroom spines compared either to 4th and 5th order dendrites (which develop later) in the same animals, or to 2nd and 3rd order dendrites in wild-type controls.

However, it remains unknown whether these effects are due to 2nd and 3rd order dendrites developing at P7, or whether these orders are uniquely vulnerable to any disruption of DISC1 around that time. To investigate this, we delayed the tamoxifen injection (and thus the disruption of DISC1) until P9.

When injected with tamoxifen at P9, 2nd and 3rd order dendrites showed spine density and morphology similar to that in wild-type controls. However, 4th order dendrites showed lower spine density and 5th order dendrites had fewer mushroom spines. The effects of DISC1 disruption starting at P9 were more variable than at P7, which might be due to more variance in distance to the soma and thus a more variable age of development. However, these data clearly show that DISC1 disruption only affects spine density and morphology at a point in time when the parent dendrite is forming.

Abstract: Inhibitory interneurons of the hippocampus and neocortex are derived from two lineages within the embryonic medial- and caudal ganglionic eminences (MGE and CGE,). Their MGE or CGE origin determines many features including their glutamate receptor subunit expression profiles. However, despite the early specification of synaptic receptor subtype some aspects of neuronal plasticity are sustained through adulthood. MGE-derived inhibitory interneurons that express calcium permeable GluA2-lacking AMPARs exhibit a form of NMDAR plasticity that converts GluN2B- to GluN2A-containing NMDARs during development. This switch can also be triggered prematurely with high frequency excitatory input by a mechanism dependent on an elevation of Ca^{2+} occurring through calcium permeable AMPARs, but not NMDARs. This mechanism of NMDAR plasticity is absent from CGE-derived interneurons that typically express GluA2 containing AMPARs and GluN2B-containing NMDARs throughout life. How much of this synaptic plasticity is genetically dictated and how much of it is an adaptation to environmental cues? To answer this question we selectively eliminated GluA2 subunit expression in CGE derived interneurons thus converting Ca^{2+}-impermeable AMPARs to Ca^{2+}-permeable AMPARs. GluA2 loss in CGE-derived interneurons was verified with AMPARs IV curves that showed strong inward rectification and synaptic currents that were sensitive to philanthotoxin block. Despite this shift to an MGE-like AMPAR profile, the NMDA/AMPA ratio of the evoked responses in GluA2-KO CGE derived interneurons remained the same as WT. However GluA2 loss of function triggered a reduction in the NMDAR decay time constant in neonatal animals indicating an increase in GluN2A subunit expression, suggesting a premature GluN2B to GluN2A subunit switch. Of interest, the frequency of spontaneous excitatory synaptic activity in CGE-KO interneurons was 50% lower than that observed in WT interneurons. However, despite this reorganization of glutamatergic synapses on GluA2-KO interneurons, sIPSCs had similar properties as WT interneurons in terms of frequency, amplitude and decay kinetics ruling out a possible cross talk between glutamatergic and GABAergic syanpses. These data suggest that Ca^{2+} entry via AMPARs are critical determinants of both synaptic NMDAR and AMPAR phenotype of hippocampal interneurons.

Abstract: The stabilization of dendritic spines depends on afferent synaptic inputs and requires changes in actin cytoskeleton dynamics and protein synthesis. However, the underlying molecular mechanism remains unclear. Here, we identified calmodulin kinase-like vesicle-associated (CaMKv), a pseudokinase of the CaMK family with unknown function, as a synaptic protein crucial for dendritic spine maintenance. CaMKv mRNA localizes at dendritic spines, and its protein synthesis is regulated by neuronal activity. CaMKv function is inhibited upon phosphorylation by cyclin-dependent kinase 5 (Cdk5) at Thr-345. Furthermore, CaMKv knockdown in hippocampal CA1 pyramidal neurons *in vivo* impairs synaptic transmission and plasticity, resulting in hyperactivity and spatial memory impairment in mice. These findings collectively indicate that the precise regulation of CaMKv through activity-dependent synthesis and post-translational phosphorylation is critical for dendritic spine maintenance. Thus, this

study reveals an unusual signaling pathway involving a pseudokinase that regulates synaptic transmission and brain function.

Title: Knockout of RICH2, a SHANK3 interacting protein, leads to enlarged dendritic spines via RAC1 dependent Actin remodeling and causes neophobia in mice

Authors: *T. SAROWAR[1,2], S. GRABRUCKER[3], T. BOECKERS[3], A. GRABRUCKER[1,2]; [1]Dept. of Neurol., Inst. of Anat. & Cell Biol., Ulm, Germany; [2]WG Mol. Analysis of Synaptopathies, Neurol. Department., Neurocenter of Ulm Univ., Ulm, Germany; [3]Inst. for Anat. and Cell Biology, Ulm Univ., Ulm, Germany

Abstract: The post-synaptic densities (PSD) in the dendritic spines are functional units of signal transduction, structural stability, neuronal morphogenesis and synaptic activity. Many neurological and psychiatric disorders have been characterized in terms of the alteration of signaling, and structural and functional proteins in the PSD. There, activity dependent signaling molecules such as small GTPases interact with each other. The disruption of their interactions may lead to abnormal spine morphology and function, and, ultimately, behavioral phenotypes. The PSD protein Shank3 is very well characterized in terms of its central role in synaptopathies such as Autism Spectrum Disorders (ASD). RICH2 was identified as an interaction partner of Shank3 at excitatory glutamatergic synapses. RICH2 is a brain specific PSD protein comprising of three domains - an N-BAR domain, a RhoGAP domain and a C-terminal PDZ domain. We have generated a mouse model which lacks all the isoforms of RICH2. The disruption of the

Shank3-Rich2 interaction results in alteration in synaptic protein composition, receptors and signaling molecules. In Golgi analyses, alterations in the morphology of dendritic spines were detected that can be correlated to changes in the number of PSDs in specific brain regions. The changes are caused by increased activity of Rac1 and Cdc42, two key components of small Rho GTPases, leading to alteration in actin dynamics in spines. Interestingly, on behavioral level, besides increased repetitive behaviors, a pronounced neophobia and impaired motor learning have been observed in RICH2 knock-out mice. This mouse model points towards the importance of fine tuning among scaffolding molecules like Shank3, Rho GTPases and actin at the PSD mediated by the Shank3 interacting protein Rich2 that might be especially affected in the amygdala given the phobia observed in RICH2 knock-out mice.

Title: Axonal input to nearby Purkinje cells in early postnatal mouse cerebellum analyzed with serial section electron microscopy

Authors: ***A. M. WILSON**[1], R. SCHALEK[1], A. SUISSA-PELEG[1], T. JONES[1], S. KNOWLES-BARLEY[2], J. LICHTMAN[1];
[1]Harvard Univ., Cambridge, MA; [2]Google, Seattle, WA

Abstract: In both the peripheral and central nervous systems of developing mammals, axons prune branches to innervate fewer postsynaptic target cells, causing these cells to become innervated by fewer but stronger inputs. This synaptic reorganization is regulated by synaptic activity. This phenomenon has been mainly studied with optical techniques in parts of the peripheral nervous system, but the small sizes and dense arrangements of cells and synapses

have undermined comparable optical approaches in the central nervous system. In order to overcome the barriers to exploration of synaptic rewiring in the central nervous system, we used serial section scanning electron microscopy to produce 3D volumes of high-resolution images from cerebella of early postnatal mice. The resolution of electron microscopy suffices to identify virtually all synapses in a tissue sample. We used a recent adaptation of this technique (ATUM) in which long series of thin sections are collected on tape and automatically imaged with scanning electron microscopy. We focused on developing cerebellum because it undergoes large scale changes in connectivity and is intrinsically less complicated than cerebral cortex. We have reconstructed neonatal Purkinje cells and for one cell all of its climbing fiber, parallel fiber and inhibitory inputs. In addition we identified other Purkinje cells that shared the same climbing fiber inputs. We did this kind of analysis at several different developmental ages. We have found that parallel fibers form progressively more synapses onto Purkinje cells during the first week of postnatal life. We have also found that multiple climbing fiber axons innervate the same developing Purkinje cell. These climbing fiber axons extend over large distances in the Purkinje layer both in the sagittal and coronal dimensions. Their terminal arbors branch frequently in the Purkinje layer and form small branches and varicosities, in contrast with other axon types. Developing climbing fibers innervate a subset of closely positioned Purkinje cells. We are now inquiring whether these subsets are specific or random.

Title: Serial section super-resolution (STORM) imaging of the perineuronal net and synaptic maturation during critical period development

Authors: ***Y. SIGAL**[1], L. BOGART[1], H. BAE[1], X. ZHUANG[1,2], T. K. HENSCH[1,3]; [1]Harvard Univ., Cambridge, MA; [2]Howard Hughes Med. Inst., Cambridge, MA; [3]Boston Chirdrens Hosp., Boston, MA

Abstract: Perineuronal nets (PNNs) are specialized extracellular matrix structures which tightly enwrap a subset of parvalbumin-positive (PV+) inhibitory neurons in the mature neocortex.

Potential PNN functions include synapse stabilization, molecular signaling and protection against oxidative stress characteristic of mental illnesses. Notably, PV+ circuit maturation is pivotal for establishing critical periods of brain development during which sensitivity of synaptic connectivity to environmental stimuli is heightened. Yet, many details underlying these structural rearrangements remain unknown. Here, we applied our previously developed super-resolution STORM imaging platform for volumetric imaging and automated analysis of neuronal and synaptic structures to the studies of the PNN. Using this technique, we visualized and quantified chondroitin-sulfate proteoglycan (CSPG) labeling and synaptic 'holes' within the PNN and analyzed morphological changes across three conditions. First, during and after the normal critical period (postnatal days 30 and 90, respectively), we observed that PNNs in layers 4/5 of primary visual cortex increased in intensity and local CSPG density concomitant with a condensed lattice around the cell body and a smaller, more uniform hole size within the PNN mesh. Over this same period, synaptotagmin-2 positive (PV) boutons increased in intensity and spatial organization on the PV+ somata, as well as in interactions with the PNN proper, consistent with a role of the PNN in stabilizing inhibitory contacts. Second, we explored critical period delay by the complete absence of visual experience from birth. Postnatal day 90 dark-reared mice exhibited immature organizational aspects comparable to young light-reared animals. Third, we examined a complementary disease model of precocious critical period onset. Mice lacking MECP2 - a model of Rett Syndrome - displayed a more mature PNN profile at postnatal day 30 as compared to age-matched wildtype littermates. This was notably accompanied by a relative increase in excitatory contacts. Taken together, STORM imaging provides novel insights into the molecular and circuit level changes underlying critical period development in visual cortex, as well as the imbalanced synaptic distribution of excitatory and inhibitory contacts associated with their altered trajectory by deprivation or autism risk genes.

Title: Cooperative action of neuroligins and BDNF mediates presynaptic maturation

Authors: *A. PETKOVA[1], N. GÖDECKE[2], M. KORTE[2], T. DRESBACH[1];
[1]Inst. for Anat. and Embryology, Synaptogenesis Group, Univ. Med. Ctr. Goettingen, Goettingen, Germany; [2]Cell. Neurobio., Tech. Univ. Braunschweig, Braunschweig, Germany

Abstract: Synaptic maturation is a process that allows synapses to acquire their full functionality, and failures in synaptic maturation are thought to contribute to psychiatric disorders such as autism. Neuroligins are postsynaptic cell-adhesion molecules essential for postsynaptic and presynaptic maturation, but the transsynaptic pathways by which Neuroligins act to regulate presynaptic maturation are incompletely understood.
Here, we show that presynaptic maturation relies on the cooperative action of Neuroligins and brain-derived neurotrophic factor (BDNF). Applying BDNF to neuronal cultures mimicked the maturation-promoting effect of the overexpressed Neuroligin isoforms NL1 and NL2. Reducing the levels of BDNF by applying a BDNF scavenger (TrkB-Fc) or by Cre-induced depletion of BDNF blocked the action of NL1 and NL2. In particular, inhibiting endogenous BDNF signaling reduced the positive effects of NL1 on presynaptic maturation and of NL2 on synapse formation. Applying BDNF to cultures from NL1-knockout mice rescued defective presynaptic maturation both in early (DIV6) and late (DIV15) culture stages, indicating that BDNF acts downstream of NL1-mediated cell adhesion.
Our data introduce BDNF as a novel and essential component in a transsynaptic pathway linking NL-mediated cell adhesion, neurotrophin action and presynaptic maturation.

Title: Synapse tagging by C1q

Authors: *J. W. HAMMOND, H. A. GELBARD;
Ctr. for Neural Develop. and Dis., Univ. of Rochester, Rochester, NY

Abstract: The classical complement system has been shown to play a role in synapse elimination during development and disease. However, little is known about how complement

activation at synaptic terminals is regulated or how synapses are tagged by the initiating complement member, C1q. In order to address the question of C1q synapse tagging, we added C1q to *in vitro* hippocampal cultures and looked for changes in binding due to changes in neuronal activity or neuronal stress. We also sought to identify binding partners of C1q at synapses. We noted that addition of C1q, surprisingly, resulted in an increased number of synapses. This is reminiscent of other members of the C1q superfamily expressed in the nervous system (C1qL1-4 and Cbln1-4) that have been shown to act as trans-synaptic organizers recruiting select presynaptic and postsynaptic receptors in order to strengthen and maintain synapses between particular neurons. We hypothesize that C1q may bind synaptic proteins and facilitate synapse organization in a similar manner. We show that C1q binds the Bai family of adhesion G-protein coupled receptors. Bai1 and 3 in neurons have been shown to play a key role in synapse development and plasticity. On the other hand, Bai1 is also a phagocytosis receptor used by microglia and macrophages. Thus, this C1q-Bai interaction could have important implications for the role of C1q in both synapse tagging and phagocytic pruning of synapses by glia cells during development and disease.

Title: An inducing role for the pre-synaptic cadherin/catenin/p140Cap complex in functional synapse formation in the neocortex

Authors: M.-Y. LI, W.-Y. MIAO, S.-J. HE, *X. YU;
Inst. of Neurosci., Shanghai City, China

Abstract: The formation of functional synapses requires coordinated assembly of pre-synaptic transmitter release machinery and post-synaptic trafficking of functional receptors and scaffolds.

Here, we show that cadherin/catenin cell adhesion complexes are necessary and sufficient for functional synapse formation and spinogenesis in the developing mouse somatosensory cortex. Importantly, pre-synaptic expression of stabilized β-catenin in either layer 4 (L4) excitatory neurons or L2/3 pyramidal neurons significantly up-regulated excitatory synaptic transmission and dendritic spine density in L2/3 pyramidal neurons, while its sparse post-synaptic expression in L2/3 neurons had no such effects. In addition to increasing synapse density, pre-synaptic β-catenin expression also enhanced release probability of glutamatergic synapses; both effects required β-catenin interacting protein p140Cap specifically in the presynaptic locus. Together, our results demonstrate that cadherin/catenin complexes contribute significantly to functional synapse formation through anterograde signaling in the neocortex, providing important molecular evidence for an inducing role of pre-synaptic components in the formation of excitatory synapses in the neocortex.

Abstract: Several recent studies have demonstrated that microglia contribute to synaptic maturation during postnatal brain development. *In vivo* time-lapse imaging in the mouse brain has shown that microglia occasionally contact synapses and experiments in fixed brain tissue identified synaptic material inside microglia, suggesting that engulfment of synapses by microglia may contribute to synapse elimination and circuit maturation during development. However, until now no evidence exists to support the selective phagocytosis of synaptic material by microglia under non-pathological conditions. Here we have used high-resolution time-lapse multicolor fluorescent lightsheet microscopy to image microglia-synapse interactions in organotypic hippocampal cultures. This approach allowed us to systematically identify, follow, and quantify transient contacts between microglia processes and dendritic spines. In parallel, we carried out volume correlative light-electron microscopy (CLEM) to produce 3D images of microglia-synapse interaction ultrastructure.

Title: Beta arrestin 2 couples $mGlu_5$ to fmrp-regulated protein synthesis and is a novel target for the treatment of fragile x syndrome

Authors: ***R. K. SENTER**[1], L. J. STOPPEL[1], B. D. AUERBACH[2], A. R. PREZA[1], R. J. LEFKOWITZ[3], M. F. BEAR[1];
[1]Picower Inst. of Learning and Memory, MIT, Cambridge, MA; [2]The Ctr. for Hearing and Deafness, Dept. of Communicative Disorders and Sci., The State Univ. of New York at Buffalo, Buffalo, NY; [3]Dept. of Medicine, Howard Hughes Med. Inst., Duke Univ. Med. Ctr., Durham, NC

Abstract: Fragile X Syndrome (FX) is caused by silencing the FMR1 gene, and consequent loss of the encoded protein FMRP. Considerable evidence suggests that dysregulated synaptic protein synthesis downstream of metabotropic glutamate receptor 5 ($mGlu_5$) activation is a major contributor to disease pathogenesis. Therapies targeting this dysregulation, however, have yet to succeed in clinical trials, possibly due to our incomplete understanding of the signaling pathways that couple $mGlu_5$ activation to neuronal mRNA translation. Here, we demonstrate that β-arrestin2 is a critical link between $mGlu_5$ activation, FMRP-regulated translation, and synaptic plasticity. Heterozygous deletion of β-arrestin2 severely blunts $mGlu_5$-stimulated protein synthesis, ERK activation, and $mGlu_5$-LTD while preserving canonical Gq signaling. Interestingly, genetic reduction of β-arrestin2 in *Fmr1*-null mice is sufficient to correct many recognized deficits, including exaggerated protein synthesis and $mGlu_5$-LTD as well as many cognitive and behavioral impairments. Importantly, this reduction in β-arrestin2 does not induce the same psychotomimetic side effects associated with full $mGlu_5$ inhibitors, indicating that targeting β-arrestin2-mediated signaling may be a more selective approach to the treatment of FX.

Title: Neuromodulation of synaptic transmission by group I mGluRs in MNTB neurons in a mouse model of fragile X syndrome

Authors: *Y. LU;
Dept Anat. & Neurobiol, Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Fragile X syndrome (FXS) is the leading single-gene cause for mental retardation. Among other deficits, FXS patients experience compromised sensory processing. Previous research has shown that in a fragile X mental retardation gene 1 (FMR1) knock out mouse model (Fmr1 KO), auditory cortical neurons exhibit abnormal auditory responses and impaired neural plasticity. In the medial nucleus of trapezoid body (MNTB, a critical nucleus in the brainstem sound localization circuit), the presynaptic terminal (calyx) become larger, cell size decreases, and Kv channels change their distribution. The loss of FMR protein function also results in exaggerated activity of group I metabotropic glutamate receptors (mGluR I). Altered neuromodulation may underlie compromised auditory processing. Here, we investigated mGluR I neuromodulation of synaptic transmission in MNTB neurons in Fmr1 KO and wild type (WT) mice, using whole-cell recordings from brainstem slices obtained from P12-P22 mice. The basal level of excitatory transmission in the KO was slightly reduced and compromised, whereas the basal level of inhibitory transmission was strengthened. MNTB neurons of the WT showed primarily all-or-none evoked EPSCs (eEPSCs), while most KO neurons showed graded input-output functions. Proportionally more KO neurons exhibited synaptic facilitation in a paired-pulse paradigm. In about half of the recorded neurons, activation of mGluR I by 3,5-DHPG (200 μM) suppressed eEPSCs, and the suppression in the KO was moderately stronger than in the WT. 3,5-DHPG also produced an inward current at the holding potential of -60 mV. Surprisingly, 3,5-DHPG increased spontaneous EPSC (sEPSC) frequency in both WT and KO neurons. Similarly, 3,5-DHPG enhanced sIPSCs, without affecting eIPSCs. The differential modulation of spontaneous versus evoked transmitter release suggests that the vesicle pools

responsible for these two different modes of release, as well as the mechanisms underlying mGluR modulation of the two release machineries, are different.

Title: Maturation of fast-spiking neurons in the cortex is delayed in Fragile X mice

Authors: *T. NOMURA[1], A. CONTRACTOR[2];
[1]Physiol., [2]Northwestern Univ., Chicago, IL

Abstract: Fragile X Syndrome (FXS) is a prototypical neurodevelopmental disorder that causes intellectual disability and autism. The mouse model of FXS (*Fmr1* KO) recapitulates aspects of the human disorder including alteration in sensory processing. There is a delay in the development of synapses and a shift in the timing of the critical period for plasticity in the somatosensory cortex (barrel cortex) of *Fmr1* KO mice and sensory evoked responses in the cortex are exaggerated. There are known alterations in GABA signaling that have been described in the cortex of FXS mice, however the extent of these alterations and how they contribute to synaptic development are not fully characterized. In the visual cortex there is strong evidence that fast-spiking (FS) interneurons are central to establishing cortical critical periods. Here we proposed to map the functional development of FS interneurons in the somatosensory cortex during the course of the critical period in *Fmr1* KO mice. We crossed *Fmr1* KO mice with a strain expressing eGFP in parvalbumin containing interneurons to facilitate the targeted patch clamp recording of FS interneurons in a slice. As a measure of FS interneuron maturation, we examined the degree of spike adaptation, quantified as spike ratio (the initial to final spike frequency during a train of action potentials). Comparison of the firing characteristics of FS interneurons in *Fmr1* WT and *Fmr1* KO neonatal mice demonstrated a reduction in spike ratio in *Fmr1* KO mice during the critical period in the barrel cortex. In *Fmr1* WT mice at postnatal day (P) 9, the spike ratio was 0.69 ± 0.01 ($n = 37$), whereas in *Fmr1* KO mice the measured spike

ratio was 0.62 ± 0.01 (n = 25) ($p < 0.01$). These data demonstrate that at P9 FS interneurons spiking shows greater adaptation and suggests that FS interneuron maturation is delayed in the somatosensory cortex of *Fmr1* KO mice. It is well established that the trophic factor BDNF has a crucial role in neuronal maturation. Therefore we determined if the administration of a TrkB receptor agonist (LM22A-4) to neonates could reverse the delays in FS neuron maturation. Daily administration of a TrkB receptor agonist normalized functional measures of FS interneuron maturation in *Fmr1* KO mice. The spike ratio at P9 was 0.61 ± 0.02 (n = 36) and 0.69 ± 0.01 (n = 39) in vehicle and LM22A-4 treated group in *Fmr1* KO mice ($p < 0.01$) demonstrating that there was a normalization of this measure in KO mice treated with a TrkB agonist. Administration of LM22A-4 had no effect on the spike ratio in WT mice. These results demonstrate that there is a delay in FS interneuron maturation in the cortex of *Fmr1* KO mice that is due to a deficit in BDNF - TrkB signaling.

Abstract: Fragile X Syndrome (FXS) is the most common form of inherited intellectual disability, frequently associated with epilepsy and autism. *Fmr1* KO mice, a model of FXS, display excessive metabotropic glutamate receptor-mediated long-term depression (mGluR-

LTD), altered dendritic spine morphology, learning deficit and autistic behavior. We have shown that 5-HT_7 receptor (5-HT7R) agonists reverse mGluR-LTD in wt and *Fmr1* KO mice (Costa et al., Biol. Psych. 2012, 72:924-933). We have preliminary data showing that 5-HT7R agonists also rescue dendritic spine morphology, learning and behavior in *Fmr1*KO mice, suggesting that they might become a novel therapeutic strategy for FXS.
To identify the mechanisms underlying 5-HT7R-mediated effects, we used patch clamp on hippocampal slices from wild-type (wt) and *Fmr1* KO mice to test the effects of 5-HT7R agonists on mGluR-LTD in the presence of specific blockers of intracellular messengers. LP-211, a selective 5-HT_7 R agonist, reversed mGluR-LTD in the CA3-CA1 synapse in wt and *Fmr1* KO slices. The effect of LP-211 was mimicked by forskolin and was abolished by the adenylate cyclase inhibitor SQ22536. The effect of LP-211 persisted in the presence of cAMPS-Rp or PKA inhibitor peptide fragment 6-22 (PKA inhibitors) or PD98059 (a MEK/ERK inhibitor), but was reduced in the presence of lithium (a PI3K/GSK3 inhibitor) and was completely abolished in the presence of SB216763 (a GSK3 inhibitor), roscovitine (a Cdk5 inhibitor) or anisomycin (a protein translation inhibitor). Taken together our data show that 5-HT_7 receptor activation reverses mGluR-LTD acting through a cAMP-dependent mechanism involving Cdk5 and GSK3 kinases and protein synthesis; we are currently investigating at which level these pathways interact.

Title: Reduced lateral inhibition impairs olfactory computations and behaviors in a *Drosophila* model of Fragile X Syndrome

Authors: *L. M. FRANCO MÉNDEZ[1,2], Z. OKRAY[1], B. A. HASSAN[1,3], E. YAKSI[2,4]; [1]VIB Ctr. for The Biol. Of Dis., [2]Neuroelectronics Res. Flanders (NERF), KU Leuven, Leuven, Belgium; [3]Inst. du Cerveau et de la Moelle Epinière (ICM), Hôpital Pitié-Salpétrière, Paris,

France; [4]Kavli Inst. for Systems Neurosci. and Ctr. for Neural Computation, NTNU, Trondheim, Norway

Abstract: Fragile X syndrome (FXS) patients present neuronal alterations that lead to severe intellectual disability, but the underlying neuronal circuit mechanisms are poorly understood. An exciting hypothesis postulates that reduced GABAergic inhibition of excitatory neurons is a key component in the pathophysiology of FXS. Here, we directly test this idea. First, we show that a FXS *Drosophila* model exhibits strongly impaired olfactory behaviors. In line with this, olfactory representations are less odor-specific due to broader response tuning of excitatory projection neurons. We find that impaired inhibitory interactions underlie reduced specificity in olfactory representations. Finally, we show that defective lateral inhibition across projection neurons is caused by weaker inhibition from GABAergic interneurons. We provide direct evidence that deficient inhibition impairs sensory computations and behavior in an *in vivo* model of FXS. Together with evidence of impaired inhibition in autism and Rett syndrome, these findings suggest a potentially general mechanism for intellectual disability.

Title: PQBP1 mutations promote FMRP degradation

Authors: *X.-Y. ZHANG[1,2], Y.-Q. SHEN[2], X. LIU[2], Z. ZHANG[2];
[1]Inst. of Lifescience, Jiangsu, China; [2]Inst. of life sciences, Nanjing, China

Abstract: Renpenning syndrome is a group of X-linked intellectual disability (XLID) syndromes caused by mutations in human polyglutamine-binding protein 1 (*PQBP1*) gene. Little is known about the molecular pathogenesis of the various mutations that cause the notable variability in patients. In this study, we examined the synaptic and cellular functions of the most common mutations found the patients: c.461_462delAG, c.459-462delAGAG, and c.463_464dupAG in an AG hexamer in PQBP1 exon 4. All three mutations result in the frame-shifts and premature termination. In contrast to current loss-of-function pathogenic hypothesis, we discovered that the

frame-shifted sequences of PQBP1 c.459_462delAGAG and c.463_464dupAG mutations encode a new C-terminal epitope that preferentially binds non-phosphorylated fragile X mental retardation protein (FMRP) and promotes its ubiquitinmediated degradation. Consequently, the PQBP1 mutant-induced reduction of FMRP relieves its inhibition on translation and leads to the up-regulation of its targets such as MAP1B. Elevated MAP1B disrupts the local cytoskeleton structure and results in a remarkable synaptic over-growth in the neuromuscular junction (NMJ) of PQBP1 c.463_464dupAG transgenic flies, which can be rescued by exogenously expressing dFMRP. Our evidence strongly supports a gain-of-function pathogenic mechanism of the prevailing mutations of Renpenning syndrome PQBP1 c.459_462delAGAG and c.463_464dupAG. In addition, we reveal that the pathology of Renpenning syndrome is directly linked to Fragile X syndrome. These findings will reshape our thinking of therapeutic strategies for X-linked intellectual disability.

Title: Synaptic translation of neuroligins 1, 2 and 3 is regulated by FMRP

Authors: ***M. DZIEMBOWSKA**, J. PODSIADŁOWSKA, K. JĄCZYŃSKA, J. MIŁEK, B. KUŹNIEWSKA;
Ctr. of New Technologies, Univ. of Warsaw, Warszawa, Poland

Abstract: Neuroligins (NLGNs) are postsynaptic cell adhesion proteins which bind to their presynaptic partner neurexin across the synaptic cleft. Neuroligins play a key role in the formation, maturation and maintenance of synapses. Here, we sought to determine whether the synaptic translation of NLGN mRNA is regulated by fragile X protein. The mRNA for three studied neuroligins NLGN1, NLGN2 and NLGN3 was immunoprecipitated with anti-FMRP antibody suggesting that FMRP regulates synaptic translation of neuroligins. We have also observed a rapid, activity-dependent polyadenylation of NLG1 mRNA. The profile of polyribosomes isolated from Fmr1 KO synaptoneurosomes confirms its elevated translation in the basal state and the lack of response to stimulation. Moreover our results indicate that excessive neuroligin synthesis at the synapse of Fmr1KO mice leads to their higher abundance

on the synapse that was detected in synaptoneurosomes by the biotynylation assay. We have also observed that in synaptoneurosomes, glutamate-induced signaling can stimulate cleavage of neuroligin1 both in WT and Fmr1 KO mice. The correct level of synaptic NLGNs may be responsible for proper synapse formation and stability of the synaptic connections which are deregulated in fragile X syndrome. Characterizing NLGN1, NLGN2 and NLGN3 mRNAs as FMRP substrates will contribute to understanding the synaptic defects of FXS.

Title: Astrocyte purinergic signaling significantly altered in fragile x syndrome model

Authors: *A. L. SCOTT, A. CHEN, L. DOERING;
Dept. of Pathology and Mol. Med., McMaster Univ., Hamilton, ON, Canada

Abstract: Neural communication and the intricate choreography of signals required for the formation and preservation of neural connections is heavily dependent on reciprocal neuronal and glial interactions. Astrocytes are key participants in neurodevelopmental processes and defects to astrocyte signaling are implicated in disorders such as Fragile X Syndrome (FXS). In FXS, the loss of the Fragile X mental retardation protein (FMRP) expression from astrocytes is associated with delayed dendrite maturation and improper synapse formation. These findings emphasize the importance of astrocyte-derived signals to neuronal connections and illustrate the devastating consequences an imbalance to these signals can cause. During development astrocytes release a wide range of gliotransmitters; however, the use of ATP is one of the predominant means of communication between astrocytes and neurons within the CNS. ATP is a fast, excitatory neurotransmitter known to act on astrocytes, modulate glio-neuronal transmission, and in this way regulate synaptic function. Given the integral role of ATP and its various metabolites to the regulation of synaptic development and function, we compared the

physiological responses of astrocytes isolated from either post-natal wild-type ($FMRP^{+/+}$) mice or from transgenic *fmr 1* knockout ($FMRP^{-/-}$) mice to exogenous purinergic stimulation. The quantitative analysis of intracellular calcium levels revealed a significantly greater flux of intracellular calcium in $FMRP^{-/-}$ astrocytes in response to ATP (and UTP) than observed in $FMRP^{+/+}$ astrocytes. Interestingly, blockade of several purinergic receptors with suramin returned abnormal astrocytic calcium flux to wild-type levels. In addition, immunocytochemical and protein analysis demonstrated greater expression of purinergic receptors, P2Y2 and P2Y4 in particular, in $FMRP^{-/-}$ astrocytes over the wild-type counterparts in astrocytes alone. The differential expression may underlie the enhanced sensitivity of $FMRP^{-/-}$ astrocytes and lead to atypical neural communication during development in FXS. Future analysis of the effects on astrocyte-neuron purinergic signaling in the $FMRP^{-/-}$ model will help elucidate the role these signals play in synapse function and the potential therapeutic relevance to FXS.

Title: Fragile X circuits show differential developmental delays of spontaneous and evoked network activity but normal homeostatic plasticity

Authors: *H. MOTANIS, D. BUONOMANO;
Dept. of Neurobio. and Pshychology, and Integrative center for learning, UCLA, Los Angeles, CA

Abstract: Since the generation of the first mouse model of Fragile X (FX) syndrome a broad range of neurophysiological phenotypes have been reported. However, it remains unclear which phenotypes are casually related to the cognitive deficits associated with FX and which are an indirect consequence of abnormal development or experience. FX syndrome is characterized by developmental delays, and recently we have demonstrated an *in vitro* developmental delay of spontaneous Up state activity (Motanis et al., 2015)—suggesting that this neural phenotype is a direct consequence of the FX mutation as opposed to an indirect product of compensation or abnormal development. Here we use this *in vitro* approach to characterize developmental delays of network-level activity and to determine whether FX circuits adapt normally to chronic

external inputs. At 11-15 days *in vitro* (DIV) evoked EPSP strength was not different between WT and FX cortical circuits, however evoked network activity was significantly reduced in FX circuits ($p<0.01$). At 25-30 DIV WT circuits exhibited a developmental change in synaptic strength as evidenced by an increase in the asymptote of the input-output curves, EPSPs in FX circuits, however, were significantly weaker ($p<0.005$). By 35-40 DIV there were no differences in EPSPs strength or evoked network activity between WT and FX circuit—indicating that evoked activity is developmentally delayed in FX circuits. Next we explored network-level plasticity, by examining activity-dependent modulation of evoked activity. We used chronic optogenetic stimulation (COS) to emulate an increase in externally driven activity and induce homeostatic plasticity of network activity. WT and FX slices were stimulated for two days. COS resulted in significant reduction of evoked EPSP strength ($p<10^{-7}$), with no genotype difference. These results indicate that FX circuits exhibit normal homeostatic plasticity and hint at the possibility that some previously described neural phenotypes observed in FX may be compensatory. We are currently examining whether FX circuits exhibit deficits in a form of "*in vitro* learning". Specifically, it has been shown that slices exposed to patterned stimulation, in the form of different intervals between electrical and optical stimulation, learn the interval used during training (Goel et al., 2016). In WT experiments in which one electrical pathway (CS+) was paired with optical stimulation and the other was not (CS-), there was an increase in network activity evoked by the CS+ pathway compared to the unpaired electrical pathway ($p=0.02$), and are currently determining whether there is a difference in the form of plasticity between WT and FX circuits.

Title: Testing the mGluR5 theory of FXS in the laboratory rat

Authors: S. VEERARAGAVAN, L. YUVA, R. PAYLOR, *R. C. SAMACO;
Mol. and Human Genet., Baylor Col. of Medicine/Jan and Dan Duncan Neurolog. Res. Inst., Houston, TX

Abstract: The group I metabotropic glutamate receptor 5 (mGluR5) encoded by *GRM5* mediates aspects of synaptic plasticity and behavior, and studies in human have linked disruptions in mGluR5 signaling with several neuropsychiatric conditions including schizophrenia and attention-deficit/hyperactivity disorder. In addition, excessive mGluR5 signaling has been proposed as a primary contributor to features of Fragile X syndrome (FXS) as evident in a series of mouse model studies; however, recent clinical trials targeting this pathway in individuals with FXS have not been successful to date. Among the several reasons put forth to explain the lack of success of these clinical trials, we hypothesized that perhaps the reliance on findings solely from the laboratory mouse may be one contributing factor and previously found that behavioral phenotypes are not entirely overlapping in male rats and mice lacking *Fmr1*. Therefore, in preparation for genetic and pharmacologic studies to re-evaluate the findings that decreased dosage of mGluR5 in a second mammalian rodent species may improve *Fmr1*-related phenotypes, we conducted two independent replication studies characterizing the behavioral features of *Fmr1* rats, as well as evaluated the behavioral consequences of mGluR5 deficiency in parallel studies of *Grm5* rat and mouse models. Ongoing work suggests that deficits in play behavior are reproducible across cohorts of animals and across individual testers. Furthermore, heterozygous deficiency of mGluR5 in rats and mice tested at the same ages do not result in behavioral impairments as previously observed. Interestingly, *Grm5* rats and mice with complete loss of mGluR5 do not show identical behavioral impairments with the exception of hyperactivity. Taken together, these findings provide the framework for future studies in the rat that will evaluate the hypothesis that targeting the mGluR5 signaling may improve phenotypic outcome.

Title: Prefrontal cortex dysfunction in Fragile X Syndrome: Single-unit responses of excitatory and inhibitory neurons correlated with behavior.

Authors: *J. J. SIEGEL, R. A. CHITWOOD, W. TAYLOR, J. M. DING, R. GRAY, D. JOHNSTON;
Ctr. for Learning & Memory, Univ. of Texas at Austin, Austin, TX

Abstract: Fragile X Syndrome (FX) is an autism spectrum disorder and the most common heritable cause of mental disability, resulting from an inability to produce the protein FMRP. FX patients show a number of cognitive and emotional impairments, including working memory deficits due to prefrontal cortex (PFC) dysfunction. Identifying behavioral tasks in the FX mouse model that capture the impairments observed in the human patient population has been challenging. We have developed a task for use in mice that directly engages the same neural mechanism in the PFC believed to support working memory (persistent spiking), known traditionally as trace eyeblink conditioning (TEC). We show here that FX mice are profoundly impaired in TEC (Wilcoxon Test, $U=319.5$, $p<0.0005$; Day 12 median response rate; FX: n=25, 1.89%; C57: n=16, 62.62%). Furthermore, knockout of FMRP in the PFC alone was sufficient to observe deficits (n= 15 and 16, $U=157.5$, $p=0.06$). The observed impairment appears to be one of the most striking behavioral deficits reported for FX mice, and offers a new tool to investigate PFC dysfunction in FX. Despite the profound deficit, a modest proportion of FX mice (~one-third) were able to overcome the dysfunction with additional training and ultimately express learning. To determine how a minority of FX mice were able to compensate for dysfunction and eventually learn, we recorded single-unit activity in the PFC of FX mice during TEC and compared neural responses between FX nonlearners to the atypical FX "learner". No differences were observed in the average firing rates or spike widths of putative excitatory or inhibitory PFC cells between FX and wild-type mice. The excitatory cells of FX mice showed persistent spiking to conditional stimuli, similar to that observed in wild-type mice. Putative inhibitory cells in FX mice, however, showed remarkably strong persistent spiking in response to conditional stimuli relative to that observed in wild-type mice (bootstrap test, $p<0.001$ each 50 ms trial time bin). The excitatory cells of wild-type mice showed increased persistent spiking in association with learning. For the FX mice that were able to express learning, excitatory cells did not increase in association with learning. Instead, learning in FX mice was associated with reliable decreases in the responses of inhibitory cells, which was not observed in the more typical FX non-learner. The data suggest that a training-associated decrease in inhibition during the conditional stimulus may be a compensatory mechanism to allow learning in FX mice, perhaps by restoring the excitatory/inhibitory balance thought to underlie cortical dysfunction in FX and other autistic disorders.

Title: Inhibitory function in the piriform cortex of the Fragile X Syndrome mouse model

Authors: *A. WIDMER, J. LARSON;
Psychiatry, Univ. of Illinois at Chicago Dept. of Psychiatry, Chicago, IL

Abstract: Fragile X Syndrome (FXS), the major inherited cause of intellectual disability and a leading contributor to autism, is a complicated disorder characterized by altered synaptic function, network hyperexcitability, and cognitive impairment. Though the genetic underpinning of the disease is relatively well understood, the consequences of the silencing of the *Fmr1* gene are varied. Reports of altered function in both excitatory and inhibitory synaptic activity have been published in recent years, but there is still no clear cause of the excitatory/inhibitory imbalance observed in the FXS brain. The current research utilizes complementary techniques in order to characterize the inhibitory circuitry in a select region, the primary olfactory cortex. By combining different methodologies, one can comprehensively map the distribution and quantities of select gamma-aminobutyric acid subtype A (GABA-A) receptor species and correlate these data with differences in electrophysiological function. The GABA-A receptor is a heteromeric receptor protein, and the subunit makeup of the receptor can alter both its distribution within the neural tissue and its function. Of particular interest in FXS is the inhibitory conductance mediated by tonically active GABA-A receptors. Changes in the expression of these specific receptors may underpin many of the observed pathologies associated with FXS, such as disordered information processing, epilepsy, and abnormal sensorimotor integration. This work provides a comprehensive measure of the contribution of both phasic and tonic GABA-A receptors to the inhibitory environment of the primary olfactory cortex. Single-cell analysis of GABAergic events provides an excellent measure of miniature inhibitory postsynaptic currents, revealing parity between FXS and wild-type inhibitory synapses. Parameters such as peak amplitude, rise and decay constants, and temporal spacing are similar between the two genotypes tested, suggesting no derangement of synaptic inhibition in this region in the FXS model. Specific agonism and antagonism of extrasynaptic receptor subunits is planned to provide further data about the tonic current mediated by these receptor species. Additionally, parallel investigations using molecular biological techniques will be conducted to quantify the levels of subunit mRNA transcripts and protein expression in the cortical principal cells. Through the use

of these varied research approaches, we will gain a multifaceted understanding of the inhibitory mechanisms in FXS within a single cortical brain region.

Title: Calcium-binding protein regulation in a *Drosophila* model of fragile x syndrome

Authors: *C. R. TESSIER[1], C. G. SWINFORD[2];
[1]Indiana Univ. Sch. of Medicine-South Bend, South Bend, IN; [2]Univ. of Notre Dame, Notre Dame, IN

Abstract: Intracellular calcium levels are tightly regulated by a host of proteins which function to transport, sequester, and store calcium ions under different physiological circumstances. Defects in calcium homeostasis are known to have profound consequences ranging from improper circuit development to aberrant cognitive behaviors. Fragile X Syndrome (FXS) is an autism spectrum disorder that arises from improper neuronal development and is hallmarked by increased synaptic transmission and augmented calcium transients. The dysregulation of calcium homeostasis in FXS is further evidenced by the misexpression of many calcium-binding proteins in the *Drosophila* model of the disease. The *Drosophila* calcium-binding protein Cbp53E is the single homolog of a small vertebrate calcium-binding protein family consisting of calbindin, calretinin, and secretagogin. These proteins function principally as calcium buffers during acute changes in intracellular calcium levels. Cbp53E expression is reduced in the *Drosophila* model of FXS and loss of function of Cbp53E leads to increased neuronal growth which is consistent with the increased neuronal elaboration seen in FXS. Interestingly, overexpression of Cbp53E is able to rescue the synaptic overgrowth seen in the central nervous system of the *Drosophila* FXS model. These findings suggest that restoring proper neuronal calcium signaling may restore molecular and behavioral defects of FXS animals as well. Given the fundamental necessity for proper calcium regulation in neurons, manipulating calcium-binding proteins may serve as a useful therapeutic strategy for FXS and other diseases.

Title: Fragile X-associated tremor/ataxia syndrome: linking calcium dysregulation and DNA damage responses

Authors: *G. A. ROBIN[1], J. R. LÓPEZ[1], S. HULSIZER[1], P. J. HAGERMAN[2,3], I. N. PESSAH[1,3];
[1]Mol. Biosci., UC Davis, Davis, CA; [2]Dept. of Biochem. and Mol. Med., UC Davis,, Davis, CA; [3]Med. Investigations of Neurodevelopmental Disorders (M.I.N.D) Inst., Sacramento, CA

Abstract: Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset, neurodegenerative disorder that affects carriers of the premutation CGG-repeat allele (preCGG; 55-200 repeats) of the fragile X mental retardation 1 (*FMR1*) gene. Early abnormal growth and Ca^{2+} dynamics in *FMR1* premutation preCGG knock-in mice and human iPSC-derived preCGG neurons precede neurodegeneration and FXTAS. Whether intranuclear inclusions containing DNA damage response (DDR) proteins, pathologic hallmark of FXTAS, causally link Ca^{2+} dysregulation with abnormal neuronal growth and survival is unknown. We hypothesize a role for CdK5 and ATM in FXTAS pathogenesis, two key signaling kinases involved in both DDR and synaptic signaling. FMRP expression in postnatal day 0 (P_0), 6-week- and 6-month-old preCGG mouse brain is reduced by 60-, 50- and 30% compared to *wt,* respectively. In primary preCGG hippocampal neurons, FMRP reduction is more pronounced in soma (20% reduction, $p<0.0001$) compared to neurites (5% reduction, $p=0.0177$). Resting cytoplasmic calcium concentration ($[Ca^{2+}]_i$) in preCGG hippocampal neurons is chronically elevated 3-fold compared to *wt* at 7 DIV, 14 DIV and 21DIV, and can be reversed by acute exposure to 10μM dantrolene. Elevated $[Ca^{2+}]_i$-dependent calpain activity (20-40% increase) and p25/p35 (20-45% increase) at 6-weeks and 6-months in preCGG cortex indicate abnormal CdK5 regulation. CdK5 substrate ATM is upregulated by 1.5-2-fold and P-Ser^{1981}-ATM is increased by 1.5-fold ($p<0.01$-0.007) compared to *wt* at P_0 and 6 months in preCGG brain. Finally, the ratio Bax:Bcl-2 is higher by 30% in 6-months-old cortical and hippocampal tissue in preCGG mice compared to *wt*, that might indicate a greater vulnerability to apoptotic activation. We propose that chronic Ca^{2+} dysregulation amplifies Cdk5/ATM signaling pathway activity possibly linking impaired DDR and neurodegeneration leading to FXTAS with early abnormal $[Ca^{2+}]_i$ and synaptic activity.

Title: The actin depolymerizing factor cofilin is critical to spine abnormalities and autism relevant behaviors in a mouse model of fragile x syndrome

Authors: *A. PYRONNEAU, M. PORCH, R. ZUKIN;
Albert Einstein Col. of Med., Bronx, NY

Abstract: Fragile X Syndrome (FXS) is the most common inherited cause of intellectual disabilities and a leading cause of autism. The neuroanatomical hallmark of Fragile X is an overabundance of immature dendritic spines, a factor thought to underlie impaired cognition. Although aberrant spine morphology and density in Fragile X has been an area of intense interest for nearly two decades, the mechanisms that underlie this defect are as yet unclear. Here we show that the actin depolymerizing factor cofilin, a downstream target of the Rho GTPase Rac1 and major determinant of dendritic spine structure, is dysregulated in Fragile X and is causally related to these spine abnormalities. Cofilin phosphorylation was elevated (indicative of inactivation) in the somatosensory cortex of young *Fmr1* KO mice. Consistent with this, the filamentous to globular (F/G) actin ratio, a functional readout of cofilin inactivation, was elevated. We further show that phosphorylation/activation of Lim kinase-1 and phosphorylation/inactivation of the phosphatase Slingshot were also elevated. This is significant in that Slingshot and LimK are downstream targets of Rac1/PAK1 and upstream regulators of cofilin. Inhibition of PAK1 with a small molecule inhibitor rescues cofilin signaling in Fragile X mice, indicating a causal relation between PAK1 and cofilin signaling. Viral delivery of a constitutively active cofilin mutant (cofilin-S3A) into the somatosensory cortex of *Fmr1* KO mice rescued the immature dendritic spine phenotype and elevated spine density. Moreover, PAK inhibition rescued sensory hypersensitivity and impaired whisker-dependent texture discrimination in Fragile X mice. These findings demonstrate a causal relation between elevated Rac1/cofilin signaling, spine defects and autism relevant behaviors in Fragile X and uncover a

previously unappreciated role for unchecked cofilin activity in the aberrant spine morphology and spine density associated with this devastating human condition.

Abstract: Fragile X syndrome (FXS) is a leading monogenic cause of intellectual disability and autism spectrum disorder. Over the past decade investigations in the mouse model of FXS have revealed that one of the key pathological deficits in the FXS brain is an increase in cerebral protein synthesis [1]-[3]. Interestingly, pharmacological strategies that reduce protein synthesis, such as inhibitors of $mGlu_5$ or ERK1/2, alleviate many of the additional synaptic and behavioural abnormalities in the *Fmr1* knockout (KO) mouse [2]-[4]. Despite these advances no treatment strategy has successfully completed clinical trails indicating the urgency to identify new therapeutic targets that regulate protein synthesis in the FXS brain.
Using a metabolic labelling assay in hippocampal slices obtained from *Fmr1* KO and WT mice, we have identified the ionotropic NMDA receptor (NMDAR) as a key regulator of protein synthesis. From these studies we have found that inhibition of the NMDAR leads to an increase in hippocampal protein synthesis whilst exacerbating elevated protein synthesis in *Fmr1* KO mice. In contrast, positive modulators of the NMDAR restore protein synthesis to WT levels, which is consistent with previous studies that have demonstrated NMDAR co-agonists restore deficient LTP in the dentate gyrus and the deficits in contextual fear conditioning [5]. Interestingly, experiments using a unique mutant mouse reveal that protein synthesis downstream of the NMDAR is altered when the C-terminal domain (CTD) of the GluN2A subunit is swapped with that of the GluN2B subunit ($GluN2A^{2B(CTD)}$). This finding indicates that the GluN2B

subunit of the NMDAR may act tonically to control protein synthesis by coupling to intracellular signalling pathways via the C-terminus. The intriguing possibility is that modulation of intracellular signalling cascades that couple to GluN2B may be a novel strategy for normalizing protein synthesis in the mouse model of FXS.

Title: Cell type specific analysis of mRNA translation in fragile X syndrome

Authors: *S. R. THOMSON[1], S. S. SEO[1], O. DANDO[1], S. A. BARNES[1], P. C. KIND[1], M. F. BEAR[2], E. K. OSTERWEIL[1];

Abstract: Fragile X Syndrome (FXS) is a neurodevelopmental disorder with a high incidence of autism, epilepsy, and intellectual disability (ID). Many of the neurological disturbances associated with FXS are believed to be the results of excessive cerebral protein synthesis. This includes the exaggeration of long-term synaptic depression (LTD) downstream of metabotropic glutamate receptor 5 (mGluR5). Previous evidence suggests that reduction of protein synthesis

can alleviate several phenotypes in the *Fmr1*$^{-/y}$ mouse model (*Fmr1*$^{-/y}$), however the mRNAs that are aberrantly translated have not been identified. This information is key for understanding the underlying pathways that contribute to FXS symptoms, and it may be an important strategy for uncovering new targets for therapeutic intervention.
Previous attempts to identify mistranslated proteins in FXS have been limited by both insufficient sensitivity to low yield proteins, and a lack of cell type specificity. To overcome these issues, we have used Translating Ribosome Affinity Purification (TRAP) to isolate translating mRNAs from specific subpopulations of neurons in the FXS mouse model (*Fmr1*$^{-/y}$). We have combined TRAP with RNA sequencing (RNAseq) to produce an unbiased list of differentially translated mRNAs in hippocampal CA1 pyramidal neurons, which express the exaggerated LTD phenotype in the *Fmr1*$^{-/y}$ mouse.
Surprisingly, our analysis revealed an overexpression of mRNAs encoding specific subtypes of muscarinic acetylcholine receptor (mAChR) in *Fmr1*$^{-/y}$ CA1 pyramidal neurons. Further qPCR and immunofluorescence analyses of isolated CA1 neurons confirm these findings. Ongoing investigations in the hippocampus of the *Fmr1*$^{-/y}$ mouse have revealed perturbed cholinergic function, which is consistent with a change in mAChR expression. Together, these results show that cell type specific analysis of mRNA translation reveals novel information about the impact of excessive protein synthesis on neuronal function in the FXS brain.

Title: Altered surface expression of delta subunit-containing $GABA_A$ receptors in a mouse model of Fragile X syndrome

Authors: N. ZHANG[1], A. K. LINDEMEYER[2], Z. PENG[1], Y. CETINA[1], C. S. HUANG[1], R. W. OLSEN[2], *C. R. HOUSER[1];
[1]Dept. Neurobiol, [2]Dept. Mol. and Med. Pharm, David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: While numerous changes in the GABA system have been identified in models of Fragile X Syndrome (FXS), alterations in subunits of the $GABA_A$ receptor ($GABA_AR$) that mediate tonic inhibition are particularly intriguing. Considering the key role of tonic inhibition in regulating neuronal excitability, reduced tonic inhibition could contribute to FXS-associated disorders such as hyperactivity, altered anxiety and increased seizure susceptibility. Our studies have focused on altered expression and function of the δ subunit of the $GABA_AR$, a major subunit involved in tonic inhibition, in Fragile X mental retardation protein 1 (Fmr1) knockout (KO) mice. We found a small but consistent decrease in immunolabeling of the δ subunit in Fmr1 KO mice compared to wildtype (WT) littermates in the molecular layer of the dentate gyrus. However, electrophysiological studies in dentate granule cells (DGCs) revealed a marked, nearly four-fold, decrease in tonic inhibition in the Fmr1 KO mice, as well as reduced effects of two δ subunit-selective pharmacological agents, THIP and DS2, supporting the suggestion that δ subunit-containing $GABA_ARs$ are compromised in the Fmr1 KO mice. The discrepancy between the large deficits in GABA-mediated tonic inhibition in the DGCs in the Fmr1 KO mice and the modest reductions in immunolabeling of the δ subunit in the dentate gyrus led us to examine the surface expression of the δ subunit. To measure cell surface protein levels, cross-linking experiments followed by Western blot analysis were performed, and these demonstrated a small but non-significant decrease in total δ subunit protein in the Fmr1 KO mouse. However, a six-fold decrease in surface expression of the δ subunit was found in the KO mice. We then used postembedding immunogold labeling to determine the subcellular localization of the δ subunit on dendrites of DGCs, where the δ subunit is normally located at perisynaptic and extrasynaptic sites. All symmetric synapses with clear postsynaptic densities were photographed with an electron microscope. The presence and location of immunogold labeling was determined at each synapse. In WT mice, immunogold particles were localized along the plasma membrane at perisynaptic locations at approximately 79.0% of the synapses. In contrast, only 21.8% of GABAergic synapses exhibited surface labeling at perisynaptic sites in the Fmr1 KO mice. Together these findings suggest that, in the dentate gyrus, altered surface expression, rather than a decrease in δ subunit expression alone, may be limiting tonic inhibition in this model of FXS. Thus finding ways of increasing surface expression of the δ subunit could be a novel new approach to treatment in FXS.

Title: Insulin signaling misregulation underlies circadian and cognitive deficits in a *Drosophila* Fragile X Model

Authors: *S. M. MCBRIDE[1], R. E. MONYAK[2], D. EMERSON[1], B. SCHOENFELD[1], X. ZHENG[3], D. CHAMBERS[5], C. ROSENFELT[5], P. HINCHEY[6], C. CHOI[7], T. MCDONALD[6], F. BOLDUC[5], A. SEHGAL[4], T. A. JONGENS[2];

Abstract: Fragile X syndrome (FXS) is an undertreated neurodevelopmental disorder characterized by low IQ and a wide range of other symptoms including disordered sleep and autism. Although FXS is the most prevalent inherited cause of intellectual disability, its mechanistic underpinnings are not well understood. Using Drosophila as a model of FXS, we showed that select expression of dfmr1 in the insulin-producing cells (IPCs) of the brain was sufficient to restore normal circadian behavior and to rescue the memory deficits in the fragile X mutant fly. Examination of the insulin signaling (IS) pathway revealed elevated levels of Drosophila insulin like peptide 2 (Dilp2) in the IPCs and elevated IS in the dfmr1 mutant brain. Consistent with a causal role for elevated IS in dfmr1 mutant phenotypes, the expression of dfmr1 specifically in the IPCs reduced IS, and genetic reduction of the insulin pathway also led to amelioration of circadian and memory defects. Furthermore, we showed that treatment with the FDA-approved drug metformin also rescued memory. Finally, we showed that reduction of IS is required at different time points to rescue circadian behavior and memory. Our results indicate that insulin misregulation underlies the circadian and cognitive phenotypes displayed by the Drosophila fragile X model, and thus reveal a metabolic pathway that can be targeted by new and already approved drugs to treat fragile X patients.

Title: Maturation of adult-born dentate granule cells in fragile x mice.

Authors: *C. REMMERS[1], A. CONTRACTOR[1,2];
[1]Dept. of Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Dept. of Neurobio., Northwestern Univ. Weinberg Col. of Arts and Sci., Chicago, IL

Abstract: Fragile X syndrome (FXS) is the most common form of inherited mental retardation and the most common known cause of autism. Loss of FMRP in mice (*Fmr1* KO) leads to alterations in synaptic and circuit maturation in the hippocampus, which correlates with alterations in hippocampal dependent behaviors. Previous studies have demonstrated that the rate of proliferation of progenitor cells is increased in the dentate gyrus of *Fmr1* KO mice. Loss of Fmrp specifically in adult progenitors disrupts the acquisition of a hippocampal dependent conditioning task. While these studies have demonstrated a role for Fmrp in adult neurogenesis, it is not known whether the functional synaptic maturation and circuit integration of adult-born dentate granule cells (DGCs) is altered in the *Fmr1* KO. In this study we used retroviral labeling to express a fluorescent protein to birth date newborn DGCs in 6-8 week old *Fmr1* KO mice. This allowed us to use targeted patch clamp recording to measure synaptic inputs to these neurons at precise time points based on the number of days post injection (dpi) we recorded from labeled DGCs. Adult born DGCs are initially innervated by tonic GABA before establishing GABAergic and then glutamatergic synapses. To determine whether the temporal profile of these events is altered we first measured the tonic GABA mediated currents in *Fmr1* KO and littermate controls at 7, 14, and 21 dpi. Contrary to what has been previously reported we found that tonic GABA current was not prominent in either *Fmr1* KO (present in 0/6 cells at 7 dpi, 1/5 at 14 dpi, and 0/6 at 21 dpi) or control mice (only in 0/5 at 7 dpi, 1/8 at 14 dpi, and 2/6 at 21 dpi), whereas we could record a large amplitude tonic current in all mature DGCs we recorded from (19.2 ± 2.2 pA, n = 21 in *Fmr1* KO and 21.4 ± 2.2 pA, n = 24 in controls). We next recorded spontaneous $GABA_A$ mediated synaptic events from labeled DGCs at 21 and 28 dpi. The amplitude of GABA events was 35.6 ± 1.5 pA, n = 10 at 21 dpi and 31.1 ± 2.3 pA, n = 5 at 28 dpi in *Fmr1* KO, and 37.3 ± 5.1 pA, n = 8 at 21 dpi and 33.2 ± 3.6 pA, n = 6 at 28 dpi in control ($p>0.05$ at 21 and 28 dpi). The frequency of GABA events was 0.43 ± 0.06 Hz, n = 10 at 21 dpi and 0.91 ± 0.08 Hz, n = 5 at 28 dpi in *Fmr1* KO, and 0.31 ± 0.07 Hz, n = 8 at 21 dpi and 1.2 ± 0.34 Hz, n = 6 at 28 dpi in control ($p>0.05$ at 21 and 28 dpi). These initial data suggest that the

development of GABAergic synapses is not altered in the first four weeks of maturation. In ongoing experiments we are recording from neurons at 28 and 42 dpi to determine if inhibitory and excitatory synaptic input to more mature DGCs is altered in *Fmr1* KO mice. Together these studies will be the first to systematically determine the effects of loss of FMRP on the maturation of newborn neurons in *Fmr1* KO mice.

Title: Modulation of mitochondrial efficiency and its potential application in the treatment of fragile x syndrome.

Authors: *P. LICZNERSKI[1], P. MIRANDA[1], H.-A. PARK[1], M. BROWN[2], L. K. KACZMAREK[2], R. J. LEVY[3], E. A. JONAS[1];

Abstract: Fragile X syndrome is caused by loss of function of the gene encoding Fragile X mental retardation protein (FMRP), an RNA-binding protein. That leads to abnormally elevated protein synthesis. It has been reported that loss of FMRP causes abnormally high survival rates in the brain leading to excessive numbers of neurons and insufficient synaptic pruning, associated with a significant elevation in levels of the anti-apoptotic mitochondrial protein Bcl-xL. Moreover, Bcl-xL and FMRP target to mitochondria and depletion of FMRP disrupts mitochondrial membrane potential. We find that the elevated levels of protein translation in FMRP KO mouse neurons can be reduced by treatment with modulators of the ATP synthase, which increases the efficiency of mitochondrial metabolism. Total protein translation can also be affected by manipulating the levels of Bcl-xL. The present study examines the mechanism of normalizing enhanced protein translation in FMRP KO by pharmacological or molecular enhancement of the efficiency of mitochondrial metabolism.

Title: Disrupted synaptic transmission and protein homeostasis in an Angelman Syndrome (AS) mouse model

Authors: ***G. LI**[1,2], M. ANDERSON[2], M. PIECHOWICZ[2], L. ZHANG[2], X. MA[2], J. WU[3], S. QIU[2];

Abstract: Angelman syndrome (AS) is a neurodevelopmental disorder characterized by developmental delays, intellectual disabilities, impaired language and speech, and movement defects. Most AS cases are caused by dysfunction of a maternally-expressed E3 ubiquitin ligase (UBE3A, also known as E6 associated protein (E6-AP)) in neurons. Currently, the mechanism on how loss-of-function of the enzyme influences the nervous system development remains unknown. We hypothesize that impaired metabolism of proteins, most likely those related to E6-AP substrates, may alter the developmental trajectory of neuronal structures including dendrites, spines and synaptic proteins, which leads to disrupted activity/experience-dependent synaptic plasticity and maturation. To test this hypothesis, we conducted a detailed investigation on neuronal morphology and electrophysiological properties in prefrontal cortex layer V pyramidal neurons. We found smaller soma size with increased basal dendritic processes in the maternal *Ube3a* deficient mice (m^-/p^+; 'AS' mice) at postnatal 4 weeks. Surprisingly, both excitatory and inhibitory miniature postsynaptic currents (mEPSCs and mIPSCs) on these neurons are decreased. Western blot analysis revealed that autophagy pathway may be disrupted and the function of Golgi apparatus and apoptosis may be enhanced in AS. Currently, we are investigating whether abnormal protein homeostasis accounts for the impaired neuronal morphology and synaptic deficits observed in L5 neurons, and whether restoring normal protein homeostasis may correct the morphological and physiological phenotypes in AS mice.

Abstract: During development, the localized expression of genes drives proper segmentation and development of various brain regions and several proteins are known to contribute to localized gene expression. Disturbances in the expression of these proteins are known to contribute to mid-hindbrain malformations. We will present a novel mid-hindbrain malformation phenotype in two affected children of a consanguineous family of Kurdish-Turkish descent and delineate the genetic cause. We identified the mutation in the causative gene through whole exome sequencing. The effect of mutation on mRNA and protein levels were checked through qPCR and Western blot, respectively. The rescue experiments were performed to serve as a proof of principle. With our study, we report for the first time, a novel mid-hindbrain malformation in humans.

Title: Anatomical underpinnings of decreased white matter volume in angelman syndrome model mice

Authors: *M. C. JUDSON, C. L. THAXTON, A. C. BURETTE, A. L. PRIBISKO, A. M. RUMPLE, B. PANIAGUA, R. J. WEINBERG, B. D. PHILPOT;
UNC-Chapel Hill, Chapel Hill, NC

Abstract: Angelman syndrome (AS) is a severe neurodevelopmental disorder characterized by profound deficits in cognition, motor function, and speech. Microcephaly is highly comorbid in AS – penetrant in 80-90% of cases – indicating problems with brain growth and development that belie grossly normal brain architecture. Accordingly, structural neuroimaging of children with AS has revealed deficits in white matter volume and integrity for which the underlying anatomy remains unclear. Here we utilize AS model mice to explore relationships between brain growth, white matter volume, and the ultrastructural integrity of white matter tracts. We find that AS model mice exhibit microcephaly with onset during the second postnatal week, mirroring the altered brain growth trajectory of people with AS. This trajectory culminates in reduced brain weight (8-10%) and generalized reductions in white matter volume (12-15%) in adult AS model mice. Electron microscopic analyses of the anterior corpus callosum and sciatic nerve reveal largely normal myelination and little or no evidence of axon degeneration; however, axon caliber is significantly reduced in these tracts in adult AS model mice (~20%), explaining deficits in white matter volume and, perhaps, abnormal nerve conduction. Our findings implicate deficits in axon growth and development in the pathogenesis of AS, and support the possibility that structural neuroimaging could serve as a noninvasive biomarker for gauging the efficacy of AS therapeutics.

Title: Altered EEG spectral power in the NS-Pten knock-out model of cortical dysplasia with epilepsy

Authors: *S. AVILA[1], A. REGNIER-GOLANOV[3], Y. A. DABAGHIAN[2], L. NGUYEN[4], A. BREWSTER[4], N. SUNNEN[4], A. E. ANDERSON[5];

Abstract: Cortical dysplasia is a devastating disease often associated with catastrophic epilepsy. NS-*Pten* knock-out (KO) mice model aspects of the human disorder, including abnormal electroencephalography (EEG) recordings with frequent epileptiform activity (spikes, polyspikes, and seizures) and disruption of normal background EEG activity. Previous studies reported suppression of epileptiform activity and subjectively identified improvements in the background EEG in KO mice following rapamycin treatment. Quantitative EEG analysis showed the frequency spectra were different between KO and WT. In this study, to characterize EEG differences between the KO and wild type (WT) mice, we used analysis of prevalent amplitudes and power spectra of the EEG at 4, 8 & 13 wks. Mice were video-EEG monitored for 2 to 4h at 4, 8, and 13 weeks of age (Nicolet v32 Amplifier). 500,000 data points of baseline interictal were sampled at 200Hz. To quantify the differences between the KO and WT animals, we studied changes in the Δ amplitudes (Hilbert transform) and in the frequency spectra (Fast Fourier transform) of the recorded EEG signal. The results were then averaged for KO and WT groups. NS-*Pten* KO have a normal EEG at 3-4 weeks of age and start to develop spikes and seizures along with higher background noise. At 4 weeks the profiles of the amplitude distribution were similar between WT and KO with Δ amplitude KO: 33μV vs WT: 42μV ($p>0.05$, n=4-5). At 8 and 13weeks of age, Δ amplitude shifted toward wider amplitude distribution (8 weeks, Δ amplitude KO: 63μV vs 36μV; 13weeks, Δ amplitude KO: 60μV vs WT 33μV, $p>0.05$, n=3-4). The frequency spectra did not differ by their profiles and their peaks at 4, 8 or 13 weeks between genotypes during baseline recordings. Power curves from KO and WT mice displayed peak power levels in the theta-alpha-beta range (6-18Hz, peak at 12Hz, n=11). At 13 weeks the power spectra were significantly higher in KO mice compared to WT ($p>0.05$). Our results demonstrated an increase in the overall power in all frequencies that could indicate insufficient synaptic pruning. Furthermore, the power spectrum and amplitude analysis provide tools to quantify the instability of the EEG signal typical for NS-*Pten* KO.

Abstract: Hereditary Congenital Facial Palsy (HCFP) is an autosomal dominant disorder caused by uni- or bi-lateral maldevelopment of the VIIth cranial nerve (facial). Normal development of the middle ear bones is crucial for the correct development of the facial nerve canal. In this study, we identified a heterozygous frameshift variant c.1273del (p.Gln425Lysfs*38) in *MEPE* in a HCFP family with mixed hearing loss associated with diploeic thickening and sclerosis of the skull. *MEPE* encodes a matrix extracellular phosphoglycoprotein and plays an inhibitory role in bone mineralization. We next hypothesized that this gene might also be important in otosclerosis bone remodeling disorder and screened 91 individuals with familial otosclerosis. We identified two additional heterozygous frameshift variants in *MEPE*, c.209_212del (p.Lys70Ilefs*26) in two families with otosclerosis, and c.617del (p.Ser206Ilefs*3) in an isolated otosclerosis case. Furthermore, we screened 1398 unrelated cases with otosclerosis and 1447 random controls of white ethnicity. We observed the rare c.209_212del frameshift variant in eight affected individuals with otosclerosis only, but in none of the controls, and two other rare variants (c.184G>T; p.Glu62* and c.229G>A; p.Ala77Thr) were found in cases and not in the controls (p=0.0020). Our results pinpoint MEPE as a key player in temperal bone and ossicle mineralization, essential for facial nerve development and implicated in the pathogenesis of otosclerosis and other craniofacial bone disorders associated with mixed hearing loss.

Title: A gain-of-function mutation in the human GRIK2 gene causes neurodevelopmental and intellectual deficits

Authors: *Y. F. GUZMAN[1], K. RAMSEY[2], J. R. STOLZ[1], V. NARAYANAN[2], G. T. SWANSON[1];

Abstract: Kainate receptors are ionotropic glutamate-gated channels that exert a modulatory role on neuronal excitability and synaptic transmission. Loss-of-function mutations in genes coding for different kainate receptor subunits, the *GRIK* genes, have been associated with neurodevelopmental disease and intellectual disabilities in humans. The aim of this project is to study the effects of a mutation in the *GRIK2* gene of a nine-year old patient displaying Angelman-like symptomatology that includes ataxia, passive motor tone, a highly social demeanor, and learning disabilities. Genetic testing showed no alteration in the genes responsible for Angelman, Rett, Prader-Willi, and Fragile-X syndromes, or for spinal muscular atrophy and myotonic dystrophy. Whole-exome sequencing of the proband, however, revealed a heterozygous *de novo* single point mutation in *GRIK2,* the gene coding for the GluK2 subunit. The mutation is analogous to the Lurcher (Lc) mutation described for δ2 receptors and consists of a single nucleotide alteration that changes the encoded alanine to a threonine within a highly conserved motif in the third transmembrane domain of the GluK2 kainate receptor subunit.
As a first approach towards understanding the mechanistic basis for the human pathology, we characterized the biophysical properties of kainate receptors containing the GluK2-(A657T) mutation (referred to as GluK2^{Lc}). Electrophysiological recordings from HEK293T/17 cells expressing GluK2^{Lc} revealed a significant slowing in the rate of desensitization of homomeric glutamate-gated currents (average weighted tau = 55.8 ± 12.0 ms, n=4). Furthermore, heteromeric GluK2^{Lc}/GluK5 receptors exhibited a significant level of constitutive activation that became apparent upon desensitization with 10 mM glutamate application. In accordance with tonic activation of the mutant receptor, the open channel blocker, 1-Naphthylacetyl spermine (NASPM), significantly reduced the whole-cell holding current of cells expressing GluK2^{Lc}/GluK5 receptors. Kainate receptors are likely to be heteromeric *in vivo* and therefore we characterize the GluK2^{Lc} mutation as a gain-of-function alteration in channel properties. These results are the first time a gain-of-function mutation in a GRIK gene has been associated with developmental and learning disabilities. Future work will characterize the effects of this mutation on neuronal development and learning processes with the use of human iPSC-derived neurons and a GluK2^{Lc} mouse model.

Title: Interaction between Gabrb3 haploinsufficiency and prenatal LPS exposure exacerbates placental and fetal brain vulnerability in mice

Authors: *H. MOON[1], P. A. CARPENTIER[1], V. SARAVANAPANDIAN[1], U. HADITSCH[1], J. SU[1], M. L. CHIN[1], K. MUENCH[1], A. R. MOORE[1], A. BORMANN[2], N. NIMA[2], G. SUBRAMANYAM[3], M. RIVERA[1], T. D. PALMER[1];

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disability defined by social interaction deficits and stereotyped behaviors but the underlying pathophysiological mechanisms are poorly understood. ASD heterogeneity may result from dynamic interplay between genetic and environmental risk factors. Maternal immune activation (MIA) caused by prenatal infections, asthma, allergy, or other immunological mechanisms are known environmental risk factors that increase fetal vulnerability. Epidemiological studies also associate MIA with higher incidence of ASD and MIA-induced immune signaling is alone sufficient to alter fetal brain development in mouse models.
The present study highlights gene-environment interactions between ASD-related genetic susceptibility and MIA. The GABA type A receptor ($GABA_AR$) subunit beta 3 (*GABRB3*) in the human chromosomal loci 15q11-13 is implicated in Angelman Syndrome, Prader-Willi Syndrome and ASD. Peripheral $GABA_ARs$ are also involved in modulating immune signaling.

Here we show that *Gabrb3* haploinsufficiency combined with prenatal lipopolysaccharide (LPS)-mediated MIA accentuates placental vulnerability and exacerbates neurodevelopmental abnormalities in developing fetuses. *Gabrb3* heterozygous pregnant dams injected with LPS at embryonic day 12.5 showed elevated maternal cytokines/chemokines relative to wild-type controls. Increased placental necrosis and impaired proliferation of neocortical progenitor cells are found in LPS-treated *Gabrb3* heterozygous placentas and fetal brains, respectively. Alterations in neuronal subtype specification and abundance were also notable in the developing fetal cortex. Importantly, $GABA_AR$-selective agonists and antagonists were shown to modulate cytokine production in cultured macrophages. Gaboxadol, a $GABA_AR$-selective agonist, administered in combination with LPS significantly attenuated LPS-induced cytokine elevation, suggesting a possible convergence of immunomodulatory signaling pathways between $GABA_AR$/GABRB3 and LPS-induced MIA responses in the placenta and developing fetus. Together, our data provide evidence that *Gabrb3* haploinsufficiency and MIA may synergistically increase placental and fetal brain vulnerability by altering the immune microenvironment at the maternal-fetal interface. We anticipate that additional genetic risk factors may also elevate placental and/or fetal brain vulnerability to MIA and these gene-immune interactions may significantly contribute to the spectrum of phenotypes noted in ASD, schizophrenia, and other neurodevelopmental disorders.

Abstract: The axon guidance receptor Deleted in colorectal cancer (DCC) and its ligand Netrin-1 (NTN1) are necessary for the formation of white matter tracts throughout the neuraxis in a number of model CNS systems (Lai Wing Sun et al., 2011). Mice homozygous for *Dcc* mutations display complete agenesis of the corpus callosum (ACC), as well as defects in the corticospinal tract (CST) and other cerebral commissures (Fazeli et al., 1997; Fothergill et al., 2014). In humans, DCC haploinsufficiency is associated with mirror movements (MM, OMIM#157600), but has not been associated with ACC (OMIM#217990, Srour et al., 2010). The corpus callosum is the largest forebrain commissure in humans, and facilitates the transfer of information between hemispheres. ACC is one of the most common brain malformations (incidence of 1/4,000 newborns); however, the genetics underlying cases of ACC are incompletely understood (Edwards et al., 2014). We utilized whole exome sequencing and a custom in-house gene panel to identify mutations in *DCC* in two families with varying degrees of MM and ACC. These mutations affect highly conserved residues located within the DCC/NTN1 binding interface, and both mutations were predicted to disrupt receptor/ligand interactions. Individuals from both families also displayed reduced crossing of the CST at the pyramidal decussation. We show for the first time in humans that *DCC* mutations result in ACC and MM associated with aberrant CST projections. These results demonstrate that DCC plays a highly conserved role throughout evolution in the formation of contralateral projections within the brain and CST.

Title: Everolimus restores mTOR signaling disrupted by a novel TSC2 mutation and improves neuropsychiatric symptoms in a tuberous sclerosis patient

Authors: *J.-E. YANG[1], S.-K. HWANG[2], K. LEE[3], J.-H. LEE[4], J.-A. LEE[5], Y.-S. LEE[6], B.-K. KAANG[1], C.-S. LIM[1];

Abstract: Tuberous sclerosis complex (TSC) is a rare genetic disease with multiple symptoms including neuropsychological deficits such as seizures, intellectual disability, and autism. TSC is caused by mutations in either the *TSC1* or *TSC2* genes, which regulate the mammalian target of rapamycin (mTOR) signaling pathway. Recent studies have suggested that mTOR inhibitors improve TSC-related deficits in rodent models of TSC. In addition, clinical trials are ongoing to test the efficacy of mTOR inhibitors against the psychiatric symptoms of TSC. In this study, we report a case study of a Korean TSC patient carrying novel *TSC2* mutation. We performed whole exome sequencing and identified a novel small deletion mutation in *TSC2.* The novel deletion mutant abnormally activated the mTOR signaling and everolimus, the mTOR inhibitor, rescued the mTOR signaling in HEK293T cells. Furthermore, everolimus treatment showed not only reduction in SEGA size, but also dramatically improvement of behavioral deficits including autism-related behaviors in the patient. In summary, we identified a novel small deletion mutation in *TSC2* associated with severe TSC in a Korean family that enhances the activation of mTOR signaling *in vitro*. Everolimus treatment not only restored mTOR signaling *in vitro*, but also improved behavioral deficits in the patient.

Title: Neural correlates of impaired visuospatial cognition in children with Williams syndrome

Authors: T. NASH[1], J. CARRASCO[1], J. P. MIKHAIEL[1], O. RAVINDRANATH[1], L. YANKOWITZ[1], R. PRABAKARAN[1], M. SOTTILE[1], K. ROE[1], P. KOHN[1], J. S. KIPPENHAN[1], D. EISENBERG[1], M. D. GREGORY[1], C. B. MERVIS[2], *K. F. BERMAN[1]; [1]Section on Integrative Neuroimaging, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Dept. Psych and Brain Sci., Univ. of Louisville, Louisville, KY

Abstract: Williams syndrome (WS) is a rare neurodevelopmental disorder caused by microdeletion of ~25 genes on chromosome 7. Previous studies in adults with WS have identified alterations in frontolimbic circuitry and in the dorsal visual processing stream as neural correlates of the characteristic hypersociability and visuospatial construction problems. Here, in children with WS and normal-range IQs we tested white matter integrity with diffusion tensor imaging (DTI), neural function using an fMRI task that taps into dorsal and ventral processing streams (DS and VS), and the relationship of white matter integrity to visuospatial construction ability assessed by the Differential Ability Scales (DAS-II).

DTI data were acquired in 23 children with WS (mean age=11, range 6-18; 9 males) and 21 typically developing children (TDC; mean age=12, range 6-18; 9 males) and data were processed with TORTOISE. Each child's native space fractional anisotropy (FA) map was warped into study-specific template space and smoothed at 4 mm FWHM. Between-group analyses controlled for age and sex and were thresholded at $p<0.01$, FDR corrected. Average FA values for each child were extracted from DS regions that significantly differed between groups, and were examined in relation to the DAS-II Spatial cluster standard score (SCss).3T fMRI data were acquired in a subset of 14 children with WS (mean age=12, range 8-18; 4 males) and 17 TDC (mean age=14, range 8-18; 7 males). During fMRI, children judged either the location (DS) or the content (VS) of images on the screen. Both of these conditions were contrasted against a sensorimotor control condition. Analyses of each of these contrasts controlled for age and sex and were thresholded at $p<0.001$ uncorrected.

Children with WS had increased FA in the right orbitofrontal cortex but decreased FA in the corticospinal tract and in white matter adjacent to the intraparietal sulcus (IPS) bilaterally. Increased left IPS FA predicted higher SCss in TDC ($p < 0.05$). During the DS task, children with WS had significantly decreased activation in the IPS bilaterally as well as in the right middle temporal gyrus. During the VS task, children with WS had less deactivation of default mode network regions.

In children with WS, we found altered microstructural integrity in portions of white matter tracts that are related to the hypersocial personality and visuospatial problems in the syndrome. Structural integrity in white matter adjacent to the IPS predicted visuospatial abilities, indicating that the reduction in FA here in WS may play a role in the visuospatial cognition impairment. Future research will elucidate the developmental trajectory of these alterations.

Title: Prenatal paracetamol exposure decreases anxiety-related behaviors and disrupts memory in mice

Authors: ***T. M. MILEWSKI**[1], R. A. ANTONAWICH[1], D. WOOD[1], P. T. ORR[1,2];
[1]Neurosci. Program, [2]Psychology, Univ. of Scranton, Scranton, PA

Abstract: The over the counter drug paracetamol has long been in use, but little work has investigated the full range of cognitive and behavioral effects of this drug. In this study, mice were exposed to paracetamol prenatally, weaned and reared normally, and were tested as adults for anxiety-related behavior in an open field. These mice were also tested in an object recognition task. Mice were placed in an open field arena and allowed to explore freely for five minutes. Anxious behavior in the open field was assessed by quantifying both time spent in the center and time spent near the wall (thigmotaxis) of the arena. Mice exposed to paracetamol spent significantly less time near the wall ($t(49.692) = 2.297$, $p = .026$). There was a non-significant trend toward mice exposed to paracetamol spending more time in the center of the open field ($t(57) = 1.866$, $p = .067$). Overall, prenatal chronic exposure to paracetamol generated mice who were less anxious. This conclusion is supported by an analysis of grid crossings during the habituation phase of object recognition. Mice exposed to paracetamol made significantly more crossings into the inner grid squares ($t(56) = 2.812$, $p = .007$) and inner crossings were a greater proportion of total crossings for these mice ($t(56) = 2.767$, $p = .008$). During memory testing, neither group showed a significant side preference during training. During testing, control mice spent significantly more time with the novel object ($t(27) = 2.403$, $p = .023$),

indicating memory, whereas mice exposed to paracetamol did not show a preference for the novel object ($t(23) = .911$, $p = .372$), indicating that these mice did not remember the familiar object. Overall, prenatal paracetamol exposure results in adult mice which are less anxious and have disrupted memory.

Title: Prospective associations between maternal interleukin-6 concentrations during pregnancy and newborn amygdala volume and connectivity.

Authors: *C. BUSS[1,2], A. M. GRAHAM[3], J. RASMUSSEN[2], M. D. RUDOLPH[3], C. H. HEIM[1,4], J. H. GILMORE[5], M. A. STYNER[5], S. ENTRINGER[1,2], P. D. WADHWA[2], D. A. FAIR[3];
[1]Charité Univ. Med. Berlin, Berlin, Germany; [2]Univ. of California Irvine, Irvine, CA; [3]Oregon Hlth. and Sci. Univ., Portland, OR; [4]Penn State Univ., State College, PA; [5]Univ. of North Carolina, Chapel Hill, NC

Abstract: Exposures to maternal infection and excess stress during pregnancy represent intrauterine conditions that have been associated with an increased susceptibility for schizophrenia and autism. While inflammatory cytokines are requisite for typical fetal brain development, animal models of maternal immune activation have demonstrated negative neurodevelopmental consequences of excess interleukin-6 (IL-6). Here, we test, in humans, the hypothesis that *in utero* exposure to elevated maternal IL-6 concentration predicts alterations in newborn limbic circuitry with a specific focus on amygdala anatomy and connectivity. Participants were recruited in early pregnancy and maternal blood samples were collected in each trimester. Newborns (N=85 underwent anatomical, diffusion tensor imaging (DTI) and functional connectivity (rs-fcMRI) magnetic resonance imaging (MRI) during natural sleep.

Newborn amygdala were segmented using a semiautomatic method to quantify amygdala volumes, and served as seed regions for rs-fcMRI analyses. Structural connectivity was characterized by fractional anisotropy (FA) along fronto-limbic white matter tracts (uncinate fasciculus and fornix). Prospective associations between average maternal IL-6 concentrations throughout pregnancy and newborn amygdala volume and functional connectivity, and fronto-limbic FA, were examined.
Higher maternal IL-6 concentrations were associated with larger right amygdala volume ($p=.002$), increased amygdala functional connectivity to right anterior insula and bilateral caudate (p-corrected<.05), and reduced FA in bilateral uncinate and left fornix (p-corrected<.05). These results provide converging evidence across multiple modalities for alterations in limbic-circuitry in the context of elevated *in utero* inflammation. The pattern of results suggests that inflammation may lead to acceleration in development of limbic circuitry involved in emotional reactivity and delays in development of circuitry involved in emotion regulation. The circuitry identified is highly relevant for psychopathology across the lifespan, and these results may therefore facilitate increased understanding of the connections between prenatal immune stress and offspring risk for mental health disorders.

Title: Prevention of an infection-induced maternal adenosine surge during gestation prevents the development of schizophrenia symptoms in mice.

Authors: *D. M. OSBORNE[1], U. SANDAU[2], A. JONES[2], N. ETESAMI[2], M. YAHYA[2], D. BOISON[2];
[1]Legacy Hlth. Res., Portland, OR; [2]Legacy Res. Inst., Portland, OR

Abstract: Schizophrenia (SZ) is one of the most common psychiatric conditions affecting around 1% of the population, yet fully effective treatments are lacking, and pathogenic mechanisms are poorly characterized. There is now broad consensus that SZ is a

neurodevelopmental condition, with specific risk factors associated with specific time windows of gestation. In rodents the development of SZ can be studied by inducing a 'maternal infection' during gestation via the viral mimetic polyinosinic-polycytidylic acid (polyI:C). Because physiological stressors (such as infection) trigger a surge in adenosine, because adenosine is a regulator of immune and epigenetic functions, and because the fetus is protected through a placental adenosine barrier, we hypothesized that an infection-induced maternal adenosine surge initiates a cascade of events leading to the development of SZ symptoms in offspring upon reaching adulthood. If this hypothesis is true then prevention of the maternal adenosine surge should prevent the development of SZ in offspring. To test our hypothesis we administered polyI:C (2mg/kg) to pregnant mouse dams on gestational day 9 with or without co-administration of the adenosine degrading enzyme adenosine deaminase (ADA). Within an hour of polyI:C injection there was a decrease in placental adenosine kinase, while the developing offspring that did not receive ADA had a significant and persistent decrease in brain DNA methylation (5mc) consistent with adenosine's role as an inhibitor of DNA methylation. In adult male control mice from litters that received polyI:C treatment during gestation we found significant deficits in sensory motor gating, measured by prepulse inhibition (PPI). Importantly, we found that co-administration of ADA together with poly(I:C) reversed both the poly(I:C) induced epigenetic changes and the development of sensory motor gating deficits in adult offspring. Our data strongly support the interpretation that excessive adenosine exposure during gestation results in hippocampal-dependent SZ-like behaviors in adult offspring and suggest that adenosine-induced epigenetic changes play a major role in the pathogenesis of SZ.

Title: Roles of thalamocortical interactions in mouse prefrontal cortex development

Authors: ***Y. NAKAGAWA**[1], A. PROUE, 55455[2], T. NICHOLS-MEADE[2], M. BENNYWORTH[1];

[1]Dept Neurosci, Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN; [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The thalamus and the neocortex establish reciprocal connections during early development. Recent studies discovered that interactions between these two brain regions are crucial for the development of the sensory areas of the neocortex. However, it is unknown whether the thalamus plays a similar role in the development of other neocortical areas. The prefrontal cortex (PFC) is a center for higher cognitive functions and emotions, and defects of its development are implicated in many developmental brain disorders including schizophrenia and autism. In this study, we sought to determine if thalamocortical interactions are required for proper PFC development. In previous studies, we showed that the mice that lack the homeobox gene *Gbx2* in a thalamus-specific manner have defects in thalamocortical projections and that characteristic expression patterns of genes in primary sensory areas are altered at early postnatal stages so that these areas no longer exhibit clear boundaries with the surrounding higher-order sensory areas. Interestingly, however, expression of these molecular markers appeared unchanged in the PFC in thalamus-specific *Gbx2* mutant mice. This result prompted us to identify several genes that are preferentially expressed in the developing PFC. We found that one of these genes, *Cyp26b1*, which encodes an enzyme that degrades retinoic acid, was not properly induced in layer 6 of the medial and ventral PFC at early postnatal stages in *Gbx2* mutant mice. This result suggests that the thalamus may control retinoid signaling in the PFC by regulating the expression of *Cyp26b1*. In order to determine the roles of Cyp26b1 in PFC development and adult behavior, we further generated *Cyp26b1* knockout mice that are restricted to the frontal cortex including medial PFC. Preliminary analyses indicate that these mice show signs of impaired working memory, suggesting the role of the thalamus in regulating the sensitive developmental period of early postnatal PFC that is critical for normal behavior in the adult.

Abstract: Paracetamol is a common over-the-counter pain reliever, but the full extent of its effects on cognition and behavior is not known. Two previous correlational studies in humans suggest that paracetamol exposure can result in poorer gross motor development and increased risk of hyperkinetic disorders. Paracetamol is metabolized, through the enzyme FAAH, into AM404 which acts as a cannabinoid reuptake inhibitor, suggesting that motor effects of paracetamol may be mediated by cannabinoids. In this study, we experimentally manipulated prenatal paracetamol exposure and explored for an altered motor phenotype in the resultant pups. Paracetamol was added to the water of two sets of breeding trios, and two sets of breeding trios were kept as controls and given regular water. Regular drinking water was restored immediately after birth for all mice, and pups were weaned and raised to eight weeks in typical fashion. At eight weeks, the adult offspring were run on an accelerated and fixed-speed rotarod protocols and allowed to freely explore a large, empty arena for 5 minutes. Mice prenatally exposed to paracetamol spent significantly less time on the rod during the first ($t(58) = 2.007$, $p = .049$), ninth ($t(54.091) = 2.61$, $p = .012$) and tenth ($t(58) = 2.32$, $p = .024$) trials of the accelerated rotarod, and there was a non-significant trend toward these mice spending less time on the rod during the first fixed-speed trial at 6.5 rpm ($t(36.189) = 1.797$, $p = .081$). During free exploration, mice prenatally exposed to paracetamol made more grid crossings than control mice ($t(56) = 2.063$, $p = .044$), indicating hyperactivity. Overall, prenatal paracetamol exposure results in adult mice which are hyperactive and less coordinated than control mice.

Title: Ontogeny of Glutamatergic, GABAergic and Dopaminergic neurons of the embryonic mesencephalic nuclei A9 and A10

Authors: *D. A. RAMÍREZ DE LEÓN;
Lab. Biofísica Mol., Univ. Autónoma De San Luis Potosí, san luis potosi, Mexico

Abstract: The mesencephalic dopaminergic nuclei substantia nigra (A9) and Ventral Tegmental Area (A10) contain purely Glutamatergic neurons as well as Glutamatergic neurons that corelease Dopamine. The ability to release Glutamate by these neurons is given by the

expression of the vesicular Glutamate Transporter type 2 (VGluT2). The corelease of Glutamate by Dopaminergic neurons is implicated in the psychostimulant effects of cocaine and amphetamine, and plays an important pro-survival role during development. The earliest expression of VGluT2 in Dopaminergic neurons is reported until E14. However the ontogeny of purely Glutamatergic neurons is unknown. Considering that in the adulthood, the proportion of Glutamatergic neurons is about 14%, we searched for the moment in development in which the expression of VGluT2 appears in the mesencephalom of mouse embryos. Using single cell RT-PCR multiplex assays to detect the expression of tyrosine hydroxylase (TH), Dopamine Transporter (DAT), Glutamic Acid decarboxylase I (GAD), vesicular monoamine transporter type 2 (VMAT2), DOPA decarboxylase (DDC) and VGluT2, we found that 1) at E11.5, the embryonic stage in which Dopaminergic neurons appear in the mesencephalom, the expression of VGluT2 is already present; 2) at E11.0, Although TH was not yet expressed, the expression of VGluT2 was readily detected; 3) the proportion of purely Glutamatergic neurons (i.e. VGluT2 positive but negative to any marker for GABAergic or Dopaminergic neurons) decreased with the progression of embryonic development, whereas 4) the coexpression of VGluT2 with any marker for GABAergic or Dopaminergic neurons increased; 5) the Glutamatergic and GABAergic cophenotype appeared as early as E11.0; 6) Purely Glutamatergic neurons appeared at E11.0; 7) The Dopaminergic and GABAergic cophenotype appears as early as E11.5. Our results show a great heterogeny in the neuronal phenotypes expressed by embryonic mesencephalic neurons of the A9/A10 nuclei that appears as early as the first stages of midbrain development.

Title: Organization of hippocampal mossy fiber pathway in the mouse

Authors: *G. XIONG[1,2], H. METHENY[2], K. FOLWEILER[2], A. S. COHEN[2,3];

Abstract: Physiological recording along hippocampal mossy fiber pathway can be difficult. This may be partially due to the extremely complicated laminar organization of the microcircuitry. Here we injected biotinylated dextran amine into the dentate granule cell layer to initially anterograde label mossy fibers and their terminals; and subsequently infect the entorhinal cortex with GFP-tagged pseudorabies virus to transynaptically label area CA3 pyramidal neurons and their dendritic trees. Seven days after injection , we examined labeling in stratum lucidum of hippocampal slices cut at different slicing angles. We found that mossy fibers and their targeted pyramidal cell dendrites were well preserved in adjusted horizontal slices (Hippocampal-Entorhinal Cortex, HEC) but severely truncated in frontal (coronal) slices. In transverse hippocampal slices, the preservation of mossy fibers and pyramidal cell dendrites varied among cases, perhaps because of the slight difference in setting the hippocampi on stage for slicing. After immunofluorescent staining with an antibody against VGLUT1 in frontal slices, rosette arrangement of the mossy fibers could be observed encircling transversely truncated pyramidal cell dendrites. Confocal scanning laser microscopy demonstrated that each rosette consisted of 6 to 7 VGLUT1-positive puncta. Out of a mossy fiber rosette, one puncta might be labeled by biotinylated dextran. In HEC slices VGLUT1 positive puncta aggregated in patches along pyramidal cell dendrites at the proximal level, apposing thorny excrescences. The present study strongly suggests that HEC slices preserve that anatomic circuit and thus are the most suitable for physiological studies on focused on the hippocampal mossy fiber system.

Title: Exosome-delivered miRNA-146a ameliorates peripheral neuropathy in diabetic mice

Authors: *B. FAN[1], X. LIU[1], M. CHOPP[1,2], A. SZALAD[1], L. WANG[1], W. PAN[1,3], Z. ZHANG[1];
[1]Henry Ford Hosp., Detroit, MI; [2]Oakland Univ., Rochester, MI; [3]Med. Imaging Inst. of North Sichuan Med. Univ., SIchuan, China

Abstract: Background: MicroRNA-146a (miR-146a) has been implicated in the pathogenesis of diabetic peripheral neuropathy (DPN). However, the therapeutic role of miR-146a in DPN has not been investigated. Exosomes are cell-derived vesicles and play an important role in mediating intercellular communication. The present study investigated whether tailored exosomes carrying elevated miR-146a improve neurological outcomes of DPN. Methods and Results: Tailored exosomes carrying elevated miR-146a were isolated from medium of cultured miR-146a knock-in mesenchymal stromal cells (MSCs) by ultracentrifugation. Diabetic db/db mice treated with naïve exosomes or db/db mice alone (n=8/group) were employed as controls. We administered exosomes (10^{10}) via a tail vein once per week for 4 weeks (n=8). Administration of tailored miR-146a-exosomes elevated levels of miR-146a in plasma (3.97±0.69 vs 0.97±0.11) and sciatic nerve (4.7±0.52 vs 1.01±0.08). Tailored miR-146a-exosome treatment significantly increased blood flow in the footpad (60.19±2.11 vs 51.45±4.16) and sciatic nerve (27.1±2.34 vs 18.29±1.43) compared to the db/db mice treated with naïve exosomes. Electrophysiological recordings demonstrated that tailored miR-146a-exosomes markedly increased motor nerve conduction velocity (MNCV) by 10%, and significantly decreased thermal stimuli threshold assayed by radial heat plate tests (12.2±1.9 vs 19.2±1.3sec, $p<0.05$). Moreover, tailored miR-146a-exosomes significantly ($p<0.05$) enhanced the number of intraepidermal nerve fibers (16.5±0.7 vs 12.9±0.8 fibers/mm) and g ratio (0.58±0.03 vs 0.61±0.03). Western blot analysis revealed that tailored miR-146a-exosomes substantially ($p<0.05$) suppressed proteins of diabetic proinflammatory target genes including IRAK1 (0.34±0.05 vs 1.01±0.19) and TRAF6 (0.33±0.03 vs 1.02±0.14) and also decreased serum cytokine levels of TNFα (1.7±0.5 vs 4.8 ± 0.9pg/ml) and IL-1β cytokines (59.5±11.3 vs 117.2±25.7pg/ml) measured by ELISA. Conclusions: Together, our data suggest that tailored miR-146a-exosomes have a potent therapeutic effect on DPN via suppressing diabetic-induced proinflammatory genes.

Title: Myelination of prefrontal axons is accompanied by increased speed and integrity of cortical neurotransmission in rats

Authors: *A. SILVA-GOTAY[1], S. MCDOUGALL[2,5], W. M. VARGAS[3], G.-L. LI[4], H. N. RICHARDSON[2];
[2]Psychological and Brain Sci., [3]Neurosci. and Behavior Program, [4]Biol., [1]Univ. of Massachusetts Amherst, Amherst, MA; [5]New York Med. Col., Valhalla, NY

Abstract: The anterior cingulate is a subregion of the prefrontal cortex involved in emotional and cognitive processing. Cells in the anterior cingulate project to—and receive fiber projections from—other cortical and subcortical structures via the anterior branches of the corpus callosum, or forceps minor. Enhancement of cognitive ability during adolescent development corresponds with increases in frontal white matter—the axonal fiber tracts comprised primarily of myelinated axons. Myelin is a lipid-rich coating wrapped around the axons of neurons and myelination of these axons during adolescence may serve to increase the speed of communication between cells. Alternatively, the developmental increases in white matter may correspond instead with other functions such as the integrity of firing, e.g., the probability that action potentials successfully propagate along the axon to the terminal. We tested whether a developmental increase in white matter corresponds with increased speed or with enhanced integrity of neural transmission. We examined the neurophysiological properties and microstructural changes in myelinated axons in the mPFC in developing rats. There was a significant increase in the number of myelinated axons in the mPFC from postnatal days (PD) 15-43. Between PD15-22, conduction velocity increased as well. The relationship between response latency and transmission distance depended on the level of stimulation used, suggesting that different levels of stimulation preferentially activate separate fiber populations. High stimulation intensity produced a positive relationship between latency and distance in all age groups. Conversely, stimulation at threshold intensity produced no correlation between latency and distance, but did produce a positive relationship between conduction *velocity* and transmission distance. This indicates that for this population of fibers, increased conduction velocity in longer fibers may serve as a mechanism to keep response latency constant over different distances so signals may be received at the same time. Disruption of myelination of these axons in developing animals could impair the speed, integrity, and synchronization of neural signals, which could have long-term effects on cognitive processing in adulthood.

Abstract: Neuronal epigenomes, including chromosomal loopings which bypass the linear genome to move distal cis-regulatory elements into spatial proximity of target genes, could serve as 'molecular bridges' linking present-day-behavior to distant exposures of the past. However, longitudinal modeling is challenging because conventional chromosome conformation capture assays essentially provide single snapshots, reflecting genome organization at the time of brain harvest and therefore are non-informative about the past. Here, we introduce 'NeuroDam' to assess past epigenome status in longitudinal context. Short-term expression of the bacterial DNA adenine methyltransferase Dam, tethered to the *Gad1* gene promoter in mouse prefrontal cortex neurons, resulted in long-term tagging of *Gad1*-bound chromosomal contacts bearing the artificial $G^{methyl}ATC$ mark. We show by NeuroDam that mice with persistent deficits in cognition and alterations in anxiety-related behaviors, 4 months after pharmacological blockade of NMDA receptor signaling, already were affected by disrupted chromosomal conformations emerging shortly after drug exposure. NeuroDam can be easily modified to retrospectively chart transcription factor occupancies and many other epigenomic determinants that until now remain unexplored in longitudinal context modeling normal and diseased human brain development and aging.

Title: Maternal care modulates the febrile response to lipopolysaccharide through differences in glucocorticoid receptor sensitivity in the rat

Authors: *T. ZHANG[1,2], H.-B. NGUYEN[2], X. WEN[2], J. DIORIO[2], M. J. MEANEY[2,3], C. PARENT[2];
[1]Departments of Psychiatry, Douglas Mental Hlth. Univ. Institute,, [2]Ludmer Ctr. for Neuroinformatics and Mental Hlth., McGill Univ., Montreal, QC, Canada; [3]Singapore Inst. for Clin. Sci., Singapore, Singapore

Abstract: Early adversity is associated with an increased risk for infection in adulthood. The febrile response is a potent mechanism to combat infection. We found that variations in maternal care influence the febrile response to 50 μg/kg lipopolysaccharide (LPS) challenge in adult male rats while not affecting behavioural sickness responses. Offspring from low-licking/grooming (LG) mothers had an increased febrile response compared to offspring from high-LG mothers challenged with LPS. Low-LG offspring had reduced plasma IL-6 two hours post challenge compared to high-LG offspring. Binding of the transcription factor NFκB to the IL-6 promoter region in the anterior hypothalamus was greater in low-LG offspring treated with LPS than in high-LG offspring. IL-6 gene expression in the anterior hypothalamus was induced following LPS challenge in low-LG offspring but not in high-LG offspring at two hours post challenge. These findings suggest greater activation of thermoregulatory neurons in the anterior hypothalamus of low-LG compared to high-LG offspring following LPS challenge. No differences were found in plasma corticosterone levels following LPS challenge between high and low-LG offspring. Low-LG offspring had enhanced glucocorticoid receptors (GR) in the spleen compared to high-LG offspring which could indicate enhanced sensitivity to the effects of glucocorticoids. Challenge with RU-486 prior to LPS challenge eliminated differences in the febrile response between offspring of high and low-LG mothers. Individual differences in GR

sensitivity may modulate differences in the febrile response to LPS challenge, exerting a long-term influence on the capacity to recover from infection.

Title: Adolescent social stress results in sex-specific transcriptional reprogramming throughout the reward circuitry in adult mice

Authors: ***D. M. WALKER**[1], I. PURUSHOTHAMAN[1], M. E. CAHILL[1], C. K. LARDNER[1], S. MACHLOVI[1], E. S. CALIPARI[1], H. M. CATES[1], R. C. BAGOT[1], C. J. PEÑA[1], G. E. HODES[1], M. A. DOYLE[1], E. RIBEIRO[1], S. J. RUSSO[1], P. J. KENNEDY[2], E. J. NESTLER[1]; [1]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Psychology, The Univ. of California Los Angeles, Los Angeles, CA

Abstract: Adolescent social isolation (SI) alters neuronal morphology, physiology, and gene expression throughout the reward circuitry and increases preference for drugs of abuse in male rodents. However, few studies have investigated if there are sex differences in responses to adolescent SI as well as the molecular mechanisms underlying such long-term changes in reward-associated behaviors. Our preliminary data suggest that SI reverses or reduces sexually dimorphic reward- and anxiety-related behaviors. Therefore, we tested the hypothesis that SI results in persistent transcriptional changes that underlie such sex differences. Mice were socially isolated or group housed (GH) from postnatal day (P) 22 - P42, then GH until adulthood (~P90). Micropunches from 4 reward-associated brain regions (meAMY, VTA, NAc, and PFC) were collected and transcriptome-wide changes investigated by RNA-sequencing after acute or chronic cocaine or saline (7.5mg/kg) ($n = 5 – 8$/group). Those genes displaying a sex X stress interaction were significantly enriched in sexually dimorphic genes in all 4 brain regions ($p < 0.001$), an effect not observed in genes altered by SI alone, suggesting that sexually dimorphic

genes are preferentially altered by adolescent stress. Additionally, hierarchical clustering revealed that SI reversed baseline sex differences in gene expression in 3 of 4 brain regions, similar to the differences observed in behavior. Specifically, GH males cluster with SI females and vice versa for those genes displaying a sex X stress interaction in the meAMY (869 genes) and PFC (495 genes) only. In the VTA (276 genes), male SI clustered with female GH but male GH and female SI clustered separately suggesting that SI alters sex differences in the male but not female VTA. Interestingly, in the NAc (1444 genes) males and females clustered together, independent of adolescent stress. Finally, significant overlap of sexually dimorphic genes across all 4 brain regions was observed. To determine if sex differences in the response to cocaine were also reversed by SI, hierarchical clustering was used to analyze how those genes displaying a sex X stress interaction responded to the drug. Analysis revealed that sex differences in response to chronic but not acute cocaine are reversed by SI in the VTA. In the meAMY, SI females display a male-typical response to chronic but not acute cocaine. These effects were not observed in the PFC or NAc. These data suggest that adolescence is a sensitive period for development of sex differences in the reward circuitry and that adolescent stress causes sustained reversal of sexually dimorphic gene expression in key limbic brain regions.

Title: Storm, stress, and nicotine: Interaction of stress and nicotine during adolescence on adult learning and stress response systems

Authors: *E. HOLLIDAY[1], C. OLIVER[2], R. COLE[2], D. BANGASSER[2], T. GOULD[2]; [1]Univ. of Texas Med. Br., Galveston, TX; [2]Temple Univ., Philadelphia, PA

Abstract: Despite the known risks associated with tobacco use and decline of tobacco consumption in the last 50 years, nearly 18.1% of people in the United States are everyday smokers. One reason for persistent smoking rates may be due to adolescent onset of tobacco use.

In rodent models, nicotine treatment during adolescence leads to long-term deficits in hippocampus-dependent tasks later in life. Adults do not display long-term learning impairments. The results from this study suggest that these long-term impairments result from an interaction between acute stress and chronic nicotine during adolescence. This study examined the interaction of stress and nicotine in early adolescent (p23), late adolescent (p38) and adult (p54) C57BL/6 mice that were either shipped from an animal facility in Maine to our animal facility in Philadelphia (STRESS) or bred in our animal facility (NO STRESS). Follow up studies wanted to recreate the shipping stress in the laboratory using social and physical stressors and wanted to match CORT elevations to that seen in shipped mice. Following stress, all animals were implanted with osmotic mini-pumps to deliver 12.6mg/kg/day of nicotine or saline per day for a period of 12 days. Thirty days later animals were trained and tested in our contextual fear conditioning paradigm. Only early adolescent and late adolescent animals shipped in or subjected to our induced stress protocol and administered nicotine demonstrated persistent learning deficits. Additionally, blood was collected from animals not designated for behavioral tasks and analysis were run to determine the interactive effects of stress and nicotine on stress response systems. There were no interactions between stress and nicotine on baseline CORT levels at various time points but there were significant changes in GR and CRFR expression in subregions of the hippocampus. Finally, it was determined adolescent stress and adolescent nicotine attenuated stress response to an acute stressor applied in adulthood suggesting altered stress response signaling as a mechanism underlying the observed long-term learning deficits.

Title: MAGL inhibition decreases aggression after post-weaning social isolation in male and female rats

Authors: L. DAWUD[1], E. LOETZ[2], J. FONTENOT[2], D. TAUBER[1], I. BRALLIER[1], *S. T. BLAND[2];
[1]Dept of Integrative Biol., [2]Dept of Psychology, Univ. of Colorado, Denver, Denver, CO

Abstract: Post-weaning social isolation (PSI), also known as isolation rearing, interferes with normal social development and produces a behavioral phenotype that includes increased aggression. PSI also alters the endocannabinoid system in brain regions including the medial prefrontal cortex. The MAGL inhibitor MJN110 increases levels of the endocannabinoid 2-arachidonoylglycerol (2-AG) in the CNS, and we have previously shown that MJN110 impacts social behavior. Moreover, MJN110 differentially altered phosphorylation of mammalian target of rapamycin (p-mTOR) in neurons and astrocytes within the medial prefrontal cortex (mPFC). Here, we tested the hypothesis that MJN110 would decrease aggressive behavior after PSI. Male and female Sprague-Dawley rats were exposed to either 4 weeks of PSI or group housing starting on postnatal day (PND) 21, and on PND 49 underwent a 15 min trial of social interaction with a novel, same-sex juvenile rat. Prior to the social interaction trial, rats received either 0, 1, or 5 mg/kg of MJN110. The trials were recorded for later behavioral assessment, and brains were removed for p-mTOR immunohistochemistry. We observed that MJN110 dose-dependently decreased aggressive grooming while having no effects on overall social interaction or on play behaviors. Sex differences in the effects of MJN110 on p-mTOR were observed, with more robust alterations in p-mTOR in males than females. Increased 2-AG signaling may decrease aggression during adolescence, and this may involve the mPFC mTOR pathway.

Title: The impact of BDNF Val66Met single nucleotide polymorphism on rodent social interaction across development

Authors: *A. LI[1], D. JING[2], R. YANG[2], F. LEE[1,2];
[1]Sackler Inst. for Developmental Psychobiology, [2]Dept. of Psychiatry, Weill Cornell Med. Col., New York, NY

Abstract: Brain-derived neurotrophic factor (BDNF) is crucial for neuronal differentiation, survival, and plasticity (Binder & Scharfman, 2004; Chao, 2003; Huang & Reichardt, 2001; McAllister, Katz, & Lo, 1999). A common human single nucleotide polymorphism (SNP) in the BDNF gene leads to a single amino-acid substitution (Val66Met) that reduces activity-dependent BDNF secretion and neuronal plasticity (Chen et al., 2004, 2005). Consequently, the BDNF Met allele has been associated with alterations in learning, planning, and memory (Dincheva, Glatt, & Lee, 2012), as well as susceptibility to many neuropsychiatric disorders (Hall, Dhilla, Charalambous, Gogos, & Karayiorgou, 2003; Neves-Pereira et al., 2002; Ribasés et al., 2003; Sen et al., 2003; Sklar et al., 2002; Ventriglia et al., 2002). However, the impact of BDNF Met allele on social behaviors has not been extensively studied. Using a knock-in mouse containing the BDNF Met polymorphism ($BDNF_{Met}$), we investigated social behaviors across development using both a traditional three-chamber paradigm and a novel free-interaction system. Results indicate a significant age-gene interaction ($F(2,47) = 3.260$, $p < 0.05$) with reduced social interaction in the $BDNF_{Met}$ mice at postnatal day (P)25 and P60, but not at P40. Similarly, our preliminary data show altered amygdala-hippocampus connectivity in the $BDNF_{Met}$ group at P25 and P60, but not at P45. Together these findings suggest that phenotypic expression of this BDNF polymorphism in social behaviors may vary depending on developmental expression of BDNF, as well as neural circuit maturation, and suggest that developmentally timed interventions may prevent the behavioral and neuroanatomical alterations associated with the BDNF Met allele.

Title: Periodic enrichment affects the outcome of two social preference tasks in adolescent female rats

Authors: *H. JOHNSON, H. C. SKINNER, S. L. SANTIAGO, R. GUCWA, M. N. PAVELKA, K. L. PATTERSON, M. C. ZRULL;
Appalachian State Univ., Boone, NC

Abstract: Changes in behavior, often featuring increased interest in novelty and forms of risk taking, mark adolescence. For rats, changes in novelty preference include how adolescents interact with conspecifics as well as how they explore environments. Social preference (SP) can be influenced by environmental enrichment (EE), exposing an animal to a novel and enhanced environment on a regular basis, with EE apt to modulate SP by altering flexibility in novel situations. We investigated the impact of EE on SP in adolescent, female rats using two tasks. Long-Evans females (n=12) were exposed to EE for 1.5-h 18 times between postnatal days (pnd) 21 and 49. Age matched controls (n = 12) were held twice on 18 times. On pnd 49, rats performed one of two SP tasks: one involved placing a rat into a small cage with additional small cages that contained stimulus rats on either side of the experimental rat; and the other involved placing a rat in an open field with one (Trial 1) or two (Trial 2) stimulus rats. For each task, there was a sample trial, and, after a 30-min delay, Trial 2 occurred with one familiar and one novel stimulus rat. In both tasks, initiating contact and time spent with the novel stimulus rat on Trial 2 was of interest. Evoked activity in basolateral amygdala (BLA) was examined using c-fos immunohistochemistry. When separated from stimulus rats by a wire mesh wall, EE rats made equal portions of nose pokes at and spent equal time with familiar and novel stimulus rats (0.49, 0.52, SDs=0.10). In contrast, control rats made 22% more pokes at and spent 33% more time near the novel rat (p<.05). In the direct contact task, EE rats initiated contact with the novel stimulus rat 50% less often than control rats (p<.02), and while EE rats spent about an equal proportion of time interacting with novel (0.54, SD=0.13) and familiar (0.46) rats, control rats spent less time with the novel stimulus rat (p<.08). C-fos positive neuron densities indicated a history of EE suppressed evoked activity in BLA relative to control brains (-58%, p<.05). Behavioral data suggest that periodic EE during adolescence promotes adaptation to social novelty with female EE rats exhibiting balanced contact time with familiar and novel conspecifics relative to female rats without enrichment. EE rats initiate interaction less often than controls when direct contact with a novel rat is possible but spend more time interacting than controls. BLA data suggest social features of EE may reduce neural activation thought to contribute to emotional behavior in a novel social situation. If preference for contact with a new over a known conspecific is risky, then enrichment seems to suppress this type of risk taking behavior in our rat model.

Abstract: To improve the treatment of S-TBI, establish replicable animal patterns of S-TBI in experimental rats, find out the optimum trauma-causing impact force through experiments in 80 rats, and observe the correlation between pathological sections of brain and clinical brain trauma at serial time points after trauma. An improved free fall apparatus was used to give impacts on the vault of skull of anesthetized rats with a 50-400g weight from a 20-50cm height, the rats were observed for 4hr to 12days after impact, and brain was collected after anesthesia to make 652 pathological sections. The optimum impact force was determined as 10000g/cm. There was a marked correlation between pathological changes and clinical manifestation, which had a reference value to the diagnosis and treatment of S-TBI. A comparison between simulated clinical closed decompression and open decompression indicated that the latter was more favorable for the rehabilitation of brain trauma. The optimum impact force was found in rats of severe traumatic brain injury through experiments; experimental animals were significantly correlative to clinical diagnosis and treatment; open decompression was more beneficial to brain rehabilitation.

Title: Social interaction during critical developmental periods affects development of the prefrontal cortex

Authors: *W. E. MEDENDORP[1], A. PAL[1], E. PETERSEN[1], U. HOCHGESCHWENDER[2], K. JENROW[3];
[1]Neurosci., [2]Col. of Med., [3]Psychology, Central Michigan Univ., Mount Pleasant, MI

Abstract: The prefrontal cortex has been shown to participate in several roles in the regulation of social behavior. Dysfunction in the prefrontal cortex can lead to aberrant social behaviors similar to those found, for example, in autism. Critical periods of heightened plasticity are essential for normal development of the prefrontal cortex, and dysregulation during these developmental stages can result in a range of symptoms that correspond to neurodevelopmental disorders.

Socially isolated mice have been established as a model for autistic-like behaviors such as aberrant social interactions. Social isolation can also contribute to other behavioral dysfunction, including anxiety- or depressive-like behaviors, and has been demonstrated to alter the underlying neurological function in the prefrontal cortex. This suggests that social interaction with other animals contributes to the development and emergence of normal social behaviors in mice. Since development of the prefrontal cortex continues well into adolescence, it is likely that the social enrichment during this critical development stage is necessary for normalized social behavior. Correspondingly, lack of social enrichment during this critical period in adolescence likely contributes to the underdevelopment of the prefrontal cortex, giving rise to social dysfunction and aberrant social behavior. We hypothesize that social isolation during adolescence effects aberrant behavior in adult animals through changes in prefrontal neuronal morphology and electrical activity.

Male and female mice of strain C57BL/6 were weaned at 3 weeks of age and segregated into single housed or group housed cages. A minimum of six weeks later several tests were performed to assess for changes in behavior. Specifically, mice were tested behaviorally using the three chamber test to assess for social dysfunction, open field to assess any evidence of anxiety behaviors, and the forced swim test to assess depressive behaviors. These mice were then surgically implanted with recording electrodes to perform *in vivo* electrophysiology. A separate group of mice is being used to assess morphology of the cortical neurons in the prefrontal cortex. These mice express green fluorescent protein (GFP) in neurons of the cortical layer, allowing anatomical tracing of arborization by confocal microscopy and assessment of general morphology and number of neurons.

Together our studies will reveal whether behavioral changes caused by early social isolation correspond to changes in the activity or morphology of the prefrontal cortex.

Title: Enrichment affects exploration of a field containing familiarly and newly located objects by adolescent rats

Authors: *E. A. ARTZ, H. L. JOHNSON, H. C. SKINNER, S. J. SNOUSE, R. C. PIERCE-MESSICK, T. J. ARNOLD, D. E. COBB, M. C. ZRULL;
Appalachian State Univ., Boone, NC

Abstract: Enrichment experiences (EE) can advance informal learning about environments, objects, and conspecifics via opportunity for investigation and interaction. Adolescence is a time when exploratory and novelty seeking behaviors emerge, with EE likely to have an impact by affecting brain structures mediating these behaviors. We examined how EE affected aspects of exploration and novelty preference during an object in place (OiP) task in adolescent rats. Between postnatal days (pnd) 25 and 48, same-sex groups of Long-Evans rats (n=8 each) experienced 18, 1.5-h EE sessions in cages containing objects, ramps, and platforms. Age-matched controls (8 female, 8 male) were not enriched. At pnd 36 and 50, an OiP task was performed, allowing assessment of field and object exploration and preference for objects in constant or new locations. There were 3 trials, sample and 15- and 60-min delays, that took place in a gridded, 1-m square open field. Exploration and object contact times were recorded for each trial, with the locations of two objects switched before Trial 2 and of the other two objects switched before Trial 3. After testing, brain tissue was processed to view neural activity in lateral and basolateral amygdala (BLA) using c-fos as a marker. At pnd 36 across delays, EE rats spent more time with objects (+56%), more in center of the field not near objects (+67%), and less time in the field exterior (-19%) than non-EE controls (all p<.02). Controls spent more time (+23%) and less time (-32%) the switched objects at the 15 and 60 min delays (p<.05), and EE rats spent similar time with all objects across delay trials. At pnd 50, EE rats spent less time with objects (-21%, p<.01), more time in center of the field not near objects (+100%, p<.02), and similar time in the field exterior than non-EE controls. Both EE and control rats spent a similar proportion of object time with switched objects at 15 and 60 min delays. Microscopy revealed similar c-fos positive neuron densities in LA of EE and control brains but fewer task-activated neurons in BLA of EE brains (-39%, p<.05) compared to controls. For younger adolescent rats, EE promotes balanced initial investigation of regions in and features of a simple environment. For older adolescents, EE continues to promote balanced exploration of environment regions but reduces investigation of specific features within a space. Reduced BLA activation suggests EE may promote quick neural adaptation to novelty, which correlates with reduced attention to

objects in the OiP environment by older adolescent rats. Overall, EE appears to foster balanced investigation of an environment and gradually diminish preference for familiarly or newly located features.

Title: Attentional control assessment in LgDel adolescent mice through a modified five choice serial reaction time task

Authors: *M. CIAMPOLI[1], M. MEREU[2], F. PAPALEO[1];
[1]Neurosci. and Brain Technologies, Inst. Italiano Di Tecnologia, Genova, Italy; [2]Univ. degli Studi di Padova, Padova, Italy

Abstract: The 22q11.2 deletion syndrome (22q11.2DS) is the major known genetic-based vulnerability factor for developmental neuropsychiatric disorders such as schizophrenia and ADHD. These psychiatric disturbances are the most problematic, debilitating and enduring features in this syndrome. By late adolescence/early adulthood up to one-third of patients with 22q11.2DS develops schizophrenia. Adolescence is a critical period for the development and maturation of higher order cognitive functions, including the orienting of attention in the visual space. However, at the moment, no studies investigated the impact of 22q11.2 microdeletion on attentional control during this critical period in mice. This was mostly due to the lack of behavioral task able to test higher order cognitive functions in rodents during the short period of "adolescence". We set up and validated a new version of the 5-Choice Serial Reaction Time Task (5-CSRTT) in order to selectively measure in adolescent mice different cognitive functions such as impulsivity, processing speed, broad monitoring and distractibility. Results showed that 21-days old C57BL/6J mice were able to quickly and reliably acquire this task in less of twelve days. In particular, we found that our setting was able to catch selective alterations of impulsive control, reduced ability to maintain a broad focus of attention and vulnerability to distractors.

Next, we applied this test to the LgDel genetically modified mice carrying the same genetic microdeletion as in 22q11.2DS. LgDel mice were able to acquire and perform the basic part of our modified 5-CSRTT. Remarkably, as observed in 22q11.2DS, LgDel mice showed selective higher distractibility than wild-type littermates, suggesting a vulnerability of attentional control in relationship to distracting cues. Omega-3 polyunsaturated fatty acids (PUFAs) have recently been indicated as a possible cognitive enhancer. In order to set the ground for the development of new preventive strategies, we tested the effects of chronic omega-3 PUFAs administration in LgDel adolescent mice. Omega-3 PUFAs was able to selectively rescue LgDel mice deficits in distractibility. Overall, our data pave the way for an early detection and therefore early intervention in psychiatric-related symptomatology to prevent and cure its debilitating features.

Title: Adolescent binge ethanol exposure alters cholinergic cell populations, but not functional acetylcholine release

Authors: *G. M. FERNANDEZ, J. E. SANDERS, L. M. SAVAGE;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Adolescence is a malleable time period during which maladaptive alcohol consumption patterns are often initiated. Previous research has found variable effects of adolescent binge- like ethanol (EtOH) exposure on spatial learning and memory, despite a 30% reduction in forebrain cholinergic neurons. Using an adolescent intermittent ethanol exposure model (20% EtOH v/v, 5 g/kg, intragastric gavage, 2 days on/2 days off), rats were exposed to binge-like levels of EtOH from P25-P55. Cholinergic functioning was assessed using a spontaneous alternation protocol during which acetylcholine release was measured 3 weeks following EtOH exposure (P80). Across treatment, animals developed metabolic EtOH sensitization, as demonstrated by significantly increasing blood EtOH concentrations (125.8 mg/dL to 146.4 mg/dL). Despite exposure to binge-like levels of ethanol during adolescence, EtOH-treated rats had similar rates of spontaneous alternation compared to control rats. Functional hippocampal and prefrontal acetylcholine release increased during maze testing, but

there were no differential release patterns as a function of previous EtOH exposure. Additionally, no group differences were found during novel object recognition testing. Immunohistological staining for choline acetyltransferease (ChAT) indicated a 20% reduction in ChAT positive cells within the medial septum/diagonal band of EtOH exposed rats. Our results indicate that binge EtOH exposure initiated during early adolescence does not impair cholinergic functioning, despite a reduction in cholinergic staining, when assessed during early adulthood.

Title: Deprivation of social play behavior results in decreased inhibition in adult prefrontal cortex and associated behavioral changes in rats

Authors: A. OMRANI[1], M. SPOELDER[2], R. VAN DORLAND[3], C. CORNELIS[2], *L. J. VANDERSCHUREN[2], C. J. WIERENGA[3];
[1]Translational Neurosci., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [2]Utrecht University, Fac. of Vet. Med., Utrecht, Netherlands; [3]Div. of Cell Biol., Utrecht University, Fac. of Sci., Utrecht, Netherlands

Abstract: Sensory input during early life is critical for proper development of the sensory cortex. It has been proposed that experience-dependent development of neuronal connectivity also occurs in brain areas involved in complex cognitive functions, such as the prefrontal cortex (PFC). By analogy, we hypothesized that optimal PFC development requires complex input, such as social interaction. Therefore, we examined how early social experiences shape PFC circuitry and function. We focused on a particular form of social interaction that is highly abundant during post-weaning development, i.e. social play behavior. It is thought that social play behavior facilitates social and cognitive development, especially the ability to flexibly use cognitive capacities under changeable circumstances. Young rats were deprived from social interaction for 3 weeks during the period in life when the occurrence of social play behavior peaks (P21-42, ISO rats), followed by resocialization (housing in pairs) until adulthood. In a probabilistic reversal learning task, which depends on integrity of the PFC, ISO rats achieved more reversals than controls, as a result of enhanced sensitivity to recently rewarded actions. ISO

rats also showed enhanced intake of sucrose as well as an increased motivation for sucrose under a progressive ratio schedule of reinforcement. In parallel, we recorded synaptic currents in layer 5 cells in acute slices from medial PFC. While we observed no differences in excitatory synaptic currents between ISO and control rats, we found that the frequency of miniature inhibitory synaptic currents (mIPSCs) was reduced in adult ISO rats. This reduced inhibitory transmission was accompanied by an increase in mIPSC rise time. Intrinsic excitability of layer 5 cells was not different. Our data suggest that deprivation from social play behavior during post-weaning development induces a long-lasting change in the balance between excitation and inhibition in the PFC, by reducing inhibitory synaptic transmission onto layer 5 neurons. This reduction in PFC inhibition may contribute to altered behavioral flexibility and sensitivity to reward. Together, our results demonstrate that early social experiences have long-lasting consequences for brain and behavior.

Title: Neonatal vincristine administration evokes delayed mechanical pain hypersensitivity in the developing rat

Authors: *K. A. SCHAPPACHER, M. L. BACCEI;
Anesthesiol., Univ. of Cincinnati Dept. of Anesthesiol., Cincinnati, OH

Abstract: Chemotherapeutic agents induce peripheral neuropathy and severe pain in children, often necessitating a dose reduction in the chosen cancer treatment, as widely reported to occur in adults. Recent preclinical evidence suggests that peripheral nerve or tissue damage during the neonatal period leads to long-term changes in nociceptive processing. However, the degree to which pediatric chemotherapeutic regimens influence pain sensitivity throughout development remains unknown, in part due to the lack of an established animal model of chemotherapy-induced neuropathy during early life. Therefore, the present study investigated the effects of early life exposure to vincristine (VNC), commonly used in the treatment of pediatric cancers, on mechanical and thermal pain sensitivity in the developing rat.

Male and female Sprague Dawley rats received daily i.p. injections of 15, 30, 45, or 60 µg/kg VNC, or equivalent volumes of saline, with a five-day on, two-day off schedule starting on postnatal day (P)10 for a total of 10 injections. Mechanical reflex withdrawal thresholds were measured prior to each injection and then at weekly intervals until P56. Withdrawal latencies in response to noxious heat and cold stimuli were evaluated weekly between P26 and P56. VNC at 15 and 30 µg/kg did not significantly alter mechanical or thermal withdrawal thresholds at any time point compared to saline-treated littermate controls. Since the daily administration of 45 and 60 µg/kg VNC resulted in death following the third dose, we modified our dosing protocol and administered 5 i.p. injections of 60 µg/kg vincristine (or saline) every other day starting at P10. Rats routinely survived this VNC dose, although both male and female VNC-treated rats displayed reduced weight gain compared to saline controls. More importantly, VNC rats demonstrated significantly lower mechanical withdrawal thresholds compared to control groups beginning at P26. Sex did not influence the effects of VNC exposure on pain behaviors, as the delayed mechanical hypersensitivity was observed in both male and female littermates after neonatal VNC. Meanwhile, the responses to noxious heat and cold, as well as gross motor function, were unaffected by VNC in both sexes. Overall, the present results demonstrate that high dose administration of VNC during the early postnatal period selectively evokes a mechanical hypersensitivity in rats that is slow to emerge during adolescence, providing further evidence that aberrant sensory input during early life can have lifelong consequences for pain processing.

Title: Effects of estrogen on brain structural maturation during adolescence: prefrontal, amygdala and temporal cortex in female macaques

Authors: *F. LOMBARDI[1], J. R. GODFREY[1], B. R. HOWELL[1,2], M. STYNER[3], M. E. WILSON[1,2], M. M. SANCHEZ[1,2];
[1]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [2]Dept. of Psychiatry & Behavioral Sci., Emory Univ., Atlanta, GA; [3]Dept. of Psychiatry, Univ. of North Carolina, Chapel Hill, NC

Abstract: Adolescence is a developmental phase of considerable brain growth and remodeling, occurring in parallel with increases in emotional and stress reactivity. A likely factor regulating these changes in females is puberty-induced increases in gonadal hormones, particularly estradiol (E2). E2 organizational effects could contribute to brain structural remodeling, although it is difficult to disentangle these hormonal effects from effects of chronological age in human studies. Non-human primates constitute translational animal models due to their brain, neuroendocrine, developmental and complex social behavior similarities with humans. In this study we used socially-housed female rhesus monkeys (*M. mulatta*) to disentangle brain structural effects of E2 during adolescence from chronological age by investigating the effects of delayed puberty on brain development. Animals were socially housed, allowing us to assess the effects of rank, and associated differences in social stressor exposure, on these changes in middle ranking animals. We focused on prefrontal cortex (PFC), amygdala (AMYG), and temporal-parietal-occipital (TPO) region of the superior temporal sulcus (STS) due to their known roles in processing socioemotional stimuli.
Structural MRI scans were collected at pre- and peri-puberty in 21 juvenile female rhesus macaques. Thirteen of those animals received monthly injections of a gonadotropin releasing hormone agonist (GnRH, Lupron) to delay puberty. We examined total intracranial volume (ICV), and grey matter (GM), white matter (WM), and cerebrospinal fluid (CSF) volumes, as well as AMYG, PFC GM and WM, and TPO GM volumes. To assess functional correlates of brain structure changes, social and anxiety behaviors as well as measures of stress neuroendocrine function (basal and stress-induced cortisol levels, and glucocorticoid negative feedback sensitivity) were collected. Results showed that suppression of E2 by Lupron treatment resulted in smaller GM and WM volumes, both total and in PFC, as well as smaller ICV and AMYG volumes. Smaller AMYG volumes predicted decreased stress reactivity. E2 suppression also resulted in stronger glucocorticoid negative feedback. In addition, there was a significant relationship between social rank and PFC GM volume, with higher social rank predicting larger volumes, even within the narrow range of middle ranking animals. These results provide evidence that during adolescence the female primate brain undergoes significant structural changes and are linked to changes in stress neuroendocrine function that seem to be driven by developmental increases in E2 as well as exposure to social stressors.

Title: Amygdala growth from youth to adulthood in the macaque monkey.

Authors: *C. M. SCHUMANN[1], J. A. SCOTT[2], A. LEE[3], E. FLETCHER[2], M. D. BAUMAN[1], D. G. AMARAL[1];
[1]Psychiatry and Behavioral Sci., UC Davis MIND Inst., Sacramento, CA; [2]Neurol., [3]UC Davis, Sacramento, CA

Abstract: BACKGROUND: The amygdala modulates the brain's socioemotional networks. Functionally, this system is among the latest to mature in primates. In human cross-sectional MRI studies, the amygdala appears to undergo a protracted growth trajectory by continuing to increase in size throughout adolescence, coinciding with acquisition of complex socioemotional learning. This study was carried out to determine if the primate amygdala does indeed undergo protracted development relative to other brain regions. Since this study would take over 20 years to do in humans, we utilized a nonhuman primate model, rhesus macaques, with MRI's collected longitudinally over 5 years. We compared amygdala growth relative to that of total brain, cortical gray matter, cortical white matter, and hippocampus. METHODS: Longitudinal T1-weighted MRI scans were collected on naturalistically-reared male and female rhesus macaques (n=24) at age 6 months, 9 months, 1 year, 3 years, and 5 years. Amygdala and hippocampal volumes were measured from manual delineations and cortical regions with semi-automated segmentation. RESULTS: Amygdala volume increases 49% (+/-12%) from age 6 months to 5 years, a relative gain greater than overall brain growth (8% +/- 6%). The amygdala best fit a linear trajectory model, in contrast to hippocampus, which plateaus near 3 years of age (relative volume gain 38%). Amygdala volume, but not hippocampus, is larger in males than females (8.14%, p=0.013). Cortical gray matter volume slightly declines (-7% +/-3%). White mater is similar to amygdala with positive age-related changes detectable through early adulthood (17% +/-3%). CONCLUSION: The protracted increase in amygdala volume in the macaque monkey mirrors that reported in humans. This is likely due to increasing connectivity with larger socioemotional networks and extended neuronal maturation that occurs beyond that of other brain regions.

Understanding this protracted growth trajectory is essential for developing targeted therapeutics for neurodevelopmental and psychiatric disorders in which the amygdala is implicated.

Title: Physical activity during adolescence and neural reserve: a study of the brain levels of brain derived neurotrophic factor (BDNF), adrenocorticotropic hormone (ACTH) and corticosterone.

Authors: *A. D. DOMINGUEZ CARVALHO[1,2], A. B. VICTORINO[2], A. A. DE ALMEIDA[2], J. S. HENRIQUE[2], F. R. CABRAL[3], L. B. TORRES[3], R. M. ARIDA[2], S. GOMES DA SILVA[3]; [1]Exercise Neurophysiolgy, [2]Neurology/Neurosciences, Federal Univ. of Sao Paulo, Sao Paulo, Brazil; [3]Hosp. Israelita Albert Einstein, Sao Paulo, Brazil

Abstract: Background: There are reports that life experiences at early ages such as physical activity in childhood and adolescence can reduce the future risk of brain disorders and enhance lifelong brain functions. However how early physical activity promotes such effects are not well understood. A possible explanation is that physical exercise can stimulate neuronal growth, resulting in a neural reserve which could be extracted throughout the life course. Purpose: The present study was designed to investigate the hypothesis of neural reserve induced by early physical activity. To do this, we evaluated the cortical and hippocampal levels of BDNF, ACTH and corticosterone during the aging course of rats submitted to physical exercise during adolescent period. Methods: Forty- eight male Wistar rats were distributed into exercise (EX, n=24) and control (CTL, n=24) groups. Rats from EX group were submitted to an aerobic exercise program during the 21st and 60th postnatal day (P21-P60). Afterward, cortical and hippocampal levels of BDNF, ACTH and corticosterone from the EX and CTL groups were investigated at different life stages: 0 (P60), 30 (P90), 60 (P120) and 90 (P150) days after last exercise session. The BDNF, ACTH and corticosterone levels were quantified by mean of Luminex xMAP system (MAGPIX technology). Results: After the last physical training session (at P60), a significant increase of hippocampal BDNF ($p = 0.002$) and a decrease of cortical ACTH ($p = 0.03$) were detected in EX group in relation to CTL group. At P90, a significant decrease in hippocampal BDNF level was observed in the Ex group when compared to the CTL group ($p = 0.016$). At P150, levels of hippocampal ACTH ($p = 0.003$) and cortical corticosterone ($p = 0.043$) were lower in Ex group than in CTL group. Conclusion: Our results indicate that changes in the cortical and hippocampal levels of proteins and hormones linked to cellular growth and stress may occur throughout of life of rats exercised in youth.

Title: GABAergic/non-GABAergic synaptic inputs to striatal medium spiny neurons

Authors: *Y. KUBOTA[1,2], Y. KAWAGUCHI[1,2];
[1]Natl. Inst. Physiol Sci. (NIPS), Okazaki, Japan; [2]Grad Univ. Advanced Studies (SOKENDAI), Okazaki, Japan

Abstract: We analyzed GABAergic and non-GABAergic synaptic inputs along 3D-reconstructed dendritic segments of on a whole cell-recorded medium spiny (MS) cell of the rat striatum, using the serial electron microscopy with postembedding GABA immunohistochemistry. Among 108 spines in the 9 dendritic segments (total length: 113.1 μm, range: 2.8 - 30.8 μm), we found 71 spines receiving the non-GABAergic synaptic inputs, presumably excitatory glutamatergic terminals (non-GABAergic synapse density: 0.67 /μm). The two spines had two non-GABAergic synapse terminals simultaneously. Most of the non-GABAergic synapses were on the spine head (71 among 76 synapses). Ten GABAergic synapses were found on the dendritic shaft (n = 6), spine neck (n = 2), or spine head (n=2). Three spines with the GABAergic input also received the other non-GABAergic synaptic input. The GABAergic shaft synapse density was 0.05 /μm, and spine synapse density was 0.04 /μm. The inhibitory GABAergic synapses were 12 % (10 among 86 synapses) of all synaptic inputs to the MS cell.

To estimate total GABAergic and non-GABAergic synapse numbers, the total dendritic length was measured with the MS cell using Neurolucida reconstruction system. The total length of the dendrites was 2879 μm. The estimated non-GABAergic (presumably excitatory) synapse number was 1934 (1807 on spines and 127 on shafts). The estimated GABAergic inhibitory synapse number was 254 (101 on spines and 153 on shafts). The estimated number of spine innervated by both GABA-positive and -negative synapses was 76, and that by two GABA-negative synapses was 51.

Furthermore we found an FS cell showing a unique target preference by 3D reconstruction of its axon terminals from serial electron micrographs. All 16 axonal boutons exclusively innervated the spine head with no other additional synaptic inputs. The target spine head size was variable (volume: 0.08 ± 0.05 μm^3, 0.02 – 0.19 μm^3; surface area: 1.58 ± 0.83 μm^3, 0.49 – 3.26 μm^2; n = 16) . The synapse junction area (0.16 ± 0.09 μm^2, 0.03 – 0.36 μm^2; n=16) correlated with the spine volume or surface area. Most striatal FS cells make synapses on diverse surface domains (soma, dendritic shaft and spine). This finding suggests that striatal FS cells may be further diversified, based on the range of domain selectivity.

Title: Contacts between the ER and other membranes in neurons: an inter-organelle connectome

Authors: *Y. WU[1], S. XU[2], H. KENNETH[2], H. HESS[2], P. DE CAMILLI[1];
[1]cell biology, Yale University, Med. Sch., New Haven, CT; [2]Janellia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Close appositions between the membrane of the endoplasmic reticulum (ER) and other membranes (membrane contact sites, MCS) play important physiological functions. One such function, which applies to contacts between the ER and either the plasma membrane (PM) or mitochondria is the regulation of Ca^{2+} dynamics. Another function, thought to apply to appositions between the ER and all other membranous organelles including the PM, is the control of lipid homeostasis via the direct transfer of lipids between the two apposed bilayers, independent of membrane fusion and fission reactions. The abundance of such contacts in neurons has not been systematically analyzed. As a complement to ongoing studies in one of our labs of proteins that are localized at MCS and participate in lipid transfer (f.e. extended-synaptotagmins and ORP proteins), we have used 3 dimensional (3D) electron microscopy techniques [Focus Ion Beam-Scanning Electron Microscopy (FIB-SEM) and tilt imaging of serial sections] to reconstruct intracellular organelles and MCSs of portions of neuronal cell bodies, dendrites, and axons. Contacts (distance less than 30 nm) between the ER and other membranes, including the plasma membrane, were observed in all neuronal compartments. ER-plasma membrane contacts were particularly abundant in cell bodies, where they involved flat and large (width in the range of micrometers) cisternae often with a very narrow lumen (thin ER), corresponding to the previously described subsurface cisternae (Rosenbluth, JCB 13, 1962). However, smaller contacts were also numerous along dendrites and axons. Contacts between ER and mitochondria covered more than 4% of the mitochondrial surface and formed cages around mitochondria likely to have an impact on mitochondria motility. Collectively, our study reveals a striking degree of interconnections of membranous organelles and suggest that such connections may play more general role in neuronal physiology than appreciated so far.

Title: Imaging of polarized light signal changes associated with neuronal activity in mouse hippocampus

Authors: ***M. KOIKE-TANI**[1], S. MEHTA[1], T. TOMINAGA[2], R. OLDENBOURG[1], T. TANI[1]; [1]MBL, Woods Hole, MA; [2]Dept. of Neurophysiology, Kagawa Sch. of Pharmaceut. Sci., Tokushima Bunri Univ., Kagawa, Japan

Abstract: We have expanded intrinsic optical signal imaging by incorporating the recording of polarization signals in addition to changes in overall transmissivity in acute mice hippocampal slices. Intrinsic optical imaging has been widely used to map patterns of brain activity *in vivo* in a non-invasive manner. Traditional intrinsic optical signals refer to changes in the transmissivity or reflectivity of brain tissue, which reflects volume changes in neurons and astrocyes in brain slices, and changes in blood flow and oxygenation of hemoglobin in the intact brain. Therefore, those signals report alternations in optical properties that include secondary results of neuronal activity in the tissue in addition to the changes that directly reflect neuronal activity. Polarization sensitive properties provide information about protein alignment and architecture of lipid membrane at the cellular level that are more directly affected by neuronal activity. Our polarization sensitive setup enables the evaluation of molecular alignments of protein assemblies/disassemblies and structures of membranous organelles. We detected reproducible spatial and temporal patterns of polarization change at stratum radiatum of area CA1 of hippocampus in response to stimulation of Schaffer collateral. The recovery time course of polarization signal change after nerve stimulation (40Hz, 50stim) was faster than that of transmittance light intensity change that was monitored through conventional intrinsic optical signal imaging. These polarization signals were partly blocked by the application of CNQX (10 microM) and D-APV (50 microM), and were completely abolished by TTX (1 microM). These signals are greatly enhanced by an application of the inhibitor of glutamate transporter, TBOA

(50 microM). Polarization signals are not affected by inhibitors of $GABA_A$ receptors (10 microM bicuculline) or group I metabotropic glutamate receptors (100 microM CPCCOEt). These results indicate that glutamatergic synaptic transmission is involved in the generation of polarization sensitive optical signals. Our results suggest that these polarization signals are generated via activity of postsynaptic glutamate receptors, following structural changes at the cellular and/or sub-cellular level, including transient changes in synaptic morphology, rearrangement of cytoskeletons, and remodeling of membranous structures. Our instrument development and applications expand intrinsic optical signal imaging to monitor synaptic activity in the brain in a non-invasive manner.

Title: Calsyntenin-3 mediates synapse development via neurexin/cbln complexes

Authors: *J. KO[1], H. KANG[2], J. KO[1], T. MORI[3], K. MATSUDA[4], S. JEON[1], M. YUZAKI[4], K. TABUCHI[3], J. UM[2];

Abstract: Postsynaptic calsyntenin-3 (CST-3) is a synaptogenic adhesion molecule that induces presynaptic differentiation via presynaptic neurexins. Here, we show that expression of α- or β-neurexin splice variants with an insert at splice site #4 (SS#4) restores impaired CST-3 activity in neurexin-deficient neurons. In addition, CST-3 forms *in vivo* complexes with SS#4-positive neurexins, but quantitative cell-surface binding assays confirm no direct interaction of CST-3 with neurexins. Affinity chromatography analyses identified cerebellin-4 (Cbln4) as a candidate

CST-3 binding partner. Moreover, hexameric Cbln1 directly interacts with cadherin repeats of CST-3, and triple knockdown (KD) of Cblns reduced CST-3 activity in hippocampal neurons. Strikingly, endogenous CST-3 is mainly localized at inhibitory synapses, although CST-3 KD decreased both excitatory and inhibitory synaptic transmission *in vivo*. Furthermore, CST-3 protein is primarily monomeric. Collectively, our data suggest a revised model that monomeric CST-3 is linked to SS#4-positive neurexins/Cblns to organize inhibitory synapse development.

Title: Shank modulates postsynaptic Wnt signaling to regulate synaptic development

Authors: *K. P. HARRIS, Y. AKBERGENOVA, R. W. CHO, M. S. BAAS-THOMAS, J. T. LITTLETON;
The Picower Inst. for Learning and Memory; Biology; Brain and Cognitive Scie, MIT, Cambridge, MA

Abstract: Prosap/Shank scaffolding proteins regulate the formation, organization, and plasticity of excitatory synapses. Mutations in *SHANK* family genes are implicated in autism spectrum disorder (ASD) and other neuropsychiatric conditions. However, the molecular mechanisms underlying Shank function are not fully understood, and no study to date has examined the consequences of complete loss of all Shank proteins *in vivo*. Here we characterize the single *Drosophila* Prosap/Shank family homolog. Shank is enriched at the postsynaptic membrane of glutamatergic neuromuscular junctions (NMJs) and controls multiple parameters of synapse biology in a dose-dependent manner. Both loss and overexpression of *Shank* result in a decrease in the total number of synaptic boutons at the NMJ and an increase in immature synaptic boutons (ghost boutons) that lack a postsynaptic scaffold. We find that Shank regulates synaptic maturity by modulating the internalization of the Wnt receptor Fz2 in the postsynaptic cell. Furthermore, a structure-function analysis of Shank reveals that conserved protein-protein interaction domains

have distinct roles in regulating synaptic bouton number. This study identifies Shank as a key component of synaptic Wnt signaling, thus defining a novel mechanism for how Shank contributes to synapse maturation during neuronal development.

Title: Developmental regulation of NMDA receptor subunits expression by drebrin

Authors: *N. KOGANEZAWA, T. SHIRAO;
Gunma Univ. Grad. Sch. of Med., Gunma, Japan

Abstract: Drebrin has critical functions in synaptic plasticity; therefore it is thought to be in a responsible position of learning and memory. Drebrin plays an important role in formation of stable actin complex in dendritic spines via modulating the helix pitch of actin filaments. Drebrin has two isoforms, embryonic (E) and adult (A) isoforms, and we have recently shown that drebrin A is indispensable for normal synaptic plasticity and its roles cannot be complemented by drebrin E (Kojima and Yasuda et al., 2016). In addition, we have previously shown that NMDA receptor (NMDAR) activation induces a bidirectional shift in subcellular distribution of drebrin (Sekino et al., 2006), and have also reported that drebrin A is required for the homeostatic up-regulation of the NR2A subunits within spines (Aoki et al., 2009). Therefore it is of interest to further examine the relationship between drebrin and NMDAR, especially focusing on the difference of drebrin isoforms. We used primary cultured hippocampal neurons prepared from drebrin knockout (DXKO) mice. The both isoforms were genetically deleted in the DXKO mice. We first examined the accumulation of NMDAR subunits immunocytochemically. At 14 days in vitro (DIV), there were more labeled NR1 in DXKO neurons than in wild-type neurons whereas there was no difference in NR2B level. On the other hand, at 21 DIV, there was no difference in NR1 level whereas the labeled NR2A was slightly less in DXKO neurons. These data suggest that there are more NR1 containing receptors in DXKO neurons. NR1 subunit could form homomeric receptors, but highly active NMDARs are usually di-teteromeric or tri-heteromeric receptors which contain two or three distinct subunits. Therefore, it is suggested that

DXKO neurons have less functional NMDAR. Because drebrin has two isoforms, we further investigated which isoform induces this less functionality of NMDAR. For this experiment, we used drebrin A specific knockout (DAKO) mice. Our preliminary data showed that primary cultured hippocampal neurons prepared from DAKO mice have comparable level of NMDAR subunits to wild-type neurons. In DAKO mice, drebrin E expresses continuously even in adult brain instead of drebrin A. Taken together, drebrin E may play an important role in the developmental regulation of NMDAR function.

Title: Quantitative analysis of synapse organization at nanoscale by cryo-electron tomography

Authors: **A. MARTINEZ-SANCHEZ**, Z. KOCHOVSKI, U. LAUGKS, W. BAUMEISTER, *V. LUCIC;
Mol. Structural Biol., Max Planck Inst. of Biochem., Martinsried, Germany

Abstract: Cryo-Electron Tomography allows comprehensive imaging of cellular components within their natural environment at a single nanometer scale. We have developed a novel segmentation and analysis procedure that is particularly suited for dense filamentous networks, such as the postsynaptic density of excitatory central nervous system synapses. Results obtained by examination of neocortical rodent synaptosomes showed that protein distribution is highly heterogeneous, thus differing from both homogeneous and random distributions. In order to detect specific patterns, we analyzed separately layers comprising synaptic cleft and the regions of pre- and postsynaptic terminals close to the synaptic membranes. We found that layers have distinct organization and identified statistical properties that are preserved among different synapses, but also that the degree of clustering and the presence of regions with a low protein density show high variability. All together, our results directly show that synaptic complexes have distinct organization at nanometer scale and point to a dynamic nature of this organization.

Title: The role of cortactin in AMPAR trafficking

Authors: *G. PARKINSON[1], S. E. L. CHAMBERLAIN[2], M. TURVEY[1], N. JAAFARI[1], J. G. HANLEY[1];
[1]Sch. of Biochem., [2]Sch. of Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) trafficking is a well-studied molecular mechanism that underlies the changes in synaptic strength associated with the alterations in neural circuits during learning events and pathologies. AMPAR associated proteins, including those that regulate the actin cytoskeleton, control AMPAR trafficking, and are therefore essential determinants of AMPAR synaptic expression and plasticity. Previous work in our laboratory has investigated the interplay between receptor trafficking and cytoskeletal rearrangement through the study of protein interacting with C kinase 1 (PICK1). We have demonstrated that PICK1-mediated inhibition of Arp2/3 mediated actin polymerisation is required for the internalisation of GluA2 containing AMPARs and hippocampal long term depression. Here, we investigate another regulator of actin dynamics and GluA2 binding partner, cortactin, and its role in AMPAR trafficking. In contrast to PICK1, cortactin promotes actin polymerisation via Arp2/3 complex activation. While cortactin has been proposed to function in various trafficking events, its role in AMPAR trafficking is unexplored. Therefore, it is of interest to determine how these actin interactors coordinate the cytoskeleton, receptor movement and each other to regulate synaptic plasticity. In this study, we utilise molecular, immunocytochemical and electrophysiological methods to provide evidence for a role of cortactin in maintaining basal AMPAR surface expression. Additionally, we employ biochemical techniques to further characterise the actin-cortactin-AMPAR interaction and elucidate how it is regulated during synaptic plasticity. Thus, we demonstrate that cortactin is a key regulator of basal AMPAR expression and is also implicated in activity-dependent AMPAR trafficking.

Title: Identification and characterization of proteins at the synaptic cleft

Authors: A. BURCH[1], J.-H. TAO-CHENG[2], *A. DOSEMECI[1];
[1]NINDS, Lab. Neurobio., NIH, Bethesda, MD; [2]EM Facility, NINDS, NIH, Bethesda, MD

Abstract: Identification of synaptic cleft components has been hampered by the lack of a suitable preparation enriched in synaptic junctions devoid of adjoining peripheral membranes. Prior strategies for the isolation of synaptic junctions relying on detergents for the removal of peripheral membranes also resulted in substantial loss of membranes lining the cleft. Here we describe a novel detergent-free method for the preparation of a synaptic junction fraction that uses phospholipase A2. Limited digestion of synaptic plasma membrane (SPM) fraction with phospholipase A2 results in selective removal of peripheral membranes while junctional membranes remain relatively intact as observed by electron microscopy. Comparison of this 'synaptic junction' fraction to parent SPM and to total homogenate fractions by Western immunoblotting reveals significant enrichment of certain cell adhesion molecules including neurexins, neuroligins, N-cadherin, and SALM5 suggesting their preferential localization to the synaptic cleft. Other adhesion molecules, including SynCAM, NCAM, ephrin-B, EphA4, SALM2, and SALM4 do not show significant enrichment, indicating a more widespread distribution. Immuno-electron microscopy is applied to verify localization of selected putative cleft components. As expected, neurexins and neuroligins are found to be specifically localized to the synaptic junctions at pre-and postsynaptic sites, respectively. The synaptic junction preparation is further used to characterize post-translational modifications of cleft proteins with preliminary results indicating high levels of glycosylation. Ultimately, the preparation will be used for the estimation of the stoichiometry of cleft components.

Title: Gephyrin splice variant dependent gamma aminobutyric type a receptor clustering

Authors: *Y. MERKLER[1,2], G. SCHWARZ[1,2,3];
[1]Inst. for Biochem., Univ. of Cologne, Koeln, Germany; [2]CECAD Cologne Excellence in Aging Res., Cologne, Germany; [3]Ctr. for Mol. Med. Cologne, Cologne, Germany

Abstract: At inhibitory synapses of the central nervous system, gephyrin is the main scaffolding protein to anchor and cluster gamma-aminobutyric type A receptors ($GABA_AR$) at postsynaptic densities, thereby ensuring fast and proper signal transmission. Gephyrin is a multi-domain protein with an N-terminal G-domain, a central C-domain and C-terminal E-domain. Despite its function in the CNS, gephyrin is ubiquitously expressed in all tissues due to its function in basic metabolism catalyzing the terminal steps in molybdenum cofactor biosynthesis. Tissue specificity of gephyrin is believed to rely on alternative splicing of the *GPHN* gene. A high diversity of gephyrin variants results from alternative splicing affecting the C-domain. Cassette C3 plays a role in molybdenum cofactor biosynthesis and is therefore highly expressed in liver and glia cells[1]. The C4 cluster harbors three alternatively spliced exons in rodents and an additional fourth one in humans, which are inserted at the same position between residues 288 and 289 (mouse numbering)[2]. Previous studies have reported the expression of cassettes C4a, C4c and C4d in the CNS[3]. In this study, we investigated the clustering of $GABA_AR$ by various gephyrin splice variants in cultured hippocampal neurons.
Following the depletion of endogenous gephyrin by shRNA-knock down in hippocampal neurons, we expressed different gephyrin slice variants and used confocal laser scanning microscopy to monitor the formation of gephyrin-positive clusters and determined their co-localization with either a presynaptic marker (vGAT) or α2 subunit-containing $GABA_AR$ clusters. On one hand, we found that gephyrin with either of the C4 splice cassettes is able to form postsynaptic clusters with similar properties as compared to gephyrin lacking a C4 cassette. However, presence of either of the C4 cassettes increased synaptic localization of gephyrin clusters and induced α2 subunit-containing $GABA_AR$ cluster formation. The opposite was found for gephyrin containing the C3 splice cassette, which increased size of gephyrin-positive clusters on the expense of the number of clusters localized at postsynaptic sites. Finally, using qRT-PCR we found a developmental expression of different gephyrin variants in hippocampal and cortical neurons.

Title: An automatic pipeline to optimize subcellular models of transynaptic signaling at inhibitory synapses

Authors: ***M. MIGLIORE**[1], C. A. LUPASCU[2], A. MORABITO[3], E. MERENDA[3], S. MARINELLI[3], C. MARCHETTI[3], R. MIGLIORE[1], E. CHERUBINI[3];
[2]Inst. of Biophysics, [1]Natl. Res. Council, Palermo, Italy; [3]European Brain Res. Inst., Rome, Italy

Abstract: Computational modeling of subcellular processes requires the tuning of many parameters that are difficult to determine from experimental data. We present an automatic approach to fit individual synaptic events recorded from voltage clamp experiments. Starting from any given kinetic model description (mod file) in the NEURON simulation environment, the procedure exploits user-defined constraints, dependencies, and rules for the parameters of the model to fit the time course of individual spontaneous synaptic events recorded experimentally. To test the efficiency of the pipeline, a custom Python code was implemented as a standalone task in the Collaboratory Portal of the Human Brain Project. The task is publicly available. Here we propose an use case scenario for testing the pipeline with a model implementing relatively simple gephyrin and gephyrin-dependent pathways, as a suitable example of a kinetic model of synaptic transmission. We used various sets of experimental data on GABAergic inhibitory synapses, recorded in hippocampal pyramidal CA1 neurons. The results suggest how and to what extent gephyrin-dependent subcellular pathways can shape synaptic events at the level of single cell, neuron, animal, or experiment. The correlation between the optimized model' parameters suggests how the transsynaptic signal can be strongly dependent not only on the postsynaptic gephyrin level, but also on the turnover rate of gephyrin-dependent presynaptic proteins, and on the extrasynaptic diffusion of neurotransmitter molecules. Small changes of these mechanisms can have large effects on the synaptic current, and these can be cell- or event-specific, with individual events that can be correlated with functional or pathological aspects at different levels.

Title: Consequences of mGluR5-dependent regulation of the spinophilin/sapap3 interaction.

Authors: ***C. W. MORRIS**[1], M. C. EDLER[2], A. J. BAUCUM, II[2,3];
[1]Chem. and Psychology, [2]Biol., Indiana Univ. Purdue Univ. at Indianapolis, Indianapolis, IN;
[3]Stark Neurosciences Res. Inst., Indianapolis, IN

Abstract: Signaling perturbations in the basal ganglia result in a range of neuronal disorders. Specific molecular footprints that reside within the striatum—the major input nuclei of the basal ganglia—characterize many of these, however, understanding the molecular mechanisms regulating disease pathology remains of great interest. Moreover, indecorous inputs from the forebrain and midbrain result in altered synaptic protein phosphorylation and subsequent perturbations in synaptic protein complex formation and dendritic spine pathologies. Spinophilin, a protein phosphatase 1 targeting protein, functions to regulate the density of dendritic spines—which is attenuated in Parkinson's Disease (PD). Of these synaptic complexes, preliminary data demonstrates spinophilin interacts with SAP90/PSD95-associtated protein 3 (SAPAP3), and that this complex is significantly reduced in 6-hydroxy dopamine lesioned mice, a common model of PD. In itself, SAPAP3 has been associated with its ability to suppress obsessive-compulsive disorder (OCD)-like phenotypes in a metabotropic glutamate receptor 5 (mGluR5) dependent manner. Here, proteomic and pharmacological studies are performed to investigate the molecular events regulating the association of these proteins. Biochemically, we found that SAPAP3 associates with the coiled-coil region on spinophilin. Moreover, our preliminary data suggest that mGluR5 overexpression significantly increases the association of spinophilin and SAPAP3. Further studies will both delineate the mechanisms by which mGluR5 modulates this association as well as characterize the downstream functional and physiological consequences of modulating

this interaction. Data regarding this novel protein interaction may provide implications in underlying disease pathology, such as PD and OCD.

Abstract: Inhibitory synaptic abnormalities result in multiple neurodevelopmental disorders that emerge in childhood, including autism spectrum disorders (ASD), epilepsy, neonatal hyperekplexia, and intellectual disability (ID). Like their excitatory counterparts, inhibitory synaptic properties are dynamic- their density, size, and receptor content is plastic during development and in response to activity. However compared to the excitatory synapse, the molecular components of the inhibitory synapse are not well defined, since this synaptic structure is not easily purified. This has impeded the systematic identification and analysis of the mechanisms underlying inhibitory synaptic function. Here we present a new *in vivo* chemico-genetic approach to isolate proteins of the inhibitory synapse. We find many proteins previously not known to target inhibitory synapses and we characterize these by biochemical, immunostaining, and electrophysiological approaches in neurons. One of the novel proteins, InSyn1, interacts with gephyrin and is localized to the inhibitory synapse in hippocampal neurons. Targeting of *InSyn1* in single neurons with the CRISPR/Cas9 system, results in a reduction in mIPSC frequency, suggesting InSyn1 is critical for functional inhibitory synapses. These data validate the feasibility of a novel proteomic approach to target synaptic structures and reveal new proteins important for the molecular machinery of the inhibitory synapse.

Title: Screening and functional analysis of neuroligin 1 interacting proteins

Authors: *R. DANG[1], A. LIU[1], W. XIE[1], Z. ZHOU[1], Z. JIA[2];

Abstract: Neuroligin (NLG)1 is a postsynaptic cell adhesion protein that specifically localized on excitatory synapse. It can bind with both presynaptic Neurexins and postsynaptic PSD95, then functions as pre- and post-synaptic linkers and maintains the normal functions of the synapse. NLG1 is a type I membrane protein with a longer extracellular domain and a shorter intracellular domain, previous studies showed that the shorter intracellular domain can bind with various protein and has important functions. Conventional yeast two-hybrid system used C terminus of NLG1 as the bait. To screen for NLG1 binding proteins in its native condition, we performed DUALmembrane yeast two-hybrid system that can identify prey proteins using membrane-localized full-length NLG1. We found a number of novel NLG1 interacting proteins including Golgi apparatus membrane proteins, endoplasmic reticulum membrane proteins and transport vesicle proteins.

Title: Ketamine-induced antidepressant effects and psychosis: A role for postsynaptic supercomplexes revealed using mouse genetic models and synaptome mapping.

Authors: *S. LEMPRIERE[1], J. NITHIANANTHARAJAH[2], F. ZHU[3], Z. QIU[1], N. H. KOMIYAMA[1], S. G. N. GRANT[1];
[1]Ctr. for Clin. Brain Sci., Univ. of Edinburgh, Edinburgh, United Kingdom; [2]The Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia; [3]Dept. of Neurodegenerative Dis., Univ. Col. London, London, United Kingdom

Abstract: Ketamine is a widely-used anaesthetic and analgesic. At sub anaesthetic doses it causes a transient psychosis clinically indistinguishable from schizophrenia (Moore et al. 2011), this is followed by a long-lasting antidepressant response (Berman et al. 2000). Although it is known that ketamine is a non-competitive NMDA receptor antagonist (MacDonald et al. 1987), it is unclear how this receptor would mediate these different behavioural effects.
The NMDA receptor is assembled into supercomplexes with PSD95, Arc/Arg3.1 and other proteins via the critical role of the GluN2B cytoplasmic tail (Frank et al. 2016). Ketamine induces long-lasting (72hr) upregulation of PSD95 and Arc (Li et al. 2010), suggesting these molecules may be relevant to the dose- and time-dependent effects of ketamine.
To investigate the mechanisms used by the NMDA receptor to couple to PSD95 and Arc, we first examined ketamine-induced hyperlocomotion in mice carrying mutations in the cytoplasmic domains of GluN2A and GluN2B (Ryan et al. 2013) and knockouts of PSD95. Ketamine-induced hyperlocomotion was absent in mice lacking PSD95 and in mice with the cytoplasmic tail of the GluN2B NMDA receptor subtype replaced with that of the GluN2A receptor subtype.
Next we used a line of mice in which endogenous Arc was modified to express a fusion protein with Venus (Arc-Venus). These mice exhibit activity-dependent punctate postsynaptic labelling, which we quantify using high-throughput spinning-disk confocal microscopy in brain regions of adult mice. Since literature suggests that 10mg/kg ketamine induces a long-lasting (>24hr) antidepressant response (Ma et al. 2013), and 100mg/kg does not (Chatterjee et al. 2011), we treated Arc-Venus mice with these two doses. At 1hr the response of Arc to ketamine was the same for both doses: the density of Arc-Venus puncta was increased in dendritic sub-regions of hippocampus and in cortex. However, at 6hr post-ketamine the 100mg/kg dose produced a decrease in puncta number, while the earlier (1hr) increase was maintained in the 10mg/kg group.
These findings provide evidence for the involvement of the supercomplex formed by NMDA receptors, PSD95 and other proteins in the action of ketamine and the utility of genetically modified mice in dissecting signalling pathways in pharmacological studies.

Title: Mechanisms underlying spinophilin-dependent regulation of the association of PP1 with the NMDA receptor

Authors: *A. BEIRAGHI SALEK[1], J. MCBRIDE[2], M. C. EDLER[1], A. J. BAUCUM, II[1,3]; [1]Biol., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Northwestern Univ., Chicago, IL; [3]Stark Neurosciences Res. Inst., Indianapolis, IN

Abstract: Normal brain function requires proper organization of downstream signaling pathways. This organization can be modulated by phosphorylation of synaptic proteins. Protein phosphorylation is a balance of phosphatases, such as protein phosphatase 1 (PP1), and kinases such as protein kinase A (PKA) and cyclin dependent kinase 5 (CDK5). This proper targeting of synaptic proteins is critical for their normal function and is perturbed in various disease states. Spinophilin is critical in targeting PP1 to various substrates, making it important in regulating the phosphorylation state and thus the function of synaptic proteins such as the NMDA-type glutamate receptors. NMDARs are abundant postsynaptic proteins that are critical for normal synaptic communication. It has been reported that NMDAR phosphorylation modulates channel function. Here we aim to understand the role that spinophilin plays in targeting PP1 to the NMDAR as well as mechanisms by which the spinophilin/NMDAR interaction are altered. We have found that the presence of spinophilin actually decreases the amount of PP1 bound to the GluN2B subunit of the NMDAR in a heterologous cell system. This effect required spinophilin binding to PP1 as it was not observed when a PP1 binding-deficient spinophilin mutant (F451A)

was expressed. Furthermore activation of endogenous PKA and/or overexpression of PKA catalytic subunit robustly increased the association between spinophilin and the GluN2B subunit of the NMDAR. Conversely, these associations were decreased when CDK5, along with its activator, p35, was overexpressed. Our future studies will evaluate the role of spinophilin in regulating the phosphorylation state of the NMDAR. Taken together, our data demonstrate that spinophilin can associate with the NMDAR in HEK293 cells and that protein kinases can biphasically modulate this association.

Title: Chemogenetic control of hilar mossy cell excitability regulates emotional behaviors

Authors: *K.-Y. WANG[1], C.-C. LIEN[1,2,3];
[1]Inst. of Neurosci., [2]Inst. of Brain Sci., [3]Brain Res. Ctr., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Hilar mossy cells (MCs), the glutamatergic neurons located in the hilus of the hippocampal dentate gyrus (DG), have been known to play an important role in network function and complex information processing such as pattern separation. However, their role in emotional behavior remains largely unexplored. To address this question, we bidirectionally manipulated the activity of MCs in the dorsal DG using a chemogenetic approach. Selective expression of designer receptors exclusively activated by designer drugs (DREADDs) was achieved by injecting a virus encoding Cre-dependent DREADDs into a mossy/CA3-Cre driver, a mouse line specifically expressing Cre recombinase in the hilar MCs and CA3 cells. By specifically expressing inhibitory DREADDs (i.e., hM4Di receptor) on the membrane of the MCs in the dorsal DG, we found that decreasing the activity of MCs increased the mouse anxiety level.

Conversely, elevating the activity of MCs by expressing excitatory DREADDs (i.e., hM3Dq receptor) decreased their anxiety level. In addition, we tested the effect of manipulating the MC activity during and after contextual fear conditioning. We found that decreasing the MC activity induced the fear-like behavior in the retrieval phase, although mice performed normally during learning phase. In contrast, elevating the MC activity reduced the freezing level in the retrieval phase. In summary, switching the MC activity of MCs by using chemogenetic manipulations, we demonstrated that MCs in dorsal DG would participate in
controlling the anxiety- and fear-like behaviors.

Title: Acute and chronic noradrenergic effects on cortical excitability in healthy humans

Authors: *M.-F. KUO[1], H.-I. KUO[1,2], W. PAULUS[2], G. BATSIKADZE[2], A. JAMIR[2], M. A. NITSCHE[1,3];
[1]Psychology and Neurosci., Leibniz Res. Ctr. For Working Envrn. An, Dortmund, Germany; [2]Clin. Neurophysiol., Georg-August-University Göttingen, Göttingen, Germany; [3]Neurol., Univ. Med. Hosp. Bergmannsheil Bochum, Bochum, Germany

Abstract: Noradrenaline has been proposed as a critical neuromodulator in the central nervous system, which in turn is thought to influence functional recovery from neuropsychiatric diseases. Previous transcranial magnetic stimulation (TMS) studies have shown that acute selective noradrenaline reuptake inhibitor (NRI) application enhanced cortical excitability in humans. However, it usually takes prolonged treatment for selective NRI to get the therapeutic effects in clinical populations. The purpose of the study is to investigate the acute and chronic effects of selective NRI reboxetine on cortical excitability by applying different TMS protocols in healthy humans with a double-blinded, placebo-controlled, randomized crossover design. 16 subjects were assessed with different TMS measurements: motor thresholds (MTs), input-output curve (I-O curve), short-latency intracortical inhibition (SICI) and facilitation (ICF), I-wave facilitation,

and short-latency afferent inhibition (SAI) before and after placebo or reboxetine (8mg) administration. Afterwards, the same subjects took reboxetine (8mg/ day) consecutively for 21 days. During this period, TMS measurements were assessed before and after drug intake (placebo or reboxetine) on the day of experimental sessions. Both acute and chronic administration of reboxetine increased cortical excitability with regard to the enhancement of I-O curve, ICF, and I-wave facilitation, as well as decreased SICI and SAI compared to placebo condition. The results demonstrate that reboxetine enhances cortical excitability which might be a mechanism underlying the beneficial effect of reboxetine in neuropsychiatric diseases, as chronic reboxetine showed much more stable enhancement of ICF and I-wave facilitation. The finding might partially explain the prolonged treatment impact of selective NRI in clinical application.

Title: Neurosteroid induction of NMDA and AMPA receptor trafficking

Authors: ***V. KUMARESAN**[1], K. SUGUNAN[1], R. M. BADOLATO[1], R. SINGH[1], J. LUEBKE[2], J. M. ADAMS[1], D. H. FARB[1];

Abstract: Neurosteroids modulate both excitatory and inhibitory neurotransmission in the CNS. Recently, we reported that physiological concentrations of pregnenolone sulfate (PregS) (low picomolar) increase intracellular Ca^{2+} and CREB phosphorylation via a synaptic but not extrasynaptic NMDA receptor-dependent mechanism. We have previously reported that micromolar PregS stimulates the trafficking of GluN1 subunits to the cell surface of *Xenopus laevis* oocytes and cultured rat cortical neurons (7 DIV) as determined by electrophysiology and surface labeling respectively. Here we report that a 10^6 - fold lower concentration of PregS (50

pM for 10 minutes) increases surface GluN2A-containing NMDA receptors but surprisingly, with no change in surface GluN1 as determined by immunofluorescence. Increase in surface GluN2A-containing NMDA receptors is casein kinase 2 (CK2), L-Type voltage gated channel and GluN2B-containing NMDA receptor dependent mechanism. PregS does not alter the association of GluN2A with PSD 95, suggesting that the increase in GluN2A-containing NMDA receptors is initially extrasynaptic. PregS increases AMPA receptor mediated sEPSCs by ~2-fold without altering sEPSC amplitude or passive membrane properties. PregS also induces AMPA receptor trafficking, increasing surface and synaptic GluA1-containing AMPA receptors. Physiological concentrations of PregS therefore modulates critical aspects of synaptic plasticity by either increasing the frequency of neurotransmitter release or activating silent synapses. This research is a summary of the doctoral dissertation for Kavitha Sugunan Dissertation Research is presented

Title: Chronic toluene exposure alters medial prefrontal cortex synaptic transmission of adolescent rats

Authors: *M. I. TORRES-FLORES, S. L. CRUZ, E. J. GALVÁN;
CINVESTAV, Ciudad DE Mexico, Mexico

Abstract: Toluene is an organic solvent commonly misused by adolescents for its psychoactive effects. It has been reported that chronic toluene exposure produces learning and memory deficits, particularly in working memory. Toluene exerts its actions in the central nervous system by blocking NMDA receptors and increasing $GABA_A$-mediated responses. In addition, toluene alters the firing rate and the spike threshold of pyramidal neurons of medial prefrontal cortex (mPFC). Toluene also increases dopamine (DA) release, which modulates synaptic activity in the

mPFC. However, it is not known if toluene modifies synaptic transmission or the modulatory actions of DA in animals chronically exposed to this solvent. Male Wistar rats (22 days of age) were exposed to toluene (8000 ppm) 30 min, twice a day, for 10 days. Immediately after the last exposure, animals were euthanized to obtain coronal brain slices containing the mPFC. Extracellular field recordings were performed in mPFC layer V neurons. Our results show that chronic toluene exposure induces: a) increased synaptic responsiveness, evaluated by mean of input-output curves (I-O curves; n=9); b) increased excitatory postsynaptic potentials (fEPSP) in response to smaller presynaptic volleys (n=9), and c) decreased interneuron-mediated recurrent inhibition assessed by a paired-pulse protocol (n=9). In another group of experiments, stimulation with exogenous DA (100 µM, 10 min) induced a biphasic effect on the mPFC fEPSP; an early depression of synaptic responses followed by a long-lasting enhancement of the synaptic responses (n=9). In contrast, animals exposed to toluene exhibited a sustained fEPSP depression (n=9). In conclusion, our results show that chronic toluene inhalation induces hyperexcitability and reduces the GABAergic inhibition in the mPFC circuit. In addition, toluene alters mPFC dopaminergic modulation. These effects might underlie the cognitive dysfunctions observed in animals chronically treated with toluene.

Title: Effect of Carbenoxolone on gap junction in the hippocampus of rats with epileptiform activity induced by 4-aminopyridine.

Authors: *C. VENTURA[1], R. BELTRÁN-RAMÍREZ[2], S. D. CONTRERAS-DELATORRE[3], G. ZARATE-RODRÍGUEZ[3], B. VILLANUEVA-AVALOS[3], N. S. MUÑOZ-FILIPPETTI[3]; [1]Ctr. Abstract: Epilepsy is a neuronal disorder that affects people worldwide which is characterized by the continued discharge and abnormally synchronic activity observed in a group of neurons. We have examined the influence of the gap junction and the gap junctional blocker, carbenoxolone (CBX), on epileptiform activity induced by 4-aminopyridine (4-AP) in the rat entorhinal cortex (EC) and the CA1 hippocampal region. A cannula and deep electrodes were

implanted into the brain to administer drugs and to monitor electrical activity. The deep electrodes will be implanted with a new automated system implantation of depth electrodes, to avoid manipulation of the people on the rat and avoid the generation of noise during the EEG record. This system implantation of depth electrodes will have a vertical movement to lead to different levels of depth this will give us the option to register several brain areas in the hippocampus. The injection of 4-AP (10 nmol) produced epileptiform discharge trains of high amplitude and frequency associated with seizure behavior rated between 0 and 5 in the Racine scale. On the other hand are evidence for the involvement of gap junctions (electrical synapses) in epilepsy, however, there are not studies related to the modulation on epileptiform activity by electrical synapses through an automated system implantation of depth electrodes. In this work we investigated the effect of carbenoxolone on epileptiform activity in the hippocampus of rats with seizures induced by 4-aminopyridine in order to determine the possible modulation of epileptiform activity by electrical synapses with an automated system implantation of depth electrodes. For these purpose intracranial EEG recordings from hippocampus were made in Wistar rats with seizures induced by EC 4-aminopyridine administration (10nmol), to determine the amplitude of the epileptiform activity, the duration of each seizure of the epileptiform activity, the frequency (Hz) of the seizure before and during carbenoxolone administration (dosage 50nmols) into the entorhinal cortex. During carbenoxolone injection a decrease in the amplitude of epileptiform activity in anterior hippocampus (80%) and posterior hippocampus (85%) was observed, as well in the duration for each seizure (85%, anterior hippocampus; 89%, posterior hippocampus), while the average of the seizure frequency decreased (89%, anterior hippocampus; 90%, posterior hippocampus) compared to data obtained before carbenoxolone administration. These findings suggest a possible modulation of epileptiform activity by electrical synapses, but are necessary to corroborate the present data with more additional studies.

Title: Restraint stress differentially alters Beta1- and Beta2-Adrenergic Receptor modulation of glutamatergic transmission in the Ventral Bed Nucleus of the Stria Terminalis

Authors: *Y. SILBERMAN;
Neural and Behavioral Sci., Penn State Col. of Med., Hershey, PA

Abstract: The bed nucleus of the stria terminalis (BNST) plays a critical role in physiologic responses to stress. Stress enhances norepinephrine signaling to the BNST, but the mechanism by which stress and norepinephrine modulate BNST glutamatergic neurotransmission is not fully understood. Previous work has established that stimulation of beta1-Adrenergic Receptors (β1-ARs) enhances glutamatergic transmission in the dorsal lateral subregion of the BNST (dBNST) via modulation of local corticotropin releasing factor (CRF) signaling. Few studies have, however, examined potential mechanisms by which β-AR activation may modulate glutamatergic transmission in the ventral lateral subregion of the BNST (vBNST). This study therefore examined mechanisms by which β1- and β2-ARs modulate spontaneous excitatory postsynaptic currents (sEPSCs) in the vBNST of adult male C57Bl/6J mice utilizing whole-cell patch clamp electrophysiology in acutely prepared brain slices. Mice were either stress naïve or exposed to a single 1 hour restraint stress followed by 30 min in their home cage prior to study. In stress-naïve mice, bath application of the β-AR agonist Isoproterenol (3μM, 10 min) significantly enhanced vBNST sEPSC frequency (88.0 ± 14.4% increase from baseline, $p<0.001$) with no significant changes to sEPSC amplitude (6.0 ± 7.0 % decrease from baseline, $p>0.05$). Similar to previous findings in the dBNST, Isoproterenol enhancement of vBNST sEPSC frequency could be blocked by pretreatment with the CRFR1 antagonist NBI27914 (7.0 ±13.1% increase from baseline, $p>0.05$). In contrast to previous work in the dBNST, where restraint stress functionally occludes further effects of Isoproterenol, restraint stress did not alter Isoproterenol enhancement of vBNST sEPSC frequency (59.6± 20.4% increase from baseline, $p<0.05$; Isoproterenol effects in stress vs. naïve mice, $p>0.05$). Bath application of the β2-AR agonist, Clenbuterol (10μM, 10 min), did not alter vBNST sEPSC frequency in naïve mice (3.9±8.3% increase from baseline, $p>0.05$) but significantly inhibited sEPSC amplitude (20.8 ±4.9% decrease from baseline, $p<0.01$). In stress-exposed mice, Clenbuterol surprisingly enhanced sEPSC frequency (42.4±17.4% increase from baseline, $p<0.05$) even though basal sEPSC frequency is significantly higher in stress mice compared to naïve mice (7.5±1.3 Hz vs. 3.6±0.6 Hz, $p<0.05$). These results suggest dissociable pre- and post-synaptic effects of β1- and β2-AR stimulation on vBNST excitatory synaptic transmission in naïve mice and novel emergence of β2-AR mediated enhancement of presynaptic glutamate release in the vBNST of stress-exposed mice.

Title: Peptidergic modulation of spontaneous and evoked synaptic activity in ca1 pyramidal cells of rat hippocampal slices.

Authors: *V. G. SKREBITSKY[1], R. KONDRATENKO[2], I. POVAROV[2], S. KOLBAEV[2]; [1]Res. Ctr. of Neurology., Moskva, Russian Federation; [2]Res. Ctr. of Neurol., Moskva, Russian Federation

Abstract: The aim of this study was to investigate whether novel prolin- containing dipeptide Noopept (NP) influences synaptic transmission in central neurons. NP was synthesized as peptide analog of piracetam which is known as one of the first generation nootropics racetam group (Giurgea, 1972; Winblad, 2005). NP is similar to piracetam in its chemical structure and memory- enhancing ability but displays the effect in much lower concentration. In addition to nootropic activity NP also displays an anxiolitic effect (Ostrovskaya et al, 2006). We examined the effect of NP on spontaneous and evoked IPSCs in CA1 pyramidal cells in rat hippocampal slices using patch-clamp technique in whole- cell configuration. It was found that NP(1μM) increased spike- dependant release of GABA from terminals of inhibitory interneurons on CA1 pyramidal cells. The effect manifested itself in the increase of amplitude and frequency of spontaneous TTX-sensitive sIPSCs whereas TTX- non sensitive mIPSCs remained unchanged. We also found that IPSCs evoked by Shaffer collaterals stimulation, either short -latency (feed-forward), or long- latency (feed-back) ones increased after NP application. We hypothesized that NP directly excited inhibitory interneurons which terminate on CA1 pyramidal cells. To check this hypothesis we performed current clamp egistration of several (n =5) interneurons resigning in stratum radiatum (SR). In all cases NP induced a 2-3 fold increase of spiking rate that was accompanied by depolarization of cell membrane to 3-5 mV. In the experiments with direct measurement of neuronal [Ca2+]i in hippocampal organotypic slices we revealed that NP selectively increased [Ca2+]i activity in SR interneurons without significantly changing it in stratum pyramidal neurons. Taken together these date clarify that the target of NP action is inhibitory interneurons located in SR of hippocampus.

Title: L-proline, a metabolite linked to neuropsychiatric disorders and associated with the 22q11.2 deletion syndrome, specifically disrupts GABA-ergic transmission in the mPFC.

Authors: *G. W. CRABTREE[1], J. A. GOGOS[2];
[1]Physiol. and Cell. Biophysics, [2]Dept. of Neurosci., Columbia Univ. Med. Ctr., New York, NY

Abstract: Accumulation of L-proline within the CNS,has been repeatedly correlated with predisposition to psychotic disorders. Proline dehydrogenase (PRODH), which degrades L-proline, resides within the 22q11.2 deletion a strong genetic risk factor for schizophrenia further suggesting L-proline may be neuroactive and directly contribute significantly to neuropsychiatric symptomology. Despite the strength of these clinical data, targets affected by disease-relevant concentrations of L-proline have not been convincingly described. Using an mouse model with a severely hypomorphic *Prodh* allele and employing a range of biochemical and electrophysiological assays in acute brain slices, cultured neurons, and heterologous expression systems we assessed L-proline impact upon neuronal function. At layer II/III mPFC pyramidal neurons we found that both basic synaptic transmission and very short-term synaptic plasticity of both glutamatergic and GABA-ergic transmission were unaltered. Similarly, medium to high frequency evoked glutamatergic transmission was unaltered in *Prodh*-mutant mice. We found, however, that mice with elevated CNS L-proline showed specific disruptions of high-frequency GABA-ergic transmission, consistent with deficits in sustained GABA release. Here we show that L-proline is GABA-mimetic and can act at multiple GABA-ergic targets *in vitro*. L-proline can activate both GABA-A and GABA-B receptors although this is only observed at L-proline concentrations far above CNS disease-relevant levels. At disease-relevant concentrations, L-proline GABA-mimesis was limited to competitive blockade of glutamate decarboxylase (GAD) leading to reductions in GABA production. The disruptions of high-frequency GABA-ergic transmission we observed in *Prodh*-mutant mice could be mimicked in WT mice with acute pharmacological blockade of GAD. Further, sustained GABA release deficits observed in *Prodh*-mutant mice could be reversed by enhancing net GABA production through pharmacological blockade of GABA transaminase. Together these findings suggest a novel neural mechanism in neuropsychiatric disorders whereby disease-linked mutations lead to accumulation of neuroactive metabolites that disrupt precise molecular targets leading to circumscribed, well-

defined synaptic dysfunction. (This work was supported by NIH grants R21MH10069 and R01MH096274).

Title: Electrophysiological signatures of modulation of GABA-A α5 receptor activity by S 44819 in human cortex

Authors: *G. DARMANI[1], C. ZIPSER[1], G. M. BÖHMER[2], F. MÜLLER-MAHLHAUS[1], P. BELARDINELLI[1], M. SCHWAB[3], K. DESCHET[4], U. ZIEMANN[1];

Tübingen, Tuebingen, Germany; [3]Dept. of Pharm. and Biochem., Univ. of Tübingen, and Dr. Margarete Fischer-Bosch Inst. of Clin. Pharmacol., Stuttgart, Germany; [4]Inst. de Recherches Internationales Servier, Suresnes, France

Abstract: Combining transcranial magnetic stimulation (TMS) and electromyography (EMG) or electroencephalography (EEG) allows to record in real time changes of human cortex excitability. Active motor threshold (AMT) and stimulus intensity to evoke a motor evoked potential of 0.5mV (SI0.5mV) are two single-pulse TMS-EMG measures representing corticospinal excitability. Also, recent findings provided evidence that the amplitude of two negative EEG deflections elicited by a single TMS pulse over primary motor cortex (M1), namely N45 and N100, reflects GABA-A and GABA-B receptor activation, respectively (Premoli et al., 2014). These measures provide a novel way to characterize drug effects on the GABAergic systems in the human cortex non-invasively. *In vitro*, S 44819 is a potent and competitive selective antagonist of GABA-A receptors that interacts selectively at the GABA-binding site of α5 subunit. The GABA-A α5 receptor is located extrasynaptically and has been shown to be involved in tonic inhibition controlling pyramidal neuron excitability. Its overactivation contributes to increased tonic inhibition in the peri-infarct zone after ischemic stroke. Investigating to what extent S 44819 is able to decrease tonic inhibition *in vivo* in humans is of much interest, as this may lead to a clinical trial to test its efficacy to enhance functional recovery after stroke. Here, we investigated the pharmacological effects of S 44819 on cortical

and corticospinal excitability measured by TMS-EMG and TMS-EEG in 18 healthy male volunteers. A randomized, placebo-controlled, double-blind crossover phase I clinical study was conducted, testing a single oral dose of 50mg and 100mg of S 44819. At the dose of 100mg S 44819 significantly decreased AMT and SI0.5mV, i.e. increased corticospinal excitability in response to TMS. In addition, the 100mg dose of S 44819 induced a significant decrease in the N45 amplitude, an effect opposite to benzodiazepines, while the N100 amplitude remained unaffected. These findings suggest that the GABA-A α5 receptor plays a role in generation of the N45 potential. Results also suggest that S 44819 increases neuronal excitability by reducing GABA-A receptor mediated inhibition and thus might be a promising candidate drug for improving functional recovery in post-stroke patients.

Title: Effects of olanzapine and haloperidol on mtorc1 signaling, dendritic outgrowth, and synaptic proteins in rat primary hippocampal neuron under toxic conditions

Authors: M. SEO[1], H. CHO[1], C. LEE[1], Y. KIM[1,2,3], J. LEE[1,2,3,4], *S. PARK[1,3];

Abstract: Purpose: The aim of the present study was to determine whether alterations in mTORC1 signaling are observable following treatment with olanzapine and haloperidol under toxic conditions. Additionally, we investigated whether these drugs affect dendritic outgrowth and synaptic proteins expression through mTORC1 signaling pathway.

Methods: Using Western blotting, we measured changes in the mTORC1-mediated proteins and synaptic proteins under toxic conditions induced by B27 deprivation, which causes hippocampal cell death. Dendritic outgrowth was determined by neurite assay.
Results: Olanzapine significantly increased phosphorylation levels of mTORC1, its downstream effectors (4E-BP-1, p70S6K, eIF4B, and S6), and upstream effectors (Akt and ERK), whereas haloperidol did not affect the levels of these proteins. Increased phosphor-mTOR induced by olanzapine was significantly blocked in the presence of specific PI3K, MEK or mTOR inhibitors. Olanzapine also increased dendritic outgrowth and synaptic proteins levels (BDNF, PSD-95, and synaptophysin); all of these effects were blocked by rapamycin. However, haloperidol had no effect in these regards.
Conclusions: In current study, we demonstrated that olanzapine activates the mTORC1 signaling pathway and increases dendritic outgrowth and synaptic proteins through mTORC1 signaling activation in rat primary hippocampal neurons.

Title: Electrophysiological characterization of S 47445, a novel positive allosteric modulator of AMPA type glutamate receptors

Authors: *L. DANOBER[1], T. SCHAER[2], K. KAMBARAT[2], F. MARGER[2], S. BRETIN[3], D. BERTRAND[2];
[1]Inst. De Recherches SERVIER, PIT-NPS, Croissy sur Seine, France; [2]HiQScreen Sarl, Geneva, Switzerland; [3]Neuropsychiatry Innovation Pole, Inst. de Recherches Internationales Servier, Suresnes Cedex, France

Abstract: Positive allosteric modulators (PAM-AMPAs) have been described and developed for the treatment of schizophrenia, depression or Alzheimer's disease (Ward et al., 2010; Pirotte et al., 2013). We previously report the in vitro characterization of the compound S 47445, a novel PAM-AMPA on different classes of ionotropic glutamate receptors (Danober et al., SFN 2014). Here, the modulatory function of S 47445 was conducted at recombinant human AMPA receptors using GluA1, GluA2 and GluA4 flip and flop variants expressed in *Xenopus* oocytes. GluA2 were expressed as heteromeric complexes with GluA1 and GluA4 subunits. Finally, the

identification of the allosteric binding site of the compound was assessed using an AMPA-kainate chimera approach encompassing segments from the AMPA GluA1flop subtype and the kainate receptors. S 47445 dose-dependently potentiated currents evoked by a saturated concentration of glutamate (100 μM) in oocytes expressing homomeric GluA1 and GluA4 flip and flop splice variants. EC_{50} values did not differ among the different GluA recombinants. However, some difference was observed for GluA4 subtypes as GluA4o presented a lower EC_{50} value compared to GluA4i subtypes ($p \leq 0.001$, unpaired T-test). Moreover, the amount of potentiation evoked by S 47445 (100 μM) was consistently much greater for flop variants (around 9 fold more) compared to flip variants at GluA1 AMPA receptors. Analysis of the glutamate evoked responses recorded in *Xenopus* oocytes or in HEK293 cells using patch clamp revealed that S 47445 reduced receptor desensitization. For the AMPA-kainate chimera approach, the selectivity of S 47445 towards AMPA receptors was first confirmed on human receptors, since S 47445 up to 100 μM did not modified glutamate-evoked current on human GluK2 kainate receptors. The potentiation of glutamate-evoked current also persisted after S 47445 application on AMPA/Kainate chimera GluA1(K2NTD), with exchange of amino-acid segment at the N-Terminal portion and presented an EC_{50} similar to those obtained on GluA1flop subtype (4.2 μM [1.3; 13.6], n=5). In contrast, the effect of S 47445 was lost in AMPA/Kainate chimerae GluA1(K2S1), with exchange of the amino-acid segment corresponding to the putative binding site of AMPA positive modulators. Altogether these data illustrate that S 47445 acts as a powerful allosteric modulator at all human AMPA subunits tested with greater amount of potentiation on flop variants. S 47445 was shown to slow AMPA receptor desensitization and bind to the same binding pocket located on the ligand-binding domain (LBD) near the first transmembrane domain as previously described for other PAM-AMPAs (Lynch, 2006).

Title: Effects of the antipsychotic drug loxapine on synaptic transmission in the superficial lamina of the dorsal horn

Authors: *K. EVELY[1,2], S. HAJ-DAHMANE[3], A. BHATTACHARJEE[4];
[1]Univ. At Buffalo - Downtown Campus, Buffalo, NY; [2]Program for Neurosci., [3]Res. Inst. on Addictions, [4]Pharmacol. and Toxicology, Univ. at Buffalo, Buffalo, NY

Abstract: Loxapine is an antipsychotic drug that is clinically approved for the treatment of schizophrenia and is patented for its potential to treat pain. It is also a known opener of the sodium-activated potassium channel Slack (Kcnt1) and has been shown to ameliorate neuropathic pain behavior in Slack-dependent manner (Lu et al., 2015). Slack channels are expressed in the dorsal root ganglion and spinal cord dorsal horn that transmit pain information from the periphery to the brain. The underlying mechanism and level of the pain pathway responsible for the analgesic effects of loxapine remain unknown. Here, we investigate the effect of loxapine on glutamatergic synaptic transmission in the superficial, pain processing lamina of the dorsal horn. Transverse slices of the lumbar spinal cord were prepared and whole cell patch clamp recordings were performed. Intrinsic firing properties, as well as, spontaneous and evoked excitatory postsynaptic currents (EPSCs) were measured. Neurons were classified as inhibitory or excitatory based on previously described firing phenotypes (Punnakkal et al., 2014; Smith et al., 2015). Regardless of classification, bath application of loxapine (50μM) decreased the frequency but not the amplitude of spontaneous EPSCs, indicating a decrease in the network activity of lamina II. To investigate primary afferent synapses, we measured the amplitude EPSCs evoked by electrical stimulation of the dorsal root entry zone. We found that bath application of loxapine increased the amplitude of EPSCs in neurons classified as inhibitory but not excitatory. This suggests that at primary afferent synapses, loxapine acts to strengthen input to inhibitory interneurons within lamina I/II. Ongoing studies will investigate the underlying mechanism and incorporate Slack knockout mice to determine whether channel activation contributes to the effects of loxapine reported here.

Title: Dystrophins in the cerebellum: a first look at the role of Dp71 role in Purkinje neurons and Bergmann glia.

Authors: *R. HELLERINGER, O. JOLY, M. BELMAADI-CHERKAOUI, H. DANIEL, C. VAILLEND, M. GALANTE;
Neuropsi, Paris-South Univ., Orsay, France

Abstract: In Duchenne muscular dystrophy (DMD), the genetic loss of dystrophin leads to fatal muscle weakness. In addition to muscle, dystrophins are largely expressed in the nervous system (yielding full-length dystrophin and its truncated isoforms) and their loss may explain the cognitive disturbances reported in DMD patients consisting in low IQ mental retardation and verbal processing impairment.
Dp71, a short isoform of dystrophin, is the most prominent dystrophin in the adult brain. The brain mechanisms that involve Dp71, as well as the functional outcome of Dp71 deficiency, are still poorly understood and appear to be quite complex, as Dp71 likely endorses multiple functions in brain due to its expression in both neuronal and glial cells. In fact a fraction of Dp71 is expressed at glutamatergic synapses and normally interacts with adapter proteins associated with glutamate receptor complexes. Nonetheless, Dp71 is mainly located in glial cells where it is required for proper localization of Kir4.1 and AQP4 channels to plasma membrane suggesting that its loss may affect extracellular K^+ buffering and water balance.
In this work, we want to study the role of Dp71 in the cerebellum as clinical studies recently highlighted a role of cerebellar-dependent cognitive dysfunctions in DMD patients. We first focused on the glutamatergic transmission at parallel fiber/climbing fiber synapses onto Purkinje neurons, the only output element of the cerebellar cortex. Patch clamp experiments and pharmacology revealed that electrically evoked excitatory post-synaptic currents (EPSCs) are altered in Purkinje neurons from Dp71-null mice. Furthermore, our immunohistochemistry results had shown that in the cerebellar cortex, Dp71 seems to localize in Bergmann glia processes, in particular at perivascular end-feet and at the *glia limitans*. On the basis of the pivotal function of these radial glial cells in the control of extracellular ion homeostasis, we are investigating the ability of Bergmann cells to buffer extracellular ions in WT and Dp71-null mice combining patch clamp, optogenetics and ion-sensitive microelectrode recordings.
This work will allow a preliminary evaluation of the impact of Dp71 loss on cerebellar neuron and glial functions.

Title: Synergistic effects on calcium entry and transmitter release of a potassium channel blocker and a calcium channel gating modifier at the NMJ

Authors: R. LAGHAEI[1], M. WU[2], A. PUGLIONESI[2], T. TARR[2], M. DITTRICH[1], *S. D. MERINEY[3];
[1]Pittsburgh Supercomputing Ctr., Carnegie Mellon Univ., Pittsburgh, PA; [2]Neurosci., [3]Univ. Pittsburgh, Pittsburgh, PA

Abstract: We have previously reported the development of novel, first-in-class, Cav2 gating modifiers (GV-58) that prolong channel deactivation. These compounds effectively increase calcium flux during an action potential by stabilizing the open state of the channel. At synapses, this effect increases neurotransmitter release, and these compounds are being developed as potential treatments for diseases that cause neuromuscular weakness. Because these calcium channel gating modifiers require that the channel be in the open state before they can modify gating, and since action potentials are normally very brief (1-2 msec), only a fraction of channels are typically modified. This is relevant to potential treatment of neuromuscular diseases like Lambert-Eaton myasthenic syndrome (LEMS) since these patients are currently managed using a potassium channel blocker (DAP) that broadens the presynaptic action potential. DAP provides modest symptomatic relief for LEMS patients, and we hypothesize that a combination of DAP plus our calcium channel gating modifier would work synergistically to provide a stronger and more complete relief of neuromuscular weakness. Before moving into in vivo animal models, we have explored the dose-response relationship of this hypothesis in a previously validated MCell model of the presynaptic neuromuscular active zone. The advantage of this computer modeling approach is that we can explore various combinations of these two pharmacologic agents, and study the spatio-temporal dynamics of presynaptic calcium influx and the subsequent impact on transmitter release. Within MCell, we modeled DAP effects by increasing the amplitude (5-10%) and prolonging the decay time (5-15%) of the presynaptic action potential. To model the effects of GV-58, we edited our calcium channel gating scheme to include drug bound states with kinetic rates that resulted in modeled calcium current that matched our patch clamp recordings of calcium current modulation by GV-58. Then we used these two modifications in both control and LEMS MCell model active zone architectures to evaluate the effects on transmitter release.

In addition, we extracted from the model the spatio-temporal dynamics of buffered calcium diffusion within the nerve terminal, and also the stochastic dynamics of calcium ion binding to synaptotagmin-based calcium sensors on docked synaptic vesicles. We find that broadening the presynaptic action potential increases the effectiveness of our gating modifier, and we are currently studying the dose-response details of this synergistic effect using our MCell model before moving to in vivo testing in animals.

Abstract: Genetic aspects of autism spectrum disorders (ASDs) have recently been extensively explored, but environmental influences that affect ASDs have received considerably less attention. Zinc (Zn) is a nutritional factor implicated in ASDs, but evidence for a strong association and linking mechanism is largely lacking. Here we report that trans-synaptic Zn mobilization rapidly rescues social interaction in two independent mouse models of ASD. In mice lacking Shank2, an excitatory postsynaptic scaffolding protein, postsynaptic Zn elevation induced by clioquinol (a Zn chelator and ionophore) improves social interaction. Postsynaptic Zn is mainly derived from presynaptic pools and activates NMDA receptors (NMDARs) through postsynaptic activation of the tyrosine kinase Src. Clioquinol also improves social interaction in mice haploinsufficient for the transcription factor Tbr1, which accompanies NMDAR activation in the amygdala. These results suggest that trans-synaptic Zn mobilization induced by clioquinol

rescues social deficits in mouse models of ASD through postsynaptic Src and NMDAR activation.

Title: Functional endpoint assays to assess neurotoxicity with human iPSC-derived neurons

Authors: S. DELAURA[1], *E. M. JONES[2], K. KIM[1], C. KANNEMEIER[1], R. LEWIS[1], K. MANGAN[1], B. SWANSON[1], C. CARLSON[1];
[1]Cell. Dynamics Intl., Madison, WI; [2]Gist Consulting, Middleton, WI

Abstract: Human cell types differentiated from induced pluripotent stem cells (iPSC) offer a unique source of cellular material for toxicity screening. Several examples have been presented recently on the use of iPSC- derived cardiomyocytes and hepatocytes, for example, in safety toxicology studies. Equally as important, however, is comparative neurotoxicity assessment in neuronal cell types for safety toxicology and uncovering molecular mechanisms underlying excitotoxic cell death pathways. Advances in iPSC technology provide access to previously unattainable cell types from the human brain opening new opportunities to address the shortcomings and limitations of rodent primary cells and immortalized cell lines Here we highlight examples using human iPSC- derived neurons in image- based screens, as well as on multi- electrode arrays (MEA) to assess the effects of both developmental and environmental neurotoxicants. In our recent studies, we demonstrated the neurotoxic effects of the excitatory neurotransmitter glutamate and related compounds across a panel of cell types, including iPSC-derived GABAergic and glutamatergic cortical neurons, as well as midbrain dopaminergic neurons. For comparison, the cytotoxicity of a broad spectrum kinase inhibitor, staurosporine (STS), was also evaluated. To achieve robust signals across these different iPSC- derived neuron types, we have optimized the cell culture protocols (i.e., media, time in culture, cell plating density, etc.). Under the various conditions tested, we confirmed differential responses for glutamatergic compounds (e.g. glutamate, NMDA, AMPA, and kainic acid) versus STS, suggesting the toxicity responses were due to excitotoxic effects of neuronal synaptic receptors and not other mechanisms. Importantly, toxicity induced by glutamate could be reversed with antagonists of the AMPA and NMDA receptors, DNQX and D- AP5, respectively. Additionally,

with an emphasis on analysis to decipher the complexity of neuronal activity in a dish, we were able to quantify the development of highly network- level bursting behaviors in the cultures. Overall, these iPSC- derived neurons exhibit functional glutamate pathways that respond appropriately to known agonists and antagonists, thus providing biologically relevant models for identifying emerging targets for excitotoxicity research. Together with the developmental and environmental toxicity studies, these data establish a clear utility for these each of these cell types in neurotoxicology studies.

Title: pre- and postsynaptic dopamine receptors differentially modulate the subicular inputs to layer V pyramidal neurons in medial and lateral entorhinal cortex

Authors: *H. KIM, J. KWAG;
Korea Univ., Seoul, Korea, Republic of

Abstract: Medial entorhinal cortex (MEC) and lateral entorhinal cortex (LEC) are known to process spatial and non-spatial information, respectively. Interestingly, layer V pyramidal neurons in both MEC and LEC receive inputs from subiculum (Sb), which conveys information to the hippocampus. We previously demonstrated that DA-Rs modulate the properties of Sb-MEC synapse (Sb-MEC) and Sb-LEC synapse (Sb-LEC) but whether such dopaminergic modulations are due to DA-Rs in pre- or postsynaptic loci are yet unknown. To distinguish synaptic location of DA-Rs, we measured the paired-pulse ratio (PPR, 2 stimuli at 50 Hz) of excitatory postsynaptic currents (EPSCs) and synaptic integration (SI, 10 stimuli at 30 Hz) of excitatory postsynaptic potentials (EPSPs) through whole-cell voltage- and current-clamp recordings by stimulating distal Sb. SI was analyzed by calculating area of summated EPSPs (mV·s). To activate DA-R, 50 μM dopamine (DA) was used and 10 μM SCH 23390 (D1-R antagonist) and 100 nM Raclopride (D2-R antagonist) were applied in the presence of DA to study the roles of DA-R subtypes. Two-tailed paired Student's *t*-test was used for all significance tests.

To investigate whether there is a presynaptic DA-R modulation of synaptic transmission, PPR was analyzed. Sb-MEC showed paired-pulse facilitation (PPF), which was preserved after DA application (Control *vs* DA: 115.21±13.92% *vs* 105.22±25.04, n=5, p>0.05). In contrast, Sb-LEC showed paired-pulse depression (PPD) but DA application converted PPD to PPF (Control *vs* DA: 67.78±2.47% *vs* 118.0±7.14%, n=5, $p<0.01$), suggesting that Sb-LEC is modulated by presynaptic DA-R. When D1-R or D2-R antagonist were applied in the presence of DA, in our preliminary experiment, D2-R antagonist blocked the DA effect (DA *vs* D2: 118.0±7.14% *vs* 64.80±7.25%, n=5, $p<0.01$), while D1-R antagonist had no effect (DA *vs* D1: 152.06±27.43% *vs* 159.81±12.42%, n=3, $p>0.05$) at Sb-LEC.
To study postsynaptic DA-R modulation, of Sb-EC synapse, SI was analyzed by calculating summated EPSP area (mV·s). SI of Sb-MEC was reduced by DA (Control vs DA: 5.74±0.47 *vs* 4.30±0.50, n=11, $p<0.05$), but not in Sb-LEC (Control *vs* DA: 6.14±1.14 *vs* 4.93±1.0, n=12, $p>0.05$). DA effect of SI at Sb-MEC was blocked by D1 antagonist (Control *vs* D1: 5.20±0.80 *vs* 5.08±1.33, n=5, $p>0.05$), but not by D2-R antagonist (Control *vs* D2, 5.93±0.60 *vs* 3.70±0.60, n=5, $p<0.05$) in Sb-MEC, indicating that SI at Sb-MEC is modulated by postsynaptic D1-R. Overall, here we found that Sb-LEC was modulated by presynaptic D2-R while Sb-MEC was modulated by D1-R, which may have implications in understanding how DA influences spatial and learning information processing in the entorhino-hippocampal circuit.

Title: Corticosterone and neuromodulators display similar rapid effects on inhibitory cortical networks

Authors: *C. A. WOTTON, E. F. QUON, L. K. BEKAR;
Pharmacol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Stress is associated with activation of the hypothalamic-pituitary-adrenal axis that results in liberation of corticosterone into the blood to act on all tissues of the body including the brain. In addition, stress activates neuromodulatory networks throughout the brain to alter information flow and processing to optimize the fear-fight-flight response for survival. Given

that both neuromodulators and corticosterone are present in the brain during stress responses, we assessed the impact of corticosterone, norepinephrine and serotonin alone or in combination on frequency transmission in a simple cortical network in acutely isolated mouse brain slices. We used a paired-stimulation paradigm to enable evaluation of effects on excitatory as well as inhibitory activity, as paired-stimulation suppression in the cortex is known to be dependent on recruitment of inhibitory circuits. Application of norepinephrine to the slice perfusate produced a decrease in the amplitude of both pulse 1 and pulse 2. In contrast, application of either serotonin or corticosterone decreased the amplitude of pulse 1, while increasing pulse 2. All three lead to a significant increase in the paired-pulse ratio. The striking similarities in corticosterone and serotonin effects suggest a potential common mechanism. Indeed, application of corticosterone and serotonin in the presence of the $GABA_A$-receptor antagonist, bicuculline, affected the responses similarly, now showing a decrease in both pulse 1 and pulse 2 like that of norepinephrine. Additional experiments were performed with serotonin in the presence and absence of corticosterone to evaluate commonality between their mechanisms of action. Corticosterone alters the direction and amplitude of pulse 2 in the serotonin response, resulting in a response that resembles that of norepinephrine. Taken together, this suggests that both corticosterone and serotonin alter $GABA_A$ signaling pathways to exert their modulatory action. Given that chronic stress leads to depression and that altered serotonin signaling is central to the etiology of depression, the similarity in corticosterone and serotonin neuromodulatory actions highlights an interesting interaction that may lead to future treatment options for depression.

Title: α_2-Adrenergic receptor and isoflurane modulation of presynaptic Ca^{2+} influx and exocytosis in hippocampal neurons

Authors: *Z.-Y. ZHOU[1], M. HARA[1,3], H. C. HEMMINGS, Jr.[1,2];
[1]Dept. of Anesthesiol., [2]Dept. of Pharmacol., Weill Cornell Med. Col., New York, NY; [3]Dept. of Anesthesiol., Kurume Univ. Sch. of Med., Kurume, Fukuoka, NY

Abstract: Evidence indicates that the anesthetic-sparing effects of α_2-adrenergic receptor (AR) agonists involve α_{2A}-AR heteroreceptors on non-adrenergic neurons. Since volatile anesthetics inhibit neurotransmitter release by reducing synaptic vesicle (SV) exocytosis, we hypothesized that α_2-AR agonists inhibit non-adrenergic SV exocytosis and thereby potentiate presynaptic inhibition of exocytosis by isoflurane. Quantitative imaging of fluorescent biosensors of action potential (AP) evoked SV exocytosis (synaptophysin-pHlourin) and Ca^{2+} influx (GCaMP6) were used to characterize presynaptic actions of the clinically used α_2-AR agonists dexmedetomidine (DEX) and clonidine (CLO), and their interaction with isoflurane, in cultured rat hippocampal neurons. DEX (0.1 μM, n = 10) or CLO (0.5 μM, n = 8) inhibited AP-evoked exocytosis (54 ± 5% and 59 ± 8% of control, respectively; $p < 0.001$). Effects on exocytosis were blocked by the subtype-nonselective α_2-AR antagonist atipamezole or the α_{2A}-AR selective antagonist BRL 44408, but not by the α_{2C}-AR selective antagonist JP 1302. DEX inhibited exocytosis and presynaptic Ca^{2+} influx without affecting Ca^{2+} coupling to exocytosis, consistent with an effect upstream of Ca^{2+}-exocytosis coupling. Exocytosis coupled to both N-type and P/Q-type Ca^{2+} channels was inhibited by DEX or CLO. DEX potentiated inhibition of exocytosis by 0.7 mM isoflurane (to 42 ± 5%, compared to 63 ± 8% for isoflurane alone; $p < 0.05$). Our data suggest that hippocampal SV exocytosis is inhibited by α_{2A}-AR activation in proportion to reduced Ca^{2+} entry. These effects are additive with those of isoflurane, consistent with a role for α_{2A}-AR presynaptic heteroreceptor inhibition of non-adrenergic synaptic transmission in the anesthetic-sparing effects of α_{2A}-AR agonists.

Title: Modulation of entorhinal cortical input to hippocampal granule cells through activation of local inhibitory network in the dentate gyrus

Authors: *Y. MIRCHEVA, M. R. PERALTA, III, K. TOTH;
Ctr. De Recherche De L'Institut Universitaire En, Quebec City, QC, Canada

Abstract: Entorhinal cortex (EC) projections to the dentate gyrus (DG) are the main excitatory entry in the hippocampus. Input integration is strongly influenced by local inhibitory networks of interneurons situated in the molecular layer of the DG. Direct excitatory signals in DG granule cells (GCs) interplay with slow and fast inhibition signals in order to achieve high computational power during information processing. In this study we investigated how activation of the local inhibitory circuits through perforant path (PP) stimulation, could impact EC input integration in GCs. Slow inhibition is of particular interest as it has the potential to reduce granule cell's excitability and might be involved in shaping their preferential "burst" firing pattern. Our results show that activation of EC inputs can trigger a prolonged inhibitory response that can abolish GC firing for duration of 1-2 seconds. Given the possible functional consequences that such a slow inhibitory signal could have on information processing and transfer, we further investigated the mechanism and the properties of PP-evoked long lasting hyperpolarization. Long lasting hyperpolarization (LLH) was first observed *in vitro* after direct activation of the perforant path terminals (5 pulses at 50 Hz). PP excitatory responses in GCs were followed by prolonged IPSP (16.14 ± 0.73 mV; 1946 ± 159.7 ms, n=6). Optogenetic isolation of EC input and light activation of PP, similarly induced long lasting hyperpolarization that could last up to 2s. This slow inhibition has the potential to alter GCs firing pattern by critically decreasing the probability of the cell to emit action potentials, suggesting that LLH is a mechanism for regulating dentate gyrus excitability. Using a pharmacological approach we investigated LLH properties in detail. It is mediated by the co-activation of postsynaptic $GABA_A$, $GABA_B$ and mGluR1 receptors. Moreover, LLH is activity-dependent, being most efficiently induced by high frequency PP stimulation. Interestingly, LLH develops in an age-dependent manner: LLH is most prominent in adult mice (2047 ±68 ms; 7.3 ±0.9 mV, n = 4) and absent in juvenile animals (393±67.9 ms; 1.9 ±0.2 mV). These results demonstrate the presence of an exceptionally slow hyperpolarization in GCs due to activation of postsynaptic GABA receptors and mGluR. We hypothesize that this slow inhibition is induced through PP activation of local interneurons of the feed-forward inhibition circuit. Further investigation of the mechanism and the cells at its origin as well as its physiological relevance, will improve our current understanding t of the complex interactions at the EC-DG gateway.

Title: Adenosine provides fine-tuned and highly localised negative-feedback control of spatiotemporal activity in the neocortex

Authors: *M. J. WALL[1], A. NEWTON[2], M. G. THOMAS[2], M. J. E. RICHARDSON[2];
[2]Ctr. of Systems Biol., [1]Univ. of Warwick, Coventry, United Kingdom

Abstract: Neocortical networks support a multitude of well-defined activity states. For many of these states, the mechanisms of how they are activated, sustained and terminated still remains unclear. Negative feedback via the endogenous neuromodulator adenosine is likely to have a significant influence on network activity as there is dense adenosine-receptor expression in the neocortex and gathering evidence for its role in controlling synaptic strength. In this study we have combined electrophysiology, microelectrode biosensors, fast-scan cyclic voltammetry together with mathematical and computational modelling to quantify the spatiotemporal properties of adenosine release, transport, action and removal during physiological and pathological network activity. We found that both low-rate and high-rate network activity can be modulated by adenosine receptor activation, illustrating a wide dynamic range for the adenosine signaling mechanism with little receptor saturation. During network activity adenosine was found to be released in a neocortical layer-dependent manner. Additionally, we found that the concentration of extracellular adenosine is a highly local variable determined by activity over distances less than 100 um. Modulating the removal of adenosine by either inhibiting adenosine deaminase or blocking uptake by equilibrative transporters significantly changes the time course of adenosine kinetics and can result in the accumulation of adenosine in the extracellular space. Mathematical modelling constrained by these experimental findings suggests that high receptor density coupled with efficient adenosine removal underlies a negative-feedback mechanism with a fine spatiotemporal control of local network activity.

Title: Effect of electrode morphology on the frequency spectrum of local field potentials in the rat ventral tegmental area

Authors: C. DELAIRESSE[1], G. BECKER[1], A. PLENEVAUX[1], *V. M. SEUTIN[2], S. KOULCHITSKY[1];

Abstract: Implantable microelectrode arrays for chronic neural recordings receive an attention by a number of research groups investigating ensemble spike activity and local field potentials. Due to that interest, various types of arrays have been developed. In the present study we compared the LFP signals recorded from the ventral tegmental area (VTA) of freely moving male Wistar rats using the two types of arrays: microelectrode microwire arrays, and silicon-based planar probes. The microwire electrodes have a three-dimensional recording surface around their tips. This presumably allows them to record the signal from all angles with similar accuracy. In contrast, the electrode contacts of the planar probe are patterned on one side of the silicon shaft (often named top-side, the other one being named back-side). This configuration probably allows to record the signal from the top-side of the shaft, while the signal from the back-side may get attenuated. Microwire arrays used in this study consisted of 8 sharpened platinum iridium wires, coated with parylene-C, except for the tip allowing the recording (Alpha Omega GmbH, Israel). Planar probes (ATLAS Neuroengineering, Belgium) had 16 iridium oxide electrode contacts implemented in the 4 silicon shafts, 4 electrode contacts per shaft. The recording was performed using a wireless system (W-Basic-System, Multi Channel Systems MCS GmbH, Germany). The probes were implanted in two orientations: top-side facing the midline, and top-side facing the lateral plane of the brain. For verification of the recording area the rats were anaesthetized and perfused with 4% paraformaldehyde containing 1 % gadolinium. The brains were removed from the skull and placed in a specific material for MRI scanning. Frequency spectra of LFPs recorded by the microwire arrays, and by the planar probes oriented to the lateral plane of the brain contained a prominent peak in the theta range (6-8 Hz). In contrast, the signals recorded using the planar probes oriented to the midline lacked such a peak and were more variable. We attribute the observed difference to the geometry of the recording arrays.

Title: Probing the ventral fronto-temporal pathway in the language dominant hemisphere - an intraoperative cortico-cortical evoked potential study

Authors: *T. NAKAE[1], R. MATSUMOTO[2], T. KUNIEDA[4], Y. ARAKAWA[1], T. KOBAYASHI[1], T. INADA[1], Y. TAKAHASHI[1], S. NISHIDA[1], K. KOBAYASHI[3], A. SHIMOTAKE[3], M. MATSUHASHI[5], R. INANO[1], Y. YAMAO[6], T. KIKUCHI[1], K. YOSHIDA[1], A. IKEDA[2], S. MIYAMOTO[1];

Hosp., Touon-shi, Japan; [5]Human Brain Res. Ctr., Kyoto Univ., Kyoto-Shi, Japan; [6]Dept. of Neurosurg., Kouseikai Takeda Hosp., Kyoto-Shi, Japan

Abstract: Background: Recent intraoperative high frequency electrical stimulation of the white matter has indicated an active role of inferior fronto-occipital fascicle (IFOF) in semantic processing. Although IFOF is regarded as a major fiber in the ventral language pathway, by definition it has no terminations in the temporal lobe which is heavily involved in semantic aspects of language. Our objective is to delineate functional connectivity between the inferior frontal gyrus (IFG) and the three temporal gyri (STG, MTG, ITG) to clarify this puzzling situation by means of an electrical tract tracing method of cortico-cortical evoked potential (CCEP).
Methods: Subjects are 13 patients (11 tumor, 2 epilepsy) who underwent intraoperative monitoring for lesionectomy around the language cortices or fibers in the language dominant hemisphere (IRB C573). Single-pulse stimuli (0.3 ms, 15 mA, alternating polarity, 30 x 2 trials) were applied to the IFG through the two adjacent subdural electrodes (3-7 stimulus sites per patient). CCEP was recorded from subdural electrodes (16-24 electrodes per patient) placed on the lateral temporal area. Remote CCEP fields were identified by focusing on the early negative potential (N1: peak latency < 100 ms). Electrodes with > 80% of the maximum responses were included for analysis. The locations of stimulus and response sites were analyzed in terms of the anterior-posterior dimension.
Results: Stimulation of the posterior part of IFG (< 40 mm from the precentral sulcus (PreCS)) elicited CCEP from all the three gyri (STG, MTG, ITG). In contrast, the anterior part of IFG (> 40 mm from PreCS) elicited CCEPs only in MTG and ITG. Linear regression line analysis revealed significant positive correlation between the stimulus sites (the distance from PreCS: range 3-58 mm) and the response sites (that from the temporal pole: range 37-93 mm) in MTG

(R^2 = 0.36) and ITG (R^2 = 0.71).
Conclusion: IFG connection to STG was confined to the posterior part of IFG, and most likely represented the dorsal fiber pathway. Connections to MTG/ITG were observed from all parts of IFG. Different from the current dichotomy of UF vs. IFOF, the anterior-posterior gradient between IFG stimulus sites and MTG/ITG response sites implicates the continuum of the two fibers, namely, more "fanning" nature of the ventral fronto-
temporal pathway as originally Dejerine addressed (1895). Further investigation, such as comprehensive white matter electrical stimulation, is warranted to clarify the role of the ventral fronto-temporal fibers in language and semantic functions.

Title: The capacity of active memory

Authors: ***E. P. FRADY**[1], G. ISELY[1], F. T. SOMMER[1], P. KANERVA[2];
[1]Neurosci., UC Berkeley, Berkeley, CA; [2]Neurosci., Redwood Ctr. for Theoretical Neurosci., Berkeley, CA

Abstract: Although the mechanisms of working memory are unclear, many theories suggest that information about the past is maintained through recurrent neural activity. However, the information capacity that can be maintained in neural activity is unknown. We explore the

information capacity in two computational models of working memory, holographic reduced representations (Plate, 2003) and hyperdimensional computing (Kanerva, 2009). These models use key-binding schemes to encode working memory traces in high-dimensional vectors, where arbitrary memory items can be directly decoded. We illustrate how to superimpose memory items in a linear recurrent neural network based on these computational algebras. As more items are superimposed, cross-talk reduces the quality of decoding memory items which ultimately limits the memory capacity. We analytically derive the fundamental capacity limits of these systems and verify their applicability by simulation experiments. We found an approximately linear relationship between the number of elements stored and the number of neurons required to maintain the information at a given tolerance: roughly 10-15 neurons are needed for each bit of information stored in active memory. Further, we show that our results also apply to more sophisticated machine learning models by training recurrent neural networks and LSTMs to perform computational tasks which require large working memories. The proposed information capacity estimates how many neurons a network requires to solve a problem based on the problem's computational complexity (e.g. the amount of information needed maintained in working memory). Our results demonstrate that performance drops drastically as this condition is violated. All told, the presented results form a theoretical foundation for analyzing the computational properties of neural activity both in experiments and machine-learning, and might also be important to understand human performance in working-memory tasks.

Title: Sleep in clock mutant mice, clock$^{\Delta 5\text{-}6}$, responds to light changes and sleep deprivation very differently

Authors: *B. QIN[1,2], A. AKLADIOUS[3], P. FENG[4,3];
[1]Res., Case Western Reserve University/Va Med., Cleveland, OH; [2]Res., [3]Louis Stokes Cleveland DVA Med. Ctr., Cleveland, OH; [4]Case Western Reserve Univ., Cleveland, OH

Abstract: *Clock* is one of the important genes that regulate circadian rhythms and sleep. Mouse with *Clock* mutation (*Clock*$^{\Delta 5\text{-}6}$) has been demonstrated to have normal activity rhythms with altered response to lighting (Debruyne et al., 2006). However, how *clock* deficiency impact sleep/wake regulation is not known. Therefore, we conducted a polysomnographic (PSG) study in wild mice (n=8) and mice with *Clock*$^{\Delta 5\text{-}6\ -/-}$ (n=10).
Electrodes for EEG and EMG recording were implanted under standard anesthesia. Two days of baseline PSG recording was conducted ten days after post-surgical recovery under normal light/dark cycle, i.e., LD12:12 (light was on at 9:00 am and off at 9:00 pm). Then, PSG recording was continued for 6 hours of total sleep deprivation by gentle handling started at light onset (Zeitgeber [ZT] 0) followed by 18 hours of recovery. To study the effect of clock mutation in response to long darkness, light was turned off continuously for 7 days, i.e., constant darkness (DD) from the fourth day of PSG recording. Then, we studied the light effect on both genotype animals by turning on lights constantly (LL) for 7 days. PSG data was analyzed as rapid eye movement (REM) sleep, non-REM (NREM) sleep and wake in 10-second epoch. Data scoring has been completed for one baseline day, sleep deprivation and recovery day, DD day 1 and 7 and LL day 1 and 7.
Baseline sleep/wake features of the *Clock*$^{\Delta 5\text{-}6\ -/-}$ mouse were the same as of wild mouse. However, the *clock* mutation mouse had significant less total sleep and NREM sleep in post-sleep deprivation recovery period than the wild mouse. Sleep states in wild mouse and *Clock*$^{\Delta 5\text{-}6\ -/-}$ mice were similar in the first DD day but significantly different in the 7th DD day. In DD7, total sleep ($p<0.001$) and NREM sleep ($p<0.001$) was significantly less in the *clock*$^{\Delta 5\text{-}6\ -/-}$ mouse in the period of ZT5-8. The mean of REM sleep was higher in the *clock* mutation mouse in ZT 13-16 but not significant. When turn to LL period from DD period, mice with *clock* mutation had significantly ($p=0.028$) less total sleep and NREM sleep ($p=0.021$). In the last LL day, clock mutation mouse had significantly ($p=0.024$) more total sleep and significantly more NREM sleep ($p=0.019$) in the ZT13-16 time period indicating that clock deficiency reduced activity stimulation induced wake response. Interestingly, differences of REM sleep between wild and mutation groups were significant only in LL7, ZT0-4 period. EEG power analysis and micro-features of sleep will be analyzed in the future.
In summary, although rhythmic sleep/wake state remains the same in both the wild and the *clock* mutation mice, the capability of the mutation mice response to the challenge of sleep deprivation and light change is altered.

Title: Network's critical state and its relation to the inverted-U profile of dopamine related working memory performance

Authors: G. HU, X. HUANG, T. JIANG, *S. YU;
Brainnetome Ctr., Inst. of Automation, Chinese Acad. of Sci., Beijing, China

Abstract: It has been known that the working memory (WM) performance is modulated by dopamine (DA), with a characteristic inverted-U profile. That is, too strong or too weak of DA's activation in the prefrontal cortex (PFC) would be detrimental for WM, while an intermediate level of DA activation is required to maintain an optimal WM performance. In addition, it has been reported that such an intermediate level of dopamine D1 activation in the PFC is associated with the network being organized close to a critical state, while too strong or too weak D1 activation pushes the system away from it. Given the advantages of the critical state in information processing, it has been then hypothesized that the role of dopamine in the PFC is to adjust the system's overall state, with the critical point as the desirable target. This may provide a deep insight into the mechanisms underlying DA's inverted-U profile in WM performance. In the current study, we aim to test this hypothesis in a network model. To this end, we adapted a neural network model that was proposed to perform the WM task though calcium-dependent short-term synaptic plasticity. According to experimental as well as modeling results, dopamine's modulation was simulated as inserting a nonlinear function on the efficacy of excitatory synapses, which are slightly different between the pyramidal-pyramidal synapses and pyramidal-interneuron synapses. By systematically changing DA's 'concentration', we observed that the system operated close to the critical state with an intermediate level of DA activation, while a too high or too low concentration of DA renders the system sub-critical. Importantly, this critical state demonstrated the maximized sensitivity in WM task. That is, under such a condition, the network was able to memorize the weakest external input. In-depth analyses further revealed the mechanisms, including the balance between the excitation and the inhibition, underlying such a phenomenon. Our results provide a mechanistic link between the observed inverted-U profile for DA-related WM performance and DA-dependent critical state in the PFC network, suggesting that the former can be satisfactorily explained by considering DA's role in modulating the overall state of the PFC network around the critical point.

Title: Enhanced signal propagation and nonnormality in a large scale circuit model of the primate cortex

Authors: ***M. JOGLEKAR**[1], J. MEJIAS[1], G. R. YANG[1], X.-J. WANG[1,2];
[1]Ctr. for Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY; [2]NYU-ECNU Joint Inst. of Brain and Cognitive Sci., NYU Shanghai, Shanghai, China

Abstract: Stable transmission of signals in a multi-area feedforward network represents a long-standing challenge: as a signal propagates across areas, it may either die out or explode (Diesmann et al., Nature 1999, Moldakarimov et al., PNAS 2015). In previous studies on signal transmission, areas are identical and inter-areal connection strengths are uniform and not constrained by data. We re-examined the problem of signal propagation using a newly developed large-scale network model of the primate cortex (Chaudhuri et al., Neuron 2015). The model is based on the recently published dataset of directed and weighted connectivity of the macaque cortex from Henry Kennedy's group at INSERM, France (Markov et. al., Cereb. Cortex 2014). This network displays complex feedforward and feedback projections with a wide range of connection strengths (spanning five-orders of magnitude), posing new questions about signal propagation. We quantified effective signal transmission in terms of the amount of attenuation of the peak firing rate as the signal propagates to areas higher in the brain's hierarchy. We found two regimes of stable signal propagation. The underlying principle governing both the regimes is strong long-range excitation that boosts inter-areal signal transmission, followed by strong delayed inhibition that stabilizes the network dynamics. In this sense, this work represents a generalization of the concept of balanced amplification (Murphy et al., Neuron 2009) from local circuits to large-scale cortical systems. Consistent with Murphy et al. showing that this mechanism is characterized by the non-normality of the network connection matrix, in our large-scale model, an improvement in propagation is correlated with an increase in the non-normality measure (Henrici, Numer. Math. 1962) of the large-scale connectivity matrix. Our regimes

improve signal propagation by 100 fold, from an attenuation of 1/10,000 (Chaudhuri et al., Neuron 2015) to 1/100.

Title: Pacap modulates amygdalar-bnst interactions in control of anxiety

Authors: Y. LI, R. ANDERO, K. J. RESSLER, *V. Y. BOLSHAKOV;
Psychiatry, McLean Hosp- Harvard Med. Sch., Belmont, MA

Abstract: Previous studies provide experimental evidence for the role of pituitary adenylate cyclase-activating polypeptide (PACAP)-mediated signaling in regulation of anxiety in both experimental animals and human subjects. It has been demonstrated that PACAP may regulate anxiety-related behavioral processes through its actions in two interacting brain regions, the amygdala and the bed nucleus of the stria terminalis (BNST). However, synaptic and network mechanisms of PACAP-mediated effects in the brain are poorly understood. In this study, we addressed specific questions about the nature of PACAP-induced synaptic and network-level modifications in BLA-BNST circuits, contributing to control of anxiety states. We expressed channelrhodopsin-2 (ChR2) under control of the neuron-specific promoter CaMKIIα in BLA neurons and photostimulated the corresponding fibers synapsing on neurons in two BNST subdivisions, ovBNST and adBNST, known to regulate anxiety in opposite directions—activation of ovBNST was shown to induce anxiety, whereas activation of adBNST is anxiolytic. Consistent with our finding that PACAP-containing fibers were observed in ovBNST only, we found that PACAP potentiated excitatory synaptic responses at inputs to ovBNST but not at inputs to adBNST, selectively increasing the synaptically-driven spike output of ovBNST neurons in response to activation of projections from the BLA. The enhanced firing of ovBNST neurons resulted in inhibition of adBNST, since ovBNST neurons, projecting to adBNST, are GABAergic. By using a combination of retrograde tracing, immunohistochemistry and in vivo optogenetics, we demonstrated that neurons in the parabrachial nucleus (PBn) in the brainstem are the source of PACAPergic innervations of the ovBNST. Thus, we showed that neuropeptide PACAP contributes to regulation of anxiety states by differentially affecting synaptic efficacy at

BLA projections to different BNST subdivisions, and, therefore, modifying the signal flow in BLA-ovBNST-adBNST circuits in such a way that adBNST is inhibited. This would explain the ability of PACAP in BNST to trigger anxiety, as direct optogenetic inhibition of adBNST was shown to be anxiogenic.

Abstract: As we navigate the world our perception of sensory stimuli is not only defined by our ongoing experiences, but also by the summation of our previous experiences, preserved as memories. The hippocampus, a deep brain structure long considered the seat of learning and memory, receives input crucial to this function from an adjacent cortical area, the entorhinal cortex. The entorhinal cortex acts as a hub, processing sensory and associational input from many brain regions, and projecting to the hippocampus to enable memory formation. While we know a great deal about this forward circuit, we know very little about the reciprocal input from the hippocampus to the entorhinal cortex. We hypothesize that the hippocampus modulates the integration of sensory information occurring in the entorhinal cortex, providing a mechanism by which previous memories within the hippocampus shape the future processing of new experiences. In this study we examine the functional connectivity of the hippocampal back-projections and the role of this pathway in modulating activity within the entorhinal cortical microcircuit, using whole-cell electrophysiology, optogenetics and viral tracing approaches *in vitro* in the adult mouse. Furthermore, we are exploring the importance of these backprojections in hippocampal-dependent behavioral paradigms including contextual fear conditioning and novel object recognition using loss of function approaches and two-photon imaging.

Title: Using multielectrode arrays to investigate the spontaneous firing patterns and functional connectivity in large neural assemblies

Authors: ***T. FENG**, N. X. KODAMA, R. FERNANDEZ GALAN;
Case Western Reserve Univ., Cleveland, OH

Abstract: The brain is active even in the absence of stimulation. Its spontaneous activity is not random but highly structured and can be used to investigate properties of neuronal circuits, such as their functional connectivity and the presence of endogenous pacemakers, which are crucial to understand how neuronal circuits process information. To address this questions it is necessary to record from large populations of neurons simultaneously, and overcome the traditional tradeoffs between spatial and temporal resolutions of standard electrophysiological and imaging methods. We attempt to solve this problem using high-density, two-dimensional, multielectrode arrays (MEA) to investigate spontaneous activity from the mouse neocortex *in vitro*. The arrays consist of 120 electrodes evenly spaced with 100 um pitch over an octagonal area spanning over 1.2 x 1.2 mm^2. This technology enables the study of activity patterns with unprecedented temporal and spatial resolutions over a few cortical columns. Using spike-sorting algorithms, action potentials from multiple cells can be resolved from each electrode in the MEA, so that we can potentially identify on the order of hundreds of neurons in a single experiment. In preliminary studies, the neurons displayed different types of spontaneous firing patterns at different frequencies, typically below 10 Hz. Some neurons fired tonically, some transiently, and some in regular bursts. From the firing patterns we were able to investigate functional connections between neurons at different locations in the neocortex, and identify neurons with important roles in the network. In particular, the relative lags between action potentials from certain neuron pairs were well preserved over time, indicating direct connections between those neurons. Some other neurons behaved as potential pacemakers in the cortex. These results open up a new avenue to investigate the activity and functional connectivity of neural circuits.

Title: Spherical harmonics reveal standing EEG waves and long-range neural synchronization in the sleeping brain

Authors: ***S. S. SIVAKUMAR**, A. G. NAMATH, R. FERNANDEZ GALAN;
Case Western Reserve Univ., Cleveland, OH

Abstract: Previous work from our lab has demonstrated how the connectivity of brain circuits constrains the repertoire of activity patterns that those circuits can display. Specifically, we have shown that the principal components of spontaneous neural activity are uniquely determined by the underlying circuit connections, and that although the principal components do not uniquely resolve the circuit structure, they do reveal important features about it. Expanding upon this framework on a larger scale of neural dynamics, we have analyzed electroencephalogram (EEG) data recorded with the standard 10-20 electrode system from 41 neurologically normal children and adolescents during stage 2, non-rapid eye movement (non-REM) sleep. We show that the principal components of EEG spindles, or sigma waves (10-16 Hz), reveal non-propagating, standing waves in the form of spherical harmonics. We mathematically demonstrate that standing EEG waves exist when the spatial covariance and the Laplacian operator on the head's surface commute. This in turn implies that the covariance between two EEG channels decreases with the inverse of their relative distance, a relationship that we corroborate with empirical data. Using volume conduction theory, we then demonstrate that superficial current sources are more synchronized at larger distances, and determine the characteristic length of large-scale neural synchronization as 1.31 times the head radius, on average. Moreover, consistent with the hypothesis that EEG spindles are driven by thalamo-cortical rather than cortico-cortical loops, we also show that eight additional patients with hypoplasia or complete agenesis of the corpus callosum, i.e., with deficient or no connectivity between cortical hemispheres, similarly exhibit standing EEG waves in the form of spherical harmonics. We conclude that spherical harmonics are a hallmark of spontaneous, large-scale synchronization of neural activity in the brain, which are associated with unconscious, light sleep. The analogy with spherical harmonics in quantum mechanics suggests that the variances (eigenvalues) of the principal components follow a

Boltzmann distribution, or equivalently, that standing waves are in a sort of "thermodynamic" equilibrium during non-REM sleep. By extension, we speculate that consciousness emerges as the brain dynamics deviate from such equilibrium.

Title: Propagation of spike timing and firing rate across multiple layers in networks of cultured neurons

Authors: *J. BARRAL, A. REYES, X.-J. WANG;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The sequence of action potentials produced by neurons defines a coding strategy to transmit information in neuronal networks. Information may either be represented as the average number of spikes per unit time (rate coding) or by their precise timing (temporal coding). The nervous system utilizes both strategies and there appears to be a continuum between these two extremes. A rudimentary feature of most neural networks consists of several neurons' pools arranged in a feedforward manner, like the multiple cortical areas. The feedforward network model provides a minimal framework for studying information processing in the brain and has been investigated by computer simulations. They revealed that synchronous spikes propagate faithfully only when each layer contains a sufficient number of neurons. In networks of lower density, spikes volley disperses and eventually dies out. However, experimental support is lacking to test this hypothesis.
Here, we studied experimentally how spikes propagated in modular networks. We reconstructed *in vitro* networks by culturing cortical neurons in microfabricated chambers with sequentially connected compartments and controlled the density of neurons in each layer. Excitatory neurons of the first layer were activated optogenetically which allowed precise control of the timing and magnitude of the input (packet) as well as the spatial spread and number of stimulated neurons. Spikes and membrane potential of neurons in subsequent layers were recorded using patch-

clamp. In sparse networks where synaptic connections are strong, spikes propagated through the network and became progressively more synchronous when the input packet delivered to the first layer was sufficiently narrow and large, in agreement with previous theoretical results on exclusively feedforward networks. However, in dense networks where connections are weak, spikes propagated reliably but were temporally more dispersed and delayed, in contradiction with previous results. In this case, the input/output firing rate relation was linear for small range suggesting that these networks could transmit firing rate information. To mimic the increasing number of inputs in progressively higher order brain regions, we varied the number of neurons systematically along the network. We found that propagation was more efficient in cultures where the number of neurons increased progressively with layer, suggesting that propagation could be amplified by networks of larger density. These results indicate that spike propagation depends quantitatively and qualitatively (timing vs rate) not only on the input pulse packet but also on network architecture and density.

Title: Network plasticity facilitating the neural excitation propagation between the perirhinal and entorhinal cortices as revealed by voltage-sensitive dye imaging

Authors: *R. KAJIWARA[1], Y. WAKAYAMA[1], Y. TOMINAGA[2], T. TOMINAGA[2];
[1]Meiji Univ. / Dept. of Electro. & Bioinfo., Kawasaki, Japan; [2]TokushimaBunri Univ. / Dept. of Neurophysiol., Sanuki, Japan

Abstract: The rhinal cortices, such as perirhinal (PC) and entorhinal (EC) cortices, are located on the bi-directional pathway between the neocortex (NC) and the hippocampus (HP). The synchronous neural activation via the rhinal cortices between the NC and HP is essential for the formation and recall of context-dependent memories. However, previous electrophysiological experiments in the guinea pig isolated brains indicated that propagation of neural activity between PC and EC occurs with an extremely low probability. However, we found that the area

35 of PC started to allow the neuronal signal propagation from the NC to HP under certain specific physiological conditions with the voltage-sensitive dye imaging. That is, the area 35 of PC might act as a gate. Here, we examined the neuronal mechanism of the gate by visualizing the pharmacological effect on neural propagation patterns in mouse brains and analyzed the network plasticity having a strong effect on the gate. To assess the physiological property of the neural transmission throughout the rhinal cortices, horizontal slices of mouse brains that contained the PC, EC, and HP regions were used for the VSD imaging. Depolarized response evoked by electrical stimulation at 40Hz delivered to the superficial layers in area 36 of the PC spread across a wide area of the PC, under partial suppression of the $GABA_A$ system by 1 μM gabazine. But this experimental procedure did not cause the spread of neural activities across the PC/EC gate. We examined the effect of slowly inactivating potassium conductance (ID) of late-spiking neurons predominating in area 35 that can inhibit the generation of action potentials necessary for the entorhinal activation by perfusing a low concentration (40 μM) of 4-aminopyridine (4AP). 4-AP enhanced the neural activity in PC and eventually the area 35 started to show prolonged and repetitive depolarization. Once area 35 showed the long and repetitive depolarization, that induced synchronized oscillatory activity in the EC neuronal circuit. In other words, the gate opened. Interestingly, washing out the 4AP cannot inhibit the entorhinal activation anymore, i.e., the gate stayed open for more than one hour. When once the PC/EC gate was open, even weak stimulation to the PC initiated the spread of the neural activity throughout the rhinal cortices. Thus, the enhancement of network activity across the PC/EC gate observed in the study can be said as a new class of the long-term plasticity of the network activity. Such plasticity might play a crucial role in the hippocampal memory processing and pathological phenomena something like the epilepsy.

Title: Propagation of neural activity induced by single-pulse electrical stimulation during various sleep stages

Authors: *K. USAMI[1], A. KORZENIEWSKA[1], R. MATSUMOTO[2], T. KUNIEDA[3], N. MIKUNI[5], K. KOBAYASHI[4], T. KIKUCHI[3], K. YOSHIDA[3], S. MIYAMOTO[3], R. TAKAHASHI[4], A. IKEDA[2], N. E. CRONE[1];

Abstract: Introduction: Single-pulse electrical stimulation (SPES) to human cortex evokes phase-locked potentials called cortico-cortical evoked potentials (CCEP) or non-phase-locked high gamma responses (HGR: > 80 Hz). The latter index changes in neuronal firing and/or synchrony. These responses may be mediated through direct or indirect anatomical connections with the stimulation site, but it is unknown whether propagation occurs beyond these 1st order connections. Previous reports have indicated that effective connectivity breaks down during non-rapid eye movement (NREM) sleep compared to awake and rapid eye movement (REM) sleep. We investigated whether these different brain states affect the propagation of high gamma activity evoked by SPES.
Methods: Four patients underwent invasive presurgical evaluation for intractable partial epilepsy using subdural electrodes (IRB No.443 in Kyoto University). Repetitive single-pulse electrical stimulation (SPES) at alternating polarity was delivered to the cortical surface during wakefulness and different sleep stages, and electrophysiological responses, including CCEPs, were recorded from all electrodes except for the stimulation sites. We applied event-related causality (ERC) analysis based on short-term direct directed transfer function (SdDTF) to estimate the dynamics, directionality, and magnitude of propagation of neural activity among electrodes with HGR (80-150 Hz) at least 100 ms after stimulation. Finally, we compared the propagations we observed during wakefulness and different sleep stages.
Results: We observed different patterns of neural activity propagation during wakefulness vs. different sleep stages. In all patients, we observed more propagation in the awake stage. The electrodes that showed significant CCEPs appeared to be sources of neural propagation to electrodes with and without CCEPs. During wakefulness, magnitudes of propagation were higher than during NREM and REM sleep stages.
Conclusion: Event-related causality (ERC) analyses revealed different patterns of neural activity propagation during wakefulness and different sleep stages. These observations suggest that sites with significant CCEPs can serve as sources of neural propagation especially during

wakefulness. This secondary propagation may be suppressed during sleep, possibly reflecting a state with lower effective connectivity across large-scale cortical networks.

Abstract: The neurophysiological processes that can cause theta-to-gamma frequency range (4-80 Hz) network oscillations in the rhinal cortical-hippocampal system and the potential connectivity-based interactions of such forebrain rhythms are a topic of intensive investigation. Here, using selective Channelrhodopsin-2 (ChR2) expression in mouse forebrain glutamatergic cells, we were able to locally, temporally precisely, and reliably induce fast (20-40 Hz) field potential oscillations in hippocampal area CA1 *in vitro* and *in vivo* (i.e., slightly anesthetized NEX-Cre-ChR2 mice). As revealed by pharmacological analyses and patch-clamp recordings from pyramidal cells and GABAergic interneurons *in vitro*, these light-triggered oscillations can exclusively arise from sustained suprathreshold depolarization (~200 ms or longer) and feedback inhibition of CA1 pyramidal neurons, as being mandatory for prototypic pyramidal-interneuron network (P-I) oscillations. Consistently, the oscillations comprised rhythmically occurring population spikes (generated by pyramidal cells) and their frequency increased with increasing spectral power. We further demonstrate that the optogenetically driven CA1 oscillations, which remain stable over repeated evocations, are impaired by the stress hormone corticotropin-releasing factor (CRF) *in vitro* and, even more remarkably, found that they are accompanied by concurrent states of enforced theta activity in the memory-associated perirhinal cortex (PrC) *in vivo*. The latter phenomenon most likely derives from neurotransmission via a known, but poorly studied excitatory CA1→PrC pathway. Collectively, our data provide evidence for the existence of a prototypic (CRF-sensitive) P-I gamma rhythm generator in area CA1 and suggest that CA1

P-I oscillations can rapidly up-regulate theta activity strength in hippocampus-innervated rhinal networks, at least in the PrC.

Title: Patch clamp recordings of cellular and synaptic properties in adult mouse thoracic paravertebral ganglia

Authors: *M. L. MCKINNON, S. HOCHMAN;
Physiol., Emory Univ., Atlanta, GA

Abstract: Thoracic intraspinal preganglionic neurons project to sympathetic postganglionic neurons (SPNs) within paravertebral chain ganglia. While little is known of thoracic SPN functional properties, a major function is to control vasomotor tone. Paravertebral ganglia were traditionally thought to faithfully relay information from the spinal cord to the periphery, but this is an overly simplified viewpoint. To address this, we developed an *in vitro* approach for whole-cell recordings in intact thoracic ganglia (T3-T12) to characterize cellular and synaptic properties. Mean resting membrane potential was -57 mV. Average cell input resistance was 928 MΩ, and membrane time constant was 82 ms (n=8). These values are much higher than seen with sharp electrodes. A longer membrane time constant supports a greater temporal range for synaptic integration. In response to depolarizing current steps from rest, mean rheobase was 20 pA (n=3), and all exhibited a post-spike after-hyperpolarization. Some cells displayed post-inhibitory rebound spiking. While previous studies with sharp electrodes report phasic firing, we always observed sustained tonic firing and firing rate increased with increased current magnitude with a quasi-linear *f*-I relation. Sustained firing rates peaked at 17 Hz. Spontaneous EPSPs occupied a continuous range of amplitudes with a skewed distribution (mean=3.1mV, median=2.8mV). Several instances of temporal summation of EPSPs leading to spike recruitment were observed. We used ChAT::ChR2 mice to optogenetically recruit cholinergic axons to characterize synaptic responses. Blue light fiber-optic illumination typically elicited suprathreshold EPSPs and evoked responses fatigued dramatically with repeated stimulation.

The rate of recovery after fatigue was characterized using a paired pulse protocol. Synaptic fatigue lasted several seconds before synapses fully recovered (n=5). We also characterized multisegmental convergence with optogenetic activation of preganglionic axons in ventral roots. Thoracic postganglionic neurons received presynaptic innervation from several contiguous spinal segments, and synaptic response amplitude varied with more proximal segments having a greater amplitude. In summary, thoracic SPNs have greater capacity for synaptic integration and spiking than previously considered, largely due to a reduced membrane leak, but recruitment may be restricted by severe synaptic fatigue observed at preganglionic cholinergic synapses. These data highlight the role of thoracic ganglia as active participants in vasomotor signal conditioning rather than passive relays of information.

Title: Anatomy of mouse thoracic sympathetic chain ganglia and electrophysiological assessment of their multisegmental preganglionic input

Authors: *M. HALDER[1], M. CHOI[2], C. MACDOWELL[2], M. MCKINNON[2], M. SAWCHUK[2], S. HOCHMAN[2];
[1]Emory Univ., Alpharetta, GA; [2]Emory Univ., Atlanta, GA

Abstract: Paravertebral thoracic sympathetic postganglionic neurons (tSPNs) predominantly control vascular function in the upper/middle extremities yet their chain ganglia are practically inaccessible for physiological study. We developed an ex vivo adult mouse model that retains these chain ganglia in situ with intact ventral root (VR) connections to study pre- to post-ganglionic interconnections and undertook parallel anatomical studies to assess tSPN ganglia composition.We used thoracic VR stimulation to recruit segmental preganglionics to examine tSPN intersegmental population responses recorded with suction electrodes attached to individual ganglia. We observed multisegmental convergence of preganglionics onto individual thoracic ganglia. When recording from the T12 ganglia, we observed orthodromic responses after stimulation of T7-T12 VR. Overall, VR axons from the same segment usually evoked the largest responses in individual ganglia. Widespread divergence was also seen, particularly for

mid-thoracic segments. For example, T6 VR stimulation evoked responses in all recorded ganglia (T2-T12). We examined the sensitivity of evoked synaptic responses to stimulus frequency and nicotinic acetylcholine receptor (nAChR) antagonists. Evoked responses were reproducible at 0.1 Hz but progressively depressed at 1 and 10 Hz. The common nAChR ganglionic blockers hexamethonium and mecamylamine depressed evoked responses consistent with actions on α3β4-containing nAChRs. Tubocurarine also depressed responses but DHβE did not. We used immunohistochemistry to determine the numbers and soma diameters of choline acetyltransferase$^+$ (ChAT$^+$) cholinergic and tyrosine hydroxylase$^+$ (TH$^+$) noradrenergic neurons in thoracic ganglia T1-T13 (n=2). Neuron numbers peaked at T7 and T8. TH$^+$ neurons comprised 97% of tSPNs which had slightly larger diameters than ChAT$^+$ neurons (17.5 vs. 16.7μm, respectively). There were more ChAT$^+$ tSPNs in segments rostral to T6. When counts of select ganglia from other mice were included, a remarkable inter-animal variability in ganglion neuron numbers was seen. We conclude that; (i) preganglionic convergence and divergence patterns onto tSPNs are abundant and multisegmental, (ii) evoked synaptic responses have nAChR pharmacology consistent with actions on α3β4-containing nAChRs, and (iii) tSPN ganglia have highly variable neuron numbers but are composed almost entirely of TH$^+$ adrenergic neurons.

Abstract: Neuropathic pain can deteriorate quality of life in patients with a spinal cord injury(SCI), but the mechanism by which SCI causes dysfunctional pain signaling remains unclear. A reduction in gamma-aminobutyric acid(GABA)ergic signaling in the zona incerta(ZI) of a thoracic hemisection-SCI rat model has been suggested, but not clearly demonstrated. To test whether these GABAergic signals influence SCI-induced neuropathic pain, we recorded and compared *in vivo* single-unit, neuronal activity between hemisection-SCI and sham-treated rat models. Furthermore, we analyzed neuronal activity in these groups following treatment with a $GABA_A$ receptor agonist (muscimol) or antagonist (bicuculline). The hemisection-SCI rats show reduced hindpaw withdrawal thresholds, latencies, and decreased ZI neuronal activity, compared with those of the sham-treated controls. Importantly, muscimol treatment increased, whereas bicuculline decreased, the firing rates of the ZI neurons. The muscimol treated, hemisection-SCI rats also exhibited increased hindpaw withdrawal thresholds and latencies. Together, these data provide evidence that neuropathic pain after SCI is caused by decreased GABAergic signaling in the ZI. Furthermore, our data demonstrate that GABAergic drug infusion into the ZI could restore its inhibitory action and improve neuropathic pain behaviors.

Title: Exact analysis of spike-timing and higher-order interactions of neurons at the threshold regime suggests network architecture underlying sparse population activity

Authors: *S. RASHID SHOMALI[1], M. NILI AHMADABADI[2], S. RASULI[3], H. SHIMAZAKI[4];
[1]Sch. of Cognitive Sciences, SCS, Inst. For Res. In Fundamental Sci., Tehran, Iran, Islamic Republic of; [2]Sch. of Electrical and Computer Engin., Univ. of Tehran, Tehran, Iran, Islamic Republic of; [3]Dept. of Physics, Univ. of Guilan, Rasht, Iran, Islamic Republic of; [4]RIKEN Brain Sci. Inst., Wako, Japan

Abstract: The accurate prediction of how spiking of a presynaptic neuron affects spike timing of a postsynaptic neuron in vivo has significant importance in a variety of questions in

Neuroscience. An exact solution for this problem under conditions resembling in vivo, however, is lacking due to the nonlinearity of the neuron's spike generation mechanism. Neural activity in vivo exhibits significant variability. It is suggested that this variability reflects neuronal activity near the threshold regime, where small fluctuations of presynaptic neurons can significantly affect postsynaptic spike-timing. Here, we analytically investigate impact of a signaling input on a leaky integrate-and-fire neuron that receives background noise at the threshold regime. The signaling input models a synaptic or an assembly of nearly synchronous synaptic activity that conveys information while the background noise represents ongoing activity of many weak synapses. We demonstrate that, at the threshold regime, it is possible to obtain an exact solution that explains how the signaling input changes the spike-timing distribution. We then use the result to predict higher-order interactions of population activity caused by shared signaling inputs under different network architectures. This prediction allows us to uncover network architecture behind the population activity. In particular, we suggest architecture behind sparse population activity observed in monkey V1 or rat hippocampal neurons, which involves higher-order interactions. Contrary to common intuition, we find it unlikely that common inhibition causes the sparse activity; instead, we quantitatively show that the observed activity can result from local excitatory common inputs by comparing the theoretical prediction with empirical results obtained from the monkey V1 neurons.

Title: 5ht3a+ interneurons inhibit pv+ interneurons to enhance signal fidelity in hippocampal area ca1

Authors: *B. SUUTARI, S. M. COHEN, A. SALAH, R. W. TSIEN;
NYU Neurosci. Inst., New York, NY

Abstract: Inhibitory interneurons control gating of information transmitted from CA3 to CA1 of the hippocampus. Fast-spiking, parvalbumin+ interneurons (PV+ INs) are critical for feedforward inhibition to counterbalance excitatory synaptic inputs and provide fast, reliable control of pyramidal cell excitability and spike timing. However, PV+ INs are but one example of the much larger and more diverse population of inhibitory interneurons in the hippocampus. Non-PV+ INs containing the ionotropic 5HT3a receptor (5HT3aR) also participate in direct inhibition of CA1 pyramidal cells. In addition, these interneurons may mediate pyramidal cell disinhibition by inhibiting other interneuron types, including PV+ interneurons. The role 5HT3AR+ INs play in regulating pyramidal cell excitability in the CA1 microcircuit has not been fully explored.
We investigated the effects of 5HT3a+ interneurons' activity on the CA1 microcircuit, focusing on their specific control of pyramidal cell excitability and spike timing. We find that upon application of a 5HT3a receptor specific agonist (mCPBG), pyramidal cells spike more reliably, more precisely and with shorter latencies in response to Schaffer collateral stimulation. Furthermore, ChR2 stimulation of 5HT3a+ INs reduces the feed forward disynaptic inhibitory current, which is responsible for controlling pyramidal cell spike probability and timing. Given the critical role of PV+ interneurons in generating feed forward inhibition, we directly examined their excitability and spike timing while stimulating 5HT3a+ interneurons with mCPBG. PV+ interneurons responded to 5HT3a+ interneuron stimulation with lower spike probabilities, longer latencies, and increased inhibitory drive. These effects were the inverse of those seen in pyramidal cells, consistent with a disinhibitory role for 5HT3a+ interneurons. To understand how 5HT3a+ INs contribute to pyramidal cell inhibition vs. PV+ IN inhibition, we crossed 5HT3a-Cre mice with Lhx6-GFP mice. In future studies, these mice will allow us to optogenetically excite 5HT3a INs and record direct inhibitory responses in MGE-derived interneurons (both SST+ INs and PV+ INs). To explore potential network properties of the PYR-PV+-5HT3a+ IN circuit, we have developed a computational model to explore the impact of varying 5HT3a+ IN intrinsic biophysical and synaptic parameters with Monte Carlo simulations.

Title: Propagation patterns in spontaneous activity are state and frequency-dependent

Authors: *A. MITRA, P. W. WRIGHT, A. Z. SNYDER, G. A. BAXTER, A. Q. BAUER, J. P. CULVER, M. E. RAICHLE;
Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Spontaneous neural activity is widely known to exhibit correlation patterns described as resting state functional connectivity networks (Fox et al. 2005; White et al. 2011). The spatial topographies of these networks are stable over a wide range of frequencies (0.001-4 Hz) (Chan et al. 2015) and across different physiological states (e.g., wake vs. anesthesia) (Silasi et al. 2016). More recent work has demonstrated the existence of stereo-typed propagation patterns in spontaneous activity (Mitra et al. 2015; Mohajerani et al. 2010); however, it is not known how cortical propagation patterns compare across frequencies and states. Here, we apply wide-field optical imaging of a neuronally-expressed fluorescent calcium indicator in a *Thy1*/GCAMP6 transgenic mouse model to explore propagation patterns across a wide range of frequencies, 0.001-4 Hz, in both awake and ketamine/xylazine-anesthetized conditions. We find two distinct propagation regimes: one in the infra-slow frequencies (0.01-0.1 Hz) and one in delta frequencies (1-4 Hz). Infra-slow and delta activity generally propagate in opposite directions, although the propagation speeds between the two frequencies are different by an order of magnitude. Moreover, the directions of both infra-slow and delta propagation reverse across wake and anesthesia. Therefore, neural communication, as measured through propagation of activity, is radically re-organized across frequency and state.

Title: Closed-loop modulation of hippocampal gamma reveals a role of recurrent excitation in setting the oscillatory frequency

Authors: *E. NICHOLSON[1], D. KUZMIN[2], M. LEITE[2], T. AKAM[3], D. M. KULLMANN[2]; [1]Dept. of Clin. and Exptl. Epilepsy, UCL, London, United Kingdom; [2]Dept. of Clin. and Exptl. Epilepsy, Inst. of Neuology, UCL, London, United Kingdom; [3]Champalimaud Ctr. for the Unknown, Champalimaud Neurosci. Programme, Lisbon, Portugal

Abstract: Gamma oscillations in anatomically coupled brain areas can entrain one another they also show differences in their characteristic frequencies. Hippocampal CA3 oscillates at approximately 30 Hz, whereas CA1 can either be entrained to CA3, or oscillate at 50 Hz or higher frequencies, either from an intrinsic generator or by entrainment with entorhinal cortex. IPSC amplitudes and decay kinetics play a role in setting the frequency. However, a brief optogenetic excitatory pulse targeted to pyramidal neurons can advance or delay subsequent cycles of gamma depending on the phase at which it is delivered (Akam et al., 2012). This implies that phasic excitatory inputs to pyramidal neurons may also have an important role in setting the frequency of hippocampal gamma. We therefore asked whether continuous closed-loop optogenetic modulation of pyramidal neuron excitability could modulate the kinetic properties of gamma. The optogenetic actuator CIVI was expressed either in CA1 or in CA3 pyramidal cells by injecting an AAV with a Camk2a promoter. Hippocampal slices were perfused in a submerged recording chamber mounted on an upright microscope. Upon exposure to an increasing ramp of light delivered through the objective, the local field potential (LFP) recorded in the pyramidal cell layer exhibited a gamma oscillation. We used the instantaneous LFP, or its time derivative, to modulate the light intensity. In a subset of experiments we simultaneously recorded action potentials from individual pyramidal cells, or else recorded membrane currents while voltage-clamping neurons at the ionotropic GABAergic or glutamatergic reversal potential. Consistent with previous studies the frequency of gamma during unmodulated ramps was higher in CA1 than in CA3. Cycle-averaging whole-cell voltage clamp recordings revealed phasic glutamatergic and GABAergic currents in pyramidal neurons that reflect recurrent excitation and inhibition. Closed-loop modulation designed to change the phase and/or amplitude of phasic excitatory currents in pyramidal neurons led to characteristic changes in oscillatory frequency and amplitude. Advancing or delaying the phase of the excitatory drive

relative to inhibitory currents increased and decreased the gamma frequency, respectively. In addition, attenuating the amplitude of the phasic excitatory current increased the gamma frequency while reducing its amplitude. Conversely, amplifying the excitatory current reduced the gamma frequency while increasing its amplitude. We speculate that recurrent excitation among pyramidal neurons in CA3 contributes to the lower characteristic frequency of gamma compared with CA1.

Title: Gain control across cortical layers can be mediated by balanced oscillatory coupling.

Authors: *E. PETERSON, B. VOYTEK;
Cognitive Sci., U.C. San Diego, San Diego, CA

Abstract: The balance of “bottom-up” information from the senses with “top-down” goals, attention, and memories is one the most fundamental and heavily studied examples of information conflict in the human brain. Despite substantial work establishing the reality of top-down/bottom-up exchange in sensory cortices, the mechanism underlying this interchange is unknown. Neural oscillations, especially kinds of phase-amplitude coupling (PAC), are thought to play a key role. We've previously described a new mechanism that can explain biophysically how PAC can control information flow. When external oscillations interact with an asynchronous neural population via balanced excitatory-inhibitory input this enhances information flow, by improving the ability of the downstream population to separate signal from noise. In contrast, when oscillatory coupling is unbalanced, driven either by excitation or inhibition, information flow is obstructed. We now put this general mechanism to work in a extremely detailed neural mass model, derived directly from the Blue Brain neocortical microcircuit. This model demonstrates how oscillations and PAC can selectively route top-down versus bottom-up information within the cortical circuit, modeled as tradeoff between thalamic or cortico-cortico connectivity.

Title: Directional propagation of ketamine-induced high-frequency oscillations between the striatum, hippocampus, and motor cortex

Authors: ***M. B. SCHMIT**[1,2], T. YE[1,3], M. J. BARTLETT[1,4,5], T. FALK[1,5,4], S. L. COWEN[1,3,6]; [2]Neurosci., [3]Psychology, [4]Neurol., [5]Pharmacol., [6]Evelyn F. McKnight Brain Inst., [1]Univ. of Arizona, Tucson, AZ

Abstract: High-frequency oscillations (HFOs, 110-160 Hz) are relatively understudied patterns of activity found in the hippocampus, cortex, and basal ganglia (Tort et al., 2013). Although HFOs couple strongly to theta oscillations (Tort et al., 2008) they appear to be distinct from gamma oscillations in their mechanism (Jackson et al., 2011). They are also distinguished from gamma oscillations in their high coherence across different brain regions and between hemispheres (Haufler and Pare, 2014). Other studies have shown HFO coherence between regions, but the directionality of this coherence has not been studied. We hypothesize that HFOs follow a circuit, spreading sequentially through brain structures. We investigated this hypothesis by implanting electrode arrays in the nucleus accumbens (NAc), striatum, M1, and hippocampus of healthy rats. Rats received 5 injections of ketamine (20mg/kg, *i.p*) every 2 hours over an 11-hour period. Local-field and single-unit activity was continuously recorded from awake and freely-behaving animals. We found that repeated exposure to ketamine induced strong, highly coherent HFOs across multiple brain regions. To analyze the directionality of HFO propagation between regions, we used Granger prediction applied to local-field signals restricted to the HFO band. We found that, following ketamine injection, Granger prediction was directional from the NAc to DLS ($p < 0.05$, t-test) and NAc to CA3 ($p < 0.0001$, t-test). No significant difference in prediction direction was observed between M1 and DLS ($p = 0.74$, t-test). This suggests that the NAc is the first step in the circuit, with high-frequency activity propagating from this region to the cortex, striatum, and hippocampus. To control for issues related to volume conduction, electrodes were re-referenced relative to electrodes ~700 μM from the target electrode. Results from this analysis suggest that HFOs in NAc and M1 precede HFOs in the DLS (NAc to DLS $p < 0.0001$, M1 to DLS $p < 0.0001$). This also supports the idea that HFOs are locally generated in the NAc and M1, and that these generators influence the power of HFO activity in other regions.

This is consistent with findings by Hunt et al. (2013) that inactivation of the NAc with tetrodotoxin eliminates HFOs induced by NMDA antagonists. Our data suggests further that M1 contributes to the coordination of HFOs in connected structures. Given these results, it is conceivable that ketamine's therapeutic effects for the treatment of depression (P.R. Diamond, et al. 2014) and levodopa-induced dyskinesia (Bartlett et al., 2016) result from altered network-level communication in the HFO band.

Title: Intracellular dynamics during self-generated theta oscillations in the whole hippocampal preparation

Authors: ***F. FURMANOV**[1,2], S. WILLIAMS[3], J. A. WHITE[1];
[1]Biomed. Engin., Boston Univ., Boston, MA; [2]Interdepartmental Program in Neurosci., Univ. of Utah, Salt Lake City, UT; [3]Dept. of Psychiatry, Douglas Mental Hlth. Univ. Institute, McGill Univ., Montreal, QC, Canada

Abstract: In rodents, theta (4-12 Hz) oscillations are generated during movement related behavior and REM sleep, and are specifically associated with the encoding of spatial information during place cell activity. However, the mechanisms underlying network theta oscillations remain unclear. Intrinsic cellular properties such as membrane resonance and post-inhibitory rebound spiking have been proposed to have an important role in theta generation. To determine if such properties are critical, we took advantage of a whole hippocampal preparation that self-generates stable theta oscillations for over an hour. Using two-photon microscopy to visualize and target specific neuron subtypes expressing genetically encoded fluorophores, we carried out intracellular whole-cell recordings of inhibitory and excitatory cells in subiculum during ongoing network theta generation. Intracellular measures in current- and voltage-clamp indicate that CaMKII+ pyramidal cells exhibit a near-simultaneous increase in excitatory and inhibitory conductance during the rising phase of the LFP oscillation, resulting in spikes that occur near the peak of the oscillation. Further analyses of intracellular data indicate that spike timing is driven

by intense synaptic activity and not intrinsic mechanisms involving resonance or rebound spiking. In GAD2+ inhibitory interneurons, we observed two types of responses during theta oscillations. The first response was associated with lower impedance cells and characterized by spike discharge near the peak of theta, resulting from large depolarizations generated by an increase in excitatory conductance. Identical responses were observed in recordings targeting PV+ interneurons. A second, higher impedance GAD2+ population generated more variable responses and received a mixture of phase-locked excitation and inhibition, resulting in spike generation either at the trough or peak of theta. Overall, our data indicates that spike timing in pyramidal cells during theta oscillations is set by synaptic input consisting of recurrent excitation from other pyramidal cells and inhibition from two distinct interneuron populations.

Title: Specialized contributions of individual GABAergic medial septal neurons to hippocampal network activity

Authors: ***G. UNAL**[1], M. G. CRUMP[1], T. J. VINEY[1], T. ELTES[2], T. KLAUSBERGER[1], P. SOMOGYI[1];

Abstract: GABAergic neurons of the medial septum innervate the hippocampus and/or related extra-hippocampal cortical areas, and contribute to the coordination of network activity, such as theta oscillations and sharp wave-associated ripples (SWR), via a preferential innervation of GABAergic interneurons (Unal et al., 2015). Individual septal neurons show a wide range of activity patterns, which may be related to their different hippocampal/cortical target areas and/or different types of interneuron they innervate. We tested this hypothesis by extracellular single cell recordings and juxtacellular labeling of individual GABAergic medial septal neurons in vivo in urethane anaesthetized rats. We revealed that individual septal neurons display diverse hippocampal theta phase selectivity in their firing, and terminate in restricted parts of a single or limited number of hippocampal areas and layers. One group of neurons were silent during

SWRs, fired phase-coupled to the descending phase of the CA1 theta oscillatory cycle, and maintained their firing rate between theta and non-theta epochs. In contrast, a second group of neurons were active during SWRs, preferentially fired at the ascending phase of the CA1 theta cycle, and significantly increased their firing during theta oscillations compared to non-theta epochs. Individual medial septal GABAergic axons targeted only a limited range of interneurons in the hippocampus, as established on the basis of expression of molecular markers which are restricted to subsets of interneuron types. The results demonstrate great diversity in septal GABAergic neurons and suggest that they coordinate hippocampal and cortical activity between functionally related areas through highly specialized, target area and cell type-selective projections.

Title: Cell-type specific participation in sharp-wave dynamics in the CA3 region of the hippocampus

Authors: *N. P. SPRUSTON[1], D. L. HUNT[2];
[1]HHMI Janelia Res. Campus, Ashburn, VA; [2]HHMI Janelia research campus, Ashburn, VA

Abstract: Sharp-waves are network oscillations that occur during stationary wakefulness, slow-wave sleep, and under light anesthetics. These events emerge from recurrent network dynamics, reflecting the synchronous population activity of CA3 pyramids. Several reports have demonstrated that the CA3a/b sub-region is the preferential locus of initiation for sharp-waves, but little is known about the cellular and circuit mechanisms that give rise to these population events. To gain insight into the functional roles of CA3 cell-types during sharp-waves, we recorded juxtacellularlly, acquiring single units, multiunit activity (MUA), and the local field potential (LFP) from the CA3a/b sub-regions during the spontaneous occurrence of sharp-waves

in-vivo. We previously showed that there are at least two types of pyramidal neurons in CA3 (SfN abstract 576.09/B111), so juxtacellular units were loaded with biocytin for histological validation of cell-type based on the presence or absence of thorny excrescences and the fraction of spikes that were part of a burst (burst index). We analyzed juxtacellular activity relative to locally generated sharp-wave events detected in the LFP, which coincided with a transient increase in MUA measured at that location. We find that high burst-index cells, which lack thorny excrescences, emit a complex spike approximately 200-100ms prior to the peak of the LFP. This initial burst event lead to a slow accumulation of MUA up to a threshold point, at which an additional complex spike initiated a rapid, supralinear increase in MUA. This nonlinear increase in MUA consisted primarily of low burst index cells synchronously firing a single action potential, generating the LFP. These data suggest a revision to the classical picture of the CA3 recurrent network to include a functional segregation into thorny cells (with low burst index) that contribute single spikes to population activity, and athorny cells (with high burst index) that drive the accumulation of network activity to a threshold where a complex spike initiates a nonlinear increase in MUA.

Title: Spiking correlates and temporal variability of oscillatory frequency modulation

Authors: *R. GAO[1], E. J. PETERSON[2], B. VOYTEK[2,3,4];
[1]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, ; [2]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA; [3]UCSD Inst. for Neural Computation, La Jolla, CA; [4]Neurosciences Grad. Program, UCSD, La Jolla, CA

Abstract: Neural oscillations are extensively studied due to the putative role of dynamic changes in oscillatory power in neural communication, cognition, and disease. Canonically, oscillations are binned into discrete and functional bands such as theta (4-8Hz) or alpha (8-12Hz). Coherence

in these frequency bands has been used to identify long-range cortical networks in MEG (magnetoencephalography) and ECoG (electrocorticography) recordings. Recently, evidence from both empirical and computational studies has suggested that oscillatory frequency within a single band can itself shift dynamically, impacting behavioral outcomes. For example, in anticipation of an upcoming visual stimulus, alpha frequency can speed up or slow down, within the 8-12Hz bandwidth, to optimize perceptual outcomes.
Here, we analyze the moment-to-moment variation of band-limited oscillatory center frequency, bandwidth, and power in relation to single- and multi-unit activity, across several datasets from three species (human, rat, and macaque). Center frequency and bandwidth are defined as the median and interquartile range of instantaneous frequency, respectively, within a sliding window. Corroborating recent findings, oscillatory frequency within a single band is non-stationary and varies rapidly, suggesting a reevaluation of the stationarity assumption of Fourier analysis on neural electrophysiological data. We report consistently negative correlations between center frequency and bandwidth, but variable relationship between center frequency and oscillatory power (and firing rate) across different brain regions. Furthermore, local networks can be identified from clusters of recording electrodes with shared temporal variation of oscillatory frequency. Finally, we investigate possible mechanisms of frequency dynamics via computational modeling, exploring how frequency shifting in a single network and coherence between networks can impact observed neural oscillations.

Title: Bdnf val66met polymorphism impairs network oscillations in the hippocampus

Authors: *Y. HUANG;
Tongji Univ., Shanghai City, China

Abstract: Brain-derived neurotrophic factor (BDNF) is a key regulator of neuronal plasticity and cognitive functions. BDNF val66met polymorphism, a human single-nucleotide polymorphism in the pro-domain of BDNF gene, is common in human populations with an allele frequency of 20 to 30% in Caucasian populations, which is associated with deficits in hippocampus-dependent memory. As revealed in our results, reduction of total number of cells in hippocampal CA1 region of met/met mice was found. There was a trend of increase in the percentage of

parvalbumin (PV)-positive interneuron, yet the change of the number of PV-positive interneurons was not found. Hippocampal gamma and theta oscillations in CA1 region were impaired in met/met mice, whereas theta burst induced long-term potentiation (LTP) was not altered. In addition, the mRNA expression of GAD65 in the hippocampus was elevated in met/met mice compared with that in WT mice, but the expression level of GAD67 was not affected by BDNF val66met polymorphism. Moreover, hippocampal expressions of β2 and β3 subunit of GABA receptor were up-regulated in met/met mice compared with WT mice. Our results suggested that BDNF val66met polymorphism changes activity of subtypes of interneuron in the hippocampus, which may underlie neural network dysfunction and cognition impairment.

Title: Volitional control of beta-band oscillations by brain machine interface affects sensorimotor behavior of primates

Authors: *O. PELES[1,2], U. WERNER-REISS[1,2], H. BERGMAN[1,2], Z. ISRAEL[3], E. VAADIA[1,2];
[1]Dept Of Med. Neurobio., [2]Edmond and Lily Safra Ctr. for Brain Sci., Hebrew Univ., Jerusalem, Israel; [3]Hadassah Univ. Hosp., Jerusalem, Israel

Abstract: It is widely accepted that beta-band oscillatory activity plays an important role in the facilitation of neural synchrony essential for complex tasks such as planning and execution of

sensorimotor behavior. Previous studies suggested that beta-band oscillations in the motor cortex increase during hold periods, attenuate during movement initiation and re-emerge thereafter. However, the exact function of these oscillations is not yet understood.
We investigated the effect of beta-band oscillations on behavior by training two macaque monkeys, implanted with arrays of 96 electrodes in the motor cortex, to volitionally enhance beta-band (20-30Hz) oscillatory activity at local selected sites by neural operant conditioning, using a real time brain machine interface (BMI) platform. The monkeys were engaged in a behavioral task involving color discrimination. In addition, we tested the effect of electrical intracortical micro-stimulation (ICMS) on these spatiotemporal patterns.
We demonstrate that beta-band cortical oscillations can be robustly increased and that many neurons were phase locked to these oscillations. Furthermore, we found that the LFP beta-power before the execution of the motor action was positively correlated with the reaction times, and negatively correlated with behavioral performance (success rate).
Our results suggest that during high beta epochs new motor actions take longer to initiate and the perception of sensory inputs is impaired. These findings may support the widely accepted hypothesis that beta oscillations are tied to preservation of current motor state and help in unraveling the functional role of cortical oscillations and their effect on neural synchrony.

Title: Extracting neural networks formed by consistent between-cell spike timing from unit recordings

Authors: *R. VAN DER MEIJ[1], E. MARIS[2], B. VOYTEK[1];
[1]Dept. of Cognitive Sci., Univ. of California San Diego, La Jolla, CA; [2]Donders Inst. for Brain, Cognition, and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: It is widely assumed that distributed and overlapping neuronal networks are fundamental to brain functioning. These networks are thought to form in an ad hoc manner and encode information by the temporal activity patterns of the neurons that form them. How this occurs however, is not well understood. A hypothesis that has received recent empirical support is that information can be represented by the temporally precise spiking pattern among neurons forming a spike-timing network (also denoted as a cell assembly). Finding networks formed by consistent between-cell spike timing is challenging however, because the amount of possible spiking patterns grows exponentially with the amount of cells being recorded. At the same time, recent evidence suggests that such networks, if present, are small, making detection additionally problematic. Here, we present a technique that is capable of extracting neural networks formed by consistent between-cell spike timing from large-scale recordings of spike trains. This technique, denoted as SPACE, makes use of the spatial and temporal structure of such networks to find and separate them. Networks are described by (1) a weighting per neuron, describing how strongly they are part of the network-specific spiking pattern: (2) a set of between-neuron time delays describing the spiking pattern, and; (3) a weighting per epoch (e.g., a trial) indicating how strongly this network was present on any given trial. The latter can be used to quantify network presence between experimental conditions, and its relation to e.g., stimulus parameters or behavioral performance. Using simulations, we show that the technique is capable of finding spike-timing networks in a noisy environment, is robust to spike jitter, and can separate networks involving the same neurons. As such, the technique could be a valuable tool for investigating the prevalence and function of patterns in between-cell spike timing and uncovering functional neuronal networks in an unbiased manner.

Title: Fast-spiking neurons organize large-scale coherent oscillations and are the main generators of local field potentials in human and monkey cortex

Authors: *A. DESTEXHE[1], M. LE VAN QUYEN[2], N. DEHGHANI[3], E. HALGREN[4], S. CASH[5], N. HATSOPOULOS[6], B. TELENCZUK[1];
[1]CNRS, Gif-sur-Yvette, France; [2]ICM, Paris, France; [3]Wyss Inst., Boston, MA; [4]UCSD, San Diego, CA; [5]Harvard Med. Sch., Boston, MA; [6]Univ. of Chicago, Chicago, IL

Abstract: We analyzed recordings from Utah-type multi-electrode arrays, in human temporal cortex and monkey motor cortex, during wake and sleep states. To investigate the respective role of different cell types, we separated cells between fast-spiking (FS) and regular-spiking (RS) neurons based on spike shape, some of which were confirmed by direct pairwise interactions between cells from neighboring electrodes (Peyrache et al., PNAS 2012; Dehghani et al., Sci. Rep. 2016). FS and RS cells had different firing rates and autocorrelation attributes. Additionally, we found marked differences in their participation to LFP oscillations in the beta and gamma frequency range. Almost half of the FS cells participated actively to the oscillations, while only a smaller subset (<10%) of RS cells did participate. Furthermore, FS cells displayed long-range correlations while RS cells tended to be correlated only locally. Interestingly, during slow-wave sleep, LFP oscillations were maximally coherent, while pairwise interactions between FS cells were also the highest. Finally, we also determined the spike-triggered average LFP (stLFP), after removing correlations by whitening. The whitened stLFP propagated at the axonal speed across the array, suggesting that it represents a unitary field. The stLFP was in general broader for RS cells, while for FS cells it was sharper, of larger amplitude, and peaked earlier than for RS cells. This suggests that, not only FS cells have more impact on the LFP, but the RS cells contribution to LFP could be di-synaptic through FS cells, in which case the LFP would be generated almost exclusively by FS cells. We discuss possible biophysical mechanisms for how the LFP, although principally generated by pyramidal cells dipoles, could be generated almost exclusively by inhibitory conductances. Together, these results show that in human temporal and monkey motor cortex, FS cells have a determinant role, both at the level of the LFP signal itself, but also in the organisation of oscillations, and their large-scale coherence.

Title: Fast Oscillatory activity in the hippocampus can back-propagate electrotonically to the dentate gyrus

Authors: *F. ORTIZ[1,2], R. GUTIÉRREZ[1];
[1]CINVESTAV, Mexico City, Mexico; [2]Inst. de Fisiología Celular, UNAM, Mexico City, Mexico

Abstract: Fast ripples (FRs), which are intermittent high frequency oscillations (>250 Hz) are the hallmark of epileptic foci in the limbic system. While electrotonic coupling is a mechanism by which high frequency network activity (150-200 Hz) becomes synchronized, FRs depend mainly on chemical synaptic transmission. Although a synaptic back-projection from CA3 to the DG has been described, the mechanisms by which FRs emerge in the DG remain elusive. One possibility would be that electrical coupling between pyramidal and granule cells may be responsible for back-propagating signals. To address this, we used a traumatic brain injury model where the entorhinal cortex is disrupted *in vivo*, and that produces FRs in the hippocampus *in vitro*. We recorded extracellular field activity with a multielectrode array of 4096 microelectrodes from combined entorhinal cortex-hippocampal slices from young adult Wistar rats. We used the Granger causality test to determine the directionality of FRs propagation. Recordings were conducted under normal neurotransmission conditions (normal ACSF), after preventing chemical transmission (in low $[Ca^{++}]_o$; 0.2 mM) and, finally, after blockage of electrical transmission with mefluoquine (50 μm). Under these conditions, we assessed functional connections between neurons of CA3 and DG.
For a given experiment, FRs initiated in a restricted area of CA3b that was followed by activation of different areas of the DG before invasion of the adjacent CA3a and c regions. FRs propagation did not spread homogeneously from one site of origin, rather, activity appeared simultaneously in discontinuous sites and with different oscillatory frequencies. These results confirm the presence of a CA3-to-DG back propagation. Importantly, using the Granger causality test we confirmed that FRs in the hilus and DG were causally related to FRs originated in strata lucidum and radiatum of CA3, rather than in the pyramidal cell layer.
Perfusion of low $[Ca^{++}]_o$ ACSF suppressed FRs. Under these conditions, we used appropriate filters to record unitary activity characterized by firing of CA3 pyramidal cells and granule cells of the DG in an apparent random manner. Interestingly, functional bidirectional connections

from the DG to CA3 and from CA3 to DG could be verified by a robust correlation analysis. The perfusion of the connexin36-specific gap junction blocker mefluoquine suppressed about 50 % of functional connections. We conclude that FRs emerge in CA3 after which FRs appear in the DG and CA1 albeit with different frequencies and a measurable phase shift. Back propagation from CA3 to the DG via the mossy fibers may play a significant role in DG activation by CA3 activity.

Title: Identified cellular correlates of neocortical ripple and high gamma oscillations during spindles of natural sleep

Authors: *G. TAMAS, V. SZEMENYEI, S. BORDÉ, R. G. AVERKIN;
Univ. of Szeged, Szeged, Hungary

Abstract: Ultra-high frequency network events in the hippocampus are instrumental in a dialogue with the neocortex during memory formation, but the existence of transient ~200 Hz network events in the neocortex is not clear. Our recordings from neocortical layers layer II/III of freely behaving rats revealed locally generated field potential events at ripple and high gamma frequencies repeatedly occurring at troughs of spindle oscillations during sleep with no correlation to ongoing hippocampal ripples. Juxtacellular recordings identified subpopulations of fast spiking, parvalbumin containing basket cells with epochs of firing at ripple (~200 Hz) and high gamma (~120 Hz) frequencies detected during spindles and centered with millisecond precision at the trough of spindle waves in phase with field potential events but antiphase to pyramidal cell firing. The results suggest that basket cell subpopulation timed, spindle nested, high frequency network events might provide repeatedly occurring neocortical temporal reference states potentially involved in mnemonic processes.

Title: Intrinsic and extrinsic sources of GABAergic inhibition in the dentate gyrus

Authors: *G. G. SZABO[1], C. VARGA[2], I. SOLTESZ[1];
[1]Neurosurg., Stanford Univ., Stanford, CA; [2]Dept. of Physiol., Szentágothai Res. Center, MTA-PTE-NAP A-Entorhinal Microcircuits, Univ. of Pécs, Pécs, Hungary

Abstract: The hippocampus plays a crucial role in high order brain functions such as learning, memory and spatial navigation. The input structure to the hippocampus, the dentate gyrus (DG), appears to have a sparse coding scheme: the principal granule cells are rarely active during behavior. It is generally agreed that GABA receptor-mediated inhibition is necessary for maintaining this sparse activity. However, the exact sources of this GABAergic inhibition and their temporal and spatial organization are largely unknown. To address this question, we performed juxtacellular recordings in awake mice from rigorously identified hippocampal GABAergic cells that innervate the DG. The local interneurons we recorded belonged to four neurochemically defined categories of somatostatin (SOM), parvalbumin (PV), nitrogen-monoxide synthase (NOS) and cannabinoid type I receptor (CB1)-expressing cells. Strikingly, we also identified GABAergic neurons from each neurochemical group in the CA3 and CA1 regions that have axonal projections to the DG (DG_{GABA}EXT cells). Both local DG interneurons and DG_{GABA}EXT cells were strongly modulated by running-associated theta rhythm and gamma oscillation. We also found that all the local interneurons recorded in the hilus or in the granule cell layer increased their spiking frequency during dentate spikes, a synchronous population event thought to be triggered by population bursts in the entorhinal cortex. In addition, sharp-wave-ripples (SWRs), which are synchronous population events generated in the CA3/CA1 network, modulated the firing frequency not only of DG_{GABA}EXT cells but the spiking activity of local DG interneurons as well. The modulation of GABAergic cells during SWRs appeared to be bidirectional: most neurons increased their firing rates, while others robustly reduced their firing rate during SWRs. This reduction of spiking during SWRs is most likely due to perisomatic inhibition resulting from inhibitory-inhibitory connections. Our results show that the dentate granule cells are under the influence of both intrinsic and extrinsic sources of GABAergic

inhibition that are temporally organized by various oscillations and synchronous population patterns with local and extra-dentate origin. These findings suggest that the sparse coding in the dentate gyrus is maintained by a complex GABAergic control including contributions from hippocampal regions external to the dentate gyrus. Title: Changes in network dynamics and prefrontal spiking activity in a mouse genetic model of schizophrenia: implications for connectivity

Authors: *J. L. ZICK[1,2], K. SCHULTZ[4], T. I. NETOFF[1,3], M. V. CHAFEE[4];
[1]Neurosci., Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN; [2]Med. Scientist Training Program (MD/PhD), [3]Biomed. Engin., Univ. of Minnesota, Minneapolis, MN; [4]Brain Sci. Ctr., VA Med. Ctr., Minneapolis, MN

Abstract: Disordered connectivity appears to be a key pathophysiological feature of schizophrenia. Measures of temporal correlation between regions of the brain are consistently reduced in schizophrenic patients upon functional imaging; however, evidence for functional disconnection at the cellular level is limited. Here we describe a study in which we assessed functional connectivity between spiking neurons in a mouse genetic model of schizophrenia. Neural data were obtained from multielectrode recording arrays inserted into the infralimbic and prelimbic areas of awake Dgcr8$^{+/-}$ mice and their littermate controls. Heterozygous deletion of the Dgcr8 gene is used to model the 30-fold increase in risk for schizophrenia which is seen in human patients with DiGeorge syndrome. In order to investigate hypothesized alterations in spike timing in the disease state, we identified the distribution of interspike intervals between putative pre- and postsynaptic neurons. In our analysis we found a prominent “zero-lag” peak representing a large number of coincident (within 1 millisecond) action potentials between coupled cells in the control mouse data, but not in the Dgcr8$^{+/-}$ mice. This suggests a change in the timing of action potentials which was apparent in the absence of a change in firing rates,

precluding overall decreased activity as an explanation for reduced synchrony. Additionally, we found evidence of bursting activity consistent with hippocampal sharp wave modulation of prefrontal activity in the awake resting state. These events are significantly more frequent in Dgcr8$^{+/-}$ mice, suggesting that dysregulation of prefrontal-hippocampal communication may be a key feature of this model and of schizophrenia. In summary, these results suggest disordered functional connectivity within the prefrontal cortex and between prefrontal cortex and hippocampus which may be related to a Hebbian reduction in synaptic strength resulting from desynchronization of spiking activity.

Title: Association of ketamine, dopamine D4 receptor activation, and locomotion with gamma range activity in the prefrontal cortex and mediodorsal thalamus

Authors: *K. E. FURTH[1,2,3], A. J. MCCOY[1], J. R. WALTERS[1], A. BUONANNO[3], C. DELAVILLE[1];
[1]Neurophysiological Pharmacol., NINDS, NIH, Bethesda, MD; [2]Grad. Program for Neurosci., Boston Univ., Boston, MA; [3]Section on Neurobio., NICHD, NIH, Bethesda, MD

Abstract: An acute, subanesthetic dose of the NMDA antagonist ketamine is used to model early stage schizophrenia, and increases cortical gamma oscillation power (40-70Hz) in healthy humans and rats. As reduction of this ketamine-induced cortical gamma power has been proposed to predict antipsychotic drug efficacy, we tested the ability of a dopamine D4 receptor (D4R) agonist to decrease ketamine-induced gamma power. We also compared gamma oscillations induced by ketamine to those induced by walking in the medial prefrontal cortex (mPFC) and its major thalamic source of innervation, the mediodorsal thalamus (MD), at the

LFP and single neuron levels.
Following 10 mg/kg ketamine, recordings from chronically implanted electrodes in male Long Evans rats walking on a treadmill showed a 254% increase in gamma LFP power centered at 55Hz in the mPFC, associated with increases in pyramidal neuron firing rates (33%) and pyramidal spike-gamma LFP correlations (107%). Treadmill walking also increased gamma power (centered at ~51Hz), firing rates, and spike-gamma LFP correlations in the mPFC. Notably, these walking-induced increases were less pronounced than those induced by ketamine. By contrast, in the MD, ketamine decreased firing rates (-46%) and the correlation between spikes and gamma oscillations (-34%) and increased gamma power by 31%, whereas walking increased gamma power, firing rates and correlation between spikes and gamma oscillations. In addition, ketamine did not change the gamma range coherence between the mPFC and MD, suggesting that synchronized inputs from neither area is driving gamma activity in the other. D4R agonists and antagonists can modulate gamma power and cognitive performance in animals, making D4Rs pro-cognitive targets in schizophrenia. The D4R agonist A-412,997 increased gamma power in the mPFC and MD, and the D4R antagonist L-745,870 reversed this increase. When injected before ketamine, neither the D4R agonist nor antagonist altered ketamine-induced changes in gamma power or firing rates in the mPFC. However, the D4R agonist increased ketamine-induced gamma power in the MD and reversed ketamine's inhibitory effect on firing rates.
Results show that gamma oscillations induced by walking and ketamine are similar in the mPFC, hinting at a common circuit underlying both oscillations. However, the differences in neuronal correlates of walking- and ketamine-induced gamma oscillations in the MD suggest that these oscillations arise from different mechanisms. Thus, walking-induced gamma oscillations are more similar between the mPFC and MD thalamus, while ketamine-induced gamma oscillations show region-specific differences.

Title: Mutual influence of ROS, pH_i and chloride current in cell cycle progression of glioblastoma cancer stem cells

Authors: I. VERDUCI[1], M. PERETTI[1], F. M. RACITI[1], R. WURTH[3], F. BARBIERI[3], T. FLORIO[3], *M. MAZZANTI[2];
[1]Biosci., [2]Univ. di Milano, Milano, Italy; [3]Sezione di Farmacologia, Dept. di Medicina Interna, Univ. di Genova, Genova, Italy

Abstract: Glioblastoma (GBM) is the most aggressive and lethal among the brain tumors and finding a possible therapy still represents a big challenge. Cancer stem cells (CSCs), a small fraction of self-renewing cells, are responsible for GBM origin, progression and recurrence, also originating non-CSC population composing the bulk of the tumor. The broad aim of our investigation is to find specific pharmacological targets to eradicate CSCs.
We have previously shown a pivotal role of the Chloride intracellular channel 1 (CLIC1) protein in the tumorigenic potential of CSCs isolated from grade IV human GBM and that CLIC1 is essential for proliferation and self-renewal of GBM CSCs. In physiological conditions this protein is mostly cytoplasmic but, under stress conditions, it translocates to the membrane, where it acts as an ion channel. CLIC1 is poorly expressed in the membranes of human differentiated GBM cells and in umbilical cord mesenchymal stem cells, underlining its CSCs specificity. CLIC1 role in CSC activity occurs during cell cycle progression. CLIC1 channel inhibition leads to a partial but significant arrest of GBM CSCs in G1 phase. Previous reports showed both pH_i and reactive oxygen species (ROS) fluctuation during cell cycle. In recent investigation, the influence of pH_i changes and cytoplasmic oxidation on CLIC1 membrane translocation was demonstrated. We now report the relationships that links these three elements during G1/S phase transition. Cytoplasmic alkalization promoted by the Na^+/H^+ (NHE1) exchanger is able to enhance both CLIC1 membrane localization and chloride current. During the transition from G1 to S phase, pH_i levels increase simultaneously with CLIC1 membrane localization and the increase of chloride current. Furthermore, impairment of NHE1 function along G1 phase progression does also alter CLIC1-mediated current.
Since ROS production by NADPH oxidase is also involved in CLIC1 activity and G1/S phase progression, our current hypothesis is that CSCs undergo a tight regulation in which ROS, pH and chloride currents create a virtuous (vicious?) loop which enhances CSCs viability and is responsible for GBM aggressiveness. Giving its specificity on CSC membranes, CLIC1 represent, among the three regulatory proteins, the most suitable novel pharmacological target.

Title: Inhibition of glioma progression by a novel compound of anthraquinone

Authors: *K.-Y. CHEN[1], S.-J. KANG[2], Y.-H. CHIANG[3], J.-C. WU[3], H.-S. HUANG[4]; [2]Dept. of Med. Lab. Sci. and Biotech., [3]Dept. of Surgery, Col. of Med., [4]The Ph.D. Program of Cancer Biol. and Drug Discovery, [1]Taipei Med. Univ., Taipei, Taiwan

Abstract: Aim:
High grade gliomas are the most common type of malignant brain tumor, and cause significant morbidity and mortality. Anthraquinone drug displayed antiproliferative activity and used for carcinoma treatment. However, these drugs also have cardiotoxicity that limited their applicability. A new group of anthraquinone-based analogs, LCC, has less toxicity on the heart, and its effects and dosage is investigated on in vitro and in vivo glioma models.
Methods:
Human glioma tumor cell line U87MG was seeded in 96-well plates and treated with LCC (1, 10 and 100 μM) for 24 and 48 hours. The cell viability was analyzed by SRB assay. Apoptotic cell numbers were detected by flow cytometry. In vivo study, we used Subcutaneous Xenograft Tumor Models. U87MG was injected subcutaneously and treated with 100μM LCC for 24 hours in 0.1 ml of the cell suspension (1×10^6 cells). Then, nude mice were sacrificed and tumor volume were measured.
Results:
In our study, based on the results of SRB assay and flow cytometry analysis, we observed that cell survival was decreased and cell numbers in sub G1 phase increased after drug treatment. In addition, the tumor volume significantly reduced after LCC treatment in the Subcutaneous Xenograft Tumor Model.
Conclusion:
In conclusion, cell proliferation activity of U87MG was inhibited by LCC both in vitro and in vivo. Lastly, LCC may be a potential candidate for glioma treatment in the future.

Title: Inhibition of sonic hedgehog signaling suppresses glioma stem-like cells through inducing autophagic cell death

Authors: *P.-W. GEAN[1], H.-C. HUNG[2];
[1]Natl. Cheng-Kung Univ., Tainan 70101, Taiwan; [2]Pharmacol., Natl. Cheng-Kung Univ., Tainan, Taiwan

Abstract: Glioma stem cells (GSCs) are thought to contribute to tumorigenesis and recurrence. In this study, we isolated GSCs from human glioblastoma U87 cell line by Magnetic-activated cell sorting (MACS) using CD133 as a marker. These $CD133^+$ glioma cells exhibit self-renew property and stem cell markers. We inoculated $CD133^+$ or $CD133^-$ cells (1×10^4) subcutaneously into the nude mice and 10 days later, tumors were observed in $CD133^+$ cells but not $CD133^-$ cells inoculated mice. Western blotting analysis showed that Sonic hedgehog (Shh) expression is higher in $CD133^+$ cells than in $CD133^-$ cells. Immunocytochemical analysis revealed that over 90% of $CD133^+$ cells were positive for Shh. Application of Shh inhibitors LDE225 induced cell death and reduced the number of neurospheres. In LDE225-treated cells, appearance of large membranous vacuoles in the cytoplasm which is a characteristic feature of cells undergoing autophagy was observed. Immunoblotting revealed the conversion of LC3-I to LC3-II. In addition, p62 increased at 2 h and returned to baseline within 12 h after the treatment of LDE225. Finally, LDE225-induced cell death was reversed by autophagy inhibitor 3-methyladenine (3-MA) suggesting that autophagy plays a critical role in LDE225-induced cell death. Lenti-shRNA-*Shh* inhibited tumor growth in intracranial glioma xenograft model. These results suggest that the Shh inhibitors may be developed as a new therapeutic strategy against malignant gliomas.

Title: Sevoflurane may increase glioma cell invasion via CD44

Authors: *Z. ZUO, R. LAI, W. SHAN;
Dept of Anesthesiol, Unvi of VA, Charlottesvle, VA

Abstract: Patients with cancer often require surgery or procedure under general anesthesia. Studies have shown that anesthetics may affect cancer cell biological characteristics. Whether sevoflurane, a commonly used anesthetic in current practice, has any effects on glioma cells is still unknown. Here, we show that sevoflurane dose-dependently increased the invasion of human glioma cells. Sevoflurane also increased the expression of CD44 and calpain activity. Silencing the expression of CD44 attenuated sevoflurane-induced increase of glioma invasion and calpain activity. We conclude that CD44 mediates sevoflurane-increased invasion of human glioma cells and that a downstream event includes calpain activation.

Abstract: Glioblastoma is the most common and lethal type of brain tumor in adults. The discovery of glioblastoma stem cell (GSC) showed that the GSCs are able to repopulate the tumors and this side population is more resistant to current therapy than bulk tumor cells. Therefore, GSC targeted therapeutics is urgently needed for treatment of glioblastoma. TLX is an orphan nuclear receptor that plays important roles in maintaining normal neural stem cells at the self-renewable state. TLX has also been shown to be involved in tumorigenesis and progression of glioblastoma in mouse models. Here, we show that TLX is critical to promote the growth, self-renewal and tumorigenesis of GSCs derived from patient samples of multiple glioblastoma subtypes. TLX, as a transcription factor, regulates the self-renewal of GSC through suppressing the expression of downstream target genes such as the DNA hydroxylase Ten eleven translocation 3 (TET3), an important epigenetic regulator. Potential therapeutics including both viral vector delivered shRNA and nanovector delivered siRNA have been developed to target TLX in GSCs in patient derived xenograft models. Using DNA microarray analysis, we identified a set of novel TLX downstream target genes/pathways. How TLX regulates these downstream genes/pathways to regulate GSC self-renewal and tumorgenesis is under investigation. In addition, we are developing new ways to deliver TLX siRNAs into GSCs in order to establish more effective therapies for glioblastoma.

Title: *In vitro* antiglioma action of indomethacin is mediated via AMPK/mTOR signaling pathway

Authors: *A. PANTOVIC[1], A. PANTOVIC[2];
[1]Neurol., Military Med. Acad., Belgrade, Serbia; [2]Military Med. Acad. and Inst. for microbiology and immunology Sch. of Med. Univ. of Belgrade, Belgrade, Serbia

Abstract: We investigated the role of the intracellular energy-sensing AMP-activated protein kinase (AMPK)/ mammalian target of rapamycin (mTOR) pathway in the in vitro antiglioma effect of the cyclooxygenase inhibitor indomethacin. The toxicity of indomethacin towards U251 human glioma cell line, determined by crystal violet/MTT assay, was associated with oxidative stress, caspase activation, and the induction of apoptosis, as determined by flow cytometry. An immunoblot analysis revealed that indomethacine increased the phosphorylation of AMPK and its targets Raptor and acetyl-CoA carboxylase (ACC), while it reduced the phosphorylation of mTOR and its substrate p70S6 kinase (S6K). The phosphorylation of the upstream mTOR activator Akt was increased by indomethacine, thus excluding its involvement in the drug-induced mTOR suppression. AMPK knockdown by RNA interference, as well as the treatment with the mTOR activator leucine, prevented indomethacin-mediated mTOR inhibition and proapoptotic action. Indomethacin failed to increase beclin-1 expression, intracellular acidification, and autophagic flux, and genetic or pharmacological inhibition of autophagy had no effect on its antiglioma activity, arguing against the involvement of autophagy in the observed effect. AMPK activation by indomethacin correlated with intracellular ATP depletion, and was apparently independent of cyclooxygenase inhibition or the increase in intracellular calcium. Finally, the toxicity of indomethacin towards glioma cell lines established from glioblastoma multiforme patients was also associated with the activation of AMPK/Raptor and subsequent suppression of mTOR/S6K signaling. By demonstrating the involvement of AMPK/mTOR pathway in the antiproliferative/proapoptotic action of indomethacin in glioma cells, our results support its further exploration in glioma therapy.

Title: The impact of ionotropic glutamate receptors on glioblastoma stem-like cells upon ionizing radiation

Authors: H. LUTZ[1], *H. A. BRAUN[2], B. LAUBE[1];
[1]TU Darmstadt, Darmstadt, Germany; [2]Univ. Marburg, Marburg D-35037, Germany

Abstract: Ionizing radiation, combined with surgical resection and chemotherapeutics, is the standard therapy for people suffering from glioblastoma mulitforme. Despite this aggressive therapy the median survival of patients is in the range of 15 months due to recurrence of the cancer in almost all patients. This therapeutic resistance is probably promoted by a currently discussed and highly tumorigenic subpopulation of glioblastoma stem cells (GSC), which are in focus of many new therapeutic approaches. It is proposed that the migration of glioblastoma stem cells is induced by sub curative doses of ionizing radiation as well as glutamate. Additionally glutamate increases the viability and proliferation of glioblastoma cells, while it induces excitotoxicity in the normal neural tissue. These abilities of GSCs to resist therapy and to migrate in the surrounding tissue might promote the recurrence of the glioblastoma in close proximity to the primary tumor. Our group was able to show the functional expression of NMDA and AMPA receptors in the glioblastoma cell line LN229 by immunofluorescence staining and patch clamp technique. We used the NMDA receptor antagonist Ifenprodil and the AMPA receptor antagonist Gyki-52466 to reduce the migration of these cells significantly. In LN229 cells MK-801 and NBQX delay the repair of DNA double-strand breaks, indicated by γH2AX and 53BP1 foci, after irradiation. Latest results show that this effect is even more prominent in $CD133^+$ glioblastoma stem cells. This observation leads to the question of the role of glutamatergic signaling in glioblastoma stem cell, the underlying mechanisms and the applicability for tumor treatment.

Title: Heterogeneous glioblastoma cell responses to TNF depend on molecular subtype.

Authors: ***M. E. BARISH**[1], A. MIZES[1], B. BREWSTER[1], N. BAGHDADCHI[1], C. E. BROWN[2];
[1]Neurosciences, [2]Immuno-Oncology, Beckman Res. Inst. City of Hope, Duarte, CA

Abstract: Glioblastoma multiforme (GBM), one of the most aggressive of human cancers, displays wide variation between patient tumors. To impose an orderly classification, patient tumors have been stratified, and while the tumor subtype classifications that have emerged vary, there is a consensus that two ends of the spectrum are anchored by the proneural (PN) and mesenchymal (Mes) subtypes. PN tumors are associated with preferential expression of neural stem and progenitor cell markers, and Mes tumors with mesenchymal markers and markers of epithelial-to-mesenchymal transition (EMT). Regions within a tumor may vary in subtype, and for GBM up to one-third of total cells may be microglia and tumor associated macrophages. Overall, the interplay of intrinsic molecular subtypes with the tumor microenvironment is complex.
We examined how GBM molecular subtype and differentiation status influence invasive behaviors. The microglia/macrophages associated with GBM secrete a number of proinflammatory cytokines including tumor necrosis factor (TNF). We have reported that in vitro, TNF up-regulates GBM cell expression of the adhesion molecule VCAM-1 (Mahadev et al., PLoS One 9: e95123; 2014). To compare GBM cells of varying molecular subtype and differentiation status, we utilized a cohort of patient-derived primary glioma cell lines characterized by TCGA signature gene expression as PN or Mes (Brown et al., PLoS One 8: e7769; 2013), grown in culture with stem-like or differentiated cell properties (Brown et al., Cancer Res 69: 8886-8893; 2009). We used a “dot migration assay” that recapitulates in vivo brain tumor dissemination along blood vessels and associated ECM (Baghdadchi et al., in preparation), and measured spatial dependence of tumor cell morphology and physical interactions with other tumor cells, migration, and expression of tumor adhesion molecules and other markers, by immunofluorescence.

We examined responses to TNF by proneural (PBT003) and mesenchymal (PBT017) GBM cell lines over a period of six days (as with chronic exposure in vivo). Our most striking observation is that the (PN) PBT003 and (Mes) PNT017 cells differ markedly in their VCAM-1 expression responses to TNF. Specifically, VCAM-1 immunoreactivity is initially low on (PN) PBT003 cells and is markedly enhanced by exposure to TNF (10 ng/ml). In contrast, VCAM-1 immunoreactivity is initially higher on (Mes) PBT017 cells and is decreased on chronic exposure to TNF.
While this study is on-going, these observations suggest that patient tumor responses to activated microglia and macrophages may be regionally disparate depending on local molecular subtype.

Title: Antineoplastic activity of cannabidiol combined with DNA-damaging agents in glioma cells

Authors: ***L. DENG**[1], L. NG[1], T. OZAWA[2,3], E. C. HOLLAND[2,3], N. STELLA[1];

Abstract: DNA-damaging agents remain the main standard care treatment for patients diagnosed with gliomas. Evidence suggests that the non-psychotropic cannabis-derived compound, cannabidiol (CBD), has antineoplastic activity in multiple subtypes of cancers, including gliomas. Here we studied the anti-proliferative response and the effects on cell viability triggered by CBD alone and in combination with three DNA-damaging agents (e.g., temozolomide, carmustine and cisplatin) in glioma cells and healthy neuroprogenitor cells in culture. Cell proliferation is assessed using the bromodeoxyuridine (BrdU) cell proliferation assay whereas cell viability is measured using water soluble tetra-zolium salt (wst-1) reagent. We found that CBD induced a sharp, dose-dependent reduction on both proliferation and viability of glioma and neuroprogenitor cells with similar potency (2-5 μM). Co-treatment analyses showed that CBD

produced synergistic responses with DNA-damaging agents over a limited range of concentrations in most glioma cells tested as well as in neuroprogenitor cells. However, antagonistic responses were also observed under certain concentration conditions in selected glioma cells, including mouse glioma cells with amplified PDGF signaling. Our study suggests limited synergistic activity when combining CBD with DNA-damaging in gliomas, along with no therapeutic window when taking into account of its effects on healthy neuroprogenitor cells. Supported by NIH (DA014486 to NS).

Title: Synthesis and characterization of a novel copper-containing nano-biocomposite for potential drug delivery and imaging in brain

Authors: *M. A. DECOSTER[1,2], D. MILAM[2], A. KARAN[2], M. DELAHOUSSAYE[2]; [2]Biomed. Engin., [1]Louisiana Tech. Univ., Ruston, LA

Abstract: Nanomaterials and nanoparticles (NPs) offer opportunities for tools in neuroscience, for example, to cross the blood brain barrier, thereby targeting and delivering therapeutics to different stages of brain tumors. While comparing the relative toxicities of iron and copper NPs towards brain tumor (glioma) cells in culture (using the cell line CRL-2303 from ATCC), we discovered that over the long term (82 hours), copper NPs transformed from individual particulates ranging from 25-100 nm in diameter, to larger clumps in the micron range, and finally to large clusters with high-aspect ratio structures (HARS) similar to “urchin” like structures. Under identical conditions and concentrations iron NPs were largely inert and non-toxic. To investigate the chemical mechanism behind this transformation, we stepwise subtracted components from the glioma cell cultures, while retaining physiological conditions. We discovered by this subtractive process that a component of the cell culture media, the amino acid cystine, was responsible for the HARS development. Remarkably, we have now simplified and accelerated the process, so that copper HARS can be formed biochemically, without cells or cell culture proteins, but with only key components including cystine, water, and slightly basic

conditions using NaOH to solubilize the amino acid. Self-assembly synthesis can now be accomplished in under 6 hours. We have discovered a second synthesis route, by providing the copper source from copper sulfate. This gives a cleaner yield of HARS, as copper sulfate is completely soluble in water. Both transmission and scanning electron microscopy proved that these synthesized HARS scale from the nano- to the micro- in diameter, with lengths of a few microns to hundreds of microns. Cystine, the dimer of the amino acid cysteine, has a disulfide bond, and many sulfur-containing molecules are known to bind copper and to serve as chelators and antioxidants. We have purified and stabilized these novel copper HARS from the liquid synthesis so that they can be dried and produced in milligram quantities. Using these purified HARS we have added them back to brain tumor cells as well as brain microglia. The copper HARS are less toxic on a mass/volume level than pure copper NPS (tested at 10-200 ug/ml), and distinct from a number of other developed nanomaterials, these novel copper HARs are slowly biodegradable, being broken down and phagocytosed by brain microglia and glioma cells in culture over 2-3 days, in comparison with 8-12 hours for pure copper NPs. These properties of a novel copper containing nanocomposite may provide benefits for brain cell imaging and therapeutics, such as drug delivery.

Title: Microglial properties of glioblastoma as potential therapeutic targets

Authors: ***G. D. MANOCHA**[1], J. A. KULAS[1], T. N. SEYFRIED[2], C. K. COMBS[1];
[1]Basic Sci., Univ. of North Dakota, Grand Forks, ND; [2]Biol., Boston Col., Boston, MA

Abstract: Glioblastoma multiforme (GBM) is a highly invasive brain cancer associated with poor prognosis. It is typically characterized by heterogeneity including microglia/macrophage phenotype cells that appear to contribute to the poor outcomes. In order to better understand the contribution of microglial/macrophage-like cells to disease a highly invasive *in vivo* GBM model was developed from a spontaneous brain tumor (VM-M3). As seen in human GBM, the VM-M3 tumor cells invade throughout the brain using the “Secondary Structures of Scherer”. Additionally, the VM-M3 cells express properties similar to those of macrophages including phagocytosis and expression of a number of macrophage/microglia associated genes. We

hypothesize that the macrophage/microglia-like properties of the invasive VM-M3 tumors can be targeted therapeutically with strategies typically employed to limit microglial activation. In order to test this idea, cells grown from the VM-M3 tumors were further examined *in vitro*. As previously shown, these cells demonstrated many properties of microglia including immunoreactivity for macrophage/microglial specific proteins such CD68, CD11b, and F4/80. The cells also exhibited phagocytic uptake of fluorescently labeled β-amyloid peptide. LPS stimulation of the VM cells increased TNF-α and IL-6 secretion and activated a number of cell signaling pathways including the tyrosine kinases Lyn and Src and the MAP kinase, JNK. More importantly, the brain penetrant Src/Abl inhibitor, dasatinib, was able to inhibit proliferation of these cells. These data support the idea that strategies targeting microglial activation may be efficacious at attenuating the microglial/macrophage-like GBM cells to affect disease progression.

Abstract: Glioblastoma multiforme (GBM) is a genomically complex and aggressive primary adult brain tumor, with a median survival of 12 - 14 months. The heterogeneous nature of this disease has made the clinical treatment difficult. Using Patient Derived Xenograft (PDX) models of untreated GBM patients we have generated a model (and evaluated the efficacy of various compounds for GBM therapeutic treatments. We also generated a 3D GBM culture system for screening potential drug compounds for personalized clinical applications. The 3D GBM culture system of patient's survival model was constructed and validated on independent data sets that demonstrated an excellent prediction of GBM patients survival (log-rank test: p = 0.0001). Using

a multivariate Cox proportional hazards model we identified that our 3D GBM model is distinct from other known GBM criteria (age at diagnosis, extent of surgical resection, post-operative Karnofsky Performance (KPS) score, treatment with temozolomide (TMZ) chemoradiation, and methylation of the MGMT gene). A five -fold cross-validation of our PDX model generation procedure confirmed validation of our 3D GBM model system. The model was further validated on an independent set of compounds such as CEP5003 that is capable of crossing the blood brain barrier and selectively targeting GBM Cancer Stem Cell (CSCs). Our data demonstrate that CEP5003 selectively targets GBM CSCs and we hypothesize that the clinical use of this class of compounds will improve quality of life and overall survival of GBM patients.

Title: Brain structural changes after treatment of cerebellar tumors in children

Authors: J. TANEDO[1,2], D. SACCHETTO[1], F. YEPES[1], J. COLOIGNER[1], M. DESCOTEAUX[4], M. D. NELSON, Jr[1,3], N. LEPORE[1,3], *M. BARON NELSON[1,3]; [1]Children's Hosp. Los Angeles, Los Angeles, CA; [2]Sch. of Engin., [3]Keck Sch. of Med., USC, Los Angeles, CA; [4]Univ. of Sherbrooke, Sherbrooke, QC, Canada

Abstract: Introduction
Chemotherapy is a frontline treatment for brain tumors in very young children. However, there is evidence that chemotherapy leads to long-term brain tissue damage and resulting neurocognitive deficits in children [1,2]. MRI techniques can be used to quantify changes in brain structure due to injury. In particular, diffusion tensor imaging measures the diffusion of water in neural structures and can be used to derive indices that reflect changes to healthy brain tissue. Mean diffusivity (MD) can be used to assess cellular and fiber injury across gray and white matter as the values reflect cell size, shape and integrity, and molecular motion across tissues. Fractional anisotropy (FA) values can be used to assess axonal integrity in white matter tissue as these values reflect the degree of alignment within fiber tracts [3].

Methods
DTI was obtained as part of routine brain MRI scans for 6 subjects with posterior fossa brain tumors treated with surgery and chemotherapy at least one year ago (age at scan: 11.5 years +/- 4.5, 2M 4F) as compared to 7 age- and gender- matched healthy sibling controls (age at scan: 10 years +/-3, 3M 4F).
Imaging was acquired with a 3T Philips Achieva scanner using a novel fast DTI sequence, with parameters: 70 axial slices (1 mm thick), FOV = 256 mm x 256 mm x 140 mm, TR/TE 8657/86 ms, no gap, with a 128x126 acquisition matrix, 28 gradient images were collected with b-value=1500 . T1 images were also acquired with a voxel size of 1.0 x 1.0 x 1.0 mm with the parameters TR 9.9 ms; TE 4.6 ms; 240 x 231 matrix; FOV 24 cm; slice thickness 1 mm.
After standard preprocessing steps, all DTI images were registered to a control subject most closely related to the mean age of all subjects (mean age = 11.8, age of template subject = 12). Subsequently, statistical analysis of FA and MD were performed using AFNI's 3dttest and visualized using AFNI.
Results
Figure 1: Axial view of statistically significant changes in the FA (left image) and MD (right image) values between children with cerebellar brain tumors treated with chemotherapy versus age- and gender- matched healthy sibling controls. Blue indicates significantly decreased values whereas red indicates significantly increased values.
Children with cerebellar brain tumors had significantly decreased FA in areas of the corpus callosum, the right anterior internal capsule and the right thalamus and significantly elevated MD in the right head of the caudate as compared to controls.
Conclusion
Evidence of microstructural injury to midline grey and white matter structures may have implications for cognitive deficits in children with cerebellar tumors treated with chemotherapy.

Title: The impact of surgical stress, immune stimulation, and native immune cells on brain metasatasis

Authors: *A. BENBENISHTY[1], L. SHAASHUA[1], A. GLASNER[2], S. BEN-ELIYAHU[1], P. BLINDER[1];
[1]Tel Aviv Univ., Tel Aviv-Yafo, Israel; [2]The Hebrew Univ. Hadassah, Jerusalem, Israel

Abstract: Surgical stress responses have been shown to promote metastasis in peripheral organs through their immune-suppressive effects and through direct effects on the malignant tissue and host physiology. However, brain metastases have not been studied in these respects, and the unique brain immune milieu, blood supply, and blood-brain barrier, may react differently to such neuroendocrine challenges. Thus, we studied the effect of surgery and the consequent systemic stress response, immune-stimulation, and the role of NK cells and resident microglia, in early and late stages of brain and peripheral metastasis. Tumor cells were injected using a novel intra-carotid inoculation approach we have developed, which generates metastases with minimal injection-related interferences to brain blood flow, with better targeting to the brain. Employing this inoculation approach in C57BL/J6 mice we studied the effects of surgery on tumor retention and growth, as measured using radioactive-labeled cells and bioluminescent imaging. Various pharmacological agents were used to study the effects of systemic neuroendocrine factors secreted under physiological stress, including corticosterone, adrenaline, and prostaglandin. Next, we studied the effects of immune stimulation, using CpG-C ODN - a TLR-9 agonist having minimal adverse effects in humans. To study the role of NK cells and resident microglia in vivo, we specifically depleted these cells populations using NK1.1 antibody and a novel colony-stimulating factor 1 receptor antagonist, respectively. We followed the various steps of the metastatic process in CX3CR1-GFP mice using awake two-photon imaging, and analyzed the effects of immune-stimulation and the interaction between microglia and tumor cells in the brain. Complementary primary culture assays were used to further study the interaction between microglia and tumor cells. Our findings indicate that surgical stress results in elevation in metastases in the periphery and in the brain, while this phenomenon is mediated by systemic secretion of endocrinal factors in the periphery but not in the brain. Furthermore, CpG-C results in a profound decrease in metastases in both the periphery and brain. Interestingly, metastasis progression and the effects of immune-stimulation were mediated by NK cells in the periphery, while in the brain, microglia, but not NK cells, were found to play a key role. Our work implies surgery is a significant risk factor for brain metastases and that microglia cells are potential targets for immune-therapy, such as CpG-C treatment, which may be used prophylactically in cancer patients.

Title: Examination of FOXJ1 as a modulator of proliferation in glioblastoma

Authors: *E. M. PARONETT[1], E. P. MCCORMACK[1], T. M. MAYNARD[1], J. H. SHERMAN[2];
[2]Dept. of Neurolog. Surgery, [1]George Washington Univ., Washington, DC

Abstract: Glioblastoma tumors, derived from astroglial cells, carry a prognosis of 12-18 months. Current treatment is limited to tumor resection followed by radiation and chemotherapy. FOXJ1, a forkhead transcription factor, is required for astrocyte and radial glia differentiation in addition to neurogenesis, and therefore may be a candidate for mediating proliferation and invasiveness of glioblastoma cells. Overexpression and knockdown of FOXJ1 have demonstrated utility in predicting prognosis and progression of several types of cancer. Thus, it is possible that FOXJ1 may modulate aspects of proliferation or invasion in glioblastoma cells. The goal of our experiments was to provide evidence for the expression of FOXJ1 in glioblastoma samples and its utility as a transcription factor in neural/glial differentiation. The glioblastoma cell line U87 is known not to express FOXJ1. We transfected a FOXJ1-tdTomato plasmid into U87 cells in order to examine its influence on proliferation. In addition, a preliminary assessment of FOXJ1 expression was made via qPCR on 6 glioblastoma and 2 lower grade glioma samples from the GWU Tissue Tumor Bank. Our results demonstrate that FOXJ1 is expressed variably in both the nucleus and cytoplasm and in a subset population of glioblastoma neoplasms, which is consistent with tumor samples from a publically accessible database. Future work will assess the effect of FOXJ1 overexpression on glioblastoma proliferation as well as its effect on resistance to such treatments as radiation and chemotherapy. Understanding the role of FOXJ1 in glioblastoma may suggest new therapies and give patients with glioblastoma an alternative to the current standard of care.

Title: HIV-associated brain Lymphoma activates NAMPT/SIRT3/PGC-1α signaling

Authors: T. K. MAKAR[1,2], *S. RAY[1], D. D. PATEL[1], P. R. GUDA[1], J. L. BRYANT[3]; [1]Neurol., Univ. of Maryland Baltimore, Baltimore, MD; [2]VA Med. Ctr., Baltimore, MD; [3]Inst. of Human Virology, Baltimore, MD

Abstract: Primary central nervous system lymphoma (PCNSL) of the central nervous system (CNS) is an aggressive malignancy which is associated with HIV patients. PCNSL is a rare form of non-Hodgkin lymphoma. This type of lymphoma is mainly involves brain. Histological analysis suggests that HIV-associated lymphoma (HBL) is one type of the PCNSL. The involvement of critical brain regions are both pathologic and diagnostic challenges. Neurocognetic dysfunction is associated with HBL. HIV transgenic Tg26 mice show some of the complicacy associated with HIV infection. 15 % of these transgenic mice population develop PCNSL in brains. The aim of this study was to analyze the relationship between metabolic profile and pathological outcome in the hippocampus of PCNSL associated Tg26 mice.SIRT3 (sirtuin3) is the main deacetylase utilizing NAD+ within the mitochondrial matrix which induces aerobic metabolism regulates reactive oxygen species (ROS). There is controversy as to whether SIRT3 is involved in oncogene or a tumor suppressor and here we investigated its role in PCNSL associated hippocampal changes. We found a significantly higher expression of SIRT3 in those hippocampus regions of Tg26 mice compared to wild type (WT). In the same tissues we also determined the expression of nicotinamide phosphoribosyltransferase (NAMPT), the rate-limiting enzyme in the synthesis of NAD+. Here also we found a significant increase of NAMPT expression. Earlier it has been reported that the expression of NAMPT was generally high in the more aggressive malignant lymphoma (Olesen et.al 2011 APMIS 119: 296-303). The NAMPT inhibitor, APO866, is currently in clinical phase of trials in lymphomas. SIRT3 induces deacetylation of PGC1α. It has been reported that PGC1α reprograms cancer cell metabolism and stimulates mitochondrial biogenesis via regulating several mitochondrial genes (Vazquez et.al 2013 Cancer cell 23:287-301). Our study furthermore, showed that in the hippocampus of those mice PGC1α upregulated. Taken together these finding suggested NAMPT/SIRT3/PGC1α signaling are activated in the hippocampus of PCNSL associated with the brain of TG26 mice. In conclusion our study suggests in PCNSL associated with HIV infection, inhibition of NAMPT/SIRT3/PGC1α pathway might represent a novel therapeutic approach.

Title: Implication of mRNA binding protein HuR in PD-L1 up regulation in brain tumor.

Authors: ***N. FILIPPOVA**, X. YANG, L. B. NABORS;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: PD-L1, a programmed death ligand 1, is a transmembrane protein that is responsible for the immune escape of different types of tumors due to inhibition of T lymphocytes and B cells activation during the anti-tumor immune response. PD-L1 ligand is up regulated across several tumor types and interacts with PD1 and B7.1 receptors on T lymphocytes and B cells, therefore inhibiting their proliferation. In our current report, we provide a detailed analysis of PD-L1 expression at the mRNA and protein levels in normal and brain tumor samples as well as on glioma cell lines and describe several new mechanisms which could account for the PD-L1 up regulation. We performed a comparison of PD-L1 protein expression in array of brain tumor samples (WHO i-iv) and normal tissue samples. Overall, the PD-L1 exhibits heterogeneous distribution across the tumor samples (from 1-2 % to up to 50-60 % cells per tumor mass) with significantly stronger intensity compared to normal tissues. We confirmed almost uniformly higher total PD-L1 protein level in tumor samples compared to normal tissue by Western blot data normalized to the actin in samples content. The analysis of total PD-L1 mRNA expression (by using inventory Taqman probe against PD-L1 coding region) in 10 GBM samples versus 5 normal brain tissue samples revealed that PD-L1 mRNA level significantly exceeds averaged normal PD-L1 mRNA level in two GBM samples and significantly below of averaged normal level in three GBM samples. The sporadic PD-L1 distribution and intensity in most GBM samples suggest the persistence of the inductive nature of PD-L1 up-regulation in tumor. The analysis of PD-L1 gene revealed that the mRNA binding protein HuR may be involved in PD-L1 up regulation through the direct 3‘-UTR stabilization or indirectly through the enhancement of PD-L1 promoter function via up regulation of the transcriptional factor HIF1-alpha. We confirmed both pathways of HuR dependent PD-L1 up regulation in U251 cells by using several assays including, but not limited to: HuR overexpression assay, PD-L1 reporter assay and by

mimicking hypoxic/or metabolic HIF1-alpha potentiation via CoCl2 cells treatment. We conclude that the mRNA binding protein HuR may contribute to the PD-L1 up regulation and therefore tumor immune escape in glioma.

Title: Modelling human glioma using 3D bioprinting

Authors: ***C. C. NAUS**[1], K. HARADA[2], W. SIN[1], D. SONG[2], N. KITA[2];
[1]Dept of Cell. & Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada; [2]Cyfuse Biomed. K.K., Tokyo, Japan

Abstract: Malignant glioma is an aggressive cancer originating in the central nervous system with very poor prognosis and a median survival of about one year. The current standard for care is surgical resection, adjuvant chemotherapy and radiation therapy. Most cancer treatments aim to kill tumor cells by taking advantage of their accelerated growth. However, gliomas almost always return due to survival of invading glioma cells, often arising in a region proximal to the primary tumor site. Approaches to study human gliomas vary from in vitro culture conditions to establishing tumors in vivo in animal models. We have previously demonstrated that the loss of connexin43-mediated intercellular communication in U118 human glioma spheroids increased their invasiveness on a fibronectin substrate (Aftab et al., 2015, Oncotarget). In order to better understand how loss of connexin43 will affect glioma growth, invasion and recurrence in a multicellular environment, we used a bioprinting system (Regenova Bio-3D Printer, Cyfuse Biomedical KK, Tokyo, Japan) to generate human neural organoids consisting of iPSC-derived neurospheres printed with the "Kenzan" method. After culturing the neurospheres in chambers for several weeks, individual cellular spheroids merged to simulate an in vivo neural microenvironment. Human glioma cells grown as spheroids were implanted into this organoid. Tumor growth can be readily assessed in this system, as well as quantification of glioma cell invasion into the surrounding neural tissue, as detailed in our previous study (Sin et al., 2016, Oncogene). This platform provides a unique tool to manipulate the glioma microenvironment and assess the efficacy of various therapeutics.

Title: 3D visualisation of Collagen IV vasculature in human GBM tissue blocks: morphometric parameters relate to tumor severity and suggest mechanisms of angiogenesis

Authors: G. P. CRIBARO, E. SAAVEDRA-LÓPEZ, P. V. CASANOVA, *C. BARCIA; Univ. Autonoma De Barcelona, Barcelona, Spain

Abstract: Revisiting the basic microarchitecture of glioma vasculature is opportune given the heterogeneity of angiogenic and vasculogenic processes within the tumor, as well as the importance of understanding the blood brain barrier (BBB) state for an effective therapy. Since routine histopathological examinations are done in 5 um-thin sections, the visualization of blood vessel structure is insufficient. Here, we analyze three-dimensionally (3D) the microvasculature in 60-um thick, free floating tissue blocks from human glioma patients, visualizing the Collagen IV^+ components of the tumor microenvironment (TME) and making comparisons with normal tissue organization and the degree of tumorigenicity. We have measured morphometric parameters of micro-vessels *in situ* and identified patterns of the primary tumor vascularization and angiogenesis (cooption, looping, intussusception [splitting] and silent corollary vessels). After detection of Collagen IV^+ basement lamina in combination with $GFAP^+$ tumor cells and DAPI counterstaining, immunoflourescent-stained tissue blocks were imaged in 3D with a laser scanning confocal microscope and the resulting 3D stacks were analyzed with image analysis software (Imaris and Fiji) to quantify individual vascular units, vessel caliber, Collagen IV^+ vascular basement lamina area, branching and continuity (as an indirect measure of vessel wall disruption). These parameters were correlated with tumorigenicity levels, such as cellularity and $GFAP^+$ tumor cell density. Our analysis shows that Collagen IV^+ vascular basement lamina area, vessel caliber range and variability increase positively with tumor severity. Collagen IV^+ vessels show increased ramification in severe tumors and basement lamina disruption also increases with

tumorigenicity. In addition, all samples show abundant silent collateral vessels. Our data shows that the human glioma environment utilizes multiple strategies of vasculogenesis that correlate with the severity and the fatal outcome of the patients. Thus, an extensive understanding of the multifaceted nature of tumor neovascularization starting with an accurate 3D topography and a detailed *in situ* characterization of regional cell populations in the TME will contribute positively to more successful antiangiogenic treatment strategies.

Abstract: Glioblastoma multiforme (GBM) is one of the most devastating forms of human brain cancer. Even with treatment patients are expected to only live a few months. In the Field Neurosciences Institute laboratory at CMU, great advances are being made utilizing the release of anti-inflammatory factors from mesenchymal stem cells (MSCs), for treating a variety of neurological diseases including GBM. However, while this treatment has significant potential for treating GBM, much work is needed to more effectively shrink the volume of the tumor. To address this need, this project was based on a premise that an ideal ratio of transplanted stem cells to tumor cells needs to be determined in order to improve treatment outcome. In order to better match MSCs to GBM cells, studies examining the growth kinetics of the GBM tumor cells within the animal brain are needed. To this end, the goal of this *in vivo* study, was to investigate the proliferation rate of the GBM cells using a nuclear marker bromodeoxyuridine (BrdU). GBM cells were first transplanted into 20 brains of rats that were divided in three groups and

euthanized at different time point: one, two or three weeks after the GBM transplantation in the brain. Live images of tumor growth *in vivo* were taken at days 11, 17, 25 and 31 in a different set of animals; post-fixation immunohistochemistry was also completed for tumor growth. Results showed an increase in tumor size over the 3 weeks which was confirmed by live imaging. Ultimately, the results of this study will help to determine the optimal time for intervening with MSCs in order to reduce the proliferation of GBM cells in the brain.
Support for this study was provided by the Office of Research and Sponsored Programs at CMU, the College of Medicine, and the Field Neurosciences Institute and John G. Kulhavi Professorship

Title: Lipid droplet accumulation in glioblastoma multiforme

Authors: ***B. TAIB**, R. AHIMA;
Dept of Med, Div. of Endo, Diabetes and Metabolism, & the Inst. for Diab, Obesity & Metabolism, Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA

Abstract: Glioblastoma multiforme (GBM) is the most common primary malignant brain tumor in adults. The standard treatment for GBM is surgical resection followed by adjuvant radiotherapy and chemotherapy, but overall survival is usually less than 12 months. Analysis of brain tissues from GBM patients show that lipid droplets (LD) are highly enriched in tumor tissues but not detectable in normal brain tissues. However, the nature and functions of lipid species in GBM are not well understood. In the present study, we demonstrate that a human GBM cell line (U138) treated with oleic acid accumulate Perilipin 2-coated LD and triglycerides enriched in C18:1, C18:2 and C20:1 fatty acids. Phospholipid extracted from oleic acid treated GBM cells has higher levels of C16:0, C18:0 and C18:1 fatty acids. Oleic acid treatment increases mRNA expression of carnitine acyltransferase1 (CPT1), diacylglycerol O-acyl-transferase (DGAT)1, stimulates fatty acid oxidation and glucose utilization, and promotes

proliferation but not migration of GBM cells. Conversely, pharmacological inhibition of DGAT decreases LD and triglycerides and blunts proliferation of GBM cells. Oleic acid treatment increases phosphorylation of AKT, and this effect is reversed by inhibition of DGAT. Our findings reveal a novel LD-mediated lipid signaling pathway that provides a rational metabolic therapy for GBM.

CSHL RNA-Seq for the Next Generation

Title: Differential gene expression profiles of adherent and neurosphere-like GL261 cells

Authors: J. L. V. MONTEIRO DE BARROS, *R. L. DANIELS;
Biol., Col. of Idaho, Caldwell, ID

Abstract: Glioblastoma Multiforme is an extremely aggressive cancer with poor prognosis, comprising 15% of all primary intracranial cancers. The GL261 murine cell line is a widely utilized model system for investigating high-grade glioma pathobiology. These cells can be cultured adherently or as free-floating aggregates (neurospheres) in vitro when exposed to epidermal growth factor (EGF), fibroblast growth factor (FGF) and B-27. Additionally, in vivo studies have shown that the neurosphere phenotype forms malignant tumors that display higher infiltration rates, lethality, as well as greater similarity to cancer stem-like cells when implanted into mice, thus suggesting a different gene expression profile in comparison to the adherent phenotype. However, the fundamental differences between cells cultured under each condition and the particular changes in gene expression that lead to increased tumorigenicity in the neurosphere phenotype still remains unclear. A more thorough understanding of gene expression under both phenotypic conditions would allow better interpretation of experimental results in the GL261 literature. To address this, we have used whole transcriptome shotgun sequencing (RNA-Seq) to examine differential gene expression between GL261 cells cultured adherently or as neurospheres. A total of 538 genes were shown to be upregulated by at least a factor of 2, while 331 genes were observed to display at least halved expression levels in comparison to the

adherent phenotype. Gene ontology analyses determined that neurosphere-like Gl261 cells displayed an over-expression of genes related to cell-cell adhesion, inflammatory response, and regulation of adaptive immunity. Downregulated genes included those that have functional roles in cell cycle control and angiogenesis. A complete characterization of the gene expression profiles of both the adherent and neurosphere GL261 phenotypes will contribute to our understanding of this model system and will further our knowledge regarding the changes in gene expression that permit tumorigenesis and tumor growth. The present study provides important data regarding gene products and processes that could be targeted in drug discovery efforts. Lastly, this is the first report to compare gene expression between the two GL261 phenotypes.

Title: longitudinal functional alterations of peritumoral neurons in a murine glioma model

Authors: *E. TANTILLO[1], C. CERRI[2], F. OLIMPICO[1], S. FRANCESCHI[3], E. VANNINI[2], P. ARETINI[3], M. MENICAGLI[3], C. MAZZANTI[3], M. CALEO[2];

Abstract: Introduction Gliomas are the most common primary brain tumors of the central nervous system, with glioblastoma multiforme (GBM) being the most malignant form of this disease. A better understanding of the bidirectional interactions between glioma cells and surrounding brain tissue is required for the development of novel therapies. A successful brain tumor treatment should indeed aim at halting tumor growth and at the same time protecting neuronal cells to prevent functional deficits and cognitive deterioration, which have a strong impact on the patients' quality of life. However, currently very little is known about the functional status of peritumoral tissues during glioma progression. **Methods** in this study, we induced glioma through transplant of GL261 cells into the primary visual cortex of syngenic C57JBl6 adult mice. A chronic bipolar electrode was implanted in the same area to record local field potentials (LFPs). We performed longitudinal recordings of neural activity in awake, head-fixed animals to monitor the effect of glioma on neural tissues during its development. The visual cortex was chosen as a recording site since it can be easily activated by physiological

stimuli, and for the presence of many well established parameters to evaluate its functionality. A detailed analysis of visual evoked potentials (VEPs) and baseline LFPs was performed in order to follow changes induced by tumor growth. **Results and Discussions** In control, naive mice, field potential responses were consistently evoked by photic stimulation. We observed a progressive increase in the VEP amplitude over the recording session, indicative of stimulus-dependent response potentiation (SRP). On the contrary, in glioma-bearing mice, an initial phase of SRP was followed by rapid decay and deterioration of visual responses, that completely disappeared by day 25-28 after GL261 cell transplant. Single unit recordings showed that peritumoral neurons showed several physiological alterations including enhanced spontaneous firing, reduced visual responsiveness over a range of stimulus contrasts and reduced response reliability. Baseline LFPs recordings revealed the occurrence of seizures in a subset of the recorded animals. **Conclusions:** Our findings indicate the feasibility of longitudinal monitoring neural activity during glioma progression to better understand the interaction of tumor cells with the brain microenvironment. These data provide a set of quantitative parameters to measure dysfunction in peritumoral regions during glioma growth, and assess the impact of radiotherapy, chemotherapy, and antiepileptic drugs on neuronal activity in glioma-bearing animals.

Title: The effects of glioma growth on resting state networks

Authors: ***I. E. ORUKARI**, A. Q. BAUER, G. A. BAXTER, J. B. RUBIN, J. P. CULVER; Washington Univ. In St Louis, St Louis, MO

Abstract: Background: Gliomas are known to cause significant changes in normal brain function that lead to cognitive deficits. Disruptions in resting state networks (RSNs) are thought to underlie these changes. However, investigating the effects of glioma growth on RSNs in humans is complicated by the heterogeneity in lesion size, type, and location across subjects. In this study, we evaluated the effects of tumor growth on RSNs over time in a mouse model of glioma where glioma properties can be controlled. **Methods:** Glioma cells ($5x10^4$-10^5 U87s)

were stereotactically injected into the forepaw somatosensory cortex of adult nude mice (n=5). Disruptions in RSNs were evaluated weekly with functional connectivity optical intrinsic signal imaging (fcOIS), in conjunction with bioluminescence imaging (BLI) to monitor tumor growth. In order to characterize how tumor growth affected different RSNs over time, we calculated functional connectivity (fc) between homologous (bilateral) brain regions and the spatial similarity of regional fc maps for all brain pixels within our field of view. **Results:** Deficits in fc initiate near the lesion, and over a period of several weeks, extend more globally (Fig 1A). We observe a focal decrease in bilateral fc near the tumor injection site at week 5. This focal decrease in bilateral fc became more global at week 6 (Fig 1B). We also observed a focal decrease in the similarity of regional fc maps near the tumor injection site at week 5, which became more pronounced over the brain by week 6 (Fig 1B). These decrements in spatial similarity were found to strongly correlate with the BLI signal in each mouse and across all time points investigated (Fig 1C) indicating that increased tumor size is associated with increased RSN disruption. **Conclusions:** We have shown that fcOIS and BLI are capable of detecting alterations in mouse RSNs due to brain tumor growth. A better understanding of how RSN disruption contributes to the development of cognitive deficits in brain tumor patients may lead to better patient risk stratification and consequently improved cognitive outcomes.

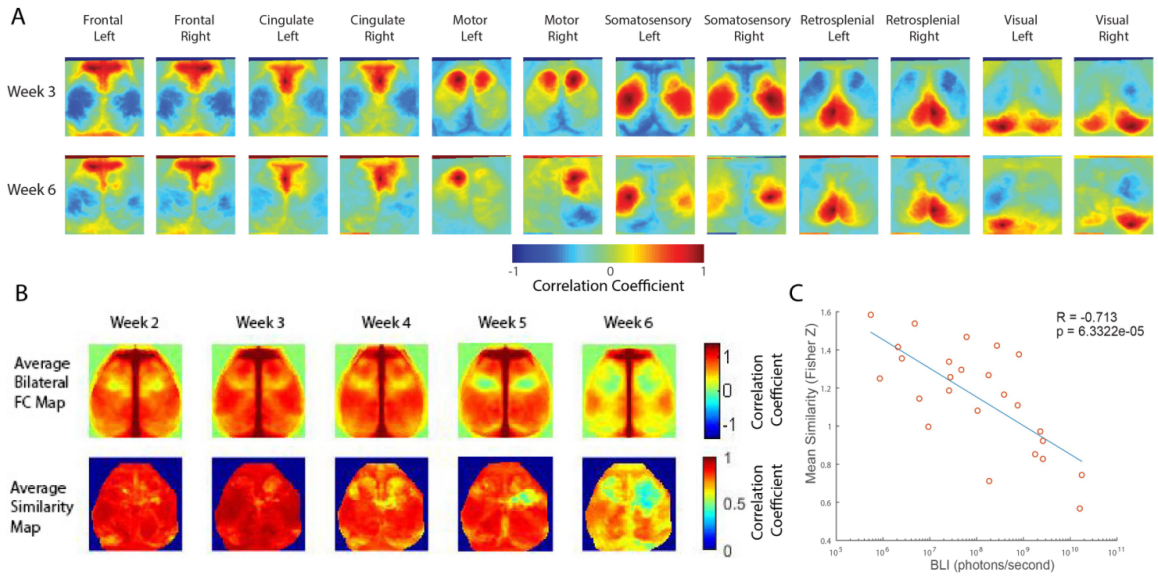

Fig 1. Alterations in functional connectivity due to glioma growth. Tumors were injected in the forepaw region of the right somatosensory cortex. A) Averge functional connectivity (fc) maps from 5 mice for 12 networks at week 3 and week 6 post injection. B) Average bilateral fc map and average similarity map for 5 mice at 5 different weeks. C) Mean similarity score across the whole brain for individual mice plotted against corresponding BLI signal.

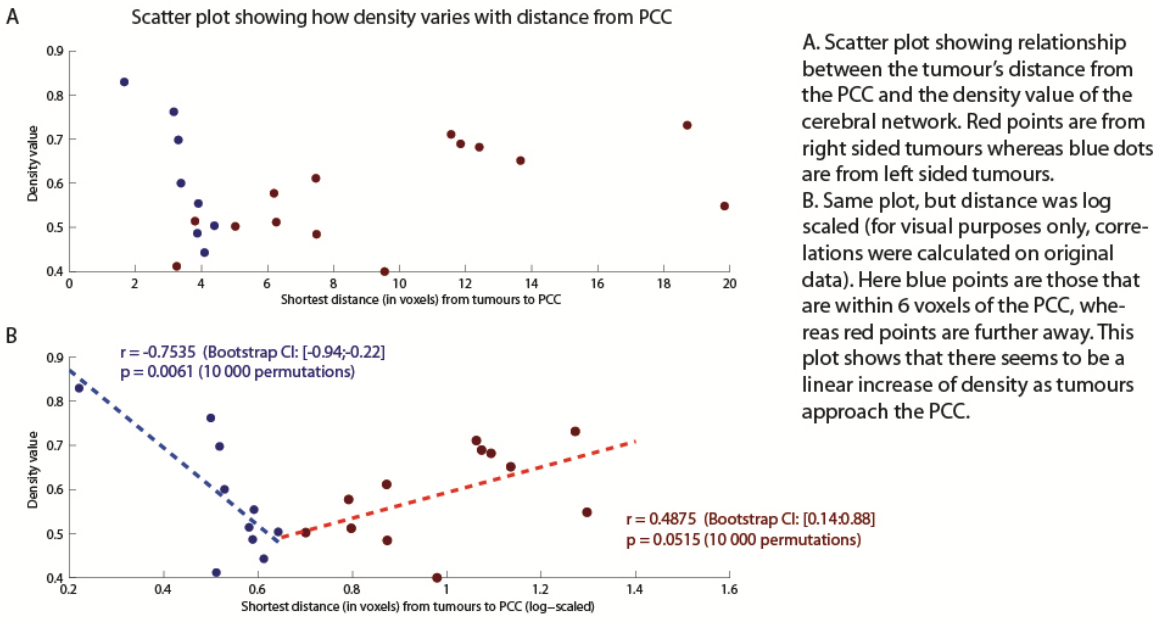
Title: Brain tumours near the posterior cingulate cortex have a larger effect on overall cerebral connectivity

Authors: *S. GHUMMAN[1], D. FORTIN[2], M. NOEL-LAMY[3], S. CUNNANE[4], K. WHITTINGSTALL[3];
[1]Dept. of nuclear medicine and radiobiology, [2]Dept. of surgery, [3]Dept. of diagnostic radiology, [4]Dept. of medicine, Univ. of Sherbrooke, Sherbrooke, QC, Canada

Abstract: Introduction : Graph theory is a method of studying cerebral networks that provides information on overall connectivity in the brain rather than probing specific networks. The goal of this study was to describe how tumours affect modularity and density of the cerebral network. Moreover, we also sought to investigate whether tumours near certain regions of the brain had larger effects on density. Material and methods: T1 MPRAGE and fMRI scans were taken in 67 patients with brain tumours and 23 healthy aging patients. fMRI data was pre-processed in accordance with modern guidelines for resting state connectivity studies. 50 ROIs were chosen by parcelling the brain with a spatially constrained spectral clustering technique. Graph theory metrics were calculated using the MATLAB toolbox "brain connectivity toolbox". Results: We found that graph theory metrics were only significantly different from healthy controls in patients with tumours in the occipital/parietal (posterior) regions of the brain. These patients had significantly decreased modularity and significantly increased density. Moreover, we also found that graph density was negatively correlated to distance from PCC for tumours within 18 mm of the PCC. Beyond this distance, density seems positively correlated with distance, although this correlation is weaker and statistically insignificant. Conclusion: Decreased modularity and increased density in patients with posterior brain tumours could reflect a plasticity response to the lesions. In fact, posteriorly located tumours are closer to the PCC, which is a known hub in the brain; cerebral hyper-connectivity (increased density) may be a reaction to tumour-induced damage to this hub. Our distance analysis supports this conclusion as tumours located nearer the PCC have a larger effect on density values.



A. Scatter plot showing relationship between the tumour's distance from the PCC and the density value of the cerebral network. Red points are from right sided tumours whereas blue dots are from left sided tumours.
B. Same plot, but distance was log scaled (for visual purposes only, correlations were calculated on original data). Here blue points are those that are within 6 voxels of the PCC, whereas red points are further away. This plot shows that there seems to be a linear increase of density as tumours approach the PCC.

Title: Mechanisms of diffuse intrinsic pontine glioma invasion of the subventricular zone

Authors: ***E. Y. QIN**[1], D. COOPER[1], S. NAGARAJA[1], A. MACKAY[2], C. JONES[2], M. MONJE[1];
[1]Neurol., Stanford Univ. Sch. of Med., Stanford, CA; [2]The Inst. of Cancer Res., Sutton, United Kingdom

Abstract: Diffuse intrinsic pontine glioma (DIPG) is a devastating childhood brain cancer characterized by its diffusely infiltrating nature. Morbidity and ultimately mortality result in part from this invasive pattern of growth, which reaches far beyond the pons during the course of the

disease. One of the major sites of DIPG spread is the subventricular zone of the lateral ventricles (LV SVZ), a stem/precursor cell niche in the postnatal brain. DIPG spread to a stem/precursor cell niche is crucial to address, as this may serve as a reservoir of tumor cells and play a role in disease recurrence. We have cultured DIPG cells from both the pons and the LV SVZ metastatic tumor from the same individual. Tumor cells from both sites exhibit the H3.3K27M mutation, but diverge in terms of other genomic aberrations and gene expression patterns central to invasive capacity, such as matrix metalloproteinase expression. DIPG cells cultured from the LV SVZ metastatic site exhibit increased invasive behavior *in vitro* and *in vivo*, with a propensity to metastasize to the cerebrum when orthotopically xenografted to the pons. Using *in vitro* invasion assays, we found that DIPG cells cultured from the LV SVZ are more invasive toward media conditioned by LV SVZ neural precursor cells than towards media conditioned by other neural precursor cell populations. In contrast, exposure to fourth ventricular zone (4VZ) neural precursor cell conditioned media increases the overall invasive behavior of DIPG cells non-directionally. Together, these results suggest that molecules secreted by 4VZ neural precursor cells increase the invasive ability of DIPG cells, which spread widely through the entire brain and have a preference for invasion toward the LV SVZ stem cell niche due to a chemoattractant effect of molecule(s) secreted by LV SVZ neural precursor cells. Proteomic analysis of LV SVZ and 4VZ neural precursor cell conditioned media revealed several candidate DIPG chemoattractants and invasion-promoting factors secreted by neural precursor cells. RNA-Seq analysis of LV SVZ metastatic DIPG cells after exposure to LV SVZ or 4VZ neural precursor cell conditioned media also revealed several upregulated gene expression pathways that may contribute to invasion. Ongoing studies investigating the necessity and sufficiency of these candidate secreted proteins and pathways may elucidate mechanisms of DIPG invasion to the supratentorial LV SVZ, which may provide targets for future therapies aimed at limiting DIPG spread.

Title: Obesity as a potential attribute for vincristine induced peripheral neuropathy

Authors: F. BOYLE[1], K. FORAN[1], *T. J. SAJDYK[2], E. SMITH[3], R. HO[4], E. WELLS[5], J. RENBARGER[1];
[1]Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Pediatrics - Hematology/Oncology, Indiana Univ. Sch. Med., Indianapolis, IN; [3]Univ. of Michigan, Ann Arbor, MI; [4]Vanderbilt Univ., Nashville, TN; [5]Children's Children Res. Inst., Washington, DC, DC

Abstract: In pediatric oncology, vincristine is a primary chemotherapeutic agent used in the treatment of acute lymphoblastic leukemia (ALL), as well as a variety of other curable pediatric malignancies. Children exposed to vincristine during treatment are at increased risk for development of highly variable cumulative dose-dependent neurotoxicity known as vincristine-induced peripheral neuropathy (VIPN). VIPN is characterized by painful numbness and tingling of the hands and feet, severe jaw pain, orthostatic hypotension, constipation, and muscle weakness that often require chemotherapy dose reduction, thereby potentially compromising effectiveness and cure rates. Our recent studies show that 78% of children receiving vincristine as part of their chemotherapy treatment develop VIPN. The objective of the current study was to evaluate the association between obesity and VIPN severity. We hypothesized that ALL patients who fall into the obese weight category will have a more severe neurotoxicity score than the ALL patients who fall into the healthy weight category. Pediatric patients between the ages of two and eighteen diagnosed with pre B-cell ALL and receiving vincristine as part of their primary chemotherapy treatment plan were enrolled prior to day 8 of initiating vincristine. Neuropathy exams were performed prospectively to assess each patient's VIPN using The Total Neuropathy Score (TNS). Weight categories were assigned to each patient based on his/her BMI percentile. An unpaired t test was done to evaluate the difference in maximum TNS-5 item score between obese and healthy patients. We found that obese pediatric ALL patients had a significantly higher maximum TNS score than pediatric ALL patients of healthy weights ($p= 0.03$). Future studies investigating healthy and obese ALL patients' recovery times from VIPN are needed to assess obesity as a risk factor not only for severity of VIPN but also chronicity of this life-altering toxicity.

Title: Potential biomarkers for early detection of neuropathy in pediatric ALL patients

Authors: *S. E. ROSS[1], E. SMITH[2], R. HO[3], E. WELLS[4], T. SAJDYK[1], J. THEN[1], L. LI[1], J. RENBARGER[1];
[1]Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Univ. of Michigan, Ann Arbor, MI; [3]Vanderbilt Univ., Nashville, TN; [4]Children's Natl. Med. Ctr., Rockville, MD

Abstract: Sixty percent of all individuals diagnosed with acute lymphoblastic leukemia (ALL) are children. Fortunately, advances in cancer treatment since 1975 have increased the 5-year survival rate from 57% to 90%. A major contributor to the increase in survival is the use of vincristine, one of the core drugs used in the treatment of ALL. Seventy-eight percent of children receiving vincristine as part of their chemotherapy developed vincristine-induced peripheral neuropathy (VIPN), the major dose-limiting toxicity. VIPN can have an impact on the cancer patient in two major ways: 1) it can induce long-term peripheral neuropathy which leads to a decreased quality of life well into adulthood and 2) it can cause the physician to alter the use of vincristine during treatment thus potentially reducing the overall effectiveness of the cancer therapy. In the current study we evaluated 27 different cytokines in pediatric patients with ALL as potential biomarkers for the development of severe peripheral neuropathy. Whole blood was collected from 72 patients from one of four sites (Indiana University, George Washington University, University of Michigan, or Vanderbilt University) while undergoing vincristine treatment. Neuropathy scores were collected from patients during their treatments including their total neuropathy score (TNS), total reflex score, NCI common terminology criteria for adverse events (CTC) motor neuropathy score, and CTC sensory neuropathy score. Plasma was isolated and analyzed for cytokine concentrations. Multivariate logistic regression was utilized to evaluate the association between cytokine concentrations, university site, and/or patient age and neuropathy score (any of the four scores listed above). Higher interleukin-13 (IL-13) expression and older age both correlated with higher TNS ($p=0.0490$ and $p=0.0278$, respectively) for these patients. Age was also directly associated with higher CTC motor ($p=0.0111$) and sensory scores ($p=0.0210$). Platelet-derived growth factor-BB (PDGF-BB) expression was inversely associated with CTC sensory scores ($p=0.0313$). Biomarkers may allow early prediction of neuropathy in pediatric ALL patients. Most importantly, biomarkers provide a method to identify VIPN sensitive infants and toddlers - a population in whom neuropathy evaluations are not feasible.

Abstract: Glioblastoma Multiforme (GBM) is an aggressive cancer that is minimally responsive to current treatments. Pharmacological inhibition of the epidermal growth factor receptor (EGFR) has shown promise as a clinical treatment; however, tumors invariably acquire resistance to continued treatment. As hyaluronic acid (HA) - a major component of the unique brain extracellular matrix (ECM) - and its corresponding membrane receptors are highly upregulated in the GBM microenvironment, we posit their interactions are key mediators of acquired resistance to EGFR inhibition. To characterize effects of the tumor microenvironment on acquired resistance in GBM, we have developed 3D culture systems that mimic the native brain microenvironment and maintain many clinical features of patient-derived GBM cells. We have successfully cultured multiple human primary GBM cell lines in HA-based hydrogels with independently varied levels of compressive modulus, HA content, and adhesive peptides. GBM cells derived from individual patients demonstrated exceptional erlotinib resistance in high HA content hydrogels compared to those with low HA content or in standard neurosphere culture (**Fig. 1A,B**). We also observed a shift in GBM-cells deposited ECM after erlotinib treatment. Integrin-binding peptides, such as RGD, conjugation to the hydrogels significantly reduced apoptosis after 3 days of treatment. In luciferase-based assay of transcription factor activity, we found that erlotinib treatment reduced the activity of P53, which increases with apoptosis, and increased activity of oncogenic transcription factors such as cMyc. Finally, we report that only HA based hydrogels maintained phosphorylation of EGFRvIII under 1 μM erlotinib treatment (**Fig. 1C**). We report development of biomimetic, modularly tunable culture platforms that maintain clinically relevant physiology of patient-derived GBM cells *ex vivo*. We have demonstrated the utility of these biomaterial platforms for mechanistic investigations of the role of the unique brain microenvironment in therapeutic resistance of GBM.

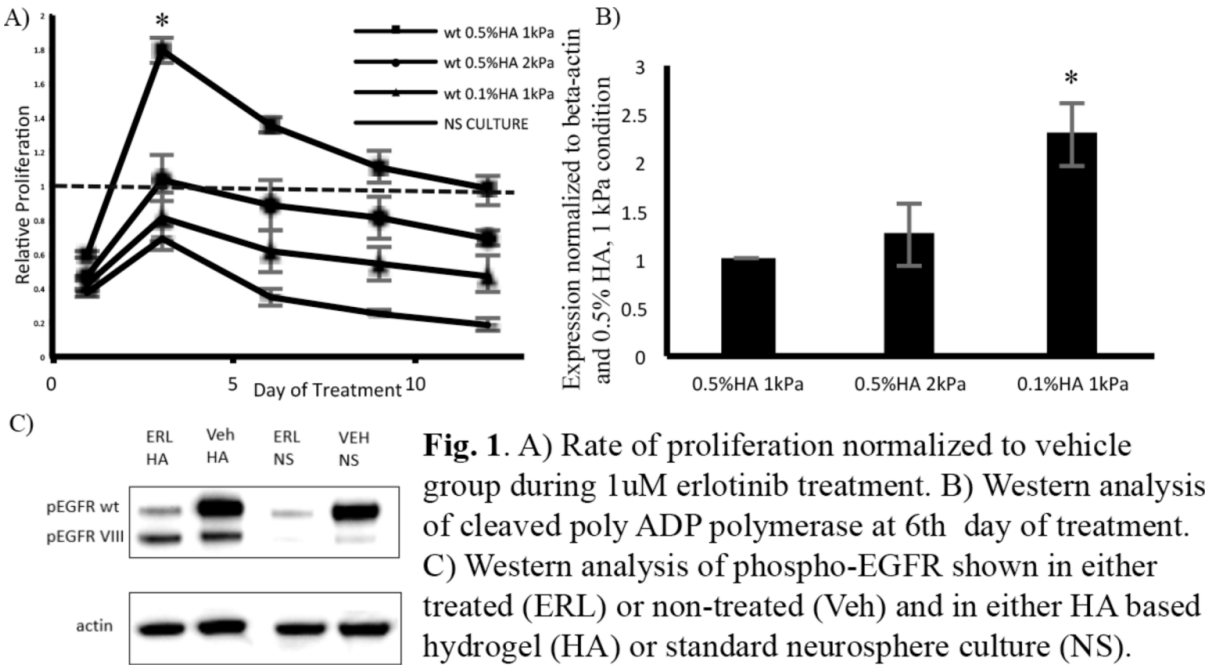

Fig. 1. A) Rate of proliferation normalized to vehicle group during 1uM erlotinib treatment. B) Western analysis of cleaved poly ADP polymerase at 6th day of treatment. C) Western analysis of phospho-EGFR shown in either treated (ERL) or non-treated (Veh) and in either HA based hydrogel (HA) or standard neurosphere culture (NS).

Title: Increased phosphorylation of the mitochondrial fission protein DRP1 in p75 neurotrophin receptor ($p75^{NTR}$)-induced glioma

Authors: *Y. AHN[1], N. SALEM[2], B. AHN[3], S. M. ROBBINS[3], D. SENGER[3], J. M. RHO[1]; [1]Pediatrics, Alberta Children'S Hosp. Res. Inst., Calgary, AB, Canada; [2]Biomed. Hlth. Sci., [3]Oncology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Glioblastoma (GBM) is the most prevalent primary brain tumor and has a median survival of only 12-18 months after diagnosis, thus ranking it among the most lethal of human cancers. Like most cancers, glioblastomas exhibit a metabolic shift toward glycolysis, a phenomenon known as the Warburg effect. This fundamental shift in bioenergetics invokes both substrates and organelles responsible for metabolic homeostasis. In this light, mitochondria are

well known to generate energy from oxidation of nutrients, and they are also highly dynamic organelles that undergo fusion, fission, trafficking and mitophagy. Each of these dynamic processes is critical to maintenance of a healthy mitochondrial population. In addition, mitochondrial dynamics have been linked to multiple functions including respiratory chain activity. Using previously established human GBM cell lines, invasive GBM (U87p75$^{NTR)}$) cells showed lower oxidative phosphorylation (OXPHOS) and cellular glycolytic activity than non-invasive (U87pcDNA) GBM cells. (Basal respiration: 194 vs. 112 pMoles/mim, maximal respiration: 474 vs. 159 pMoles/min, glycolysis: 24 vs. 13 mpH/min, and glycolytic capacity: 30 vs. 17 mpH/min, respectively). Because mitochondrial bioenergetics and dynamics influence each other in a reciprocal fashion, we further assessed mitochondrial morphology using the Tom20 antibody and mitotracker red (MTR) under immunofluorescence. We found that mitochondria in invasive GBM cells were more fragmented relative to non-invasive GBM cells (Approx. 70% vs. 50%, respectively, n=80 cells per group), suggesting that invasive GBM cells increase mitochondrial fission. Moreover, the essential mediator of mitochondrial fission, dynamin-related protein 1 (DRP1), was actively phosphorylated in invasive GBM cells. Utilizing flow cytometry we determined that mitochondrial content was higher in the invasive GBM cells (1.83 vs 1.42). This increase was confirmed with western blot analysis of VDAC protein expression (1.88 vs 1.22). No difference was found in mitochondrial membrane potential. Thus, these results suggest that the dynamic properties of mitochondria represent an important mechanism critical to brain metabolism, and we anticipate that mediators of fission and fusion (e.g., Mdivi-1, an inhibitor of fission) may provide novel molecular targets for therapeutic interventions aimed at highly invasive glioma.

Title: PAD expression and citrullination profiles in malignant glioma

Authors: E. A. SUSWAM[1], J. JYOTI[2], G. Y. GILLESPIE[3], C. P. LANGFORD[3], U. MANNE[1], *A. P. NICHOLAS[4];

[1]Pathology, [2]Microbiology, [3]Neurosurg., [4]Dept Neurol, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Background: Citrullination (or deimination) is a post-translational modification in which protein-bound arginine amino acids are converted to citrullines by a family of peptidyl arginine deiminase (PAD) enzymes. Several PAD isoforms (PAD 1-4 and 6) have been reported and demonstrate tissue specificity. Citrullination results in loss of target protein structure and has been associated with progression of various diseases, including rheumatoid arthritis and several neurological disorders. Recent studies suggest an increasing role of citrullination in cancer; increased epithelial-mesenchymal transition and breast cancer metastasis and alterations in chemotherapeutic responses in prostate cancer have been linked to GSK3β citrullination and PAD inhibition, respectively. No studies have been done to assess the contribution of citrullination to brain cancer, although PAD expression has been demonstrated in the brain. Our preliminary studies indicate high reactivity of astrocytic tumors to an anti-peptidyl citrulline antibody; hence, we analyzed malignant glioma cells and glioblastoma (GBM) tumor and xenograft tissues for PAD expression to identify citrullinated proteins in brain cancers.
Hypothesis: We hypothesize that PAD expression and citrullination are upregulated in brain cancer and modulate tumor progression and the malignant phenotype.
Methods: PAD expression was quantified from total RNA from five malignant glioma cell lines (U251, U373, JX10, LN229, D456) and normal human astrocytes by qRT-PCR. Whole cell extracts were analyzed for presence of citrullinated proteins by Western blotting using an anti-citrullination monoclonal antibody (F95). Subcellular localization was investigated by immunocytochemistry. To begin to establish the molecular identity of citrullinated proteins, the extracts were immunoprecipitated with the anti-citrullination and other antibodies. Protein citrullination in brain tumor and control tissues was investigated by immunohistochemistry.
Results: There was differential expression of PAD isoforms and a high prevalence of citrullinated proteins (MW 15-170 kDa) in brain cancer cells. Strong immunoreactivity in both nuclear and cytoplasmic compartments was detected by immunocytochemistry. Immunohistochemistry of GBM and control tissues showed higher citrullination in tumors, with both nuclear and cyoplasmic staining.
Conclusions: We conclude that PAD expression and protein citrullination are increased in brain cancer and may modulate disease progression. Further work to characterize citrullinated proteins and establish a functional role for deimination in brain cancer is on-going.

Title: The potential impact of pro-inflammatory B cells and gamma delta T cells on the progression of glioblastoma multiforme (GBM) in a syngeneic mouse model of GBM.

Authors: *S. MUKHERJEE[1], C. PEDDABOINA[2], L. DAO[2], S. HENDERSON[3], J. KAIN[2], D. LITTLE[4], M. NEWELL ROGERS[2,3];

Abstract: Background and Rationale. Glioblastoma multiforme (GBM) is a life threatening brain tumor with an average life expectancy of approximately 14 months. For many cancers, there has been a major effort to target the immune system, to provoke an anti-tumoral response and to prevent immunosuppression by cells including Tregulatory cells (Tregs) and myeloid suppressor cells (MDSCs). While the brain is considered an immune privileged site, GBM has been shown to increase permeability of the blood brain barrier (BBB). This suggests that immune cells could infiltrate the brain, but GBM progresses in spite of both BBB permeability and the potential entry of immune cells into the brain. Recent studies demonstrate a negative correlation between the frequency of Tregs in GBM and a poor prognosis. **Hypothesis**. Our work is aimed at testing the hypothesis that selective permeability of the BBB in GBM allows regulatory cells to protect the tumor from an anti-tumoral response and that this protective strategy can be reversed by the selective expansion of pro-inflammatory cells, including a subset of activated B cells that express the Class II invariant peptides (CLIP) and certain γδT cells that can elicit an anti-tumoral immune response. **Materials and Methods.** For these studies, we have used neurospheres derived from the mouse GBM cell line 261. The neurospheres were transplanted by micro-injection into the caudate nucleus. The neurospheres were injected into wild type C57Bl6 mice; into mice lacking CD74 (CD74def); into mice deficient for γδ T cells; and into wild type C57Bl6 animals treated for 10 days post tumor injection with TLR agonists. At the end of the study, tumors were dispersed into single cell suspensions, and the intra-tumoral lymphocytes were characterized by flow cytometric analysis. **Results.** For 261-injected wild type animals, the average number of days until the animals succumbed to GBM was 30 to 40 days post tumor implantation. For 261-injected CD74def mice and γδ T cell knock out mice , the average was approximately 20 to 30 days post-implantation. For wild type animals treated at day 10 post implantation with TLR modulators, there was a correlation between TLR-induced

increases in the number of CLIP+ B cells and in modulation in longevity. **Conclusions and Future Directions**. Taken together our data are consistent with the hypothesis that selective expansion of pro-inflammatory B cells and a parallel expansion of certain subsets of γδ T cells can restrict tumor progression. Our future work is aimed at understanding the molecular mechanism of this restricted growth in aid of developing novel immune-based therapies for GBM.

Title: Cellular origin influences glioma pathogenesis and treatment

Authors: *D. IRVIN[1], R. MCNEILL[2], M. VITUCCI[2], R. BASH[2], R. SCHMID[3], C. MILLER[2,3,4];
[1]Genet. and Mol. Biol., Univ. of North Carolina, Raleigh, NC; [2]Dept. of Pathology and Lab. Med., [3]Lineberger Comprehensive Cancer Ctr., [4]Dept. of Neurol. and Neurosciences Ctr., Univ. of North Carolina, Chapel Hill, NC

Abstract: The role of cellular origin during glioma development and treatment response remains elusive. We used genetic lineage tracing and fate mapping to show that Rb (T) and Pten (P) inactivating combined with Kras (R) activating (TRP) mutations transformed two subpopulations of mouse astrocytes expressing either Gfap or Glast. Both served as cells of origin for TRP-induced gliomas, but kinetics of tumor growth and progression differed. GFAP-CreER induced recombination in ~50% of astrocytes. GFAP-TRP mice harbored 6-11-fold more TdTomato$^+$ astrocytes after 8 weeks, but Glast-targeted astrocytes were 1-4 fold lower. Moreover, GFAP astrocyte transformation induced uniformly rapid growth of low-grade tumors that frequently progressed to lethal, high-grade glioblastomas (GBM). In contrast, transformation of GLAST astrocytes induced tumors that progressed to anaplastic, non-GBM tumors over a more protracted course. In the absence of mutations, genetic lineage tracing with Glast-CreER;TdTomato mice produced recombination in 8-38% of astrocytes. Astrocyte proliferation increased 8-29-fold after 3 weeks and TdTomato$^+$ cells increased 3-7-fold by 8 weeks after TRP transformation. Ki-67 labeling showed focal clonal expansion by 16 weeks in both models. Magnetic resonance imaging of GFAP-TRP mice showed stochastic progression to contrast-enhancing GBM by 12-16 weeks. In both models, transformed astrocytes maintained expression of Gfap and Blbp, yet gained expression of the stem cell marker Nestin. Nestin was expressed in 82% of transformed, proliferating GFAP astrocytes, but only 9% of GLAST astrocytes ($P<0.0001$). These results suggest that identical TRP mutations induce distinct patterns of tumor growth due to differential effects on astrocyte de-differentiation. To explore de-differentiation further, we examined cultured GFAP$^+$ TRP astrocytes and found that they gained unlimited self-renewal and multi-lineage differentiation capacity *in vitro*. These cells harbored altered chromatin landscapes associated with downregulation of astrocyte- and upregulation of stem cell-associated genes, particularly the Hoxa locus of embryonic transcription factors. TRP astrocytes formed serially-transplantable GBM allografts that were sensitive to radiation, but were resistant to temozolomide due to Mgmt expression. Radiation induced a shift in transcriptome subtype from proneural to mesenchymal in TRP allografts, similar to the shift observed after treatment in human GBM. These findings support the use of GFAP- and GLAST-TRP as tractable models for transforming astrocyte subpopulations, studying glioma stem cells, and determining treatment efficacy.

Title: Acute insulin treatment of hippocampal neurons highlights new mechanisms of action

Authors: S. MAIMAITI, H. N. FRAZIER, *K. L. ANDERSON, L. D. BREWER, N. M. PORTER, O. THIBAULT;
Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY

Abstract: Our lab studies the effects of different insulin formulations, including zinc-containing insulin and zinc–free insulin, on cognition. We identified that intranasal delivery of Levemir or Humalog (zinc-containing insulins) improves cognition in the aged F344 rats (Maimaiti et al., 2015). Intranasal Apidra (zinc-free insulin), however, was unable to improve cognition in the aged animal (Anderson et al., 2016). Growing evidence supports the concept that brain insulin defects in signaling or receptor numbers are associated with memory decline in Alzheimer's disease (AD) and advanced age. Although intranasal insulin enhances memory in AD patients, it also does so in young adult subjects with normal insulin signaling at baseline. While prior work has provided evidence that ion channels (AMPA, NMDA, GABA), glucose transporter-4, insulin degrading enzyme and vascular function, very little work has focused on voltage-gated calcium channels and intracellular Ca^{2+} as a target of insulin action in the brain. Ca^{2+} is a key neuronal molecular regulator of hippocampal-dependent memory and intracellular elevations in hippocampal neurons from aged animals are associated with poor spatial memory. We recently showed that insulin reduces the Ca^{2+} -dependent afterhyperpolarization (AHP) in hippocampal neurons in both young and aged animals (Maimaiti et al., 2015), however, the underlying mechanism for this reduction has not been studied in depth.
The goal of the present work is to test the hypothesis that insulin improves memory by reducing Ca^{2+} dysregulation, levels and currents. We used whole cell patch clamping and Ca^{2+} imaging techniques to measure voltage-gated Ca^{2+} currents (VGCCs) and intracellular Ca^{2+} levels in 13-17 DIV primary hippocampal neurons in culture. Apidra (10nM, rapid-acting, zinc-free insulin), boiled Apidra, reconstituted human insulin, and zinc were tested acutely for effects on VGCCs. Results show that both 10 nM Apidra and reconstituted insulin reduce Ca^{2+} currents. 10 nM Apidra did not reduce resting Ca^{2+} levels or spontaneous Ca^{2+} transient, but did reduce KCl-induced intracellular Ca^{2+} transients. These effects were attenuated by pretreatment with an insulin antibody. Together, these results indicate insulin can reduce intracellular calcium levels during neuronal depolarization, highlighting a potential mechanism for reducing the AHP and improving memory.

Title: Signaling and expression of a truncated, constitutively active human insulin receptor in neurons and astrocytes

Authors: *H. N. FRAZIER[1], S. MAIMAITI[1], K. L. ANDERSON[1], K. HAMPTON[1], L. D. BREWER[1], S. D. KRANER[2], C. M. NORRIS[2], R. J. CRAVEN[1], N. M. PORTER[1], O. THIBAULT[1];
[1]Pharmacol., [2]Sanders-Brown Ctr. on Aging, Univ. of Kentucky, Lexington, KY

Abstract: Insulin signaling is indispensable in the periphery and it is becoming clear that insulin is also important for normal brain function. Early stage clinical trials report a positive impact of intranasal insulin on memory recall in young subjects and patients with mild cognitive decline or Alzheimer's disease (AD). To address alternative strategies for enhancing insulin signaling in the brain, we have conducted a series of experiments using a constitutively active human insulin receptor (IR). Distribution and functional characteristics were evaluated using rat pheochromocytoma (PC12) and primary mixed hippocampal cultures.
Cells were transfected with either a mammalian expression plasmid encoding a red fluorescence protein (ires-dsRed), or a construct containing the truncated human IR beta subunit (HA-IRβ-ires-dsRed), via electroporation or a targeted lentiviral delivery system. The expression of IRβ receptor in PC12 cells was corroborated by the expression of the red fluorescent protein. A silencing site (RE1) was used to restrict expression to neurons. Photomicrographs of mixed primary hippocampal cultures confirmed expression of the lentiviral plasmid in neurons and astrocytes. The expression level and effect of IRβ overexpression on insulin signaling was confirmed in both PC12 cells and hippocampal cultures by performing Western immunoblots using antibody against HA-tagged IRβ and measuring pAkt/Akt ratio. Glucose uptake and utilization rates were measured in both neurons and astrocytes using 2-NBDG imaging. Calcium imaging (Fura-2) was also used to test for a link between glucose utilization and calcium levels both at rest and during insulin stimulation in transfected neurons and astrocytes.
Western blots of both transfected PC12 cells and mixed hippocampal cultures provide evidence that transfection with the truncated IRβ plasmid confers a greater response to insulin treatment. Lentiviral infection of mixed primary hippocampal cultures was successful for all of our constructs suggesting that this approach is viable for enhancing insulin signaling. Glucose uptake and utilization measures, together with calcium level quantification in neurons and astrocytes,

validated cellular health and sensitivity to insulin. This initial characterization provides insights into future intervention approaches to combat cognitive decline in AD and/or aging using molecular methods to enhance insulin signaling.

Title: Insulin phosphosignaling in the hippocampus of young and aged animals

Authors: K. K. HAMPTON, H. FRAZIER, K. ANDERSON, O. THIBAULT, *R. CRAVEN; Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY

Abstract: Insulin binding is reduced in the brains of aged, compared to young-adult rats. Furthermore, on post-mortem analyses, hippocampal tissues from AD and MCI patients display a reduction in insulin sensitivity compared to younger or non-demented patients. The hippocampus along with the olfactory bulb are two brain areas showing greatest insulin receptor density, suggesting intranasal delivery as an approach to combat cognitive decline. Surprisingly, both young healthy subjects and AD patients appear to benefit equally from intranasal insulin. One explanation is that adding the ligand to the brain by bypassing the blood brain barrier may compensate for the reduced insulin signaling in AD. However, these data also suggest insulin signaling may be working differently in young *vs.* aged brains. Clearly, the mechanisms involved in insulin receptor signaling across aging are critical for the advancement of insulin enhancing therapies in the treatment of cognitive decline in aging and/or AD. We have compared insulin sensitivity in acute hippocampal slices of young and aged F344 rats, where the endpoints are 24 species of phospho-proteins broadly associated with MAPK/ERK signaling. Our model is that young and aged brain tissues may employ alternate modes of insulin signaling. Slices were incubated for 5-30 minutes with 1,10, or 100 nM insulin. Different insulin formulations were tested including zinc-free Apidra, reconstituted human insulin, and humalog. In the hippocampus of young animals, insulin stimulated the phosphorylation of ERK1, JNK, p38beta and p53. When compared to young animals, the hippocampus of aged rats had increased phosphorylation of

JNK1 and JNK2 and p53, while p38alpha was diminished. For some proteins, insulin signaling was similar in young versus aged animals, for example, ERK1 phosphorylation was induced 2.1 and 1.5-fold in young and aged animals, respectively. However, insulin signaling was distinct for other proteins, particularly p38beta (4-fold induction vs. 2-fold suppression, respectively) and JNK2 (3.7-fold induction vs. no change, respectively). These results suggest a heretofore unappreciated complexity in insulin signaling in the young and aged brain. Once insulin is past the blood brain barrier, even in aged animals, it is capable of signaling robustly through intermediates such as ERK. However, our results also support a model in which some downstream effectors of insulin cannot be readily manipulated in the aged brain. Our work lends further support to continue therapeutic efforts attempting to maintain insulin signaling in the brain of the elderly population, in order to offset cognitive decline with age or with AD.

Title: Altered mitochondrial function and succinate-dependent H_2O_2 production in the cortex of type 1 diabetic rodents

Authors: *S. ROY CHOWDHURY, J. DJORDJEVIC, E. THOMSON, D. SMITH, B. C. ALBENSI, P. FERNYHOUGH;
Div. of Neurodegenerative Disorders, St. Boniface Hosp. Res. Ctr., Winnipeg, MB, Canada

Abstract: ***Rationale & Hypothesis.*** Mitochondrial dysfunction and altered levels of reactive oxygen species have been implicated in diabetic neuropathy. Abnormalities in mitochondrial

function under diabetic conditions can lead to detrimental consequences on the function of brain cells and subsequently have a pivotal role in the pathogenesis of neurodegenerative disorders. ***Objectives.*** This comprehensive study was aimed at evaluating mitochondrial function in cortical tissues and included the simultaneous assessment of mitochondrial respiration rates and membrane potential (mtMP) or H_2O_2 generation, mitochondrial enzymatic activities and proteins involved in mitochondrial complexes, antioxidant enzymes, the AMPK/SIRT/PGC1α pathway and mitochondrial dynamics. ***Methodology.*** Freshly isolated mitochondria from cortex of 5 month old streptozotocin (STZ)-induced diabetic rats or mice, a model of type 1 diabetes, and aged-match controls were used for simultaneous measurements of mitochondrial respiration rates and mtMP or H_2O_2 level (performed by Oxygraph-2K- Fluorescence LED2 module, OROBOROS instruments). Enzymatic activities were measured by a spectrophotometer. Protein levels in cortical mitochondria and homogenates were determined by Western blotting. ***Results.*** Simultaneous measurement of oxygen consumption rates (OCR) and mtMP revealed that mitochondrial coupled respiration rates in the presence of glutamate, pyruvate, malate and succinate and FCCP- titrated uncoupled respiration rates were significantly decreased in cortical mitochondria from 5-month old STZ-diabetic rats compared to controls. The mtMP was significantly depolarized in the diabetic cortical mitochondria in the presence of ADP; however, FCCP-titrated polarization status in diabetic rats was not significantly changed compared to controls. The simultaneous measurement of OCR and H_2O_2 level showed that succinate-dependent respiration rates and H_2O_2 production were significantly decreased in STZ-diabetic cortical mitochondria from rats and mice, which was accompanied by a decrease in expression of antioxidant enzymes, CuZn- and Mn-superoxide dismutases. The specific enzymatic activities of Complex I, II, and IV, protein levels of Complex I and II, mitofusion 2 (Mfn2), dynamin-related protein 1 (DRP1), phosphorylated AMPK, SIRT-2, and PGC-1α were decreased in diabetic cortical tissues. ***Conclusion.*** These results support the idea that alterations in mitochondrial function, dynamics, and antioxidant capabilities through altered AMPK/SIRT/PGC-1α pathway activity are involved in the development of neurodegenerative disease under diabetic conditions.

Title: Respiratory parameters of rat brain, liver and heart mitochondria during the aging process

Authors: *H. BARAN[1,2], K. STANIEK[3], M. BERTIGNOL-SPÖRR[2], M. ATTAM[3], B. KEPPLINGER[1];
[1]Karl Landsteiner Res. Inst. Mauer, Amstetten-Mauer, Austria; [2]Div. of Neurophysiol., [3]Mol. Pharmacol. and Toxicology, Univ. of Vet. Med. Vienna, Vienna, Austria

Abstract: Background: Tryptophan metabolism is significantly altered in various organs of mammals with aging. Kynurenine metabolites differently affect bioenergetic function of brain, liver and heart mitochondria. Therefore, we investigated the respiratory parameters of brain, heart and liver mitochondria isolated from healthy rats during the aging process.
Animals and Methods: Brain, heart and liver mitochondria isolated from 3, 12 and 26 months old male Wistar rats (n=6) were incubated with respiratory substrates glutamate/malate (5 mM each) or succinate (10 mM). Study was performed according to Austrian ethical regulations. Oxygen consumption rates were measured within a DW1 oxygen electrode chamber. Differences in respiratory parameters were analyzed by ANOVA followed by Student's t-test.
Results: With regard to investigated mitochondria of 3 months old rats, we observed that heart mitochondria exert the highest oxygen consumption rates (state 2: 22.4 ± 1.16 nmol O × min^{-1} × mg^{-1}, state 3: 140.3 ± 8.7 nmol O × min^{-1} × mg^{-1}), followed by liver mitochondria (state 2: 11.2 ± 0.5 nmol O × min^{-1} × mg^{-1}, state 3: 46.9 ± 3.7 nmol O × min^{-1} × mg^{-1}) and brain mitochondria (state 2: 4.7 ± 0.3 nmol O × min^{-1} × mg^{-1}, state 3: 19.2 ± 1.6 nmol O × min^{-1} × mg^{-1}) using glutamate/malate. Succinate-respiring mitochondria showed higher oxygen consumption rates in comparison to glutamate/malate-supplied mitochondria. However, the highest respiratory activities, as in the glutamate/malate data, were found in heart mitochondria (state 2: 92.0 ± 7.8 nmol O × min^{-1} × mg^{-1}, state 3: 285.9 ± 19.5 nmol O × min^{-1} × mg^{-1}), followed by liver mitochondria (state 2: 26.3 ± 1.9 nmol O × min^{-1} × mg^{-1}, state 3: 103.7 ± 6.7 nmol O × min^{-1} × mg^{-1}) and brain mitochondria (state 2: 8.8 ± 0.6 nmol O × min^{-1} × mg^{-1}, state 3: 30.5 ± 1.9 nmol O × min^{-1} × mg^{-1}). The highest respiratory control (RC) values were detected in glutamate/malate-respiring heart mitochondria (6.3 ± 0.2), while other RC values were in the range of 3.2-4.3. The aging process was accompanied by a significant increase of RC values in heart mitochondria incubated with glutamate/malate or succinate. RC values of liver mitochondria exposed to glutamate/malate were significantly increased during aging. The highest RC values of succinate-respiring brain mitochondria were obtained from 12 months old rats. The ADP/oxygen ratios were moderately but not significantly changed in brain, heart or liver mitochondria during aging.
Conclusion: The energy-conserving capacity of rat heart, liver and brain mitochondria was not impaired, but on the contrary, partially improved during the aging process.

Title: Metabolic syndrome impairs spatial memory & dendritic morphology of rat hippocampal neurons

Authors: *A. D. DIAZ[1], P. AGUILAR-ALONSO[1], A. MORENO-RODRIGUEZ[1], U. PEÑA-ROSAS[1], G. LÓPEZ-LÓPEZ[1], E. BRAMBILA[1], R. A. VAZQUEZ-ROQUE[2], J. GUEVARA[3], G. FLORES[2], S. TREVIÑO[1];

Abstract: A high calorie intake can to induce the metabolic syndrome (MS) appearance, which is a serious public health problem, this is characterized by impaired on glucose & triglycerides levels in blood. Recently, it has been suggested that MS can cause brain complications, since chronic hyperglycemia with insulin resistance are risk factors for neurodegeneration. The hippocampal region is sensitive of deterioration, which is reflecting in cognitive functions as well as in processes of plasticity, however, mechanism is not clear. In this study, we evaluated the spatial learning & memory, as well as their effects on neuronal morphology of hippocampus in rats with MS. Our results demonstrated that 90 days of eating a high-calorie diet, altered the main energy metabolism markers, indicating the development of MS. In the same way was observed an impairment in spatial memory, which was evaluated by testing recognition of novel objects (NORT). Therefore, the brains of animals were exposed to the solution of Golgi-cox & coronal sections was performed by Sholl analysis to develop the morphology of the regions of the hippocampus: CA1, CA3 & dentate gyrus (DG). The results of the group with MS shown a significant difference in the dendritic order, total dendritic length, & in the density of dendritic spines of the three brain regions analyzed (CA1, CA3 & DG) compared to the control group. Additionally, the immunoreactivity of sirtuin-1 & synaptophysin (markers of neuronal plasticity) decreased in the group with MS compared to the control group. Results suggest that the MS contributes to development of a neurodegenerative process & cognitive failure. In this regard, is important to understand the relationship between MS & neuronal damage, with the purpose of prevent the onset of neurodegenerative disorders. Furthermore, this work open up the possibility of researching treatments to counteract or prevent the brain damage occurrence, caused by metabolic disorders in an excessive calorie intake.

Title: Metabolic fuel switch from glucose to ketones regulatesSIRT3 in the brain

Authors: ***K. MAROSI**, S. KIM, M. P. MATTSON, R. CUTLER, S. CAMANDOLA; NIH, Baltimore, MD

Abstract: SIRT3 is a member of the Sirtuin family of NAD^+-dependent deacetylases and plays a critical role in metabolic regulation. Previously we found that neurons lacking the mitochondrial deacetylase SIRT3 are more vulnerable to dysfunction and degeneration in mouse models of epilepsy and Huntington's disease. We also showed that exercise and synaptic activity induce hippocampal SIRT3 expression to modulate mitochondrial protein acetylation and bolster neuronal resistance to oxidative stress and apoptosis. In our current study we investigated how physiological and metabolic changes resulting from dietary interventions and exercise affect SIRT3 levels and activity in the brain. We found that alternate day fasting and exercise promote a metabolic fuel switch involving elevated ketone levels and reduced blood glucose levels in C57BL/6J mice. Elevated plasma ketone levels were correlated with enhanced SIRT3 protein levels in the brain of the mice that were subjected to alternate day fasting and exercise compared to the sedentary controls. We then investigated how the ketone 3β-hydroxybutyrate (3OHB) regulates SIRT3 expression in cultured primary rat cortical neurons. 3OHB increased SIRT3 protein levels and activity in a low glucose condition, but not in a high glucose condition indicating that changes in the substrate utilization regulate SIRT3. We found that 3OHB induces ATP and NAD^+ production by bypassing glycolysis and promoting mitochondrial respiration in the neurons, which might play a role in the modulation of SIRT3 activity. We are currently employing SIRT3-/- mice to determine whether SIRT3 mediates neuroprotective effects of fasting in models of brain injury and neurodegenerative disorders. Abstract: The Healthy Brain Project (HBP; http://brain.umn.edu/brp/index.shtml) is a unique study at the Brain Sciences Center at the Minneapolis VA Medical Center and the University of Minnesota that integrates neuroimaging (magnetoencephalography, structural and functional MRI, diffusion weighted MR imaging, MR spectroscopy), genetics (apolipoprotein E genotype), cognitive, and lifestyle data to identify characteristics associated with healthy brain aging. Participants are cognitively healthy (MoCA score > 25) adults (primarily women veterans), 30-100+ years old who are being studied annually, thus enabling the search for associations among study variables cross-sectionally and their validation longitudinally. We have recently extended this rich data set to include detailed nutritional information, since nutritional status can have a major effect on brain functioning. In addition, collecting such data from a healthy population could allow for more detailed identification of dietary habits associated with healthy brain function across the lifespan. Specifically, participants are asked to prepare food journals by recording food and beverage intake for three days, two weekdays and one weekend day. The items are then entered into Nutritionist Pro Version 6 software for further analysis. Using this software, we are able to quantify 115 macro and micro-nutrients, including amino acids, trace minerals, and lipids and associate the amount of intake to neural and other information above. We have collected, up to now, such nutritional data from 100+ participants. Preliminary analyses have revealed large variety in participants' intake of several nutrients, which allows for a rigorous, ongoing, exploration of associations with other information (neural functioning,

genetics, lifestyle, etc.). Since all our participants are cognitively healthy, we expect that these analyses will yield valuable insights into the dietary habits that underlie healthy brain aging.

Title: Hippocampal damage in the offspring exposed to perinatal high sucrose diet

Authors: *I. ZARCO DE CORONADO[1], S. MOSSO-MENDOZA[2], M. A. HERRERA[3]; [2]Fisiologia, [3]Biologia Celular, [1]UNAM, Mexico DF, Mexico

Abstract: In addition to its metabolic disturbances in offspring exposed to perinatal high sucrose diet (HSD), the male subjects showed deficit in spatial learning. This study determined the influence of maternal HSD on hippocampal neurons of infantile rats. Dams were fed, since 14 gestation day to the end of lactation period, a HSD (20 % sucrose solution) or control diet. Brains were removed after lethal anesthesia, from infantile offspring. Fixed in formaldehyde 3.7%. Freeze sliced to 20 µm using Leica CM Criostat1510S. Stained Cresyl violet, Kluver Barrera and HE. Nikon Eclipse 80i microscope. Nikon DS-Fi1c digital camera, Software NIS-Elements F; Image Pro Plus 7.0 analysis. Decreased number of pale pyramidal cells in CA3 (66% in males and 61 % in females). There were vascular dilatation and increased number of glial cells. The results suggest that perinatal HSD induce previously reported obesity, dyslipemia and spatial learning acquisition deficit in male offspring associated with altered hippocampal proliferative and inflammatory activity.

Title: Oxidative stress underlies amyloid-beta toxicity and mitochondrial dysfunction in Alzheimer's disease

Authors: *L. ADLER, W. REGENOLD, S. DODDI;
Psychiatry (Geriatric), Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Background: The amyloid cascade theory hypothesizes overproduction and/or reduced clearance of Amyloid-Beta (Aβ) are etiologic in late-onset Alzheimer's Disease (LOAD). Unanswered questions persist. (1) Are these processes downstream biologic events? (2) What is the physiologic role of soluble Aβ monomers? (3) What is the physical chemistry in of Aβ aggregation? (4) Are biological factors converging with Aβ aggregation in the genesis for AD? (5) Is there a vicious cycle where disrupted energy transduction facilitates toxic Aβ aggregation and aggregation further disrupts mitochondrial energy transduction?**Objective:** Review of risk factors for LOAD which converge to dysregulate mitochondrial energy transduction.
Methods: PubMed, EMBASE, and Medline were searched using (Alzheimer's -risk factors - inflammation- mitochondria- vascular-bioenergetics- Aβ). Relevant manuscripts were reviewed to generated a coherent hypothesis of converging risk factors leading to disruption of mitochondrial function. **Results:** Age is the primary risk factor. Vascular risk factors include hypertension, hyperlipidemia, diabetes and ApoE4. Recurrent depressive episodes and their association with cortisol dysregulation confer increased risk.
Vascular burden is associated with sub-cortical CNS ischemic changes. Recurrent depressive episodes are associated with microvascular changes and with cortisol dysregulation which is neurotoxic. These events promote increases in inflammatory mediators. Reduction in proton-motive force and inability of mitochondria to buffer against reactive oxygen species (ROS) result. Mitochondrial DNA (mtDNA) is damaged by close proximity to ROS at the site of electron transport. There is insufficient energy for clearance of soluble Aβ into the CSF and in to the glymphatic system. At nanomolar concentrations. aggregated Aβ results in activate microglia- mediated inflammation. Tau hyperphosphoryllation and deposition of amyloid result, perhaps through up-regulated GSK-3β. Activation of caspases leads to neuronal apoptysis. Soluble Aβ monomers at picomolar concentrations are implicated in neurogenesis and synaptic protection.The biophysics of conversion of helical Aβ to pleated sheet Aβ aggregates requires further study; the role of chaperones needs further elucidation. **Conclusion:** Deposition of amyloid and tau are likely down-stream events resulting convergence of vascular factors,

disruption of mitochondrial energetics, subcellular and physical chemical events influencing aggregation and changes in physiology related to decrease in pulsatile energy in small arteries promoting glymphatic clearance.

Title: Neuroprotective effect of blackberry juice in rats under a hypercaloric diet

Authors: *B. PÉREZ GRIJALVA[1,2], R. MORA ESCOBEDO[2], R. GUZMAN GERONIMO[3], A. DIAZ[4], S. TREVIÑO[4], C. PEREZ CRUZ[1];

Abstract: Recent studies have shown that hyperglycemia and hyperinsulinemia conditions can produce neuroinflammation and increase the oxidative stress, resulting in neuronal damage and cognitive impairment[1,2.]. Anthocyanins and other phenolic compounds poses important antioxidant properties and can prevent Aβ aggregation and prevent the cognitive deficits in AD-like mice[4]. Blackberries are fruits rich in anthocyanin content with important anti-hyperglycemic[5], anti-inflammatory, antiproliferative and chemopreventive activities[6,7]. So far, there are no reports about blackberry fruit effect in brain health in rats under a hypercaloric diet. The objective of this study was to evaluate the neuroprotective effects of blackberry juice in rats fed a hypercaloric diet (HCD). Male Wistar rats (100 ± 20 g) were divided in 2 groups: Control group (LabDiet 5001, n=14) and HCD group (MX/E/2013/047377, n=14), and kept on this diets during 3 months. At this stage, metabolic parameters were already altered in HCD group, accompanied by cognitive deficits. Thereafter, each group as divided into 2 sub-groups: one received blackberry juice (50 mg/kg/day of anthocyanins, adjusted weekly for weight changes), and the other plain water during 21 days (n=7, each). Cognitive assessment was done before sacrifice and brain samples were taken, hippocampus and cortex were dissected for immunohistochemistry and diolistic labelling studies. Our results indicates that HCD causes neuroinflammation in hippocampus, increases oxidative stress in the cortex, and reduces the

number of dendritic spines in the CA1 region of the hippocampus, resulting in memory impairments. The blackberry juice supplementation, however, modified this neuroanatomical alterations and the behavioural performance in HCD rats. Thus, our results suggest that blackberry juice can be a potential therapeutic strategy against metabolic and cognitive deficits induced by high-caloric diets. Title: Weakened neurotrophic support and aberrant levels of neurometabolites in the brain underlie reduced lifespan of WNIN/Ob obese rats.

Authors: *J. K. SINHA[1], S. GHOSH[1], V. TIWARI[2], A. B. PATEL[2], M. RAGHUNATH[1]; [1]Natl. Inst. of Nutr. (NIN), Hyderabad, India; [2]Ctr. for Cell. and Mol. Biol., Hyderabad, India

Abstract: Aim: Wistar NIN obese (WNIN/Ob) rats developed at the National Institute of Nutrition are the heaviest inbred rat strain in the world. These rats are hyperphagic, hyperinsulinemic, hyperleptinemic and have reduced longevity (an average lifespan of 15-18 months in contrast to 36 months in normal Wistar rats). The major objective of the current study was to delineate the factors responsible for reduced longevity in the WNIN/Ob rats. **Methods:** Neurotrophic factors are responsible for the survival of developing neurons and the maintenance of mature neurons. The levels of key neurotrophic factors was estimated using BioPlex assay. The astrocytic infiltration was monitored using immunohistochemistry in different brain regions of these rats. As glutamate (Glu) and γ-aminobutyric acid (GABA) are the major excitatory and inhibitory neurotransmitters in the matured mammalian CNS, and are responsible for the majority of energy metabolism in brain. The brain energy metabolism associated with Glu and GABA pathways was measured in different brain regions of WNIN/Ob rats and their age

matched normal rats using ^{13}C Magnetic Resonance Spectroscopy (MRS) in conjunction with infusion of ^{13}C labeled [1-^{13}C]glucose. In addition, volumetric differences in the brain of WNIN/Ob rats was measured using Magnetic Resonance Imaging (MRI). **Results:** Our findings show that the levels of key neurotrophic factors were significantly altered *e.g.* decreased BDNF and increased IGF-1 in the WNIN/Ob rats which could cause degeneration of neural tissue and macromolecular damage in the brain. We have previously reported this in the cerebral cortex and hippocampus of the obese rats. There were no significant volumetric changes in the brain of the WNIN/Ob rats when compared to controls. ^{13}C MRS data indicate hypo-metabolism in the brain of WNIN/Ob rats when compared with age matched controls which shows insufficient supply of energy needs of brain at an early age. Such decreased brain metabolism could contribute to the accelerated ageing observed in the WNIN/Ob rats. **Conclusion:** To conclude we can say altered levels of neurotrophic factors and aberration in neurometabolism in the brain underlie decreased longevity of WNIN/Ob rats.

Title: Mitochondrial complex-1 assembly into supercomplexes determines mitochondrial reactive oxygen species production in neurons and astrocytes

Authors: *J. P. BOLANOS[1], I. LOPEZ-FABUEL[1], J. LE DOUCE[2], G. BONVENTO[2], A. M. JAMES[3], M. P. MURPHY[3], A. ALMEIDA[4];

[1]UNIVERSITY OF SALAMANCA, SALAMANCA, Spain; [2]Mol. Imaging Ctr. (MIRCen), Paris, France; [3]Med. Res. Council Mitochondrial Biol. Unit, Cambridge, United Kingdom; [4]Inst. of Biomed. Res. of Salamanca, Salamanca, Spain

Abstract: Neurons tightly depend on oxidative phosphorylation for energy generation, whereas astrocytes do not, a distinctive feature that is essential for neurotransmission and neuronal survival. However, whether these metabolic differences are dictated by cell-specific structural organization of the mitochondrial respiratory chain is unknown. Here, we aimed to investigate this issue and found that in neurons, mitochondrial complex I is predominantly assembled into supercomplexes, whereas in astrocytes it is mainly present as an individual complex. In consequence of this, astrocytes produce reactive oxygen species (ROS) by complex I several-fold faster than neurons. Using a complexomics approach, we identified complex I subunit, NDUFS1, to be more abundant in neurons than in astrocytes. Interestingly, NDUFS1 knockdown in neurons limited the association of complex I with supercomplexes, leading to impaired mitochondrial oxygen consumption and increased mitochondrial ROS. Conversely, over-expression of NDUFS1 in astrocytes promoted complex I incorporation into supercomplexes leading to decreased ROS. Thus, complex I assembly into supercomplexes regulates ROS production and contributes to the bioenergetic shapes of neurons and astrocytes.

Title: Aerobic glycolysis in the frontal cortex correlates with memory performance in wild-type but not APP/PS1 mice: implications for metabolic intervention in Alzheimer's disease

Authors: R. A. HARRIS[1], S. L. MACAULEY[4], D. M. HOLTZMAN[4], R. BARTHA[2], *R. C. CUMMING[3];

[1]Biol., [2]Robarts Res. Inst., [3]Dept. of Biol., Univ. of Western Ontario, London, ON, Canada; [4]Dept. of Neurol., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: The majority of glucose consumed by the adult brain is fully oxidized in the mitochondria of neurons to supply the large amounts of ATP required for synaptic transmission. However, a certain percentage of glucose in the brain is exclusively metabolized by glycolysis to generate lactate, even when oxygen is not rate limiting. This form of metabolism is known as aerobic glycolysis. Emerging evidence now suggests that aerobic glycolysis in the brain plays a critical role in generating biosynthetic metabolites during early CNS development and persists in certain regions of the adult brain to support synaptic plasticity, learning and memory. However, aerobic glycolysis steadily declines with age and virtually disappears in the elderly. Our lab has recently demonstrated that a metabolic shift to aerobic glycolysis confers nerve cells with a survival advantage against the toxic effects of amyloid beta, a key pathogenic peptide in Alzheimer's disease (AD). However, the beneficial effect of aerobic glycolysis in the AD brain remains to be fully elucidated.

Here we examined the relationship between cerebral lactate levels and memory performance over a 12 month period in the APP/PS1 mouse model of AD which progressively accumulates amyloid-β (Aβ). *In vivo* ^{1}H-magnetic resonance spectroscopy and western blot analysis of brain tissue revealed a progressive decline in aerobic glycolysis in the frontal cortex of the mouse brain with age. In 12 month old wild type mice we observed that increased expression of lactate producing enzymes in the frontal cortex correlated with better memory performance in the Morris water maze, whereas expression of LDHB, a lactate consuming enzyme, correlated with poorer memory. Interestingly, in 12 month old APP/PS1 mice the opposite effect was observed where increased expression of lactate producing enzymes, and overall lactate levels, correlated with poorer memory performance. In addition, immunofluorescent staining of brain sections revealed expression of the aerobic glycolysis enzymes PDK1 and LDHA primarily in neurons in control mice, as well as in astrocytes surrounding amyloid plaques in APP/PS1 mice. These observations collectively indicate that the production of lactate through aerobic glycolysis is beneficial for memory function in healthy subjects but declines naturally with age. In contrast, elevated lactate levels in APP/PS1 mice indicate perturbed lactate processing; a factor that may contribute to AD pathogenesis. Moreover, these findings suggest that metabolic intervention may offer a new therapeutic strategy for the treatment of AD.

Title: Functional food restores SIRT1 levels and reverses dendritic spine loss in medial prefrontal cortex of obese rats

Authors: *L. PÉREZ JIMÉNEZ[1], T. BEGUM S[1], A. RAMIREZ-MIRAFUENTES[2], M. SANCHÉZ-TAPIA[2], N. TORRES-TORRES[2], C. PEREZ-CRUZ[1];
[1]CINVESTAV, Ciudad DE Mexico, Mexico; [2]NUTRITION PHYSIOLOGY, Natl. Inst. of Med. Sci. and Nutr. Salvador Zubiran, Ciudad DE Mexico, Mexico

Abstract: Mild-life obesity has been associated with alterations in gene expression, decreased metabolic expenditure and subsequently learning and memory deficits. Sirtuin 1 (SIRT1) is a NAD- dependent class III deacetylase that function as cellular energy sensor. Diet-induce obesity (DIO) reduces SIRT1 expression in brain and liver, while SIRT1 activation reduces body weight and increases life-span. Recent investigations shows a permissive role of SIRT1 in memory consolidation and dendritic out-growth [1,2]. One therapeutic strategy against obesity-induced metabolic alterations is the use of functional food (FF). FF enhances the expression of enzymes and proteins related to energetic metabolism, and has shown neuroprotective effects in obese rats [3] . The objective of this study was to evaluate the effects of a combination of FF (5% dehydrated cactus, 20% soybean oil, 3% chia and 1% turmeric) in SIRT1 and spine density in medial prefrontal cortex (mPFC) of obese rats. Male Wistar rats weighing 250 ± 20 g were divided in two groups: Controls (fed control diet AIN-93, n=10) and High-fat-diet group (HFD, plus 5% sucrose in water, n=20). Animals were kept on this diets during 4 months. Once animals in HFD-S reached significant metabolic alterations (i.e. overweight, high plasma levels of triglycerides, cholesterol, LDL and glucose intolerance) cognitive performance was evaluated (T-maze and novel object recognition, NOR). Thereafter, HFD-S rats were divided in two groups: one has been supplemented with FF and the other remained solely as HFD-S during 3 more months. Cognitive assessment was done before sacrifice. Immunofluorescence for SIRT1 and diolistic labelling for spine quantification was performed in the right mPFC. Our results shows that obesity decreased SIRT1 protein in HFD+S compared to AIN (**$p < 0.01$) along with a reduction in mean spine density (*$p<0.05$). However, addition of FF was able to recover SIRT1 levels (HFD-S+PD vs HFD-S, ***$p<0.001$) and modify the morphology of spines by increasing the number of mushroom type-spines (HFD-S+PD vs HFD-S,*$p<0.05$), resulting in cognitive improvements. Thus, brain alterations induced by high-fat-diet affects mPFC and behavior, while FF was able to abate this alterations. The use of FF can be a therapeutic strategy to treat metabolic and cognitive alterations in obese subjects. 1. Codocedo et al.,2012. 2. Gao, J. *et al.*

Abstract: Alzheimer's disease (AD) is a multifactorial disease for which both genetic and environmental risk factors have been identified. Two such environmental risk factors are midlife obesity and age-related testosterone loss in men. Because these two factors often coexist in middle aged men, obesity and loss of testosterone may coincide to cooperatively promote AD pathogenesis. Consistent with this possibility, our recent work in young adult male rodents has shown an interaction between these risk factors, demonstrating that animals with both low testosterone and diet-induced obesity exhibit exacerbated AD-related outcomes. Moreover, we and others have shown that testosterone protects against both obesity and cognitive decline. Unclear is how obesity and testosterone interact across the lifespan. The goal of the current study was to compare interactions between these two factors in young adult, middle aged, and aged brown Norway rats, which display age-related testosterone loss. Male rats were maintained on normal (10% fat) or high fat (60% fat) diet for a 3-month period beginning at age 3, 13, or 23 months. At the onset of diet manipulations and middle-aged (13 mo) and aged (23 mo) rats were implanted subcutaneously with silastic capsules containing testosterone or vehicle. Endpoints included metabolic indices, learning and memory performance, inflammation, and neural health outcomes. Results show that high fat diet was associated with increases in body weight and leptin levels across all ages, and impaired glucose metabolism in young and middle aged rats.

Learning and memory were evaluated using the Barnes Maze task. Though aged rats were slower to learn the task, all groups demonstrated learning by the end of training. High fat diet had no significant effect on memory in young rats, but increased memory errors in middle-aged and aged animals. Testosterone protected against the effects of diet on memory. Furthermore, we found effects of age and testosterone on neuroinflammation, such that testosterone protected against age-associated increases in inflammatory markers. Overall, results show interactive effects of testosterone and high fat diet on metabolic, behavioral, and neural health outcomes that vary across age. Understanding the interactions between obesity, testosterone, and aging will provide significant insight into the both the development and prevention of age-related cognitive decline and AD.

Title: The relationship between metabolic impairment and proteasome activity the nervous system of *Drosophila*

Authors: *T. SCHMIDT-GLENEWINKEL, M. JANSEN, S. BENNETT, A. KLEIN, A. RASHID, J. NETHERCOTT;
Biol. Sci., Hunter Col. of CUNY, New York, NY

Abstract: Mitochondrial dysfunction and proteasome impairment are associated with many distinct neurodegenerative disorders. To better understand the relationship between metabolic impairment and proteasome function we use the the binary inducible GeneSwitch system to permanently disrupt the activity of ATP synthase in fruit flies. We show that 5uM of the steroid inducer RU486 is sufficient to significantly decrease the lifespan of both male and female flies. Furthermore we observe a 10-15% decline in ATP levels after flies are fed 5uM RU486 for 13 days or longer. This decline in ATP is accompanied by a significant reduction in 26S proteasome activity. Although the proteasome is functionally dependent on ATP, it is unclear how a 10-15%

decline in ATP levels can dramatically alter its function. In our studies we find that lactic acid levels are increased 2-4 fold when flies are fed 5uM RU486 for 13 days. The elevated levels of lactate observed in our study suggests that glycolysis may be elevated to compensate for a decline in mitochondrial efficiency. Glycolysis produces methylglyoxal (MG) as a toxic byproduct. MG is a powerful glycating agent that can modify proteins, lipids, and nucleic acids leading to the formation of advanced glycation end products (AGE). AGE has been implicated in the pathology of diabetes mellitus, aging, and neurodegeneration. Furthermore MG has been shown to covalently modify the catalytic pros beta5 subunit of the proteasome suggesting that it may directly inhibit the proteasome. We hypothesize that MG levels will be elevated in Act5C-GeneSwitch/UAS-ATP5B RNAi flies when they are exposed to 5uM of the steroid inducer RU486. Elevated levels of MG may indicate elevated levels of oxidative stress, which would increase the abundance of oxidatively damaged proteins, and promote a decline in proteasome function, and subsequently increases in protein aggregates.

Title: A vascular niche for highly active neurons

Authors: ***T. MIYAWAKI**[1], S. YAMAGUCHI[2], Y. IKEGAYA[1];
[1]The Univ. of Tokyo, Hongo, Japan; [2]Gifu Univ., Gifu, Japan

Abstract: Energy constrains a system's processing capacity (Laughlin, 2001). To maximize its yield of the available energy resource, the brain has developed an elaborated supply chain, the cerebral vascular network. Just like "the Smart Grid", the cerebral vascular network can tightly match the demand with the supply, by locally increasing the amount of blood flow where the amount of synaptic activity has increased (Logothetis et al., 2001).
Despite numerous studies on the coupling to the change in metabolic demand, little work has investigated the coupling to the basal heterogeneity in metabolic demand. A recent study

reported that firing rates of individual neuron showed a preconfigured and skewed distribution, suggesting that the metabolic demand is constituently heterogeneous, even within a single brain region (Mizuseki and Buzsáki, 2014).
To examine whether there would be a mechanism to couple this basal heterogeneity, we investigated the spatial relationship between highly active neurons and blood vessels. We labeled a fraction of highly active neurons using Arc-dVenus transgenic mice (Eguchi and Yamaguchi, 2009), and measured the distances to the blood vessels in 3D using the CUBIC protocol (Susaki et al., 2014). We have found that, in the neocortex, the highly active neurons resided significantly nearer the blood vessel compared to the surrogate.
Given that oxygen and other nutrients show higher concentrations in the vicinity of blood vessels, our result implies a previously unexplored coupling mechanism of the metabolic supply to the basal heterogeneity of the metabolic demand.

Title: Effects of recurrent hypoglycemia on growth hormone releasing hormone (GHRH) neurons

Authors: ***M. BAYNE**, A. ALVARSSON, S. A. STANLEY;
Diabetes, Obesity and Metabolism Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Maintenance of normal blood glucose levels is an intricate process coordinated between the central nervous system (CNS) and peripheral organs. In disease states like diabetes, recurrent hypoglycemia is a common complication that can cause cognitive and metabolic defects. While the brain monitors and adjusts blood glucose levels constantly, the neuronal adaptations to repeated hypoglycemic episodes are poorly understood. There are several counter-regulatory responses to hypoglycemia including increased growth hormone. Those neurons expressing growth hormone releasing hormone are highly responsive to low glucose. Therefore, this hypothalamic population of neurons may serve as a model to study how glucose-responsive

neurons respond and adapt to repeated hypoglycemia. We first show that plasma growth hormone levels are modulated by acute and repeated hypoglycemia in mice. Immunohistochemical examination was used to assess morphological changes in response to hypoglycemia and quantification of the neuronal activity markers, c-fos and phosphoS6, was used to evaluate changes in GHRH neural activation after single or repeated episodes of hypoglycemia. We measured changes in gene expression in GHRH-expressing neurons subjected to single or recurrent hypoglycemia. These experiments present possible adaptations to recurrent hypoglycemic episodes.

Title: Dynamics of lactate and glucose in the extracellular compartment of the motor cortex during running: Impact of intraperitoneal glucose, fructose, and insulin

Authors: *C. MESSIER[1], A. BELAND[2], P. SHUKLA[2], J. LARCHER[2];
[1]Sch. of Psychology, [2]Psychology, Univ. of Ottawa, Ottawa, ON, Canada

Abstract: As most textbooks state, glucose is the main fuel of the brain. The Neuron-to-Astrocyte-Lactate Shuttle (NALS) suggests that the lactate is a by-product product of neuronal glucose. Conversely, a competing hypothesis by Pellerin and Magistretti, the Astrocyte-to-Neuron-Lactate Shuttle (ANLS) hypothesis proposes that peripheral glucose is taken up by astrocytic end feet, converted to lactate and released in the extracellular space and used by neurons as a source of metabolic fuel. Within this context, we examine the changes in lactate and glucose in the extracellular fluid of the motor cortex during running in a running wheel following intraperitoneal (ip) injections of saline or 2g/kg of glucose, fructose, or 1.2 IU / kg insulin. Electrochemical electrodes (Pinnacle Tech.) that detect glucose or lactate were inserted in the left or right motor cortex of CD-1 male mice so that glucose and lactate could be measured simultaneously. Glucose and lactate levels were measured before and after the initiation of running and results were expressed as a percentage of pre-running values. First, we determined that small minute movements produced a sharp decrease in motor cortex extracellular lactate and to a lesser extend glucose as been shown previously with discrete brain stimulation. This result

suggests that both lactate and glucose are transferred to brain cells following neuronal activation. Sustained running in a running wheel was associated with a gradual increase in lactate (up to 140%) and a smaller (-10%) but sustained decrease in glucose. These were specific to the motor cortex limb area because sustained running did not produce any changes in the extracellular glucose and lactate in the visual cortex. In many instances, the slope of lactate increase after the onset of running appeared to predict the length of a running bout - the sharper lactate rises were associated with the longest bouts. A strong and positive correlation ($r=0.53, p < .001$) was found for lactate but not for glucose ($r=0.08, p =.69$) between individual rate of increase and their associated running length. When mice were running after receiving an injection of glucose or fructose, the rise in extracellular lactate was significantly reduced while the extracellular glucose decrease was similar to that without injection. While insulin generally reduced extracellular glucose and lactate, running still produced a small increase in extracellular lactate but no change in extracellular glucose. These results show that complex interactions influence the extracellular levels of glucose and lactate that depends on neuronal activity and blood levels of nutrients.

Title: PTG is a central regulator of glycogen synthesis in astrocytes

Authors: *I. ALLAMAN[1], E. RUCHTI[1,2], P. J. ROACH[3], A. A. DEPAOLI-ROACH[3], P. J. MAGISTRETTI[4,1,2];

Sch. of Med., Indianapolis, IN; [4]Div. of Biol. and Envrn. Sci. and Engin., King Abdullah Univ. of Sci. and Technol. (KAUST), Thuwal, Saudi Arabia

Abstract: The storage and use of glycogen, which is the main energy reserve in the brain, is a metabolic feature of astrocytes. Protein targeting to glycogen (PTG) is a member of specific glycogen-binding subunits of protein phosphatase-1 (PP-1) which positively regulates glycogen synthesis through de-phosphorylation of both glycogen synthase (activation) and glycogen phosphorylase (inactivation). To gain further insight into the role of PTG in the regulation of

astrocytic glycogen, its levels of expression were manipulated in primary cultures of mouse cortical astrocytes using adenovirus-mediated overexpression of tagged-PTG or siRNA to downregulate its expression. Infection of astrocytes with adenovirus led to a strong up-regulation of PTG expression and was associated with massive glycogen accumulation (more than 100 fold), demonstrating that increased PTG expression is sufficient to induce glycogen synthesis and accumulation. In contrast, siRNA-mediated downregulation of PTG resulted in a 1.8 fold decrease of glycogen basal values. Interestingly, PTG downregulation was also shown to significantly impair long-term astrocytic glycogen synthesis induced by insulin or noradrenaline, while mobilization of residual glycogen by short term treatment of noradrenaline was not affected. Finally, these effects of PTG down-regulation on glycogen metabolism could also be observed in cultured astrocytes isolated from PTG-KO mice. Collectively, these observations point to a major role of PTG in the regulation of glycogen synthesis in astrocytes and indicate that conditions leading to changes of PTG expression will directly impact glycogen levels in this cell type.

Title: Dorsal raphe nucleus: A locus for energy homeostasis

Authors: *B. FIELD, A. NECTOW, Y. LIANG, J. FRIEDMAN;
Rockefeller Univ., New York, NY

Abstract: The balance of food intake and energy expenditure, both from exercise and the baseline metabolic rate, determine an animal's weight gain, loss, or maintenance. In the mammalian brain, the anorexigenic hormone leptin principally works on hypothalamic neural subpopulations to control appetite. Here we investigate the role of the dorsal raphe (DRN), an extrahypothalamic structure, in behaviors modulating energy balance in wildtype and leptin-deficient mice (ob/ob). By manipulating its glutamatergic and GABAergic populations, we find

that this brainstem region is capable of exerting control over feeding-related behaviors. Via whole-brain projection mapping, we have shown that these neural populations are anatomically and molecularly distinct and have direct interaction with the hypothalamus. These data show that the dorsal raphe nucleus is a functionally significant brain region in energy homeostasis.

Title: Estradiol in the medial amygdala prevents ovariectomized induced metabolic responses in female rats

Authors: *C. ESTRADA[1], V. GHISAYS[2], E. T. NGUYEN[3], J. CALDWELL[3], J. STREICHER[3], M. B. SOLOMON[3];
[2]Psychology, [3]Psychiatry and Behavioral Neurosci., [1]Univ. of Cincinnati, Cincinnati, OH

Abstract: The posterodorsal medial amygdala (MeA) modulates energy homeostasis in rodents. For example, MeA lesions increase body weight, adiposity and circulating insulin concentrations. Notably, this metabolic phenotype is exaggerated in females relative to males. In female rodents, bilateral removal of the ovaries (ovariectomy) induces a metabolic phenotype characterized by increased body weight and visceral adiposity, elevated glucose and insulin concentrations, and decreased activity. Of note, systemic (17-β-Estradiol-(E2)) administration prevents and/or reverses many of these metabolic endpoints in ovariectomized females. The metabolically beneficial effects of systemic E2 are in part due to binding via estrogen receptors in brain regions regulating energy homeostasis. Given the prominent role of the posterodorsal medial amygdala in energy homeostasis and the abundance of estrogen receptors within this region, we tested the hypothesis that E2 administration in the MeA prevents ovariectomy-induced metabolic sequela. To test this hypothesis, adult ovariectomized female rats were implanted with bilateral E2 or cholesterol micropellets aimed at the posterodorsal MeA. In Experiment 1, females with confirmed MeA-E2 hits lost body weight relative to their cholesterol treated counterparts. When food intake was normalized to body weight there was no difference between females treated with E2 in the MeA and cholesterol treated controls suggesting that the E2-mediated effects on body weight were due to increased energy expenditure. Notably, E2

administration in the MeA decreased visceral adiposity, but had no effect on subcutaneous fat. This finding indicates a adipose depot specific effect of E2 treatment. In Experiment 2 we tested the hypothesis that E2 administration in the MeA prevents glucose intolerance in ovariectomized females. Consistent with our hypothesis, females treated with E2 in the MeA had decreased glucose concentrations in response to an oral glucose challenge. Studies are currently underway to determine the mechanisms mediating improved glucose tolerance in ovariectomized females treated with the E2 in the MeA. In addition we plan to delve further into the role of ERα signaling within the MeA on energy homeostasis in different rodent models of obesity. Taken together, the findings highlight a prominent role of the MeA as a critical node in regulating metabolic responses in ovariectomized females.

Title: Genetically dissecting a hypothalamic neural circuit controlling glucose homeostasis

Authors: *C. S. LOW, X. YI, C. BARTOLOME, J. XU, P. WANG, D. KONG;
Neurosci., Tufts Univ., Boston, MA

Abstract: Growing evidence has recently shown that neurons in the hypothalamus play important roles in regulating glucose homeostasis, and their dysfunctions contribute to the pathogenesis of diabetes. However, the complexity of the neural system and difficulties in probing neuronal function *in vivo* has left us with an incomplete understanding of both the molecular mechanism and neuro-circuitry of neuron-mediated blood glucose regulation. Fortunately, we have recently perturbed a major group of glucose-sensing neurons, arcuate hypothalamic Pro-opiomelancortin (POMC) neurons. We have validated that these neurons play a significant physiological role in regulating whole body glucose homeostasis. Improving their glucose-sensing capacity has been shown to dramatically attenuate the hyperglycemia in mouse models of both Type I and Type II diabetes. Thus, our recent work has focused on POMC neurons and elucidating their control of whole body glucose homeostasis by combining a battery of genetic approaches. Briefly, we first used a pharmacogenetic tool to acutely manipulate the firing of POMC neurons and assessed the causal effects in blood glucose control. By combining the cutting-edge genomic editing method, clustered regularly interspaced short palindromic

repeats (CRISPR), and viral tools, we went further to identify the glucose-lowering neurotransmitter released from POMC neurons. The pathological contributions to induced Type I and Type II diabetes has also been explored. Our studies demonstrate that POMC neurons in the arcuate nucleus play an essential role in whole body glucose regulation. The elucidation of the molecular mechanisms and factors in these neurons will also assist in the identification of novel therapeutic targets for treating diabetes.

Title: Physiological characterization of the hypoxia tolerant heart and brain of the naked mole rat

Authors: *D. T. APPLEATE[1], J. LARSON[2], T. PARK[2];
[1]Neurosci., Univ. of Illinois at Chicago Dept. of Neurosurg., Chicago, IL; [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Hypoxic brain damage, as occurs in stroke or after heart attacks, can lead to permanent disability and/or death. Ischemic strokes or other interruptions to cerebral oxygen supply lead to neuronal cell death that begins within a matter of minutes. The unpredictability of cerebral ischemic events and their rapidly-developing consequences make prevention and treatment of stroke-induced brain damage particularly difficult. Study of model animals that are naturally resistant to hypoxia may provide clues to the treatment of hypoxic brain injury. One organism exhibiting remarkable hypoxia tolerance is the naked mole-rat, which survives underground in a chronically oxygen-depleted environment. Previous studies have shown that hippocampal neurons in naked mole-rat brain are extremely tolerant to hypoxia in vitro. While the physiological mechanisms underlying brain hypoxia tolerance are poorly understood, insights can be gained by monitoring whole body responses to environmental oxygen depletion. To characterize the hypoxia tolerance of naked mole-rats, we asked the following questions: (1) What are the effects of hypoxia on cardiac activity? (2) How does brain activity respond to low levels of oxygen? To measure the effects of hypoxia on physiological activity of the naked mole rat, electrocardiogram and electroencephalography were used. We observed that upon exposure to hypoxia, the naked mole rat experienced a significant drop in heart rate and a suppression of brain electroencephalographic activity. These states were maintained for many minutes in a low

oxygen environment and recovered to baseline levels upon replacement of the ambient oxygen. These findings characterize the physiological response of naked mole rats to oxygen depletion and provide preliminary insights into the mechanisms underlying neuroprotection of the hypoxia tolerant brain.

Title: Alternate fuels for the brain: impact of intraperitoneal glucose, fructose, galactose, lactate, pyruvate, beta-hydroxybutyrate and insulin on glucose and lactate levels in the brains' antechamber.

Authors: *A. BELAND[1], J. COURTEMANCHE[2], J. LARCHER[2], T. YUAN[2], C. MESSIER[2]; [1]Univ. of Ottawa, Dunvegan, ON, Canada; [2]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: As most textbooks state, glucose is the main fuel of the brain. The Neuron-to-Astrocyte-Lactate Shuttle (NALS) suggests that the lactate is a by-product product of neuronal glucose. Conversely, a competing hypothesis by Pellerin and Magistretti, the Astrocyte-to-Neuron-Lactate Shuttle (ANLS) hypothesis proposes that peripheral glucose is taken up by astrocytic end feet, converted to lactate and released in the extracellular space and used by neurons as a source of metabolic fuel. Within this context, we examine the changes in lactate and glucose in the extracellular fluid of the motor cortex following intraperitoneal (ip) injections of glucose, fructose, galactose, lactate, pyruvate, beta-hydroxybutyrate and insulin. Electrochemical electrodes (Pinnacle Tech.) that detect glucose or lactate were inserted in the left or right motor cortex of CD-1 male mice so that glucose and lactate could be measured simultaneously. In separate experiments, we also measured glucose and lactate levels in tail blood using portable glucose and lactate meters. Glucose and lactate levels were measured before and after intraperitoneal injections and results were expressed as a percentage of pre-injection values. Intraperitoneal 2 g/kg glucose, fructose, lactate, pyruvate, beta-hydroxybutyrate and to a much lesser extent, galactose all raised cortical extracellular glucose levels (200%) while intraperitoneal insulin reduced cortex extracellular glucose and lactate equally. As expected, ip glucose raised and ip insulin reduced blood glucose. All ip injections raised blood lactate levels.

In contrast, extracellular cortical lactate levels remained unchanged except for a transitory raise following ip lactate and a 40% decrease following ip insulin. The present methodology does not allow determining the origin of the extracellular changes in glucose and lactating. However, the data indicates that blood increases of many potential metabolic substrates lead to increases in brain extracellular glucose but only the ip injection of lactate produced a significant but transient brain extracellular lactate increase. The observation that the ip injection of all substrates increased blood lactate raise the possibility that the extracellular glucose increase in the brain is due to brain metabolism of circulating lactate. However, the ip injection of 2g/kg of lactate does not lead to greater brain extracellular glucose. Interestingly, the extracellular glucose increase following the ip injection of glucose or lactate is almost immediate whereas the brain extracellular glucose increase is delayed following the ip injection of the other substrates.

Title: Low glucose utilization and high lactate production in the Alzheimer's disease brain

Authors: *R. J. MULLINS[1], D. REITER[2], D. KAPOGIANNIS[2];
[1]Lab. of Neurosci., Natl. Inst. On Aging, Baltimore, MD; [2]Natl. Inst. on Aging, Baltimore, MD

Abstract: Two defining neuropathological characteristics of Alzheimer’s disease (AD) are the presence of Amyloid-beta (Aβ) plaques and abnormalities in glucose metabolism. Brain regions with prominent Aβ deposition also have a higher metabolic reliance on glycolysis. The posterior cingulate/precuneus region shows early Aβ deposition and lower glucose utilization in AD. We hypothesized that AD patients show higher concentrations of glucose (due to decreased utilization) and lactate (due to greater production) in the posterior cingulate/precuneus. We studied 44 cognitively normal (CN) younger controls (42 ± 10 years old), 14 CN older controls (69 ± 8 years old), and 22 patients with high probability AD (based on low CSF Aβ, high CSF tau and/or p-tau) and a clinical dementia rating (CDR) of 0.5 or 1 (74 ± 8 years old). In exploratory models, patients with CDR 0.5 or 1 had no differences and were therefore combined into one group. Glucose and lactate levels were obtained using localized 2D J-resolved

spectroscopy (jPRESS) within a 25x18x20 mm posterior cingulate/precuneus voxel. Spectroscopy data were analyzed using ProFit to quantify metabolite concentrations normalized to creatine. We found that AD patients had higher glucose concentrations than both younger ($p < 0.0001$) and older ($p = 0.024$) CN participants. AD patients also had higher lactate concentrations than younger CN participants ($p = 0.008$). These findings suggest that metabolic abnormalities in AD result in higher glycolytic activity generating lactate while a greater portion of available glucose remains unused. We propose that glucose and lactate levels in posterior cingulate/precuneus can serve as novel biomarkers of abnormal brain metabolism in AD. Recruitment of older (60+) CN participants is ongoing. This research was supported entirely by the Intramural Research Program of the NIH, National institute on Aging.

Title: Imaging cytosolic metabolites and pH in mouse astrocytes

Authors: *J. W. DEITMER[1], J. SCHMÄLZLE[1], T. WEBER[1], I. RUMINOT[2], S. M. THEPARAMBIL[1];
[1]Univ. Kaiserslautern, D-67653, Germany; [2]CECs, Valdivia, Chile

Abstract: The high energy requirement of the mammalian brain is primarily fueled by the degradation of blood-derived glucose. Astrocytes, the major glial cells in the brain, take-up the larger portion of blood glucose, and by aerobic glycolysis they preferably produce more lactate. There is strong evidence that glucose consumption and glycolysis is highly dependent on cytosolic pH, but that it can also be stimulated by an increase in the intracellular [HCO_3^-]. Since pH and HCO_3^- shift concomitantly at constant CO_2 level, and both can be potential signals for modulating glucose metabolism, the question arises, whether the enhanced glucose consumption and glycolytic rate are mediated by proton or bicarbonate. We have asked, whether pH and the [HCO_3^-] must both rise in mouse cortical astrocytes, or if it suffices when either pH *or* HCO_3^- increases, to enhance glucose metabolism in mammalian astrocytes. We have recorded intracellular pH, using the pH-sensitive dye BCECF, and cytosolic glucose and lactate, using a FRET-based nanosensors, while imposing different intracellular pH and [CO_2]/[HCO_3^-], in cultured cortical astrocytes and in astrocytes of organotypic hippocampal brain slices. Glucose consumption and glycolytic rate were augmented by an increase in cytosolic pH, irrespective of a concomitant rise or fall in intracellular HCO_3^-. The transport of HCO_3^- into and out of astrocytes by the electrogenic sodium-bicarbonate cotransporter (NBCe1) played a crucial role for the changes in intracellular pH and [HCO_3^-], but was not obligatory for the pH-dependent changes in glucose metabolism. Our results suggest that the glycolytic rate in astrocytes is primarily augmented by the fall in $[H^+]_i$ not by a rise in $[HCO_3^-]_i$. *Supported by the Deutsche Forschungsgemeinschaft, DE 231/24-2.*

Title: Cell specific expression of alpha amylase 1 and 2A in hippocampus of non demented elders and patients with Alzheimers's disease

Authors: *E. K. BYMAN[1], N. H. SCHULZ[1], N. BRAIN BANK[2], M. WENNSTRÖM[1];
[1]Lund Univ., Malmö, Sweden; [2]Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: Amylose can be found in at least in two different forms in the brain. Either as intracellular inclusions in astrocytes, called corpora amylacea or as a high molecular weight un-branched glucose polymer, which has been associated with Alzheimer's disease. Branched glucose polymers, such as glycogen, are usually degraded by glycogen phosphorylase and glycogen de-branching enzyme in the brain. However, these enzymes are unable to cleave amylose effectively. The un-branched glucose polymer is instead known to be degraded by alpha-amylases, which cleaves 1,4 glucosidic bonds in glucose polymers. The specific cellular expression of alpha-amylase in the brain is not yet determined. We will therefore in the current study investigate the presence of alpha-amylases in different brain cells in elder individuals and patients diagnosed with Alzheimer's disease.
Postmortem brain sections of hippocampus from patients with AD and non-demented controls were immunohistochemically stained against salivary alpha-amylase (AMY1a) and pancreatic alpha-amylase (AMY2a). Immunoreactivity of AMY1a was foremost found in pericytes and neuronal dendrites, whereas AMY2a immunoreactivity was found in neuronal cellbodies as well as activated astrocytes. We further found increased numbers of AMY1a positive inclusion resembling Hirano bodies in the hippocampal subarea CA1 of individuals with AD related pathology. Some of these inclusions co-localized with p-tau positive tangles and amyloid beta (Aβ)1-42 plaques. Some of the Aβ1-42 plaques in the CA1 of AD patients were also surrounded by AMY2a positive astrocytes. In conclusion our study demonstrates a cell specific expression of AMY1a and AMY2a and an association between these two enzymes and AD related pathological changes. We hypotheses that brain cells express alpha-amylases to degrade accumulated amylose but potentially also generate energy trough an alternative cleavage pathway of glucose polymers.

Title: Role of DMH/DHA LepRb-expressing neurons in temperature-dependent neuronal circuits.

Authors: *M. FRANCOIS, S. YU, E. QUALLS-CREEKMORE, C. HUESING, C. MORRISON, H.-R. BERTHOUD, H. MUNZBERG;
Pennington Biomed. Res. Ctr., Baton Rouge, LA

Abstract: Background: Leptin receptor (LepRb) expressing neurons in the dorsomedial hypothalamus/dorsal hypothalamic area (DMH/DHA) are key actors in energy expenditure regulation. In fact, we previously showed that their chemogenetic activation increased energy expenditure and decreased body weight via both β_3-adrenoreceptor-dependent BAT thermogenesis and locomotor activity. The DMH/DHA has been proposed as downstream target of the preoptic area (POA), and both project to BAT sympathetic premotor neurons in the rostral raphe pallidus (rRPa). Even though we verified anatomically that POA-LepRb neurons project to the DMH/DHA, functional data strongly suggested that POA- and DMH/DHA-LepRb-expressing neurons act independently to modulate energy expenditure. Here, we tested if activation of DMH/DHA-LepRb neurons mediates a similar temperature-dependent change in energy expenditure as observed for POA-LepRb neurons to further indicate possible functional associations of POA and DMH/DHA-LepRb-expressing neurons. Methods: We injected a cre-dependent adeno-associated virus expressing hM3Gq-mCherry in the DMH/DHA of LepRb-cre mice, making LepRb-expressing neurons excitable by peripheral injection of Clozapine-N oxide (CNO). Oxygen consumption and locomotor activity were measured in metabolic cages with vehicle or CNO injections (1.5mg/kg ip) at different temperatures (23^{o}C, 4^{o}C and 30^{o}C). Results: Chemogenetic stimulation of DMH/DHA LepRb-expressing neurons robustly increased the oxygen consumption and locomotor activity similarly at all tested ambient temperatures. Thus, in contrast to chemogenetic activation POA-LepRb neurons, DMH/DHA-LepRb neurons regulate energy expenditure independent of ambient temperature. Conclusion: Consistent with our earlier results, these data further suggest that DMH/DHA and POA LepRb-expressing neurons act independent on thermoregulatory pathways.

Title: Allopregnanolone promotes neural stem cell differentiation to neurons and oligodendrocyte precursor cells

Authors: ***S. CHEN**[1], J. YAO[1], K. WONG[1], R. D. BRINTON[1,2];
[1]Sch. of Pharm., USC, Los Angeles, CA; [2]Ctr. for Innovation in Brain Sci. and Dept. of Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Previous studies by our group demonstrate that the endogenous neurogenic steroid Allopregnanolone promotes proliferation of both human and rodent neural stem cells *in vitro,* as well as *in vivo* in the triple transgenic mouse model of Alzheimer's disease. In this study, we investigated the impact of Allopregnanolone on neuronal differentiation. We first assessed the effect of aging and Alzheimer's-associated genotype on the differentiation capacity of adult neural stem cells in the triple transgenic mouse model. Neural stem cells from 3-, 6- and 15-month triple transgenic and non-transgenic mice were cultured and differentiation capacity was determined. We demonstrate that there is an age- and Alzheimer's gene- dependent decrease in overall neural stem cell differentiation and a shift from neuronal to glial differentiation. Allopregnanolone treatment significantly increased the ratio of MAP2-positive-neurons to GFAP-positive-astrocytes from embryonic rat and adult mouse neural stem cells. To further determine the *in vivo* efficacy of Allopregnanolone to prevent or reverse the loss of neuronal differentiative capacity, we investigated the impact of Allopregnanolone on neuronal differentiation in 5-month-old male triple transgenic mice. Flow cytometry-based analysis of new generated cells indicated that Allopregnanolone treatment increased the number of newly generated neurons as indicated by the increase in the number of BrdU positive cells and BrdU/NeuN double positive cells. Allopregnanolone enhanced expression of the neural proliferation marker, proliferation cell nuclear antigen, and the immature neuronal marker doublecortin, which was further confirmed by immunohistochemistry labeling.

Allopregnanolone treatment also increased the expression of Olig2, an oligodendrocyte precursor cell marker. Immunohistochemistry analyses showed that more Olig2 positive cells were distributed in corpus callosum area in the Allo-treated brain. The increase in neural differentiation and oligodendrocyte differentiation by Allopregnanolone treatment was paralleled by an increase in Brain-Derived Neurotrophic Factor. Collectively these findings suggest that Allopregnanolone is a regenerative therapeutic candidate to prevent or delay neurogenic deficits associated with mild cognitive impairment and Alzheimer's disease.

Title: Allopregnanolone activates LXR and PXR gene expression and signaling pathways regulating neuroinflammation, apoptosis, Aβ trafficking, and cholesterol clearance: Implications for Alzheimer's disease

Authors: *R. W. IRWIN[1], H. M. SWANSON[1], R. D. BRINTON[2,3,1];
[1]Pharmacol. and Pharmaceut. Sci., USC, Los Angeles, CA; [2]Ctr. for Innovation in Brain Sci., Univ. of Arizona, Tuscon, CA; [3]Pharmacol., Univ. of Arizona, Tuscon, AZ

Abstract: Allopregnanolone (Allo) is in early stage clinical trials as the first regenerative therapeutic for Alzheimer's disease (NCT02221622). Altered cholesterol metabolism is linked to AD pathology. Allo increases expression of two nuclear receptors, liver-X-receptor (LXR) and pregnane-X-receptor (PXR). LXR, a sensor of cholesterol levels, initiates its clearance to prevent overactivation of gamma-secretase and overproduction of amyloid-beta (Aβ). PXR activation induces CYP3A enzymes that lead to cholesterol hydroxylation and extrusion thereby decreasing Aβ and neuroinflammatory burden. Binding properties of Allo to LXR and to PXR were determined subsequent to studies of *in vivo* regulation of genes and proteins implicated in Alzheimer's pathology. Crystal structures from the Protein Data Bank for PXR/RXRα, LXRβ, and LXRα/RXRβ were used in a series of docking computations that revealed the K_i for Allo (LXRβ 0.12 μM; PXR 1.17 μM), comparable to known ligands for each receptor. The free energy of binding for Allo (LXRβ -9.44 kcal/mol; PXR -8.49 kcal/mol) signified favorable protein-ligand associations. Lipoprotein Signaling and Cholesterol Metabolism gene arrays and

protein expression immunoblots were performed for hippocampus and cortex tissue from 3xTgAD mouse. Allo increased LXRβ, LDLR, SORL1, ABCA1, Cyp46a1, and decreased NF-κB protein expression in 3xTgAD male mice. Downstream of LXR, Allo altered LDLR-associated genes: CXCL16, OLR1, LRP6, STAB2, and PCSK9. A decrease in OLR1 and PCSK9 genes leads to increased cholesterol efflux and reduced inflammation. Allo also increased gene expression of CXCL16, LRP6, HMGSC1, and Cyp51 involved in stimulation of the PI3K/Akt/Erk and Wnt pathways and cholesterol synthesis pathways. STAB2 and Idi2 gene expression also increased suggesting a reduction in neuroinflammation. Allo decreased PCSK9 and AKR1D1 genes that promote cholesterol efflux while decreased ANGPTL3 provides a mechanism for reducing plasma cholesterol levels. Our results suggest that Allo directly binds to and activates LXR and PXR, to regulate downstream gene expression and molecular signaling pathways implicated in neuroinflammation, apoptosis, Aβ trafficking, and cholesterol clearance to prevent Alzheimer's pathology. Collectively, these data further reveal Allo's systems-wide coordination and identify target systems to prevent AD pathogenesis. Early phase dose-escalating clinical studies (placebo-controlled) are underway in men and women age 55+ with MCI/earlyAD (NCT02221622).

Title: Human iPSC-based biomarker strategy to identify neuro-regenerative responders to allopregnanolone: proof of concept

Authors: *C. M. SOLINSKY[1], V. HENNES[2], J. A. PARK[4], H. C. CHUI[3], M. BLURTON-JONES[4], J. K. ICHIDA[2], R. D. BRINTON[1,5];

Abstract: Alzheimer's disease (AD) is a national and global epidemic with complex patho-etiology including compromised brain metabolic activity and decreased regenerative capacity. Allopregnanolone (Allo) is an investigational neuroregenerative therapeutic, currently in Phase 1b clinical trial for AD (NCT02221622, https://clinicaltrials.gov/ct2/show/NCT02221622?term=NCT02221622&rank=1). In rodent preclinical models, Allo promotes neural stem cell (NSC) proliferation and neural differentiation and improves mitochondrial function. To develop biomarkers to predict regenerative response to Allo, we have initiated proof of concept analyses to determine the impact of Allo on human induced pluripotent stem cells (iPSCs) and iPSC-derived neural cells. T-cells from a patient with familial AD due to the A431E presenilin-1 point mutation were reprogrammed via a non-integrating, non-viral method, to iPSCs. Additional iPSCs were provided by the University of California Irvine Alzheimer's Disease Research Center (UCI-ADRC) and the Institute for Memory Impairments and Neurological Disorders. Isogenic iPSCs were generated using CRISPR-Cas9. Using dual inhibition of SMAD signaling, iPSCs were differentiated to NSCs. Mitochondrial respiration and regenerative capacity were determined using metabolic analyzer and FACS. Mitochondrial respiration and proliferation analyses were conducted in AD-derived and healthy control iPSCs and NSCs. Initial data indicates that AD iPSCs have similar proliferation rates, but increased ATP production compared to healthy controls. Analyses were conducted to determine the regenerative and bioenergetic effect of Allo. In iPSC-derived NSCs, Allo increased basal mitochondrial respiration by 78% and maximal mitochondrial respiratory capacity by 35%. Initial data demonstrate that iPSCs from AD patients demonstrate a metabolic phenotype distinct from healthy controls and that Allo improves mitochondrial function of iPSC-derived NSCs. Going forward, this approach will be used to evaluate the effect of Allo on the regenerative capacity and metabolic phenotype of clinical trial participant iPSC-derived NSCs. These data will form the foundation for developing the first regenerative biomarker to determine and monitor response to neuro-regenerative therapeutics.

Title: Increased number of neural stem cells in the hippocampus correlates with maintenance of cognitive integrity in non-demented individuals with Alzheimer's Disease neuropathology.

Authors: *D. BRILEY[1], O. ZOLOCHEVSKA[1], R. WOLTJER[2], M.-A. MICCI[1], G. TAGLIALATELA[1];
[1]Univ. of Texas Med. Br. at Galveston, Galveston, TX; [2]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Alzheimer's Disease (AD) is a debilitating neurodegenerative disease characterized by dementia, cognitive declines. The presence of amyloid beta plaques and neurofibrillary tangles in the postmortem brain of demented individuals is the conclusive diagnostic for AD. However, certain individuals evade dementia despite the presence of extensive plaque and tangle neuropathology (here referred to as Non-Demented with Alzheimer's disease Neuropathology - NDAN). NDAN subjects thus represent a unique population in which to study the cellular mechanisms underlying this extraordinary resistance to cognitive decline. We tested the hypothesis that preserved cognitive function is correlated with enhanced neurogenesis in the hippocampus, a site heavily affected by AD and also important for its role in memory. We additionally investigated the potential epigenetic regulation of neurogenesis by specific miRNAs of interest. **Methods**. AD, mild cognitively impaired (MCI), NDAN, and age-matched healthy control was stained using established immunofluorochemical techniques for SOX2 and NeuN. Cells positive for each marker, and coexpressing cells, were counted and normalized over the DAPI signal for each image. Flow cytometry of nuclei isolated from samples was used to investigate the extent of colocalization between SOX2 and NeuN in a quantitative manner. Laser Capture Microdissection was used to isolate the granular cell layer and subgranular zone of fresh frozen human hippocampus sections. RNA was isolated and probed using qPCR for miRNA known to regulate neuronal precursor proliferation and maturation. **Results.** NDAN subjects demonstrate increased expression of SOX2, compared with AD and MCI. The number of SOX2+ cells correlates positively with cognitive performance (MMSE). Intriguingly and contrary to rodents, we also found several cells co-expressing SOX2 and NeuN that also correlated with MMSE scores. The expression of all probed miRNAs was decreased in NDAN with regard to control, while MCI and AD were comparable or increased. **Conclusions.** Our data

show that the number of progenitor cells in the hippocampus of NDAN subjects is increased as compared to AD subjects, and similar to controls. Furthermore, increased number of progenitor cells in NDAN may be driven by epigenetic modulation reflecting a deregulation of the miRNAs probed, as indicated by the trend towards reduced expression. These data strongly suggest NDAN are a unique sub-set of individuals who are neither prodromal for the disease, nor simply outlying control individuals, in which sustained neurogenesis may promote maintenance of cognitive integrity in the face of substantial AD neuropathology.

Title: D-Serine mediates adult neurogenesis in mice

Authors: *R. ROYCHAUDHURI, S. H. SNYDER;
Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Neurogenesis is the formation of newborn neurons from neural precursor cells. In the adult brain, the subventricular zone and the dentate gyrus are the two major regions in the hippocampus that continue to produce newborn neurons throughout life. Postmortem human studies and investigations in mice have shown that Alzheimer's Disease (AD) is associated with enhanced neurogenesis. However, mechanisms responsible for this effect are unknown and prior studies have shown conflicting results due to differences in promoters, age of animal, age of disease onset, transgene overexpression, neurotransmitter levels and extent of overexpression of protein. The goal of our study is to explore a possible role for D-serine in adult neurogenesis. D-amino acids like D-serine and D-aspartate occur in the brain and act as co-agonists respectively at the glycine and glutamate binding sites of the glutamate-NMDA receptor (NMDAR). We used age matched WT and $SR^{-/-}$ (serine racemase; enzyme that converts L-serine to D-serine) mice to investigate the role of D-serine in adult neurogenesis. Briefly, six week old adult male WT and $SR^{-/-}$ mice (deficient in D-serine production) were injected once daily with saline and or D-serine (50 mg/kg) intraperitoneally for 7 days. Following EdU injection on day 8 (100 mg/kg ip), brains were harvested and analyzed for proliferation by immunohistochemistry. Our results show that lack of D-serine leads to significantly diminished neurogenesis. Administration of D-serine restores neurogenesis in mice deficient in D-serine ($SR^{-/-}$ mice). We hypothesize that D-serine

acts on the NMDAR and modulates neurogenesis in adult brain via an unidentified novel mechanism. These studies may provide insights into the role of D-serine in adult neurogenesis and in the pathophysiologic mechanisms of cell loss in AD.

Title: ProNGF/p75/sortilin: potential targets to recover neurogenesis in Alzheimer's disease

Authors: *C. FLEITAS PÉREZ[1], C. RAMPON[2], R. CURIÀ[1], E. BERNAUS[1], J. EGEA[1], C. ESPINET[1];
[1]Irblleida. Univ. of Lleida, Lleida, Spain; [2]Ctr. de Recherches sur la Cognition Animale. Univ. Paul Sabatier., Toulouse, France

Abstract: The adult neurogenesis in humans has significant implications in memory formation and cognitive functions. Adult-born neurons generated in hippocampus are able to stabilize synaptic connections and mediate neuronal plasticity. The induction of neurogenesis can reverse cognitive dysfunction in animal models of Alzheimer’s disease. Previous studies have shown that the levels of pro-NGF are increased in a stage-dependent manner in human hippocampus and enthorinal cortex affected by Alzheimer’s disease. Also the proNGF receptor, p75NTR, is expressed not only in mature neurons but also in mitotic cells from mouse hippocampus. To assess the role of these signaling molecules in the adult neurogenesis, immunofluorescence analyses were performed to detect proNGF, p75NTR, sortilin and differentiation or synaptic markers in the mouse model of Alzheimer’s disease, in the hippocampal neurospheres cultured of p75NTR deficient mice, and also in the hippocampal preparations from Alzheimer’s disease affected human brains. The results showed that adult newborn cells from both human and animal models, express increased levels of p75NTR and sortilin in Alzheimer's disease. These neurons can respond to proNGF by apoptosis and/or dedifferentiation. Consequently, increased pro-NGF in adult hippocampal brain, may be responsible for the decrease of neurogenesis. Disruption of proNGF/p75/sortilin signaling would be a relevant target in regenerative therapies for Alzheimer’s disease.

Title: Neural stem cell transplantation increases the neurogenesis in double transgenic mouse model of alzheimer's disease

Authors: *B. M. LONGO[1], S. A. ROMARIZ[2], D. S. PAIVA[2];
[2]Physiol., [1]UNIFESP, São Paulo, Brazil

Abstract: In view of the lack of efficient treatments for Alzheimer´s disease (AD), it has been investigated new therapies that may reduce or prevent the progression of cognitive deficits and neuronal degeneration due to deposition of Aβ plaques. In this scenario, the neural stem cell (NSC) therapy is a promising alternative. Here, we investigated the *in vivo* potential of NSC in reducing neuronal degeneration and promoting neurogenesis through intra-hippocampal transplantation in the double-transgenic mouse model (APPswe/PS1dE9). We analyzed the effects of NSC transplantation in learning and memory behaviors, as well as the levels of BDNF and neurogenesis in the hippocampus. Immunohistochemistry for GFP indicated that the NSC transplanted in AD and WT animals were able to integrate, differentiate into astrocytes and neurons and migrate to lateral ventricle and fimbria. The total number of GFP+ cells was not different between WT and AD transplanted groups (p>0,05). Doublecortin (DCX) positive neurons and BDNF levels in the hippocampus were increased in AD transplanted animals compared to WT näive animals (p= 0,0182 and p=0,005 respectively). Although transplantation of NSC increased neurogenesis in AD mice, it was not enough to promote memory recovery in these animals, only in WT translpanted mice. We suggest that, despite not having behavioral effects. NSC transpantation increased the neurotrophic levels in the hippocampus and may be responsible for other molecular modifications involved in Alzheimer´s disease. The fact that the cells mainly migrated to the fimbria may suggest an effort to restore memory, once this structure plays a role in memory formation, connecting to cholinergic neurons in basal forebrain. This study may contribute to the understanding of the role of neural stem cells in regenerative mechanisms of transgenic AD animals and therapeutic implications in aging neurodegeneration processes.

Title: The epigenetic regulation of h3k9me3 promotes neuronal survival and functions

Authors: *L.-Q. TONG[1], S. SNIGDHA[2], C. W. COTMAN[1];
[2]MIND, [1]UC Irvine, Irvine, CA

Abstract: Epigenetic regulation of genes and proteins is fundamental to the aging process and the associated decline in learning and memory. We reported recently that pharmacological inhibition of SUV39H1 using a novel and selective inhibitor decreased levels of H3K9me3 (a repressive mark) in the hippocampus of aged mice, promoted spine formation, and improved memory performance (Snigdha et al., 2016, J Neurosci, 36(12): 3611-3622). However, the specific changes in histone methylation states in mature hippocampal neurons remains an unexplored area of research. In order to better understand the mechanisms directly in neurons, we used primary neuronal cultures where conditions are well defined and drug concentrations are precisely controlled. We evaluated the effects of H3K9me3 downregulation on neuronal structure and functions in primary cultures of hippocampal neurons using ETP69, a newly developed specific inhibitor of SUV39H1. ETP69 treatment decreased neuronal H3K9me3 levels and increased PSD-95 expression and volume of dendritic spines. Furthermore, ETP69 treatment increased phosphorylation of transcription factor CREB at Ser133. Finally, ETP69 protected neurons from glucose-oxygen deprivation-induced cell death. Collectively, these data suggest that SUV39H1 inhibition-mediated downregulation of H3K9me3 acts directly on neuronal structure and functions to promote survival and synaptic function.

Title: Discovery of novel,neuroprotective small molecules for the treatment of ER stress related toAlzheimer's disease

Authors: *K. KRAJNAK[1], F.-S. WANG[1], R. DAHL[2];
[1]Purdue Univ. Calumet, Hammond, IN; [2]Neurodon, St. John, IN

Abstract: Alzhiemer's disease (AD) is the leading cause of neurodegenerative disease and yet still very little is known about its onset. Recent findings have linked mechanisms of cellular stress to those that are also present in a whole host of diseases, such as Type II Diabetes, Parkinsons and Cardiac disease. This cell stress induces intracellular calcium dyshomeostasis resulting in endoplasmic reticulum (ER) stress and the unfolded protein response. If this stress is excessive or prolonged, apoptotic pathways are triggered resulting in cell death and overall neuron loss. It has been established that a major cause of ER stress is a dysfunctional calcium transport ATPase (SERCA), whose sole function is to bring calcium into the ER. In this study, we have screened various SERCA modulators for their neuroprotective capabilities and potential use as pharmacological treatments for AD.
Initial screenings of compounds were done for cell viability to identify potential allosteric modulators of SERCA. The ER stress of Alzheimer's disease was simulated using the stress inducers Thapsigargin. Initial high throughput screenings of novel small molecules that would potentially reduce ER stress by restoring calcium homeostasis were performed. After narrowing the molecules down to prospective targets, the assay was utilized for dose response analysis while monitoring cell cytotoxicity.
Our studies found three compounds that showed over 70% survivability with treatment, after exposure to Thapsigargin, with a statistical significance of $p<0.001$. These compounds are further being studied in neuronally differentiated cells to further evaluate their mechanisms of action and clinical potential.

Abstract: Amyloid-β (Aβ) peptide and hyperphosphorylated tau are the main pathological hallmarks of Alzheimer's disease (AD) (Reitz et al., 2014). Given the recent failure of several large-scale clinical trials and the lack of disease-modifying pharmacological treatments, there is an urgent need to develop alternative therapies. CTX0E03 is a clinical-grade human neural stem cell line which has recently passed phase I trials in people with stroke (Hick et al., 2013). However, this line has not been investigated in other neurodegenerative disorders. This study investigates the survival of CTX0E03 neural stem cells under conditions based on the underlying AD pathology. CTX0E03 cells were seeded into laminin-precoated 96-well plates at cell density $5x10^4$ cells/ml (Pollock et al., 2006). Cells were treated with amyloid peptides ($A\beta_{1-40}$ and $A\beta_{1-42}$) at concentrations of 0.5, 1, 5, 10, and 15 μM and okadaic acid (OA) at 0.5, 1, 5, 10, and 15 nM. Vehicle control cultures were treated with DMSO or PBS (control for OA and Aβ respectively). After 24 h incubation, the cells were examined for cell viability using PrestoBlue reagent and lactate dehydrogenase-cytotoxicity assay. Cell viability assays showed a concentration dependence of this cell line to the toxic effects of $A\beta_{1-42}$, but not $A\beta_{1-40}$, and OA. Notably, CTX0E03 cell line displayed toxicity at concentrations significantly higher than both rat neural stem cells and those previously reported for primary cultures. Our study indicates the ability of clinical grade CTX0E03 stem cell line to resist the inhospitable milieu associated with AD. Thus, CTX0E03 stem cells provide a potential candidate for cell therapy in AD patients.

Title: Higher resting motor threshold associated with better cognitive function in patients with mild Alzheimer's disease

Authors: *P. J. FRIED, A. JANNATI, P. DAVILA PEREZ, V. M. CHEN, D. Z. PRESS, A. PASCUAL-LEONE;
Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Background. Nearly all applications of transcranial magnetic stimulation (TMS) begin by assessing the resting motor threshold (RMT). Conventionally defined as the minimum TMS intensity needed to elicit a positive motor response 50% of the time, the RMT serves as both a metric of cortico-motor reactivity and a means to individualize the intensity of subsequent stimulation. Under normal conditions, RMT is very stable across time, with the highest test-retest reliability of any TMS-based neurophysiological measurement. RMT can inform on structural and physiological changes in the motor system across time or in response to interventions, and group differences in RMT have been observed in diseases that impact the motor system such as focal dystonia, amyotrophic lateral sclerosis, etc. By contrast, few studies have investigated how RMT relates to non-motor measures of cognition.
Objective. The primary objective of the present study was to assess the relationship of RMT to measures of global cognitive function in patients with mild Alzheimer's disease (AD).
Methods. In a retrospective cross-cohort study, data were obtained from 30 patients with mild-AD (mean ± SD age: 69.6 ± 7.4 years, 59% female) and 26 cognitively intact controls (mean ± SD age: 62.7 ± 1.8 years, 50% female). All subjects had previously participated in research for which RMT was assessed along with measures of global cognitive function, including the Mini Mental Status Examination (MMSE) and the Cognitive subscale of the Alzheimer's Disease Assessment Scale (ADAS-Cog).

Results. The AD group performed significantly worse than controls on the MMSE (AD: 21.6 ± 2.2; controls: 29.5 ± 0.8, $p < .001$) and the ADAS-Cog (AD: 23.3 ± 10.5; controls: 4.0 ± 2.0, $p < .001$). By contrast, RMT (% of maximum stimulator output) was equivalent for the two groups (AD: 57.2 ± 2.3; controls: 59.8 ± 3.2, $p = .434$). In the AD group, there were significant correlations between RMT and both MMSE ($R_{28} = .53$, $p = .004$) and ADAS-Cog ($R_{28} = -.57$, $p = .001$). Specifically, higher RMT was associated with better cognitive function. By contrast, in controls, RMT was not significantly related to either MMSE ($R_{24} = .11$, $p = .601$) or ADAS-Cog ($R_{24} = -.07$, $p = .730$).
Conclusion. Higher RMT is associated with better global cognitive function in individuals with mild AD. This is somewhat paradoxical as AD is associated with progressive cortical atrophy, which should increase the scalp-to-brain distance and thus necessitate a stronger electromagnetic field. Nevertheless, these findings suggest a potential value in RMT as a rapid and reliable surrogate biomarker of the severity of cognitive dysfunction in dementia.

Title: Blood-based biomarkers for staging of alzheimer's disease

Authors: *C. N. WINSTON[1], E. J. GOETZL[4], J. C. AKERS[2], B. S. CARTER[2], E. M. ROCKENSTEIN[1], D. R. GALASKO[1], E. MASLIAH[3], R. A. RISSMAN[1];
[1]Neurosci., [2]Neurosurg., [3]Neurosci. and Pathology, UC San Diego, LA Jolla, CA; [4]Jewish Home of San Francisco & Dept. of Med., Univ. of California, San Francisco, San Francisco, CA

Abstract: INTRODUCTION: Levels of Alzheimer's Disease (AD)-related proteins in plasma neuronal-derived exosomes (NDEs) were quantified to identify biomarkers for prediction and staging of Mild Cognitive impairment (MCI) and AD. **METHODS:** Plasma exosomes were extracted, precipitated and enriched for neuronal source by anti-L1CAM antibody absorption. NDEs were characterized by size (Nanosight) and shape (TEM), and extracted NDE protein

biomarkers were quantified by ELISAs. Plasma NDE cargo was injected into normal mice and results were characterized by IHC to determine pathogenic potential. **RESULTS:** Plasma NDE levels of P-T181-tau, P-S396-tau, and Aβ1-42 were significantly higher, whereas those of neurogranin (NRGN) and the repressor element 1-silencing transcription factor (REST) were significantly lower in AD and MCI converting to AD (ADC) patients compared to cognitively normal controls (CNC) subjects and stable MCI patients. Mice injected with plasma NDEs from ADC patients displayed increased P-tau (PHF-1 antibody)-positive cells in the CA1 region of the hippocampus compared to plasma NDEs from CNC and stable MCI patients. **CONCLUSIONS:** Abnormal plasma NDE levels of P-tau, Aβ1-42, NRGN, and REST accurately predict conversion of MCI to AD dementia. Plasma NDEs from demented patients seeded tau aggregation and induced AD-like neuropathology in normal mouse CNS.

Title: Semantic and episodic memory impairments for faces in frontotemporal dementia and Alzheimer's disease

Authors: *J. A. COLLINS[1,2], B. C. DICKERSON[1,3];
[1]Massachusetts Gen. Hosp., Charlestown, MA; [2]Dept. of Neurol., Harvard Medical School, MA; [3]Dept. of Neurol., Harvard Med. Sch., Charlestown, MA

Abstract: The ability to recognize familiar faces is vitally important to everyday function and relies on the integrity of several neuroanatomical networks involved in perception, memory, and affect. Upon encountering someone have seen before, we immediately feel a sense of familiarity for that individual and retrieve semantic information about that person's identity and contextual details regarding previous encounters with that person. Unfortunately, this complex recognition process is often impaired in individuals with frontotemporal dementia (FTD) and Alzheimer's Disease (AD) imposing a substantial burden on quality of life.
The goal of this study was to delineate the cognitive components and neural mechanisms underlying the person recognition difficulties experienced by patients with FTD and AD.

Participants included 11 older healthy controls, 11 patients with AD, 10 patients with the semantic variant of FTD (semantic dementia or SD) and 4 patients with the behavioral variant of FTD (bvFTD). To assess semantic memory for famous faces, participants were first shown a set of 15 famous faces and 15 non-famous foils and were asked if they recognized the person (yes/no), and if so to retrieve the person's name. After a 20-minute break participants began the second portion of the task, which measured episodic memory for faces. They were shown a set of 60 faces (30 old) and on each trial are asked whether they saw the person in the previous session (yes/no), and how confident they are in their decision.
Relative to healthy controls, FTD patients (both bvFTD and SD) were significantly impaired at recognizing famous faces as being familiar, suggesting a semantic memory impairment for these individuals. Patients with SD exhibited particular difficulty naming the famous faces they had endorsed as familiar. Patients with AD exhibited preserved performance on the semantic memory portion of the task, and performed significantly better than the SD sample. Contrary to our expectations, all three patient groups were significantly impaired on the episodic memory portion of the task relative to healthy controls, with no difference in performance observed between the three patient samples. The results of a preliminary whole brain cortical thickness analysis in the FTD patient group revealed areas in frontal and temporal cortex that predicted episodic and semantic memory performance.

Title: Progression of tau oligomer pathology in cholinergic nucleus basalis neurons in mild cognitive impairment and Alzheimer's disease

Authors: *C. T. TIERNAN[1], E. J. MUFSON[4], N. M. KANAAN[1,2,5], S. E. COUNTS[1,2,5,3]; [1]Translational Sci. and Mol. Med., [2]Neurosci. Program, [3]Dept. of Family Med., Michigan State

Univ., Grand Rapids, MI; [4]Dept. of Neurobio., Barrow Neurolog. Inst., Phoenix, AZ; [5]Hauestein Neurosci. Ctr., Mercy Hlth. St. Mary's, Grand Rapids, MI

Abstract: Tau is the predominant protein found in neurofibrillary tangles (NFTs) that contribute to neuronal dysfunction and cognitive decline in Alzheimer's disease (AD) and other tauopathies. Despite not fully understanding the role of tau in neurodegenerative diseases, there is accumulating evidence that the toxic tau moiety may be soluble, oligomeric tau species. In this regard, tau oligomers appear prior to NFT formation, correlate more strongly with neuronal loss than NFTs, and exhibit neurotoxicity in preclinical models. Here, we investigated the spatiotemporal progression of oligomeric tau within cholinergic basal forebrain (CBF) neurons of the nucleus basalis (NB), a brain region selectively prone to tau pathology and neurodegeneration during the progression of AD. Tissue from Rush Religious Orders Study subjects who died with a clinical diagnosis of no cognitive impairment (NCI; $n = 12$), mild cognitive impairment (MCI; $n = 10$), or AD ($n = 12$) was immunostained with the tau oligomeric complex 1 (TOC1) antibody, as a marker of tau oligomers, and $p75^{NTR}$, as a cholinergic cell marker. Initial unbiased stereology estimates of these markers ($n = 8$ NCI, 5 MCI, and 8 AD) revealed that the number of NB neurons co-labeled with $p75^{NTR}$ and TOC1 ($p75^{NTR}$/TOC1+) were relatively sparse in NCI (1007 ± 263, mean ± SEM, or ~0.5%), whereas the number of $p75^{NTR}$/TOC1+ neurons increased incrementally in MCI (2640 ± 1466, or ~1.5%) and AD (6955 ± 4144, or ~4.5%; $p < 0.05$, AD > NCI). Initial correlation analysis revealed no association between $p75^{NTR}$/TOC1+ counts and antemortem global cognitive status via the MMSE or a global *z*-score for 17 neuropsychological tests. However, significant direct correlations were found between increasing numbers of $p75^{NTR}$/TOC1+ neurons and severity of Braak ($r = 0.6$, $p < 0.01$), NIA-Reagan ($r = 0.54$, $p < 0.05$), and CERAD ($r = 0.48$, $p < 0.05$) scores. Ongoing studies are examining the spatial progression of tau oligomer pathology through the NB subfields, and the co-localization of TOC1 with established markers of tau pathology in each of the clinical stages. Taken together, these data suggest that the progression of AD is associated with accumulating oligomeric tau pathology in the selectively vulnerable NB and may represent a target for therapy.

Title: Volumetric assessment of brain areas involved in executive function deficit in Alzheimer's Disease

Authors: *F. JUNG[1], S. KAZEMIFAR[2], R. BARTHA[2], R. N. RAJAKUMAR[1];
[1]Anat. & Cell Biol., [2]Med. Biophysics, Western Univ., London, ON, Canada

Abstract: Executive functional deficits are frequent findings in Alzheimer's Disease (AD) and often reported even in mild cases. Executive function comprises several cognitive abilities including working memory, behavioural flexibility, response inhibition and attention, and involves increased activity and functional connections among a number of brain areas. Current study is to determine the pattern of volume loss in these nodal brain areas during the progress of AD using the Alzheimer Disease Neuroimaging Initiative (ADNI) database. 1.5 Tesla T1-weighted MRI images acquired at baseline and at 24 months in 139 subjects with AD were selected from the ADNI database. These structural T1-weighted images were acquired using a sagittal 3D magnetization-prepared rapid acquisition with a gradient echo MP-RAGE sequence with pixel size 1mm×1mm×1.2mm; flip angle ~8°; TE ~4 ms; TR ~8 ms; matrix, 256x256; 170 slices. Regions of interest (ROI) including the caudate nucleus, dorsolateral prefrontal cortex, fusiform cortex, insula, parietal cortex and the thalamus were manually segmented from all subjects to test for associations with their neuropsychological assessment of executive functional deficit.

Title: Genome-wide expression and methylation profiling in Medial Temporal Gyrus reveals dysregulated genes with specific methylation associated with Alzheimer's Disease

Authors: *I. S. PIRAS[1], Y. KONG[2], W. J. DANIEL[2], J. KRATE[3], E. DELVAUX[4], J. NOLZ[4], D. MASTROENI[4], M. SWAPNA[5], A. BLATTER[6], A. M. PERSICO[7], W. JEPSEN[1], K. D. SIEGMUNG[2], T. D. BEACH[8], P. W. LAIRD[9], M. J. HUENTELMAN[1], P. D. COLEMAN[4]; [1]TGEN - Neurogenomic Div., Phoenix, AZ; [2]USC, Los Angeles, CA; [3]Univ. of Arizona Col. of Med., Tucson, AZ; [4]Arizona State University-Banner Neurodegenerative Dis. Res. Ctr., Arizona State University-Banner Neurodegenerative, AZ; [5]Univ. of California, Los Angeles, CA; [6]Univ. of California, Davis, CA; [7]Univ. Campus Bio-Medico, Rome, Italy; [8]Banner Sun Hlth. Res. Inst., Sun City, AZ; [9]Van Andel Inst., Gran Rapids, MI

Abstract: We integrated the gene expression and methylation profiles of Alzheimer's Disease patients (AD) and non-demented matched controls (ND) in order to detect patterns of dysregulation in AD. Expression profiles were obtained from the Middle Temporal Gyrus (MTG) from 100 AD and 100 ND subjects using the HumanHT-12 BeadChip Array (Illumina). Methylation profiles were analyzed in a partially overlapping sample of 225 AD and 179 ND using the HM450 BeadChip array (Illumina). Data analysis was conducted using the R packages Lumi, Methylumi and Limma. P values were corrected using the False Discovery Rate (FDR) method. Expression and methylation results were combined considering common significant genes and combining P values using the Fisher's weighted Z-method (FWZ). Enrichment analysis, considering both pathways and gene ontologies, was performed using the ToppGene web tool. We detected a total of 16,947 significant DEGs (9,271 overexpressed and 7,676 underexpressed in AD). Among the top genes were: RGS4, SYT1, STMN2, CHGB and STXBP1. We performed pathway analysis using genes with Fold Change > |0.8| and identified genes associated with Synaptic Vesicle Trafficking and GABAergic transmission. The female samples were specifically enriched for the "L1CAM interaction" pathway including the CHL1 gene, a substrate for the AD-associated gene BACE1. In the methylation analysis, we detected a total of 59,602 significant differentially methylated probes (33,374 hypomethylated and 26,228 hypermethylated in AD). The top differentially methylated sites were located in: ANK1, MYO1C, TMEM104, PLAT and KIF26B. The enrichment analysis highlighted the presence of neuronal genes and, in particular, the enrichment of Rho GTPase and Rap1 pathways. The sex-specific analysis confirmed the presence of the L1CAM interaction pathway in the female sample, as detected in the gene expression results. With the combination of expression and methylation results, we detected 239 differentially expressed genes that also showed methylation changes with at least 75% of probes concordant with the methylation pattern. The top genes on the list, ordered by total number of methylation probes that were significant, are: MYT1L, RIMBP2, GABBR1, SNRPN and LRP5. The enrichment analysis confirmed the presence of neuronal and synaptic functional classes. In conclusion, we provide new information about the molecular mechanisms and genes associated with AD in a specific brain region (MTG). In particular, we explore the relationship between methylation status and gene expression, detecting new genes that potentially could have stable gene expression changes that play an important role in AD.

Title: Predicting Alzheimer’s disease risk with a deep neural network model

Authors: *K. NING[1], B. CHEN[2], F. SUN[1], Z. HOBEL[1], A. ALZHEIMER'S DISEASE GENETIC CONSORTIUM[3], A. W. TOGA[1];
[1]USC, Los Angeles, CA; [2]Caltech, Pasadena, CA; [3]Alzheimer's Dis. Genet. Consortium, Philadelphia, PA

Abstract: Introduction: Currently there is no effective treatment for late onset Alzheimer’s disease (AD), a form of dementia that primarily affects the elderly. Accurate AD risk prediction based on a person’s genetic information will allow for early interventional AD prevention for those at high risk. In this study, we predicted a person's risk of AD using a deep neural network model, a machine-learning tool which has demonstrated impressive power in extracting interactions from its predictors. This tool has been applied to problems like computer vision and natural language processing, but has not been used for disease prediction. **Methods:** We trained and assessed the risk prediction performance of our model using data from the Alzheimer's Disease Genetics Consortium. It includes genome-wide single nucleotide polymorphism (SNP) data for over 20,000 healthy controls (n=10,826) and AD patients (n=10,778). When building our multi-layer neural network model, we incorporated SNP-gene relationships as well as gene-pathway relationships to determine its structure. We evaluated the risk prediction performance of our model using 10-fold cross-validation, where the model was trained with 90% of the data and tested with the remaining 10%. **Results:** Our model achieves high prediction accuracy, with median area under the curve (AUC) = 0.88 in the testing data. This model includes SNPs moderately associated with AD, along with SNPs reaching genome-wide disease association significance (p-value <= 5E-8), which achieves higher prediction accuracy than a model that only includes SNPs reaching genome-wide significance. **Conclusion:** We believe our model has the best risk prediction performance reported for AD to date. Our model can also be used to

predict risk of other diseases based on genetic information, particularly those which have many moderately significant genetic risk loci.

Title: The preclinical pathology of Alzheimer’s disease and its modulation by ApoE

Authors: O. PLETNIKOVA[1], G. L. RUDOW[1], Y. KAGEYAMA[1], K. LACLAIR[1], D. R. FOWLER[2], L. J. MARTIN[1], *J. C. TRONCOSO[1];
[1]Neuropathol Lab., Johns Hopkins Univ., Neuropathology, Baltimore, MD; [2]Office of the Chief Med. Examiner, Baltimore, MD

Abstract: Tau and Aβ lesions are common in the cerebral cortex of older individuals and constitute the basis for the diagnosis of Alzheimer’s disease (AD). However, the extent of these pathologies in aging and preclinical AD remains unknown. Therefore, we examined cortical tau and Aβ lesions in 431 autopsy brains of subjects 30 to 65 years of age, stratified by ApoE genotype. We immunostained for tau (PHF-1) and Aβ (6E10) in hippocampus, ERC, and neocortex and measured tissue levels of Abeta 40 and Abeta 42 by ELISA.
Tau lesions in ERC/hippocampus increased steadily from 4% in subjects 30 to 34 year-old to 70% in subjects 60 to 65 year-old. These lesions consisted predominantly of subtle neuritic and perikaryal staining, neurofibrillary tangles were rare. In subjects ages 40 to 49 years, Aβ lesions were present in 15%; all of these were diffuse plaques, more frequent in neocortex than hippocampus, and not associated with local tau lesions. All subjects with Aβ deposits at this age had one or two APOE4 alleles, though many subjects with one APOE4 remained free of Aβ lesions. Over age 50, neuritic plaques could be observed, and continued to increase with age. In subjects 40 to 50 years of age, tissue levels of insoluble Abeta 42 were highest in ApoE 4/4 subjects, intermediate in ApoE 3/4 and undetectable in ApoE 3/3.

In conclusion, Aβ deposits can appear as early as 40 years of age in APOE4 allele carriers, are more abundant in neocortex than hippocampus, and are not associated with local tau changes. In our cohort, neuritic plaques first appear at age 50 and increase afterwards. These findings suggest that future AD preventive measures should consider targeting young individuals stratified by their genetic risks including ApoE genotype.

Title: Neuropsychological assessment of semantic memory in alzheimer's and primary progressive aphasia patients

Authors: *J. FERRER[1], V. PATIÑO-TORREALVA[2];
[1]UAEM, Cuernavaca, Mexico; [2]Ctr. de Investigación Transdisciplinar en Psicología, Cuernavaca, Mexico

Abstract: Neuropsychological assessment of semantic memory is commonly driven by using tasks requiring the active elicitation of explicitly stored information (Della Rosa et al, 2014). Nonetheless, there is a lack of instruments for Spanish speaking population suitable to detect specific impairments of semantic memory in Alzheimer Disease (AD) and Primary Progressive Aphasia (PPA) patients. Several previous studies have suggested that AD and PPA patients exhibit different profiles of semantic deterioration in the concrete-abstract dimension (Catricalà, Della Rosa, Plebani, Vigliocco, & Cappa, 2014; Hoffman, Jones, & Lambon Ralph, 2013; Hoffman & Ralph, 2011; Pobric, Lambon Ralph, & Jefferies, 2009; Yi, Moore, & Grossman, 2007). The present study analyzed the cognitive differences in the semantic deficit in the concrete-abstract dimension between AD and PPA patients. Four AD and three PPA patients, as well as a control group of seven healthy individuals participated in the study. After clinical diagnosis, participants performed two semantic memory tasks. One of the tasks consisted of 48 triplets of words, presented successively, each one in a card. Half of the triplets contained concrete words, and the other half abstract words. Stimuli were presented in random order. Participants were asked to select which pair of words in each triplet have similar meaning. The second task consisted in 48 written words, each one matched to a correct or incorrect definition.

Half of the words were concrete an half of them were abstract, and 50% of stimuli were correct, whereas 50% were incorrect. Participants were asked to verify whether or not each word is congruent with the respective definition. All of the words were controlled in lexical variables such as frequency familiarity, imageability and age of acquisition. Our results show impairment in the semantic processing of abstract words in AD patients, whilst APP patients are impaired in the processing of both types of words. We conclude that these results might be explained by the fact that processing concrete words require the activation of more contextual and associative information than the processing of abstract words (Schwanenflugel, 1991). According to this hypothesis, abstract word processing relies on an extended multimodal network over the temporal-parietal regions of the left hemisphere (Grossman et al., 2003, 2013), whereas the anterior temporal lobe atrophy, characteristic of the PPA, would be associated to a poor performance in the processing of both types of words, since this region would be a supramodal association zone, specialized in the general semantic processing.

Abstract: Background: The mevalonate pathway has been described to play a key role in Alzheimer's disease (AD). The present work focused on mevalonate derived non-sterol isoprenoid farnesyl pyrophosphate (FPP) and geranylgeranyl pyrophosphate (GGPP). Human FPP and GGPP synthases (hFPPs and hGGPPs) lead to protein prenylation which plays a crucial role in controlling cell signalling and proliferation and which have been shown to be associated with AD. It is hypothesised that these intermediates are implicated in tau metabolism dysregulation and the progression of AD. A better understanding of the role of hFPPs and hGGPPs in the pathophysiology of AD may prove to be essential to assess the function of the isoprenoids pathway as a potential target in the treatment or prevention of AD.
Methods: mRNA levels of hFPPs and hGGPPs were assessed by RT-qPCR whereas GGPP and FPP concentrations were quantified by liquid chromatography-tandem mass spectrometry (LC/MS/MS) in control and AD brain tissues obtained from the Douglas-Bell Brain Bank (Montréal, Canada). In a second part, hFPPs and hGGPPs candidates inhibitors chemically derived from the nitrogen-containing bisphosphonates (N-BP) were tested on human SH-SY5Y neurons and their effect on the accumulation of tau and phospho-tau was measured as a function of time and drug concentrations.
Results: hFPPs and hGGPPs mRNA prevalence and FPP and GGPP concentrations are significantly increased in frontal cortex of AD-confirmed subject (Respectively $p<0.001$, $n=124$ and $p<0.05$, $n=116$) while no significant differences were found in cerebellum. We also detected that high levels of enzymes ($p<0.05$, $n=64$) and precursors are associated with an earlier age of onset of AD. The levels of mRNA for hFFPs and hGGPPs also correlate with the amount of phospho-tau protein levels ($p<0.05$, $n=38$) and neurofibrillary tangles density ($p<0.006$, $n=40$) in frontal cortex. Finally, preliminary data indicates that our novel families of FPPs inhibitors can decrease phospho-tau levels in SH-SY5Y neurons in the low micromolar range without any detectable toxicity.
Conclusions: Together, these results suggest that neuronal isoprenoids dysregulation is associated with accumulation of phospho-tau and formation of tangles in the AD brain; a phenomenon that could be alleviated by the administration of specific and potent bi-phosphonate derivatives.

Title: EEG oscillations during word processing predict MCI conversion to Alzheimer's disease

Authors: *A. MAZAHERI[1], K. SEGAERT[1], J.-C. YANG[2], Y.-Q. NIU[4], J. OLICHNEY[3], K. SHAPIRO[1], H. BOWMAN[1];
[1]Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [3]Dept. of Neurol., [2]Ctr. for Mind and Brain, Univ. of California, Davis, Davis, CA; [4]MIND Institute, UC Davis, Sacramento, CA

Abstract: Mild cognitive impairment (MCI) is a syndrome characterized by cognitive decline that, although not interfering with daily life, is greater than expected given an individual's age. Approximately one-half of individuals diagnosed with MCI progress to dementia within 5 years of diagnosis. Identifying factors that can predict conversion of MCI to dementia could lead the way to early intervention. In the current study, we investigated oscillatory changes in the EEG induced by visual word processing for healthy controls and MCI patients, a subset of whom would go on to develop Alzheimer's disease within 3 years. We used a language comprehension task, in which a phrase describing a category (e.g., `a type of wood', `a breakfast food') was presented first, followed by a single target word that was either congruent (i.e., oak, pancake) or incongruent with the category established by the preceding phrase. The focus of our analyses was the oscillatory activity in theta and alpha frequency bands, given that prior studies have implicated these bands in specific aspects of language processing. In the MCI individuals that would go on to develop Alzheimer's disease (AD), theta activity during the processing of the word (i.e., retrieval of the lexical and semantic properties of these words) was significantly diminished. This theta attenuation served as an imminent conversion marker from MCI to Alzheimer, not only on the group level but could also be observed in the individual patients within the group. Looking at individual patients, 60% of MCI convertors (to AD dementia) had a smaller theta increase than the least amount of theta increase observed in the MCI non-convertors, as well as healthy, control group.MCI non-convertors, as well as MCI convertors, were distinguishable from healthy controls by a neural signature related to processing semantically congruous words (i.e., integration of the target word meaning with the semantic/linguistic context set up by the preceding phrase): an induced alpha suppression, as well as trial-by-trial cross-frequency coupling between the posterior theta increase and the alpha suppression. In sum, importantly for the prognosis of MCI patients, our findings suggest that basic anomalies in the lexical/semantic processing of single words picked up using EEG oscillations could serve as an objective neurophysiological marker for impending conversion of MCI to Alzheimer's disease. We believe that our study adds valuable insight into the subtle breakdown of neural circuits involved in semantic and lexical processing.

Title: Integrity of the basal forebrain cholinergic space and its relation to the hippocampus in Alzheimer's disease.

Authors: *J. L. REEP[1], B. A. ARDEKANI[3], C. E. MYERS[4,2], L. ZABORSZKY[1];
[1]Ctr. for Mol. and Behavioral Neurosci., [2]New Jersey Med. Sch., Rutgers, The State Univ. of New Jersey-Newark, Newark, NJ; [3]Nathan S. Kline Inst. for Psychiatric Res., Orangeburg, NY; [4]VA New Jersey Hlth. Care Syst., East Orange, NJ

Abstract: Neuropathological studies suggest that the basal forebrain cholinergic system (BFC) is affected in Alzheimer's disease (AD) and aging. However, much remains as to whether both its rostral (septal) and caudal or only its caudal component are affected and whether the BF process correlates with hippocampal pathology.
The *volumetric integrity*, a novel scale-invariant measure of local brain tissue density (Ardekani et al., 2016), of the cholinergic space from the ADNI database 3D T1-weighted high-resolution structural images were estimated at baseline and one-year follow-up in AD (n=120) and cognitively normal (CN= 118) subjects using the Automatic Registration Toolbox (http://www.nitrc.org/projects/art). To define the septal (Ch1-2) and the more caudal nucleus basalis compartment (Ch4), we used a postmortem 3D probabilistic map (Zaborszky et al., 2008).
The integrity of Ch1-2 compartment was significantly reduced in AD as compared to CN subjects (p=0.000). Also, the rate of reduction of Ch1-2 integrity was significantly greater in AD (p=.000). The Ch1-2 integrity and its rate of change correlated with the corresponding hippocampal values in both the AD and CN groups separately. Furthermore, the ADAS, MMSE, and CDR scores significantly correlated with both Ch1-2 integrity and its rate of decline in the AD group but not in the CN group.
The integrity of Ch4 compartment was significantly reduced in AD as compared to CN subjects (p=0.000). The rate of reduction of Ch4 integrity was also significantly greater in AD (p=.017). Ch4 integrity was correlated with the hippocampal integrity only within the patient group. Rate of decline of the Ch4 integrity was not correlated with that of hippocampus in either group. Within the AD group, the ADAS, MMSE, and CDR scores significantly correlated with Ch4 integrity, while its rate of change only correlated with the MMSE. Finally, within the AD group,

the Ch4 integrity significantly correlated with the number of APOE e4 alleles carried by the patient.
The preliminary results suggest our volumetric integrity measure is sensitive to AD pathology and cognitive deficits. Our analysis also suggests that Ch4 atrophy may occur at an earlier stage of the disease with stronger effect on APOE e4 carriers. On the other hand, at the mild to moderate AD stage, the Ch1-2 component seems to be more vulnerable to AD pathology. Further studies are needed to identify if specific integrity changes in the cholinergic space correlate with specific cognitive domains in MCI and AD patients. These studies will ascertain whether BFC integrity measurements can be used as a biomarker to select patient population at risk and lay the foundation for early intervention.

Abstract: Background: NIAGADS is a national genetics data repository that facilitates access of genotypic data to qualified investigators for the study of the genetics of late-onset Alzheimer's disease (AD) and other neurological diseases. Collaborations with large consortia such as the Alzheimer's Disease Genetics Consortium (ADGC) and the Alzheimer's Disease Genome Sequencing Project (ADSP) allows NIAGADS to lead the effort in managing large AD datasets that can be easily accessed by the research community and utilized to its fullest extent. NIAGADS’ position as the centralized location for the storage of AD genetic data and its collaboration with the National Cell Repository for AD (NCRAD) to make availability of data and samples makes it essential to the scientific community in order to achieve the National

Alzheimer's Project Act's (NAPA) research goal to discover therapeutic targets for the treatment and prevention of AD by the year 2020.
Methods: Since 2012, NIAGADS has been supported by National Institute on Aging (NIA) under a cooperative agreement (U24 AG041689). This agreement expanded the NIAGADS storage and data sharing capacity for large-scale sequencing projects. All data derived from NIA funded AD genetics studies is expected to be deposited at NIAGADS or another NIA approved site. NIAGADS has partnered with the database of Genotypes and Phenotypes (dbGaP) and the Sequencing Read Archive (SRA) in this effort. In order to facilitate research, secondary data, including GWAS summary statistics and imputation data, as well as deep phenotypes have expanded the existing ADGC collection. The redesigned Genomics Database is a searchable annotation resource that links published AD studies to AD-relevant sequence features and genome-wide annotations.
Results: As of May 2016, NIAGADS houses 35 datasets with ~50k subjects and >30 billion genotypes. With the completion of the Discovery Phase of ADSP, qualified investigators can retrieve sequencing data with ease and flexibility using the ADSP website and data portal (collaboration with dbGaP/SRA). The ADSP project generated sequencing data of >11,000 subjects; raw BAMs and quality controlled VCF files are available through the ADSP portal and dbGaP (phs000572). The ADSP is currently whole-genome sequencing (WGS) an additional 433 subjects to extend the discovery phase and is selecting ~3000 additional case/control subjects for WGS as a follow-up.
Conclusions: With a streamlined application and submission process, NIAGADS is a rich resource for AD researchers to utilize. Datasets, guidelines, and new features are available on our website at https://www.niagads.org and https://www.niagads.org/adsp/.

Title: Gender differences in alzheimer's disease: brain atrophy, gender differences in alzheimer's disease: brain atrophy, histopathology burden and cognition

Authors: G. E. SERRANO, J. FILON, L. SUE, *T. G. BEACH;
Banner Sun Hlth. Res. Inst., Sun City, AZ

Abstract: Multiple studies have suggested that females are affected by Alzheimer's disease (AD) more severely and more frequently than males. Other studies have failed to confirm this and there has been no clear resolution of the issue. Difficulties include differences in study methods and male versus female life expectancy. Another element of uncertainty is that the majority of studies lack neuropathological confirmation of diagnosis. We compared clinical and pathological AD severity in more than 1000 deceased subjects with full neuropathological examinations. Age of dementia onset did not differ by gender but females were more likely to proceed to very severe disease, both clinically and pathologically, with significantly higher proportions of females having a Mini Mental State Examination score of 5 or less and Braak stage VI neurofibrillary degeneration. Median neuritic plaque densities were similar in AD females and males but females had significantly greater tangle density scores. In addition, we found that AD-control brain weight differences were significantly greater for females, even after adjustment for age, disease duration and comorbid conditions. These suggest that, when affected by AD, females progress more often to severe cognitive dysfunction, due to more severe neurofibrillary degeneration and greater loss of brain parenchyma.

Abstract: Alzheimer's disease (AD) pathology is characterized by accumulation of beta amyloid plaques, neurofibrillary tangles of tau, marked neuroinflammation and widespread neuronal loss. Unlike the human disease, mouse models of AD show minimal neurodegeneration. Therefore, The Jackson Laboratory, in collaboration with Indiana University, is working to generate, characterize, and make available improved resources for AD research. Traditional mouse models of AD involve the introduction of single or multiple AD-relevant genes onto a single mouse strain, C57BL/6J. One key difference between the AD patient population and current models concerns genetic diversity, thus we have established a panel of seven inbred strains that captures the greatest degree of genetic diversity available. Chosen strains represent the founders of the Collaborative Cross and Diversity Outbred (DO) (C57BL/6J, 129S1/SvlmJ, NZO/HiLtJ, NOD/ShiLtJ, WSB/EiJ, CAST/EiJ, PWK/PhJ). Transcriptional profiling of DO mice indicates naturally occurring variations in AD-relevant genes including *Trem2*, *Bin1*, *Abca7* and *Clu*. Each of these new strains carries the transgene developed by the Borchelt lab containing familial mutations in amyloid precursor protein (APP) and presenilin 1 (PS1). Male and female mice (APP/PS1 and wild type controls) were aged to 6 months and a variety of phenotypes were measured including metabolic profiles (e.g. weight, blood glucose and core body temperature), sleep patterns, motor activity, stress response and spatial memory. Initial analyses showed significant variation amongst the strains in response to the transgene, particularly in metabolic measures, sleep disturbance and in differential processing of APP, and plaque deposition. Both NZO.*APP/PS1* and PWK.*APP/PS1* (strains that are models of hyperinsulinemia) had significant weight loss and higher blood glucose, while WSB.*APP/PS1* (a strain resistant to diet-induced obesity) had significant weight gain, supporting a strong interaction between mechanisms involved in metabolic syndrome and AD. CAST.*APP/PS1* mice showed a significant decrease in overall plaque deposition and microglia activation state, while NOD.*APP/PS1* showed a significant increase in plaque load, evidence of tau hyperphosphorylation and neuronal loss. Transcriptional profiling is now being performed to identify genes and pathways that modulate susceptibility and resiliency to endophenotypes. This genetically diverse panel of AD mouse models represents a unique resource to improve translatability of preclinical trials and lays the foundation for further genetic studies to identify novel therapeutic targets for AD.

Title: Evaluation of cGMP concentrations in CSF as biomarker for PDE2A inhition in the dog brain.

Authors: *H. BORGHYS, P. BUIJNSTERS, D. DHUYVETTER, M. SOMERS, R. VREEKEN;
Janssen Res. & Develop., Beerse, Belgium

Abstract: PDE2A is expressed both in the periphery and in the central nervous system, however, PDE2A is most abundant in the brain. More specifically, PDE2A is the most prevalent of all PDEs in the caudate putamen, the nucleus accumbens, all cortical regions and the hippocampus. This suggests that PDE2A plays a role in the regulation of intraneuronal cGMP and cAMP levels in brain areas involved in emotion, perception, concentration, learning, memory, and CNS disorders such as depression and anxiety. PDE2A inhibitors are being investigated for treatment of cognitive impairment in Alzheimer’s disease. In general, rodents are chosen as a preclinical species to look at activity of PDE2A inhibitors in the brain. However, since rodents are not the appropriate species to evaluate compounds which are Pgp substrates, an in vivo assay in a non-rodent species is sometimes needed. Additionally, an in vivo assay in a larger non-rodent species will have more translational value since biomarkers in CSF can be monitored longitudinally as in humans. We aim to use the dog as a non-rodent species to examine PDE2A inhibition in the brain. cGMP in CSF is chosen as a biomarker for functional activity following PDE2A inhibition. However, before evaluating compounds, the variability of baseline concentrations of cGMP in CSF needs to be assessed. In a first experiment, a sampling schedule mimicking a routine in-house PK/PD study for central active compounds in dogs was followed. CSF was sampled from the lateral ventricle in conscious animals instrumented with a needle guide in the skull. Six beagle dogs were sampled 4 times: in the morning (7-8 am, day -4), between 11 am and 12 pm and 3-4 pm (day 1) and again in the morning (day 2). In a second study, the group was increased to 12 animals and all animals were sampled in the morning, at noon and in the afternoon, with at least 2 days in between two consecutive samples. Thus, any effect of a previous sample on cGMP was minimized. Over this period no diurnal rhythm of the day and no sex differences were observed. The baseline cGMP concentrations varied in individual and between animals, however, they were all below 40 ng/mL albeit with exception of one measurement (49 ng/mL). The range of the CSF cGMP concentrations in the animals, which were sampled in the two schedules, was somewhat comparable for both profiles. Remarkably,

animals which are in general more active, show a trend to have higher baseline cGMP levels compared to less active animals. However, this needs to be confirmed in a larger group of animals. Based on these data, the group size required to pick up a two-fold increase from baseline cGMP concentration in CSF following compound administration was determined.

Title: Eeg markers of leukoaraiosis in older adults

Authors: ***N. B. LAM**, A. RAJAN, N. SCHWAB, R. LIU, M. DING;
Univ. of Florida, Gainesville, FL

Abstract: Leukoaraiosis (LA), detected by high intensity in MRI T2 images, is a white matter disorder thought to be related to small vessel disease. High levels of LA in older adults are associated with declined cognitive performance and increased risk of memory dysfunction. LA is known to be in higher concentrations along the cholinergic tracts. Considering that acetylcholine is an important neurotransmitter underlying the generation and modulation of EEG oscillatory activities, we hypothesize that impaired cholinergic transmission due to LA alters EEG alpha rhythms (8 to 12 Hz). To test this hypothesis, eight minutes of resting state EEG data, 4-minutes eyes-closed (EC) and 4-minutes eyes-open (EO), were recorded from eleven older adults with high LA and nine older adults with low LA. EC to EO alpha reactivity (i.e., alpha power in EC/alpha power in EO) and individual alpha frequency (IAF) during both EO and EC were calculated for each subject. We found that higher levels of LA were associated with lower alpha reactivity ($p = 0.0285$) as well as lower IAF (EC: $p = 0.0070$). These results demonstrate that features of EEG alpha rhythm may provide simple markers for the presence of LA. Future work will be directed at confirming these results with larger samples.

Title: Frontal beta oscillations time-locked to corrective sub-movements in Parkinson's disease: modulation by L-dopa

Authors: ***A. HAJIHOSSEINI**[1], C. GONZALEZ[2], M. OISHI[2], M. J. MCKEOWN[1]; [1]Med., Univ. of British Columbia, Vancouver, BC, Canada; [2]Univ. of New Mexico, Albuquerque, NM

Abstract: Parkinson's disease (PD) is associated with abnormal oscillations in the basal ganglia (BG) and the cortex and electroencephalogram (EEG) studies have shown that L-dopa medication increases frontal beta power (13-30 Hz) in PD (George et al., 2013). In healthy subjects, frontal high-beta (20-30 Hz) oscillations are proposed to have a role in communication of task-related information (e.g., reward feedback) between the prefrontal cortex and the BG (HajiHosseini & Holroyd, 2015). This may relate to the notion that motor impairment in PD is due to a disrupted oscillatory link between motivational factors such as rewards and movement "vigour" i.e., speed and size of movement (Mazzoni, et al., 2007). We investigated whether EEG oscillations in PD during a manual-tracking task with performance feedback were affected by L-dopa.

EEG was recorded from14 subjects with PD (on and off L-dopa) and 9 age-matched control subjects in a joystick-tracking task with continuous visual feedback. The behavioural data were analyzed using a hybrid control theory framework (Oishi, et al., 2010) to extract the onsets of corrective sub-movements that were then used as temporal markers for the EEG. EEG data from all subjects were pre-processed by Independent Component Analysis followed by component clustering in EEGLAB. Bootstrapping revealed a significant frontal-central cluster where EEG was significant throughout the task.

We found that ~1s before a corrective sub-movement , beta power was higher in PD subjects on-L-dopa compared to the same group off-L-dopa. High-beta power was significantly greater in PD subjects on-L-dopa compared to healthy control subjects, but theta (4-7 Hz) power was lower in PD subjects off-L-dopa compared to healthy control subjects. In the time domain, the grand

average event-related potentials preceding the corrective sub-movements were significantly more positive in PD subjects off-L-dopa compared to on-L-dopa and compared to healthy controls. Our results suggest that L-dopa modifies frontal EEG oscillations preceding corrections guided by feedback in PD subjects. We speculate the increase in frontal beta power is a compensatory mechanism to correct for impaired movement vigour in PD. The decrease of frontal theta power in PD patients might represent impairment of frontal control mechanisms (perhaps due to medial prefrontal dopamine deficits), that remain largely unaffected by L-dopa medication. In sum, time-locked spectral and time-domain changes in EEG can provide useful information about the mechanisms underlying common treatments in PD and could serve as biomarkers to test alternative treatments for PD such as non-invasive brain stimulation.

Title: Movement related subthalamic ß oscillatory neurons in patients with Parkinson’s disease

Authors: *P. ZHUANG[1], R. CHEN[2], M. HALLETT[3], Q. CUI[1], Y. ZHANG[1], J. LI[1], Y. LI[1]; [1]Xuanwu Hosp, Capital Med. Uni, Beijing, China; [2]Krembil Res. Institute, Univ. of Toronto, Toronto, ON, Canada; [3]Human Motor Control Section, NINDS,NIH, Bethesda, MD

Abstract: Bacground: How the human basal ganglia processes information in generation of movement is still largely unknown. **Objective:** To explore voluntary movement related neuronal activity in the subthalamic nucleus in patients with Parkinson’s disease (PD).**Methods:** 17 PD patients (M:7; F:10) who underwent STN deep brain stimulation (DBS) for parkinsonian symptoms were studied.Their mean age was 58.5±5.4 years and mean disease duration was 6.9±3.6 years. Microelectrode recordings in the STN and EMG recording on the contralateral limbs to surgery were simultaneously performed.Patients performed at least 10 self-paced wrist extension movements at 10 sec intervals during the recordings. All patients were trained to

perform the task before surgery. Single-unit analysis with mean neuronal firing rate and coefficient of variation (CV) of inter-spike interval (ISI) were calculated.Power spectral analysis was used to evaluate neuronal oscillation patterns.Based on the movement onset, four periods were determined: baseline (2 s), pre-movement (3 s), movement execution and post-movement (2 s). ANOVA and Bonferroni test were performed to compare the change of mean firing rate and CV of neurons among four periods of movement. **Results:** 119 neurons were identified from 21 STN.Of these neurons,38.7% (n=46) were neurons with β oscillation at range of 13~30 Hz (mean 21.0 ± 5.1 Hz). Of these ß oscillatory neurons, 43.5% (n=20) were related wrist movement. 26.1% (n=12) were desynchronized with reduced firing rate, and 17.4% (n=8) were synchronized with increased firing rate. Bonferroni test showed that there were significant changes of mean firing rate between baseline and movement execution in neurons desynchronized (37.5±7.6 Hz vs 20.4±5.2 Hz, n=12) or synchronized (39.7±7.3 Hz vs 53.9±9.5 Hz, n=8) during self-paced wrist movement. Furthermore, these movement related neurons were localized in the dorsal half of the STN. **Conclusions:** These preliminary data support the view that the STN ß oscillatory neurons are modulated with the execution of self-paced wrist movement. The desynchronized or synchronized STN ß oscillatory activity might play a role in whether a movement is facilitated or suppressed. Moreover, the localizations of the movement related ß oscillatory neurons is within the dorsal portion of the STN, adding to the evidence that this is the motor part of the STN.

Title: Globus Pallidus internus low beta phase-amplitude coupling correlates with motor impairment in Parkinson’s disease

Authors: *M. MALEKMOHAMMADI[1], N. AUYONG[2], N. POURATIAN[2];
[1]Neurosurg., Univ. of California Los Angeles, Los Angeles, CA; [2]Neurosurg., UCLA, LOS ANGELES, CA

Abstract: Objective: The β (12-30 Hz) band is often investigated as a single entity in Parkinson’s disease (PD) pathophysiology. However, there is growing evidence that there exists functionally distinct “low” and “high” β sub-bands. Recent studies have suggested that low β

signal in the subthalamic nucleus (STN) is reflective of local activity and is responsive to therapeutic interventions. It remains to be determined if the the neuronal network within the Globus Pallidus internus (GPi), a main basal ganglia output nuclei also exhibits similar β characteristics. In this study, we aim to delineate the differential role of the low and high β sub-bands within the GPi, with respect to disease severity and contralateral hand movement in PD subjects undergoing Deep Brain Stimulation (DBS) implantation surgery. **Methods:** Intra-operative local field potentials (LFP) were recorded after placement of DBS leads (Medtronic Inc., model 3387) within motor part of GPi in 19 PD subjects bilaterally (38 GPi) (2.4 kHz sampling frequency, 500 Hz Low pass filtered). Rest trials without artifact, tremor, or voluntary movement, and trials with left hand movement were selected for analysis. Power spectral density analysis was done using Welch method (1 second windows, 90% overlap, 1 Hz frequency resolution) and Phase Amplitude Coupling (PAC) was calculated by modulation index (MI) (phase: 1-35 Hz with 2 Hz bandwidth; amplitude: 50-400 Hz with bandwidth of double phase encoding frequency). 100 surrogate data sets were generated to assess the statistical significance of MI values at $P< 0.05$ and P-values were corrected for multiple comparisons. Pearson's Correlation with clinical scores (lateralized UPDRS scores, and separate scores for tremor, rigidity and bradykinesia) was calculated ($P<0.05$) and one sample t-test was used to test significance level of movement related modulation in both power and PAC. **Results:** We found a bimodal distribution of spectral peaks at 15.63±2.44 and 24.5± 5.05 Hz for low and high β, respectively. Although both low and high β power decrease with contralateral hand movement; neither showed significant correlation to the lateralized UPDRS scores. In addition, low β-encoded PAC in motor GPi was significantly reduced with hand movement. The low β PAC ratio between movement and rest was significantly correlated to lateralized scores for bradykinesia and rigidity. **Conclusions:** With the emerging concept of the differential role of low and high β frequencies in PD pathophysiology, we present findings for shared β sub-bands properties between GPi and STN that suggests that β sub-bands oscillations are related to both movement and disease severity.

Title: Neural and motor responses to temporally non-regular deep brain stimulation in Parkinson's disease

Authors: *B. D. SWAN[1], D. BROCKER[1], C. OZA[1], D. TURNER[2], W. GRILL[1];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Neurosurg., Duke Univ. Med. Ctr., Durham, NC

Abstract: Abnormal oscillatory and synchronized neural activity in the basal ganglia is increasingly implicated in the pathophysiology of Parkinson's disease (PD). Local field potentials (LFPs) recorded from the subthalamic nucleus (STN) of humans with PD exhibit increased oscillatory activity in the beta band (10-35 Hz) that correlates with decreased motor performance. Deep brain stimulation (DBS) of the STN is an effective therapy that alleviates motor symptoms in PD and suppresses beta band activity. We previously found that specific temporally non-regular patterns of DBS improved motor task performance and suppressed beta oscillatory activity in a computational model of the basal ganglia (Brocker et al., 2013). Here we conducted intraoperative measurements of STN LFPs and PD motor symptoms in human subjects during temporally non-regular DBS to investigate the effects on neural oscillations in the beta frequency band. Following informed consent, six human subjects with PD participated in our study during STN DBS implant surgery. We quantified neural and motor responses to high frequency temporally regular and non-regular DBS by recording STN LFPs during tremor or an alternating finger tapping task. Neural recordings showed high oscillatory activity in the beta frequency band in the absence of DBS, and behavioral measures reflected poor motor task performance. Temporally regular and non-regular patterns of DBS reduced beta band power and improved PD motor symptoms in some, but not all subjects. These data further demonstrate that temporal pattern influences the efficacy of DBS in PD. Additionally, neural recordings confirm that non-regular patterns of DBS suppress pathological oscillatory activity in the human STN. Further design of temporally patterned DBS may help elucidate the mechanisms of action of DBS in PD and improve the efficacy of the therapy in ameliorating motor symptoms.

Title: High resolution electrocorticography in prefrontal cortex in Parkinson's disease patients

Authors: *C. DE HEMPTINNE[1], W. CHEN[2], A. MILLER[2], C. RACINE[2], P. STARR[2]; [1]Dept. of Neurolog. Surgery, Univ. of California San Francisco, San Francisco, CA; [2]UCSF, San Francisco, CA

Abstract: Background: Parkinson's disease (PD) is characterized by a constellation of motor and non-motor symptoms including depression, anxiety and apathy. Motor symptoms have been well studied and are associated with excessive neuronal synchronization in the beta band (13-30Hz) throughout the motor basal-ganglia-thalamo-cortical (BGTC) loop. Despite results from non-invasive and imaging studies suggesting a dysfunction of the cognitive and limbic BGTC loops, the pathophysiology underlying non-motor symptoms is still largely unknown. **Objective:** To investigate the neurophysiology of mood symptoms in PD using electrocorticography (ECoG), a technique that offers high spatial and temporal resolution. **Methods:** A 28-contact ECoG strip was temporarily placed over the prefrontal cortex of 22 PD patients undergoing deep brain stimulation (DBS) implantation surgery. A strip was placed over the dorsolateral prefrontal cortex (DLPFC) in 10 patients, spanning both the ventrolateral prefrontal cortex (VLPFC) and the orbitofrontal cortex (OFC) in 12 patients. Before surgery each patient's mood was evaluated using multiple standardized rating scales including the Edinburgh Depression Scale (EDS) and the Apathy Evaluation Scale (AES). The power spectral density (PSD) was computed for each ECoG contact and averaged across the entire beta band (13-30Hz), as well as sub-divided between the low (13-20Hz) and high (20-30Hz) beta bands. Given the importance of beta in the pathophysiology of PD, the contact associated with the maximum beta power was selected to investigate the correlation between beta power and mood symptoms. **Results:** We found a prominent beta peak in the power spectrum of the prefrontal ECoG potential in most patients (20/22). Topographically, beta power was maximal over the lateral portion of the OFC (8/12 patients) and anterior portion of the DLPFC (6/10 patients). We found that depression (measured with EDS) and apathy (measured by the AES) were both significantly correlated to low beta power in OFC, but not in DLFPC. **Conclusion:** These preliminary results suggest that neuronal synchronization in the beta band extends outside the motor system to the prefrontal cortex in PD, highlighting the importance of these oscillations in the diverse pathophysiology of PD. These findings could indicate a potential role of OFC beta power in non-motor symptoms of PD.

Title: Sensorimotor beta coherence with high-resolution electrocorticography in Parkinson's disease patients

Authors: ***W. CHEN**[1], C. DE HEMPTINNE[1], N. ROWLAND[2], P. A. STARR[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Introduction: In Parkinson's disease, the basal-ganglia-thalamo-cortical circuit is hypothesized to be in a pathological state of excessive beta band (13-30 Hz) neural synchronization. Studies using noninvasive techniques report greater global cortical beta coherence, a common measure of synchronization, when patients are clinically more symptomatic. This is reduced with dopaminergic medication or during basal ganglia deep brain stimulation (DBS). To date, electrophysiological studies lack adequate spatial and/or temporal resolution to assess cortical coherence within sensorimotor areas.
Objective: To investigate the role of cortico-cortical synchronization within and between premotor (PM), primary motor (M1), and primary somatosensory (S1) cortices in disease pathophysiology, we utilized high-resolution electrocorticography (ECoG) to compare oscillatory coherence in Parkinson's disease (PD) and essential tremor (ET) patients.
Methods: We collected intraoperative high-resolution ECoG (28-contact, 4 mm spacing center to center) data from 10 PD patients and 8 ET patients undergoing awake DBS surgery, with coverage over the superior frontal gyrus, precentral gyrus, and postcentral gyrus. Neural activity was recorded both at rest and during a cued movement reaching task, which cycled between intervals of movement and movement-hold. We analyzed magnitude-squared coherence across all electrode pair combinations, averaging across the beta band, during rest, movement, and movement-hold. Following anatomic localization of each electrode, we quantified between-gyrus and within-gyrus coherence.
Results: Both at rest and during movement-hold, beta band coherence between and within M1, S1, and PM cortices were not significantly different between PD and ET patients. During movement, however, there was decreased M1-PM and M1-S1 beta coherence in PD compared to

ET. Further analysis of beta band subdivisions revealed that low beta (13-20 Hz) coherence is significantly less in M1-PM and M1-S1 in PD.
Conclusions: Our preliminary results suggest that during voluntary movement, there is reduced beta coherence within and between M1, S1, and PM cortices in PD compared to ET. This may be a compensatory mechanism by which the cortex reduces the influence of PD-related hyper-synchronization.

Title: Resetting and saving of beta oscillatory changes during motor practice in healthy subjects and in Parkinson's Disease

Authors: J. LIN[1], P. PANDAY[1], A. B. NELSON[1], M. S. VENANZI[2], C. MOISELLO[1], A. DI ROCCO[3], *M. F. GHILARDI[1];
[1]CUNY, New York, NY; [2]Univ. of Milan, Milan, Italy; [3]The Fresco Inst. for PD and Movement Disorders, NYU Langone Med. Sch., New York, NY

Abstract: In a recent EEG study, we have found that the modulation depth of beta power during movement increases with practice over the sensorimotor and frontal areas of normal subjects but not over those of patients with PD (Moisello et al., Brain Behav. 2015 Sep 23;5(10):e00374). In line with studies suggesting that such beta power changes might reflect cortical plasticity phenomena and in particular use-dependent modifications, we concluded that reduction of beta enhancement in PD might represent saturation of cortical plasticity. However, a few questions remained open: Would a second task exposure on the following day increase such phenomenon in normal subject and restore beta modulation enhancement in PD? Do practice-induced increases of beta modulation occur within each block of consecutive movements? And, if so, do

these changes occur in patients with PD? We thus recorded high-density EEG in 11 patients with PD and 13 age-matched controls in two consecutive days during a forty-minute reaching task divided in fifteen blocks of 56 movements each. The results confirmed that on day 1, with practice, beta modulation depth over the contralateral sensorimotor area significantly increased across blocks in normal controls but not in PD, while performance indices improved in both groups without significant correlations between behavioral and EEG data. The following day, beta modulation values re-started at the same baseline values of day 1 and increased across trials within the same range of day 1 in both groups, without differences between the two days. Further analyses of data of both days revealed that the increases at the end of each block were partially carried onto the successive block in controls, while no significant carry over was observed in PD. We conclude that the lack of significant practice-related increase of mean modulation depth across each session we observed in PD is likely to deficient mechanisms of potentiation permitting between-block saving of beta power enhancement. Moreover, we speculate that the resetting of beta modulation values might reflect mechanisms of homeostatic regulation.

Abstract: Parkinson’s disease (PD) is a debilitating movement disorder that affects approximately 1 million people in the US and is characterized by abnormal movements such as

resting tremor, bradykinesia, rigidity, and gait abnormalities that impair the quality of life of PD patients. Furthermore, motor deficits in PD are evaluated on a relatively long time scale by subjective measures such as the Unified Parkinson's Disease Rating Scale (UPDRS). In reality however, movement states may vary over the timescale of seconds or minutes. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) or the globus pallidus internus (GPi) is a commonly utilized therapy to treat PD motor symptoms, but remains relatively imprecise, because continuous electrical stimulation is delivered without responding to behavioral or neurophysiological states.To develop a closed-loop DBS system that can respond in real-time to functionally relevant movement fluctuations, we sought to quantify rapid changes of movement quality and determine the corresponding neural activity. States associated with or predictive of poor motor performance may be useful as biomarkers for controlling closed-loop DBS. We designed a continuous motor performance task to identify short timescale fluctuations in motor performance. PD patients used a joystick to move an on-screen cursor and were asked to follow a moving target. Some task sessions were collected alongside simultaneous local field potential (LFP) recordings from STN or GPi during DBS lead implant surgery, while others were collected pre-operatively in a clinical setting. We employed two metrics, quantifying instantaneous tremor magnitude (the absolute value of bandpass (4-12 Hz) filtered joystick data) and vector error (the difference between the velocities of the target and joystick). We observed that motor symptoms were differentiated well with those two metrics. We investigated the spectral power of LFP and the Phase-Amplitude Coupling (PAC) within STN/GPi to identify neural correlates of this behavioral variability. We found that the severity of abnormal movements was associated with increases in spectral power and with PAC features. We also applied machine learning that incorporates those features in order to predict movement states on a rapid timescale. We discuss the implications of our results in designing a closed-loop DBS system that may help to improve the efficiency of DBS treatments for PD patients.

Hosp. Duesseldorf, Duesseldorf, Germany; [8]Ctr. of Functionally Integrative Neurosci., Aarhus Univ., Aarhus, Denmark

Abstract: Patients with advanced Parkinson's disease (PD) often suffer from severe walking difficulties, called freezing of gait, while they are still able to ride a bike easily [1, 2]. This phenomenon suggests functional differences in the brain networks subserving bicycling and walking. High-frequency oscillations (HFO; > 200 Hz) observed in the basal ganglia (BG) have been assumed to be prokinetic as they increase with voluntary movement and medication [4, 5]. This study aimed to contrast HFO dynamics during bicycling and walking in the BG of PD patients.
10 PD patients (mean age 55.8 +/- 6.3 y) clinically selected for bilateral deep brain stimulation (DBS) therapy were included. Using a portable EEG system, local field potentials from the subthalamic nucleus (STN) were recorded using externalized leads the day after implantation of DBS electrodes. Patients were recorded while OFF any dopaminergic medication during unconstrained walking and bicycling on a stationary bicycle and the respective baseline conditions, i.e., standing and sitting. Spectral peaks were predominantly found in the slow HFO range (200-300 Hz) in 13 STNs that were considered for further analysis. A two-way repeated measures ANOVA was computed for slow HFO power with the within-subject factor movement (rest/move) and posture (upright/sitting on bike).
HFO power was higher in the upright condition, irrespective of the movement state ($p < 0.05$). Furthermore, the ANOVA revealed a significant interaction between movement and posture ($p < 0.05$). Post-hoc paired t-tests showed that power was significantly higher during standing compared to sitting ($p < 0.05$), whereas power during walking and pedaling was similar ($p > 0.05$). This was especially due to a power increase from sitting to pedaling, as opposed to a slight power decrease from standing to walking. Our results are in line with previous studies associating the OFF state in PD with spectral peaks in the slow HFO range [3, 4]. Our analyses

revealed a differential effect of bicycling and walking on HFO power. HFO power increased from sitting to pedaling while it decreased from standing to walking. Therefore, one may speculate that bicycling boosts the basal ganglia's HFO output and thus facilitates movement. However, power was found to be overall higher during standing and walking. This may emphasize posture and balance influencing HFO power.

Title: Effects of STN deep brain stimulation on voice motor control in Parkinson's disease

Authors: *R. BEHROOZMAND[1], P. HERATH[2], K. JOHARI[2], R. KELLEY[3], E. KAPNOULA[3], K. BRYANT[3], N. NARAYANAN[3], J. GREENLEE[3];
[1]Communication Sci. and Disorders, [2]Univ. of South Carolina, Columbia, SC; [3]Univ. of Iowa, Iowa City, IA

Abstract: The present study investigated the effects of subthalamic nucleus (STN) deep brain stimulation (DBS) on the mechanisms of voice motor control in Parkinson's disease (PD). A total of ten PD individuals with bilateral STN-DBS implantation were tested in two separate blocks with DBS OFF vs. ON while they repeatedly maintained steady vocalizations of the vowel sound /a/ at their conversational pitch and loudness for 200 trials. The duration of each

vocalization was approximately 2-3 seconds and subjects took short breaks (~ 2 seconds) between successive vocalizations. During each vocalization trial, a brief (200 ms) pitch-shift stimulus was delivered to perturb voice auditory feedback. Pitch-shift stimuli were presented randomly at upward (+100 cents) and downward (-100 cents) directions and their onset time was randomized between 800-1200 ms relative to the onset of each vocalization. Vocal responses to auditory feedback perturbation were extracted for each PD individual during DBS OFF and ON conditions. In addition, the measures of pitch, loudness, harmonic-to-noise ratio (HNR), jitter and shimmer were calculated across all vocalization trials during DBS OFF and ON. Results of the analysis indicated that all subjects produced compensatory responses that changed the pitch frequency of their voice in the opposite direction to auditory feedback perturbation. We observed that DBS significantly modulated the magnitude of compensatory vocal responses only for downward pitch-shift stimuli and subjects produced upward vocal responses that were significantly larger in magnitude during DBS ON compared with DBS OFF condition. In addition, we found that the overall variability in voice pitch was significantly reduced for DBS ON compared with DBS OFF, as indexed by the measure of voice jitter. These findings indicate that STN-DBS has a positive impact on the mechanisms of voice motor control by helping individuals better control their voice pitch. However, the differential effects of DBS on vocal responses to upward and downward pitch perturbations in the auditory feedback suggest that the mechanisms that drive vocal folds muscle contraction (raising pitch) and relaxation (lowering pitch) are not equally facilitated during DBS. These findings provide new insights into the mechanisms that incorporate auditory feedback to regulate and control voice pitch in individuals with PD.

Title: Parkinson's disease outcomes of implanting deep brain stimulation leads to the globus pallidus internus while undergoing surgery under general anesthesia

Authors: N. S. TIMONEY[1], *J. E. QUINTERO[4,2], J. H. SMITH[1], F. N. MCCARRON[3], G. A. GERHARDT[4,2], C. G. VAN HORNE[4,2,1];
[1]Neurosurg., [2]Brain Restoration Ctr., [3]Surgery, Univ. of Kentucky, Lexington, KY; [4]Anat. & Neurobio., Univ. Kentucky, Lexington, KY

Abstract: One of the chief complaints of patients with Parkinson's disease (PD) who undergo deep brain stimulation (DBS) surgery is the awake portion of the surgery. As a result, individuals who would otherwise be good candidates for DBS may elect to not have the surgery and forgo the benefits of DBS therapy. Here we describe retrospectively and prospectively collected data on individuals with PD who have undergone standard DBS surgery while under general anesthesia at our center. Susceptibility weighted imaging (SWI) was used for pre-operative planning to identify the target locations in the globus pallidus internus (GPi). DBS leads were implanted under general anesthesia (typically ~ 1.2 - 1.8% sevoflurane). Single-pass microelectrode recordings (MER) and macrostimulation testing were used to intraoperatively identify the target and side effects. MDS-Unified Parkinson's Disease Rating Scale (UPDRS) testing was evaluated before and after surgery. Post-operatively, DBS electrodes were mapped and compared to planned targets. Over 60 individuals with PD have received DBS lead implants to the GPi while undergoing the surgery asleep at our center. In 14 individuals who underwent post-surgery UPDRS assessment 6 to 18 months after surgery: pre-surgery, mean UPDRS part III (motor) score OFF therapy was 59.3 ± 15.9 (Mean ± SD) and ON therapy was 36.8 ± 17.0. After surgery, ON stimulation/OFF medication mean score was 38.1 ± 15.6 (103% of pre-surgery ON therapy) and ON stimulation/ON medication score was 26.9 ± 13.2 (73% of pre-surgery ON therapy). Post-surgery OFF stimulation/OFF medication score for 10 individuals was 59.1 ± 14.9 (99.7% of pre-surgery OFF therapy). These results support intraoperative MER and macrostimulation testing as a method for electrode placement in asleep patients while showing that implanting DBS leads to the GPi while individuals are under general anesthesia provides an alternative means of offering DBS therapy.

Title: Feasibility of 1.5T fMRI BOLD activation patterns for guiding deep brain stimulation targeting and parameter selection demonstrated in a large-animal model

Authors: T. A. JERDE[1], N. REINKING[2], M. KELLY[2], T. BILLSTROM[2], L. LENTZ[2], *R. S. RAIKE[2];
[1]New York Unveristy, New York, NY; [2]Medtronic Inc, Minneapolis, MN

Abstract: High-frequency subthalamic nucleus (STN) deep brain stimulation (DBS) is used to treat the movement disorders Parkinson's disease and dystonia. However, the therapeutic mechanisms of DBS are not well understood. Electroencephalographic (EEG) studies in patients implicate antidromic activation of the hyperdirect corticosubthalamic pathway in the therapeutic benefits of STN DBS. Similarly, functional magnetic resonance imaging (fMRI) in patients and large-animal models demonstrates that STN DBS can be associated with significant activation of blood-oxygen-level-dependent (BOLD) signals within motor cortical areas. However, due to a number of practical, technical and safety limitations, few of these studies have systematically explored stimulation parameters, which are known to drive therapeutic outcomes. Therefore, the purpose of this study was to assess the effects on motor cortical activation of different STN DBS parameters, including electrode location, and stimulation amplitude and frequency in an STN DBS sheep model. Animals were chronically implanted with clinical-grade DBS systems and imaging was performed using a 1.5T MRI system and human safety power guidelines for DBS. Activation maps revealed a dependence on DBS parameters, whereby an optimal electrode configuration, stimulation voltage and stimulation frequency range were identified that produced significant ipsilateral motor cortical BOLD activation. Conversely, non-optimal parameters were associated with more widespread or diffuse motor network activation patterns. Overall, the results support the feasibility of using 1.5T fMRI-BOLD activation patterns for guiding DBS targeting and parameter selection for movement disorders.

Title: A novel approach for measuring light-evoked neurotransmitter release

Authors: *A. K. KONRADSSON-GEUKEN, T. VIERECKEL, G. SERRA, A. WALLÉN-MACKENZIE;
Organismal Biol., Uppsala Univ., Uppsala, Sweden

Abstract: A technical challenge so far has been to record fast *in vivo* neurotransmission such as, the release of glutamate. Electrochemical measurements with amperometry allow *in vivo* quantification of specific neurotransmitters with an outstanding temporal- and spatial resolution. Most studies today utilize electrical- or pharmacological stimulation to evoke neurotransmitter release. However, these approaches lack spatial selectivity. The aim of this study was to utilize optogenetic activation of restricted cell populations of transgenic animals to measure glutamate release with *in vivo* amperometry. Mice expressing Cre recombinase in Pitx2-positive cells in the subthalamic nucleus (STN) were injected with Cre-dependent adeno-associated viruses carrying Channelrhodopsin 2. Applying light pulses of 10-, 20- and 40 Hz, glutamate release was measured in these animals at a holding potential of +0.7, using glutamate Oxidase (GluOx)-coated multi-channel electrodes. Possible laser artifacts were identified with sentinel channels lacking GluOx and the use of a holding potential of +0.25 V, at which no glutamate activity is present. Enzyme activity and electrode efficacy were tested through local exogenous glutamate application. By combining two unique methods, optogenetics with amperometry in the anesthetized mouse, we have established a new protocol for the analysis of glutamate release from spatially restricted cell populations. By utilizing our transgenic animals and the combinations of methods described above, we will be able to further explain the importance of glutamate in the STN network which could be of clinical relevance as the STN is an area used for deep brain stimulation in patients suffering from Parkinson's disease.

Title: Optogenetic stimulation parameter settings and candidate electrophysiological features for maximizing behavioral response

Authors: *T. H. SANDERS;
Biol., Emory Univ. Dept. of Biol., Atlanta, GA

Abstract: High frequency (100 - 200 Hz) electrical stimulation of the subthalamic nucleus is known to ameliorate bradykinesia in human patients. We have recently shown that high frequency optogenetic stimulation of motor-cortico-subthalamic neurons also ameliorates bradykinesia in the 6-OHDA unilaterally lesioned mouse model of Parkinson's disease. Here I report results from a study performed in a subset of these mice. In this study, mice (N = 4) were stimulated at frequencies ranging from 30-130 Hz with pulse widths that increased with decreasing frequency such that the amount of light delivered per unit time remained constant. The results suggest that certain optogenetic behavioral effects may depend on the amount of light delivered to transfected neurons, rather than the frequency of stimulation. I also show in this subset of mice that power, phase-amplitude coupling, and coherence features are significantly changed between normal, parkinsonian, and optogenetically treated states. Future studies will evaluate the suitability of these candidate features for feedback control of closed-loop stimulation.

Title: Development and implementation of a large animal model for investigation of neurochemical activity during behavior

Authors: *J. TREVATHAN, A. D. BATTON, E. N. NICOLAI, K. H. LEE, J. L. LUJAN; Mayo Clin., Rochester, MN

Abstract: Introduction: Significant research efforts have studied the role of dopamine in motor control, motivation, and reinforcement learning, as well as implicated in pathologic changes in dopamine signaling in many neurologic and psychiatric disorders. Previous studies have used fast scan cyclic voltammetry (FSCV) to study neurotransmission by chronically measuring sub-second changes in neurotransmitter release in awake small animal models (Clark et al. 2010). However, these models are not suitable for clinical translation. Additionally, the stiffness of the recording electrode and wired connections to the neurochemical recording device make existing systems unsuitable for neurochemical sensing in freely-moving large animals. Here we describe the development and implementation of a freely-moving and chronically implanted large animal model for investigation of neurochemical activity. **Methods:** We used a custom built carbon fiber microelectrode (CMF) with a flexible lead system, a deep brain stimulation electrode, and a wireless backpack mounted device, WINCS Harmoni, for simultaneous neurochemical recording and stimulation in an awake swine. To manufacture the flexible CFM, we built a sensing element, T-300 carbon fiber, into the front-end of1.27 mm diameter Silastic^{TM} tubing. A ring reference electrode was mounted proximal to the tip of the electrode. Connections to the sensing element and reference electrode were made with stainless steel wire coiled around a tungsten stylet. Using image-guided stereotactic targeting, this flexible electrode was implanted into the swine striatum. Similarly, a stimulating electrode (NuMed, Hopkinton, NY) was implanted into the substantia nigra pars compacta/ventrotegmental area. WINCS Harmoni was placed inside a backpack and connected to the externalized electrodes. Neurochemical release and associated behavioral responses were recorded in the awake animal 48 hours after implantation and once weekly thereafter to characterize changes in the neurochemical response. **Results:** A flexible CFM was developed. This electrode allowed for chronic implantation and wireless monitoring of stimulation-evoked neurochemical responses when used in combination with WINCS Harmoni. **Conclusion:** The approach described herein allows for neurochemical monitoring of awake behaving animals, which will provide novel insight into the neurochemical correlates of behavior. As such, this technique represents the first step toward studies aimed at examining the role of sub-second fluctuations in neurochemical activity during behaviors associated with neurologic health, disease, and response to treatment.

Abstract: Neuromodulation of the globus pallidus internus (GPi) alleviates Parkinson's disease symptoms, yet its mechanism is unclear. So we focus on entopeduncular nuclei(EP) in rats, which is homologous to the globus pallidus interna(GPi). We generated a hemiparkinson rat model by injecting an adeno-associated virus type-2 expressing α-synuclein (AAV2-α-syn) into the substantia nigra pars compacta (SNc) of the right brain to test whether optogenetic stimulation of the EP could alter parkinsonian behaviors or thalamic discharge. First, we confirmed parkinsonian behavior in our model using an amphetamine-induced rotation test. Then, we optogenetically activated or inhibited neurons, using the halorhodopsin (NpHR)/channelrhodopsin 2 (ChR2) system in the EP of the hemiparkinson rat model to determine downstream effects on parkinsonian behaviors and thalamic discharge *in vivo*. We assessed alterations in parkinsonian behaviors using the stepping and cylinder tests before, during, and after optogenetic stimulation. Importantly, we found that optogenetic inhibition of the EP improved parkinsonian motor behaviors. Moreover, we monitored thalamic neuronal activity following optogenetic neuromodulation *in vivo*, and we observed alterations in thalamic discharge. Taken together, our data demonstrate that optical neuromodulation in the EP can be used to successfully control contralateral forelimb movement and thalamic discharge to alleviate symptoms in an AAV2-α-syn-induced hemiparkinson rat model.

Title: Evaluating mitochondrial biogenesis in a cell model of Parkinson disease via mitochondrial DNA replication in neuron cell bodies, axons, and dendrites

Authors: *V. S. VAN LAAR[1,2], L. H. SANDERS[1,2], B. ARNOLD[1,2], E. H. HOWLETT[1,2], J. T. GREENAMYRE[1,2], S. B. BERMAN[1,2];
[1]Dept. of Neurol., [2]Pittsburgh Inst. for Neurodegenerative Dis., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Evidence implicates dysregulation of mitochondrial homeostasis and quality control in neurodegenerative diseases such as Parkinson's disease (PD). We had previously found that exposure of primary neurons to chronic, sublethal doses of rotenone, a Complex I inhibitor linked to PD, was associated first with increased mitochondrial density in distal neurites, followed by later increases in mitochondrial density in cell bodies. The increased mitochondrial density in neurites prior to cell bodies was not accounted for by changes in mitochondrial transport or localized changes in mitochondrial degradation. This suggested the possibility that localized changes in mitochondrial biogenesis could be occurring in axons/dendrites, but methodology for direct studies targeting neuroanatomical localization of mitochondrial biogenesis was lacking. We have optimized methodology to directly image, localize, and quantify replicating mitochondrial DNA (mtDNA) in neurons using BrdU incorporation and immunocytochemistry. We are able to visualize newly synthesized mtDNA replication within minutes in neurons *in vitro*. The BrdU incorporation is inhibited, as expected, by the addition of 2',3'-dideoxycytidine (ddC), inhibitor of mitochondrial DNA polymerase gamma. Interestingly, as neurons 'age' in culture from 7 to 21 days, rates of mtDNA synthesis increase. This increase is also associated with increased expression of PGC1alpha, suggesting increased mitochondrial

biogenesis with senescence. To address the effects seen in our previous studies, we are also evaluating the effects of chronic, sublethal rotenone on localized mtDNA replication. These studies give us the ability to better elucidate mtDNA replication/mitochondrial biogenesis in neurons and under PD-relevant conditions.

Title: Investigating molecular mechanisms regulating mitochondrial quality control

Authors: *K. BUSH[1], A. M. BUCKLEY[2], K. R. BARBER[2], M. WOODSON[2], M. B. SHERMAN[2], Y. WAIRKAR[2];
[1]Univ. of Texas Med. Br., Galveston, TX; [2]UTMB, Galveston, TX

Abstract: Parkinson's disease is a debilitating neurodegenerative disorder that affects an estimated 53 million people worldwide. Symptoms tend to arise later in life as characteristic tremors, and become severely incapacitating within 10-20 years, resulting in possible dementia, sleep disorders, depression, and or other emotional problems. As of now Parkinson's disease is untreatable though several proteins, genes, and their targets have been characterized as markers and possible triggers for the disease. The most well-established of these proteins are PINK1 and Parkin, both of which are part of a pathway that regulates mitochondrial fidelity in the form of quality control and fission. Mutations in the genes encoding these proteins result in loss of the ability to perform mitochondrial quality control. However, how the PINK1/PARKIN pathway regulate mitochondrial quality control is not well understood. The goal of the current project is to understand how PINK1/PARKIN regulates mitochondrial quality control. For this, we are utilizing the fly model to understand the molecular mechanism of mitochondrial quality control. One of the proteins that we found in a screen for defective synapse growth also affects mitochondrial morphology leading to the hypothesis that this protein may function in the

PINK1/PARKIN pathway. Current study is aimed toward identifying whether the protein of interest works in the PINK1/PARKIN pathway or regulates mitochondrial morphology independent of this pathway. The results of this analysis will be presented.

Title: Altered lysosomal stress markers in idiopathic Parkinson's disease and following pharmacological-induced lysosomal dysfunction via glucocerebrosidase inhibition

Authors: E. B. MOLONEY, S. LEVY, J. A. KORECKA, O. ISACSON, *P. HALLETT; Neuroregeneration Res. Inst., Harvard Med. Sch. / McLean Hos., Belmont, MA

Abstract: *GBA1* encodes for the lysosomal hydrolase, glucocerebrosidase (GCase), and heterozygous mutations in *GBA1* dramatically increase the risk for developing Parkinson's disease (PD). Our data shows that sporadic PD (with no *GBA1* mutation) mirrors *GBA1* haploinsufficiency, given that GCase activity is reduced in several brain regions including the substantia nigra, and levels of the glycolipid substrate, glucosylsphingosine (GluSph), are elevated. Moreover, similar alterations to GCase activity and glycolipid levels occur in the brain of healthy subjects and mice in normal aging, and we hypothesize that disrupted glycolipid homeostasis and lysosomal function may precipitate degenerative processes in vulnerable neurons and lower the threshold for developing PD.
Our current studies aim to determine the effect of modulating GCase activity and glycolipid levels *in vivo* on relevant cell biological mechanisms, including markers of lysosomal integrity and stress. To model altered glycolipid homeostasis in mice, we use pharmacological inhibition of GCase with conduritol-β-epoxide, CBE, a selective, irreversible inhibitor of GCase. A 28-day systemic treatment with CBE in wildtype mice leads to PD-relevant neuropathological changes including significantly elevated brain levels of the glycolipids GluSph and glucosylceramide

(GluCer), aggregation of α-synuclein in the substantia nigra, and altered levels of proteins involved in the autophagy lysosomal pathway (Rocha EM et al, Antioxid. Redox Signal., 23(6) 550-564, 2015). As a readout of cellular responses to elevated glycolipids, we have performed analysis of levels of glycoprotein non-metastatic B (GPNMB), which is a transmembrane protein expressed in the brain in neurons and glia. GPNMB levels are elevated in the brain and CSF in lysosomal storage disorders that accumulate glycolipids, including neuronopathic Gaucher disease and Niemann-Pick Type C, and a SNP variant in the *GPNMB* gene has been associated with idiopathic PD risk. Our data shows that GPNMB levels are increased in the brain in CBE-treated mice, as well as in the substantia nigra in sporadic PD. Ongoing analyses will determine the relationship between GPNMB and lysosomal stress, and will evaluate additional markers of lysosomal function in models of altered glycolipid homesostasis.
These data show the remarkable overlap between lysosomal storage diseases and age-dependent idiopathic PD.

Title: Prolyl Oligopeptidase (PREP), a novel modulator of PI3K class III regulated autophagy pathway

Authors: *R. SVARCBAHS, J. JAKOLA, T. MYÖHÄNEN;
Univ. of Helsinki, Helsinki, Finland

Abstract: Division of Pharmacology and Pharmacotherapy, Faculty of Pharmacy, Viikinkaari 5E (P.O.Box 56) 00014 University of Helsinki, Helsinki, FINLAND
Prolyl oligopeptidase (PREP) is a serine protease that hydrolyses small (less than 30 amino acids) proline containing neuropeptides. Recently, it has been shown that PREP enhances aggregation of alpha-synuclein, main component in Parkinson's disease pathology. Our previous results show that PREP overexpression reduced the autophagosome formation in cell culture while PREP inhibition by a small-molecule inhibitor, KYP-2047, led to increased macroautophagy (autophagy) via enhanced beclin1 levels in PI3K class III pathway and countered the effects of autophagy inhibitors. This led us to further investigate the effect of PREP catalytic inhibition and PREP deletion with CRISPR-cas9 system on autophagy markers in HEK-293 cells. Additionally, autophagy maker changes in PREP knock-out mouse brain tissue were measured.
PREP inhibition with 1 μM KYP-2047 in HEK-293 cells for 24 h led to a significant increase in total Bcl2 and phospho-(Ser70)-Bcl2 levels and was accompanied by increase in LC3BII and beclin1 levels. Moreover, PREP inhibition increased the levels of phospho-(Thr119)-Beclin1. PREP deletion by CRISPR-cas9 led to a significant difference in pBcl2/Bcl2 and pBeclin1/Beclin1 ratio, suggesting on positive beclin1 activity modulation.
In PREP knock-out animals there was a significant increase in total Bcl2, phoshpo-(Ser62)-Bcl-xl and LC3BII levels while decrease in Bcl-xl total level was observed, leading to increased pBcl-xl/Bcl-xl ratio.
Our results show that PREP inhibition in cell cultures can enhance the phosphorylation of Bcl2, leading to dissociation of Bcl2 from Beclin1 and Beclin1 phosphorylation that initiates autophagy in PI3K class III pathway. Although we saw increase in certain PI3K class III pathway proteins, in brain tissue of PREP knock-out mouse, Bcl-xL level was decreased. However, in contrast the pBcl-xl levels were increased, and pBcl-xl/Bcl was elevated similar to PREP inhibited and CRISPR-cas9 silenced cells. Our results suggest, that PREP inhibitors could be used as safe autophagy enhancers e.g. to degrade protein aggregates in neurodegenerative disorders.

Title: Blockade of SK channels with the scorpion venom peptide scyllatoxin protects midbrain dopamine neurons from degeneration.

Authors: *P. P. MICHEL[1], S. HAMADAT[1], D. SERVENT[2], G. MOURIER[2], E. C. HIRSCH[1]; [1]Brain and Spinal Cord Inst. (ICM), Paris, France; [2]CEA, iBiTecS, Service d'Ingénierie Moléculaire des Protéines, Gif-sur-Yvette, France

Abstract: Previous studies have suggested that inappropriate and sustained activation of Ca^{2+}-activated K^+ (SK) channels may participate actively to the death of dopamine (DA) neurons in Parkinson disease (PD). This concept is supported by studies showing that a blocker of SK channels, the bee venom peptide apamin (APA) is neuroprotective for DA neurons in cellular and animal models of the disease (Salthun-Lassalle et al, J Neurosci, 2004; Alvarez-Fischer et al, PloS One, 2013). Here, we wished to further explore this hypothesis. To this aim, we tested the neuroprotective potential of scyllatoxin (SCY), a SK channel blocker from scorpion venom whose peptide sequence is unrelated to that of APA.

Using a culture system of selective and progressive DA cell death, we showed that SCY was able to rescue a substantial fraction of DA neurons that degenerate spontaneously under these conditions. The protective effect was concentration-dependent and optimal between 0.1-1µM. Most interestingly, rescued DA neurons were functional as they had the capacity to accumulate tritiated-DA by active transport. The survival promoting effect of SCY was also highly specific to DA neurons. It was short-lived after treatment withdrawal and mimicked by the bee venom peptide APA.

Of interest, DA cell rescue mediated by SCY was compromised when Arg6 and Arg13 that are selectively required for SK channel binding, were replaced by corresponding Ala residues. Likewise, when the capacity of APA to bind SK channels was suppressed by substituting Arg with Ala residues at positions 13 and 14 of the sequence peptide, neuronal rescue was abolished. Combining SCY and APA did not further improve DA cell rescue, leading us to assume that the two peptides shared a common binding site on SK channels. Note that the neuroprotective effect of SCY and also that of APA, were entirely suppressed when voltage-gated Na^+ channels were blocked with tetrodotoxin. This suggested that SCY and APA improved the survival of DA neurons by maintaining the excitability of these neurons at a level that is also required for their survival, as suggested before (Michel et al, Faseb J, 2013). Overall, these data suggest that SK channels may represent an interesting target for neuroprotection in PD.

Title: Receptor-mediated endocytosis 8 is a new component of the protein homeostasis network in mammalian cells

Authors: *A. M. CLEMENT, A. BESEMER, J. MAUS, K. NALBACH, C. FREESE, C. VON HILCHEN, A. KERN, C. BEHL;
Univ. Med. Ctr. Mainz, Mainz, Germany

Abstract: Cellular function and activity depend on an adaptive regulation of protein folding, stabilization and degradation that prevent protein aggregation. This is of particular interest in postmitotic cells such as neurons whose functional decline and degeneration leads to several late onset neurodegenerative diseases. Protein homeostasis, called proteostasis, is regulated by a fine-tuned system of chaperones that stabilize proteins and direct instable proteins towards the proteasome or autophagy degradation pathway. We performed an RNAi-based screen in *C. elegans* following an acute heat stress paradigm to identify new components of the proteostasis network and identified, among others, receptor-mediated endocytosis 8 (RME8). The human ortholog to RME8 is called DNAJ homolog subfamily C member 13 (DNAJC13) and is characterized by the presence of the J-domain that interacts with the chaperone HSP70. Recent evidence suggests that RME8 is an essential component of the sorting processes at the endosome and modulates endosomal trafficking. Mutations in RME8 have been linked to familial forms of Parkinson's disease with Lewy body pathology, although the pathogenic molecular mechanisms are so far unknown. We have now gathered evidence that RME8 is involved in the proteostasis network. The knockdown of RME8 in *C. elegans* as well as in human cell culture systems resulted in the accumulation of aggregation prone proteins like amyloid-beta 42 and α-synuclein or mutant SOD1. As protein aggregation is reminiscent of a defect in protein degradation pathways, we investigated the role of RME8 in autophagy. Based on siRNA and overexpression experiments we determined RME8 as a positive modulator of autophagy.

Title: The involvement of ASC in Parkinson's disease: beyond an adaptor protein.

Authors: *E. ALBORNOZ BALMACEDA[1,2], R. GORDON[2], A. B. ROBERTSON[1], K. SCHRODER[1], M. A. COOPER[1], T. M. WOODRUFF[2];
[1]Inst. for molecular Biosci. (IMB), Univ. of Queensland, brisbane, Australia; [2]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: The Apoptosis-associated Speck-like protein with CARD domain (ASC), is a key component of multimeric inflammasome protein complexes that mediate innate immune and inflammatory responses. They function as intracellular sensors for infectious agents, as well as for host-derived dangers signals that are associated with neurological diseases such as Alzheimer's, stroke, meningitis and recently Parkinson's disease (PD). Inflammasome activation induces the oligomerisation of ASC and the assembly of ASC specks. ASC specks recruit and activate caspase-1, which drives the maturation of the cytokine interleukin 1β (IL-1β) and pyroptotic cell death. Recently, exciting evidence has emerged showing that ASC functions not only as an adaptor protein in the inflammasome complex, but also has extracellular and prionoid activities that propagate inflammation, revealing a new form of cell-to-cell communication. Although these studies have been in peripheral inflammatory conditions, they have profound implications for progressive neurodegenerative diseases in which cell-to-cell transmission of misfolded proteins in the CNS is emerging as a major pathological mechanism. In Parkinson's disease pathology, alpha-synuclein (Syn) aggregates have been implicated as potential candidates for inflammasome activation. The chronic neuroinflammatory response that accompanies dopaminergic degeneration has been shown to exacerbate pathology and drive disease progression. However, the role of ASC in propagating Syn pathology and spread in the CNS has not been investigated to date. Herein, we demonstrate that ASC is upregulated in PD patient brains and multiple pre-clinical models of PD. In primary microglia, we found that inflammasome activation by Syn aggregates causes ASC oligomerisation and extracellular secretion with delayed kinetics compared to canonical inflammasome activators. Crucially, we found that microglial activation with Syn aggregates caused the extracellular release of ASC specks, without causing detectable pyroptosis for up to 48 h after treatment. Collectively, our results suggest that extracellular ASC could be involved in the propagation of Syn pathology in PD, making it a potential therapeutic target to mitigate disease progression

Abstract: Mitochondrial dysfunction has been associated with many neurological diseases including Parkinson's disease (PD). Impaired mitochondrial biogenesis also contributes to mitochondrial dysfunction in PD. Therefore, identifying the cell signaling mechanisms regulating mitochondrial biogenesis is critically important to the development of new neuroprotective strategies for alleviating mitochondrial dysfunction in PD. We have recently shown that protein kinase D1 (PKD1) activation plays a neuroprotective role and that positive modulation of PKD1 can offer neuroprotection against neuronal cell death in PD models. In this study, we sought to identify downstream effectors of the PKD1 pro-survival signaling and found that PKD1 activation positively regulates PGC-1α transcriptional activity. Overexpression of constitutively active PKD1 increased PGC-1α promoter activity and mRNA and protein expression in MN9D dopaminergic neuronal cells; however, PGC-1β and PRC mRNA expression were not affected by PKD1 overexpression. Moreover, treatment of MN9D cells with a rationally designed PKD1 activator peptide enhanced the mRNA and protein expression of PGC-1α and also the mRNA expression of mitochondrial biogenesis marker genes, including TFAM, CYTB, and Cox III. Interestingly, treatment of cells with a PKD1 inhibitor, kbNB-14270, strongly suppressed the mRNA expression of PGC-1α and TFAM. Additionally, PKD1

overexpression stimulated other downstream neuroprotective targets in dopaminergic neuronal cells. More importantly, pretreatment with the PKD1 activator peptide significantly protected against 6-OHDA-induced neurotoxicity in a human mesencephalic neuronal cell model. Collectively, our results suggest that positive modulation of PKD1 induces PGC-1α transcription and may offer neuroprotection to dopaminergic neurons (NIH grants NS074443, NS78247 and ES10586).

Title: LRRK2-G2019S alters developing synapse structure and function in dorsal striatum

Authors: *B. A. MATIKAINEN-ANKNEY[1], N. KEZUNOVIC[2], G. W. HUNTLEY[2], D. L. BENSON[2];
[2]Neurosci., [1]Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Leucine-rich repeat kinase II (LRRK2) is a large, multifunctional protein highly expressed by striatal spiny projection neurons (SPNs) during early postnatal development when corticostriatal circuits are established. Mutations in LRRK2 cause Parkinson's disease that is indistinguishable from idiopathic PD, the most common of which, G2019S, confers a gain-of-kinase activity to the protein. Thus we hypothesized that G2019S mutation would alter development of corticostriatal circuitry in a kinase-dependent manner. We examined SPN structure and function in acute slices of dorsal striatum from P21 wildtype (WT) mice or those expressing knock-in mutations of G2019S or D2017A (LRRK2 kinase-dead controls). In whole-

cell recordings from WT or mutant SPNs, we found that G2019S mice exhibited a four-fold increase in frequency of action-potential dependent sEPSCs in comparison with WT or kinase-dead mutants. There were no differences in sEPSCs between WT and D2017A MSNs, indicating a gain-of-abnormal function by the G2019S mutation. Such abnormally heightened activity in G2019S mice was evident in both direct- and indirect-pathway SPNs. Moreover, such aberrant activity was normalized by isolating striatum from neocortex or by inhibiting LRRK2 kinase activity with a small-molecule pharmacological inhibitor. These data suggest that aberrant activity is driven by corticostriatal input and is kinase-dependent. We found no differences across genotypes in density of synaptic molecular markers or SPN dendritic spines. However, G2019S SPNs exhibited significantly larger spine head diameters that were matched by a shift towards larger excitatory post-synaptic response amplitudes. Together, these data demonstrate that PD-associated LRRK2-G2019S mutation significantly alters normal structural and functional development of corticostriatal circuits. Such early alterations may predispose striatal circuits to PD-associated pathophysiology later in life.

Abstract: 8-oxodG(oxidized guanine) is a non-bulky DNA lesion that can lead to misincorporation of adenine instead of cytosine in mRNA during transcription (transcriptional mutagenesis, TM). Sporadic PD is classically characterized by aggregation of alpha-synuclein (α-SYN), which forms intraneuronal inclusions. Structural studies of α-SYN have shown the sensitivity of the molecule towards amino-acid changes which makes it more aggregation prone.

We hypothesized using *SNCA* (alpha-synuclein) gene as a model, that 8-oxodG-mediated TM event can generate novel variants which contribute to the aggregation of the wild-type protein as seen in Lewy bodies. We predicted the generation of 43 possible mutants, but focused on a few which had the highest potential towards aggregation (structural analysis by algorithm TANGO). We confirmed the presence of two of the predicted mutations (*Serine42Tyrosine* (S42Y) and *Alanine53Glutamate* (A53E)) in *SNCA* mRNA from the substantia nigra of human *post-mortem* PD brain using RNaseH2 PCR. Sequencing genomic DNA of the same PD sample and same region of α-SYN revealed no mutations at the DNA level. By using cell-based biochemical assays and recombinant protein assays we have seen that S42Y-α-SYN can accelerate the aggregation process involving the wild-type protein even when present in significantly lower amount. Importantly, we developed antibody to specifically detect the S42Y-α-SYN. Immunohistochemical analysis of serial *post-mortem* PD brain sections with H&E staining, anti-ubiquitin staining and anti-S42Y staining, showed Lewy bodies that stained positively with S42Y-α-SYN. To our knowledge, this is the first report about TM related mutations of α-SYN in Parkinson's disease and their role in the pathogenesis.

Title: Alteration of cholinergic neuron activity in the l-dopa induced dyskinesia mouse model

Authors: ***S. CHOI**, T. C. MA, T. CHEUNG, Y. DING, D. SULZER, E. MOSHAROV, U. J. KANG;
Dept. of Neurol., Columbia Univ., New York, NY

Abstract: Striatal cholinergic interneurons (ChI) are implicated in motor control, associative plasticity, and reward-dependent learning. Previous studies have shown that ChIs become hyperactive in the L-DOPA induced dyskinesia (LID) mouse model (Ding 2011). Here we investigated alteration of electrophysiology and neuronal morphology of ChIs in the unilateral 6-

OHDA LID model. As shown previously (Ding 2011), spontaneous firing of ChIs decreased after 6-OHDA dopamine lesion (DA-lesion), but became hyperactive after LID induction by chronic L-DOPA treatment. However, there were no differences in basal intrinsic membrane properties such as resting membrane potential, voltage-current relationship, and rheobase between the sham, DA-lesion, and LID groups. Since HCN channels are among the factors that determine ChI spontaneous activity, we measured the ZD7288-senstive component of steady-state current in voltage clamp mode with step voltage injections (-100 to -20 mV at +10 mV increments). We found that HCN current in ChI was larger in the LID group compared to DA-lesion, which is consistent with increased ChI spontaneous firing in the LID group. To determine whether changes in input to ChI were altered by DA-lesion of LID induction, we measured spontaneous IPSCs (sIPSCs) and observed increased sIPSCs frequency in the lesion and LID groups, though the sIPSC amplitudes were unchanged. We hypothesized that changes in ChI input may indicate alterations in cell morphology. To assess this, we filled ChI with biocytin during electrophysiological recording and processed the slices for visualization with fluorescence secondary antibodies. 2D Scholl analysis showed no changes in the number of primary dendrites, but increased branching of dendrites in both the DA-lesion and LID groups, especially from 50-150 μm from the neuron soma. This was paralleled by increased total neurite length and branching for only the LID group. Analysis of the gene transcription changes relevant to these electrophysiological and morphological observations by ChAT-Ribotag RNAseq are ongoing. Together these observations indicate that the changes in ChI physiology are governed by both intrinsic (HCN channels and morphology) and extrinsic (GABAergic transmission) factors.

Title: Munc18-1 controls a-synuclein self-replicating aggregation in early infantile epileptic encephalopathy

Authors: *Y. CHAI[1,2], E. SIERECKI[3,4], V. M. TOMATIS[2], R. S. GORMAL[2], N. ARIOTTI[3], N. GILES[3,4], D. XIA[2], R. PARTON[3], B. M. COLLINS[3], Y. GAMBIN[3,4], F. A. MEUNIER[2,1]; [1]The Univ. of Queensland, St Lucia, Australia; [2]Clem Jones Ctr. for Ageing Dementia Research, Queensland Brain Institute,The Univ. of Queensland, Brisbane, Australia; [3]Inst. for Mol. Bioscience, The Univ. of Queensland, Brisbane, Australia; [4]Single Molecule Sci. Centre, EMBL Australia, The Univ. of New South Wales, Sydney, Australia

Abstract: Munc18-1 is an essential element of the exocytic machinery controlling neurotransmitter release. Munc18-1 knockout mice show no developmental phenotype but die at birth from paralysis. Surprisingly, Munc18-1 heterozygous mutations are responsible for developmental defects, neurodegenerative and epileptic phenotypes including infantile epileptic encephalopathy (EIEE). suggestive of a gain of pathological function. Here, we used single molecule analysis, gene-edited cells and neurons to demonstrate that Munc18-1 EIEE-causing mutants promote the formation of large polymers that co-aggregate wild-type Munc18-1 *in vitro* and in neurosecretory cells. Surprisingly, Munc18-1 EIEE mutants also form Lewy body-like structures that contain α-synuclein (α-Syn). We reveal that not only Munc18-1 binds α-Syn but its mutants co-aggregate α-Syn. Likewise, removal of endogenous Munc18-1 increases the aggregative propensity of α-Syn^{WT} and that of Parkinson's disease-causing α-Syn^{A30P} mutant, an effect rescued by Munc18^{WT} expression indicative of chaperone activity. Co-expression of α-Syn^{A30P} mutant with Munc18-1 reduced the size of α-Syn^{A30P} aggregates. Munc18-1 mutations may therefore lead to a pathogenic gain of function through both the corruption of native Munc18-1 and a perturbed chaperone activity for α-Syn. Our results uncovers an unexpected function of Munc18-1 in controlling α-Syn propensity to aggregate.

Title: Characterization of alpha-synuclein-enriched periglomerular cells in the olfactory bulb

Authors: *K. TAGUCHI[1], Y. WATANABE[2], A. TSUJIMURA[2], M. TANAKA[1];
[1]Dept. of Anat. and Neurobiology, Grad. Sch. of Med. Sci., [2]Dept. of Basic Geriatrics, Kyoto Prefectural Univ. of Med., Kyoto, Japan

Abstract: alpha-Synuclein, the major constituent of Lewy bodies (LBs) and Lewy neurites (LNs), is normally expressed in presynapses and is involved in synaptic function. Abnormal intracellular aggregation of alpha-synuclein is observed as LBs and LNs in neurodegenerative disorders, such as Parkinson's disease or dementia with Lewy bodies. Accumulated evidence suggests that abundant expression of alpha-synuclein is one of the risk factors for pathological aggregation. Recently, we reported brain region-dependent differential expression of alpha-synuclein. Synaptic expression of alpha-synuclein is mostly accompanied by the expression of vesicular glutamate transporter-1, an excitatory presynaptic marker. In contrast, expression of alpha-synuclein in GABAergic inhibitory synapses is different among brain regions. Furthermore, some neurons show high expression of alpha-synuclein. Intense alpha-synuclein immunoreactivity within the cell bodies is observed in those cells. These results suggest that expression of alpha-synuclein is regulated in cell-type dependent manner. In the present study, we focus on the periglomerular cells (PGCs) with high expression of alpha-synuclein in the mouse olfactory bulb. These PGCs express NeuroD1, one of key transcriptional factors which are involved in neuronal differentiation in the olfactory neurogenesis. However, these cells are not stained by monoclonal antibody against NeuN, a mature neuronal marker. Interestingly, most of the PGCs with high expression of alpha-synuclein are Sox2-positive. Taken together, our results suggest that these PGCs sustain immature state and alpha-synuclein plays an important role in the regulation of the neuronal differentiation. Further studies of these PGCs will provide new insights for understanding physiological function of alpha-synuclein.

Abstract: Parkinson's disease is characterized by Lewy bodies filled with aggregated proteins such as α-synuclein. Lewy pathology emerges quite early in olfactory structures such as the olfactory bulb and anterior olfactory nucleus (OB/AON), which may contribute to smell deficits years before the onset of motor symptoms. We injected preformed α-synuclein fibrils into the OB/AON and observed dense inclusions containing pathologically phosphorylated α-synuclein (pSer129) 3 months later in deeper rhinencephalic structures (piriform and entorhinal cortices, amygdala, hippocampal CA1, and subiculum), all of which share anatomical connections with the OB/AON. Injections of the retrograde tracer FluoroGold into the OB/AON confirmed the existence of first-order afferents at these sites. In addition, some sites harbored FluoroGold$^+$ neurons but contained no inclusions, suggesting that some neuronal subtypes may be resistant to α-synucleinopathy. Animals sacrificed 1.5h following fibril infusions exhibited dense staining for total α-synuclein within the OB/AON relative to PBS controls, but did not yet harbor pSer129$^+$ inclusions. Multiple areas close to the injection site that do not send projections to the OB/AON remained free of inclusions, suggesting a lack of nonspecific uptake of fibrils from interstitial diffusion. Sonication of the fibrils for 1h in an inexpensive waterbath dramatically improved α-synucleinopathy transmission relative to 1 min-long probe sonication. Electron microscopy revealed that increasing sonication duration reduced fibril size. Young and aged mice exhibited largely similar patterns of α-synucleinopathy and fibril-infused mice exhibited subtle changes in olfactory function according to two independent smell tests. The amyloid stain Thioflavin labeled cellular structures at the infusion site and some, but not all inclusions contained ubiquitin, a hallmark of Lewy pathology. Three-dimensional confocal analyses revealed that pSer129$^+$ inclusions were wrapped around the nuclei of cells labeled with the specific neuronal marker NeuN. Preadsorption control experiments confirmed a loss of staining following incubation of the pSer129 antibodies with the pSer129 blocking peptide. Our results support the views that 1) α-synucleinopathy is transmitted through some, but not all neuroanatomical connections, 2) pathology is largely confined to first-order projection sites at 3 months, 3) transmission is perhaps most parsimoniously explained by retrograde transport, and 4) transmission in aged animals is largely similar to that in young controls 3 months post-infusion.

Title: Alterations of oscillatory activity in the striatal-cortical circuit following repeated sub-anesthetic ketamine administration in 6-OHDA-lesioned rats.

Authors: *T. YE[1,2], M. J. BARTLETT[1,3,4], M. B. SCHMIT[1,5], S. J. SHERMAN[1,3], T. FALK[1,3], S. L. COWEN[1,2,6];
[2]Psychology, [3]Neurol., [4]Pharmacol., [5]Neurosci., [6]Evelyn F. McKnight Brain Inst., [1]Univ. of Arizona, Tucson, AZ

Abstract: Sub-anesthetic administration of ketamine has been used to successfully treat a variety of disorders such as treatment-resistant depression, post-traumatic stress disorder, and chronic pain. Recent clinical case studies from our group indicate that low-dose ketamine infusion (0.15 – 0.3 mg/kg/hr for up to 72 hrs) acutely reduces motor impairments in Parkinson's disease (PD) patients and ameliorates L-DOPA-induced dyskinesias (LID) for up to one month. Abnormal patterns of hypersynchronous oscillatory activity have been reported in all of the disorders that have been treated successfully with ketamine, suggesting that ketamine may act to disrupt network-level oscillatory activity associated with the pathology. With regard to PD, hyper-synchronous beta-band oscillations (13 – 30 Hz) in the cortex and striatum may contribute to increased immobility, and beta is reduced with deep-brain stimulation (DBS) and levodopa treatment. Furthermore, gamma oscillations (30 – 70 Hz) in the motor cortex (M1) are associated with successful motor execution in healthy subjects. Administration of ketamine has been shown to increase high-frequency oscillations (HFOs) in rats and gamma-band activity in humans. As a result, it is proposed that sub-anesthetic ketamine-induced HFOs suppresses low-frequency activity associated with PD. We investigated this hypothesis by implanting electrode arrays in the striatum, M1, and hippocampus of healthy and unilateral 6-hydroxydopamine (6-OHDA) lesioned rats, a model of PD. To reflect clinical infusion protocols, we used repeated administration (*i.p.*) of sub-anesthetic ketamine (20 mg/kg every 2 hrs). Neural activity was continuously recorded from awake and freely behaving rats for an 11-hr period. Preliminary findings suggest that, like healthy controls (n=5), a single ketamine injection triggers HFO and gamma oscillations in the dorsolateral striatum (DLS) and M1. We observed that this ketamine regimen increased gamma-band activity in M1 (p=0.02, n=15 sessions in 3 rats) of 6-OHDA rats. This observation is consistent with the idea that ketamine enhances motor function by altering the oscillatory patterns of interneuron networks in M1. Furthermore, we observed that ketamine decoupled beta and gamma oscillations in M1 and DLS of both groups. Control animals had increased HFO-theta coupling in both regions, but 6-OHDA rats showed a relative

decrease in coupling in the DLS. Given the role of abnormal oscillatory patterns in PD pathology, this decoupling may contribute to the capacity of ketamine to mitigate motor impairments. Ongoing experiments aim to integrate more rats along with the examination of effects in treating LID.

Title: Initiation and propagation of action potentials in the hyperdirect pathway during subthalamic deep brain stimulation

Authors: *R. W. ANDERSON, B. HOWELL, K. GUNALAN, C. C. MCINTYRE;
Sch. of Medicine, Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: Deep brain stimulation (DBS) of the subthalamic region is an established clinical therapy for the treatment of late stage Parkinson's disease (PD). Direct modulation of the hyperdirect pathway, which consists of corticofugal axons originating from layer V pyramidal neurons that send a collateral to the subthalamic nucleus (STN), has emerged as an important component of the therapeutic mechanisms of action of DBS. However, given their complex axonal arbors, little is known about how action potentials (APs) are directly generated in hyperdirect neurons by subthalamic DBS electrodes, or how those DBS-induced APs propagate to distant brain regions. In addition, DBS stimuli are delivered at ~130 Hz and any DBS-induced APs must propagate antidromically through multiple branch points, suggesting that the fidelity of AP initiation and propagation may be limited. To address these questions we developed an anatomically and electrically realistic multi-compartment cable model of layer V pyramidal neuron with a detailed corticofugal axonal arbor that sent a collateral to the STN. We then coupled that hyperdirect neuron model to a finite element volume conductor model of the subthalamic DBS electric field. Our results show that DBS-induced APs are generated in hyperdirect neurons at or near their axon terminals located in the STN, and these APs propagate

faithfully throughout the entire axonal arbor of the hyperdirect neuron. We found that the distant terminals of the hyperdirect axonal arbor in cortex could reliably maintain a one-to-one ratio of firing to stimulus trains at rates in excess of 200 Hz. Interestingly, somatic AP invasion in cortex became intermittent under therapeutic DBS frequencies due to the impedance mismatch of the axon connection to the somatodendritic arbor and the slower membrane dynamics of the soma. However, we propose that somatic firing of hyperdirect neurons is actually irrelevant under DBS conditions, as the high frequency DBS-induced APs collision block and override any orthodromic signaling in these neurons. Therefore, the key finding of this study is that DBS-induced APs can reach all of the axon terminals of hyperdirect neurons with nearly 100% fidelity, irrespective of the activity in the soma. In turn, these DBS modulated cortical neurons likely have a strong impact on cortical microcircuit activity via tonic high frequency release of glutamate (and other neurotransmitters) at their axon terminals which are located throughout the cortical layers.

Abstract: Despite the biochemical characteristics of Parkinson’s disease (PD) have been well described, physiological properties of PD have been argued. Especially, brain regions related to the severity of the Parkinson’s disease have not been established. To reveal those regions, we

have recorded the history of the neuronal activities in entire brain regions, and have analyzed the correlation between the neuronal activities and the tyrosine hydroxylase (TH)-immunoreactivity, which is one of the biochemical markers of PD severity, in MPTP mice model of PD. For recording the history of the neuronal activities in entire brain regions, we used one MRI technique, quantitative activation-induced manganese-enhanced MRI, which is based on the use of Mn^{2+} as a surrogate marker of Ca^{2+} influx (Kikuta et al., 2015). This method has the potential to record the history of the neuronal activities, quantitatively, because of following reasons. Mn^{2+} inflow to the active neuron through voltage-dependent Ca^{2+} channels, and Mn^{2+} shortens the longitudinal relaxation time of H^+ (T_1), which was quantified by MRI. Thus, qAIM-MRI can visualize the neuronal activities in entire brain volume.
Within the basal ganglia, the region represented elevated activity was observed in caudate-putamen (CPu) of PD model mice compared with healthy controls. Several cortical and thalamic regions also activated in PD model mice. In the PD mice, the activities in dorsolateral CPu, sensorimotor area of cortex (Ctx), and parafascicular nucleus of thalamus (PF) were significantly correlated to the TH-immunoreactivity. These results suggested that the dorsolateral part of CPu involves in PD severity, and this hyperactivity in CPu may arise from increasing activity in Ctx and PF, whose neurons innervate CPu.
Our findings pave the way for significant progress in research on PD pathophysiology, and suggest that qAIM-MRI can be utilized not only for diagnosing PD, but also potentially for the study and diagnosis of various other neurological conditions.

Title: Systems-level neurophysiological state characteristics for drug evaluation in an animal model of levodopa-induced dyskinesia

Authors: *P. HALJE, M. TAMTE, U. RICHTER, I. BRYS, P. PETERSSON;
Lund Univ., Lund, Sweden

Abstract: Disorders affecting the central nervous system have proven hard to treat, and few novel therapies reach the clinics. A general problem is our poor understanding of how changes on the ligand-receptor level translate to changes on the systems level.
We here show a general framework for how comprehensive systems-level descriptions of electrophysiological brain states can be obtained and interpreted in relation to disease states and pharmacological interventions. Through large-scale recordings in distributed neural networks in multiple brain structures we characterize neurophysiological states based on local field potentials associated with parkinsonism and levodopa-induced dyskinesia in the 6-OHDA rodent model of Parkinson's disease (PD), together with pharmacological interventions aimed at reducing dyskinetic symptoms.
We found that all disease and treatment states (including PD, dyskinesia, 8-OH-DPAT, amantadine, diazepam, levetiracetam, Way-100635 and control) were clearly separable clusters (>99% classification performance) in the state space defined by the first 30 principal components of all measured features (power spectral densities from motor cortex, premotor cortex, dorsomedial striatum, dorsolateral striatum, substantia nigra pars reticulata, globus pallidus, subthalamic nucleus and thalamus). We also found that the geometrical distance between points in the state space was reflected in differences in motor symptoms. For example, the effectiveness of an antidyskinetic treatment (reduction of abnormal involuntary movement scores) could be related to the distance from the dyskinetic cluster. Similarly, antidyskinetic treatments with strong akinetic side effects were found close to the Parkinsonian cluster.
Our results add significant information to behavioral evaluations and elucidate the underlying effects of treatments in greater detail. The results open up for studies of neurophysiological mechanisms in neurological and psychiatric conditions that until now have been hard to investigate in animal models of disease.

Title: A computational model for the progression of Parkinson’s disease in the basal ganglia

Authors: ***M. CAIOLA**, M. HOLMES;
Rensselaer Polytechnic Inst., Troy, NY

Abstract: The primary motor symptoms of Parkinson's disease (PD) are thought to be caused when dopamine producing neurons in the substantia nigra pars reticulata die, leading to changes in connection strengths and, ultimately, firing rates in the basal ganglia. This leads to net inhibition of the thalamus, restricting and slowing movement - symptoms that are characteristic with PD. As these motor symptoms advance, oscillations in the basal ganglia become pronounced at specific frequencies (such as beta). Since few human and primate studies characterize the basal ganglia changes during the transition to PD, computational models can help provide insight into how these oscillations emerge. To balance accuracy and simplicity, we use a population-based firing rate model developed by Dayan and Abbot. This model takes the average firing rate from a population of neurons and measures the effect on a connected population. Connections are either excitatory or inhibitory in nature and are assigned weights that measures the strength of the connection - the higher the value, the stronger the connection strength. Our model focuses on the cortico-basal ganglia-thalamo-cortical loop: the cortex, striatum, globus pallidus external (GPe) and internal (GPi), subthalamic nucleus (STN), substantia nigra pars compacta, and the thalamus. The GPe, GPi, and STN have been known to be the pacemakers of the basal ganglia and a possible origin of the antikinetic beta oscillations that plague PD. Allowing the PD dopaminergic change to affect just the connection weights between these populations, we are able to show a change in firing rate behavior that has been previously documented in animal models. More interestingly, we are able to derive physically realistic conditions necessary for the emergence of oscillatory behavior. The conditions are found to agree with recent experiments as well as the current understanding that the Indirect Pathway becomes more active, leading to high GPi activity and thalamic inhibition. In addition, we show that only a specific range of connection strengths lead to oscillations, while others lead to healthy steady firing rates. Further analyzing the disease progression, we parametrize the change in connection strength to effectively view the progression of PD. This allows us to visualize the dynamics of the disease and determine when and how the firing rate behavior changes. Surprisingly, we found that order of the weight changes plays a key role and it is not as linear as the previous models have assumed. By identifying these main changes in connection strength, we hope to provide new insight in the emergence of Parkinsonian symptoms and identify new targets for treatment.

Title: Development of an *In vivo* model of basal ganglia pathway isolation for study of information transmission

Authors: *K. M. LAMBERT[1], J. A. WHITE[2], A. D. DORVAL[1];
[1]Univ. of Utah, Salt Lake City, UT; [2]Boston Univ., Boston, MA

Abstract: The basal ganglia are subcortical nuclei implicated in Parkinson's disease, among other neurological disorders. Deep brain stimulation (DBS) of some basal ganglia regions — e.g., the subthalamic nucleus (STN) — can alleviate parkinsonian motor symptoms. However, despite its efficacy, the therapeutic mechanisms of STN-DBS remain unclear due in large part to an incomplete understanding of how neuronal processing within basal ganglia contributes to motor behavior. To improve our models of basal ganglia processing, we isolated the direct and indirect basal ganglia pathways, using selective pharmacological blockers against the opposing pathway, while applying STN-DBS at various frequencies (30, 200 Hz) and amplitudes (60-130μA). In otherwise naïve rats, we bilaterally injected the type-1 dopamine receptor (D1R) antagonist SCH23390 to acutely lesion the direct pathway, and/or the type-2 dopamine receptor (D2R) agonist quinpirole to acutely lesion the indirect pathway. We verified the behavioral success of each lesion — by quantifying changes in distance traversed and time spent near the chamber margins — in rodents in an open field task. The D1R antagonist SCH23390 decreased distance traversed, and increased margin time. Inversely, the D2R agonist quinpirole increased distance traversed and decreased margin time. A cocktail of both drugs reduced distance traversed, similar to the SCH23390 challenge, but also reduced margin time, similar to the quinpirole challenge. The selective nature of the drugs and the temporary nature of the behavioral results allow us to attempt multiple challenges in the same rat model interspersed with saline injection control challenges on sequential days. The acute lesion of a specific pathway should leave information through the opposite pathway to be studied in isolation. Recording from previously implanted microelectrode arrays during these behavioral challenges, we isolated single unit signals from two basal nuclei. In future analyses we will quantify changes in the neuronal activity and information content of these signals as a function of acute lesion condition and STN-DBS parameters.

Title: Neural basis for bradykinesia/akinesia in Parkinson's disease: causality of beta frequency oscillations

Authors: *C. BEHREND[1,2], D. T. BROCKER[1], W. M. GRILL[1,3];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Duke Univ. Sch. of Med., Durham, NC; [3]Neurobio. & Surgery, Duke Univ. Med. Ctr., Durham, NC

Abstract: Substantial correlative evidence links the synchronized, oscillatory neural firing patterns that emerge in Parkinson's disease (PD) in the frequency range of 13-30Hz (termed "beta band") with the development of bradykinesia and akinesia. Yet, a causal link between these beta frequency oscillations (BFO) and symptoms of bradykinesia has not been demonstrated. We tested in healthy rats the hypothesis that the synchronized, BFO that emerge in PD are causal of symptoms of bradykinesia/akinesia. We designed novel stimulation patterns to mimic the temporal characteristics of the beta oscillatory bursting pattern seen in single units in PD rats and patients. We applied these beta frequency patterned stimulus trains (BPTs) along with continuous frequency (CF) controls over a range of amplitudes via stimulating electrodes implanted unilaterally into the subthalamic nucleus (STN) of healthy rats and assessed the effects on unit activity in the substantia nigra reticulata (SNr) and performance in motor tasks. We recorded 36 SNr units from four rats and quantified the degree of unit entrainment as a function of pattern and amplitude by calculation of the excitatory effective pulse fraction (eEPF) (Agnesi et al 2015). The eEPF is a ratio (0-1) that relates the number of unit firings evoked by a stimulus pulse at a consistent latency within the inter-stimulus interval (ISI) to the number of unit firings evoked by a 'virtual' stimulus pulse at the same latency during a baseline period (Agnesi et al 2015). Using RM-ANOVA we found effects of pattern ($F(6,211.5)=4.2$, $p=0.0005$) and amplitude ($F(1,38.3)=35.2$, $p<0.0001$) and a significant interaction of pattern and amplitude ($F(6,206.2)=2.4$, $p=0.029$) on whether unit entrainment occurred within the ISI. For BPTs at the highest amplitudes, the peak of entrainment occurred in a range of 3-7.2ms following a stimulus pulse. For CF controls at the highest amplitudes, two peaks of entrainment occurred in ranges of 2.6-4.4ms and 22.6-25.4ms following a stimulus pulse. The average eEPFs of units entrained within these phases were 0.060 ± 0.018, 0.046 ± 0.007, and 0.107 ± 0.042, respectively (mean ± SEM). Finally, we quantified the impact of stimulation on motor performance in the bar test, the forelimb-use asymmetry (FUA) test, and the adjusting steps (AS) test, which assess forelimb akinesia. In the bar test, no significant difference in length of time on bar was found among BPTs, CF controls, or no stimulation controls. In the FUA and AS tests, no significant difference was found between select BPTs and no stimulation controls. Our results suggest that BFO may not be necessary or sufficient for the generation of bradykinesia/akinesia in PD.

Abstract: This study aim to identify spontaneous arrhythmias, as well as evaluate heart rate in an experimental model of Parkinson disease, 6-hidroxidopamina (6-OHDA) model. Wistar rats (n=7) weighing 250-300g received two ECG electrodes, one implanted below the xiphisternum and the other between the junction of the two sternocleidomastoideus muscles. After that five (n=5) animals were injected with 6-OHDA (experimental animals) and two (n=2) of them (shams animals) received saline solution in the striatum. Animals' ECG started to be recorded immediately after surgery recovery. Recording was carried out for 4 days for 60 minutes 3 times a day. After the third day of ECG recording, experimental animals showed a significant raise in the heart rate (360 to 540 bpm, approximately) while shams animals showed a similar heart rate recorded before surgery. The induction and establishment of 6-OHDA model is able to induce ventricular tachyarrhythmias. The present study suggests a new avenue to better understand the cardiovascular dysfunctions observed in chronic stages of Parkinson disease.

Title: Experimental reduction of nigrostriatal dopamine similar to aging in substantia nigra, but not striatum, reduces open-field locomotor activity

Authors: *M. F. SALVATORE[1], T. MCINNIS[1], B. S. PRUETT[2], C. OWENS[3];
[1]Dept. of Pharmacol. & Neurosci., Univ. of North Texas Hlth. Sci. Ctr., Ft Worth, TX; [2]Brown Univ., Providence, RI; [3]LSU Hlth. Sci. Ctr., Shreveport, LA

Abstract: Background: The risk of locomotor impairment, including bradykinesia, increases substantially during aging and arises from Parkinson's disease (PD) or aging-related Parkinsonism. It has been long believed that the neurobiological basis for the manifestation of bradykinesia in PD is >70% loss of dopamine (DA) in the striatum. However, this level of striatal DA loss has never been reported in aging studies. Coincident with bradykinesia onset in PD or in aging studies, 40-50% DA loss in the substantia nigra (SN) has been reported, but the possibility that this loss could contribute to bradykinesia has not been investigated. Here, we have experimentally created aging-related loss of DA in the striatum or the SN in a compartment-specific manner in young male (6 months) rats to determine if aging-related DA loss in the striatum or SN may reduce locomotor activity. **Hypothesis:** DA reduction in the SN alone is sufficient to reduce locomotor activity. **Approach:** To ensure that locomotor function would be devoid of aging-related confounds to locomotor performance, 6 month old Brown-Norway Fischer 344 F_1 rats were used. To selectively reduce DA tissue content in either striatum or SN in freely moving rats during the awake cycle, rats were first implanted with double guide cannula to target striatum (+1.0 AP, 2.5 ML, 5.0 DV) or the SN (-5.7 AP, 2.5 ML, 7.5 DV). Following recovery, rats were placed into an open-field for three hour sessions immediately following infusion of sterile saline or the tyrosine hydroxylase (TH) inhibitor, α-methyl-*p*-tyrosine (AMPT) in either striatum or SN. Each treatment was repeated 5 times to acquire locomotor activity and repeated measures 2 way ANOVA was used to determine each individual rats movement under AMPT infusion against movement under vehicle infusion . **Results:** Infusion of a quantity of 1.4 nmole AMPT into the SN, but not striatum, produced a significant decrease in open-field locomotor activity out to 2 hours past infusion. **Conclusions:** The inhibition of TH activity and associated reduction in DA tissue content (~40%) in the SN, but not striatum, reduces open-field locomotor activity in young rats. These results suggest that nigral DA neurotransmission contributes as a neurobiological mechanism of locomotor initiation and

activity. Aging-related reductions in nigral DA and TH function may therefore underlie aging-related bradykinesia.

Title: Functional connectivity in the cortico-basal ganglia-thalamic circuit in rodent and primate models of Parkinson's disease

Authors: *P. PETERSSON, U. RICHTER, M. TAMTE, I. BRYS;
Lund Univ., Lund, Sweden

Abstract: The cerebral cortex, the basal ganglia and thalamus together constitute a closely connected neuronal network that is thought to have a key role in the control of behavior. In the classic model, changes in average firing rate in one part of the network lead to changes in downstream firing rates that are predicted by the strength of anatomical connections. It is likely, however, that periods of synchronized neuronal activity result in stronger interaction between cell groups and, hence, more pronounced alterations in downstream neuronal activity than uncorrelated rate changes of the same magnitude. If this is true, functional connectivity should change dynamically under most natural conditions, since synchronization and oscillations in the activity of neuronal populations are known to be strongly state-dependent. Moreover, disturbed functional connectivity could in itself have a pathological role in disease states associated with

aberrant oscillatory activity.
We have here analyzed neuronal activity obtained from large-scale multi-structure recordings from the cortico-basal ganglia-thalamic circuit in both rats and marmoset monkeys. Measures of functional connectivity are compared between recordings obtained in animals that have been exposed to chronic 6-OHDA medial forebrain bundle lesions and recordings from normal control conditions. Furthermore, many rats developed levodopa-induced dyskinesia following chronic levodopa-treatment. This made it possible to study the functional connectivity specifically during dyskinesia.
In our local field potential recordings we could confirm the previously reported relative increase in power in the beta-band in the parkinsonian state and synchronized oscillations in the theta and high gamma band (~ 80 Hz) in dyskinesia. Notably however, the main oscillation frequency in the beta-band differed both between individuals and species (range: 10-35Hz). We also found a relative increase of the functional connectivity related to oscillations in these states, as reflected by an increase in coherence in these frequency bands. Interestingly, more detailed analyses indicate that these increases are more pronounced in certain parts of the circuit: While coherence in the beta and high gamma band, are more pronounced in cortico-striatal circuits, the increase in coherence in the theta band in the dyskinetic state is more specific to deeper nuclei.
These results indicate that the functional connectivity between structures in interconnected circuits is highly state-dependent and contingent on the main oscillation frequency being present in that state, and may also differ for different parts of the circuits.

Abstract: The analysis of blood-oxygen-level dependent (BOLD) signals obtained with functional magnetic resonance imaging (fMRI) allows inferring neuronal activity patterns for cognitive and motor processes. However, it is also possible to analyse BOLD signals at rest, a kind of analysis that has been termed resting-state fMRI (RS-fMRI). It examines the synchrony of the temporal BOLD signal between anatomically separated brain regions (networks) without the subject performing any particular task. This functional connectivity analysis differs from the traditional white matter structural connectivity analysis which is mainly done with Diffusion Tensor Images (DTI). Both techniques have been used to evaluate changes in patients with neurodegenerative disorders like Parkinson's disease, in which the nigro-striatal-cortical dopaminergic pathway is affected causing motor and cognitive impairments. The aim of this work was to evaluate the functional connectivity in the resting state networks, as well as the structural connectivity, in green monkeys (*Cercopitecus aethiops: n=3 per group*) in basal conditions and after MPTP administration. RS-fMRI and DTI images were acquired in a GE Discovery MR750 (General Electric, Milwaukee, WI) 3T whole-body MR scanner. The animals were anesthetized with Tiletamine/Zolazepam 125/125 mg at dose of 2 mg / kg body weight (im). The DTI sequences consisted of *Single Shot Echo Planar Imaging sequences*, acquiring 65 volumes of 26 axial slices (2 mm slice thickness and no separation), one for each of the 60 independent directions of diffusion with b= 2000 s/mm^2 and five corresponding to b=0 s/mm^2. The functional connectivity networks were created using two methodologies, first using independent Component Analysis (ICA) and second the seed-based methodology, placing anchor seeds in different regions of the striatum. White matter changes were evaluated with the FSL Tract-Based Spatial Statistics tool. We found 6 networks at rest in the healthy subjects: somatomotor, frontal, default mode, primary visual medial cerebellar and visual networks. After the administration of MPTP, we found a decrease in the activation of striatal networks (caudate and putamen) and a decrease in white matter tracts of the internal and external capsules, *corpus callosum* and cerebellum. The results show the presence of six resting-state networks in green monkeys that can be analogous to functional networks previously characterized in humans. Decrease of striatal functional connectivity and white matter tracts are congruent with the loss of cortico-striatal communication due to the death of dopaminergic neurons in the striatum.

Abstract: Introduction Diffusion Weighted Imaging(DWI) studies have shown correlation between microstructural White Matter(WM) changes in olfactory system, and decrement in smell ability in Parkinson’s Disease(PD). We examined the association of Olfactory Dysfunction(OD) in drug-naïve PD patients with structural brain connectivity, using connectometry. Methods We used the results of the odor identification test, and DWI data, for 87 PD patiens; divided into 4 groups: anosmic, severe microsmic, non-severe microsmic and normosmic patients.We mapped local connectoms and measured their associations with scores obtained from odor identification test, then we tracked the differences. Fig-1 Results Fig-2 Discussion Our results suggest that OD is correlated with changes in WM tracks, connecting Limbic System(LS) and the orbito-frontal areas containing the olfactory cortices, in drug naïve severe microsmics and anosmics. Our results reveal that the correlation between density changes of diffusion spins and odor identification scores is only present in severe microsmic and anosmic PD patients, but not in patients with mild OD. We may interpret that symptoms of OD precedes detectable DWI changes in WM. Calculating quantitative anisotropy for associated tracks may be more sensitive for detecting early WM changes.Integration of structural and functional findings e.g. fMRI may facilitate the comprehension of OD pathophysiology in PD.Conclusion We report a map of involved tracks from LS in OD among PD patients.

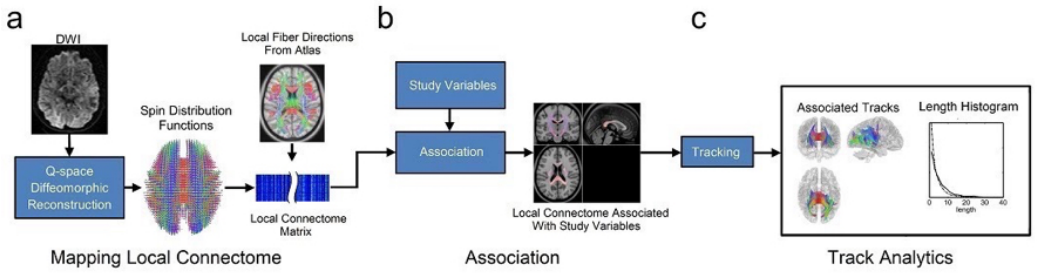

Fig-1

Adapted from: DSI-studio.labsolver.org

Method: We used odor identification test results-from the University of Pennsylvania Smell Identification Test (UPSIT), and Diffusion weighted imaging (DWI) data, acquired at a 3-T scanner, from Parkinson's Progression Markers Initiative(PPMI), for 87 Parkinson's Disease (PD) patiens. subsequently , we divided patients into 4 groups: 25 PD patients with anosmia, 23 with severe microsmia , 26 with non-severe microsmia and 9 normosmic patients. The DWI data were corrected for subject motion, eddy current distortions, and susceptible artifacts due to magnetic field inhomogeneity, using ExploreDTI toolbox. As you can see above, The diffusion data were reconstructed in the Montreal Neurological Institute (MNI) space using q-space diffeomorphic reconstruction to obtain the spin distribution functions. we matched the reconstructed diffusion data with an atlas that we created from our normosmic group. Diffusion MRI connectometry was conducted in 4 groups using a multiple regression model considering UPSIT and the local connectome matrices. A deterministic fiber tracking algorithm was conducted along the core pathway of fiber bundle to connect the selected local connectomes. To estimate the false discovery rate(FDR) , a total of 200 randomized permutations were applied to the group label to obtain the null distribution of the track length. FDR < 0.05 is deemed to be significant.

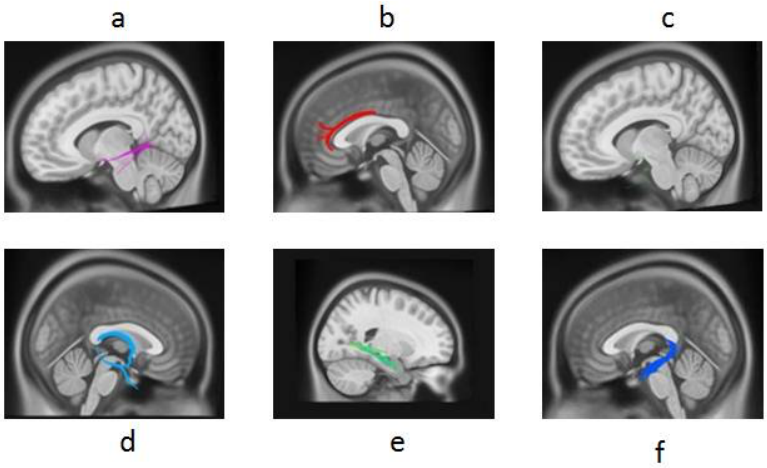

Fig.2. Results. The multiple regression analysis results illustrated positive association between UPSIT (University of Pennsylvania Smell Identification Test) score and left subgenual of cingulum(b), right inferior longitudinal fasciculus (ILF)(e), left inferior fronto-occipital fasciculus (IFOF)(a), fornix (d,f), and left uncinate fasciculus (UF)(c) in Parkinson's disease patients with anosmia [FDR=0.039]. In severe microsmia, UPSIT score positively correlate with left subgenual, right ILF, and left IFOF [FDR=0.048]. There was no association between structural brain connectivity and UPSIT score in patients without severe olfactory dysfunction. Above-mentioned tracks connect limbic system and the orbito-frontal areas.

Title: Physical activity and resting state fMRI in parkinson's disease patients with mild cognitive impairment

Authors: B. JARRAHI[1], *G. PETZINGER[2], L. HAWTHORNE[2], M. GOMEZ[2], A. PETKUS[3], B. FISHER[4], V. FILOTEO[5], S. MCEWEN[1];
[1]Dept. of Psychiatry and Behavioral Sciences,, UCLA, Los Angeles, CA; [2]Dept Neurol, [3]Dept. of Psychology, [4]Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA; [5]department of psychiatry, UCSD, San Diego, CA

Abstract: Physical Activity has been shown to promote brain connectivity within the aging brain, leading to improved cognitive-motor performance. In Parkinson's disease (PD), resting-state functional magnetic resonance imaging (rs-fMRI) has revealed abnormal functional connectivity in several intrinsic networks. It is unclear, however, how physical activity affects the spatial and temporal features of theses networks in PD patients with mild cognitive impairment (MCI). We applied multivariate analysis of covariance (MANCOVA) based on independent component analysis (ICA) of rs-fMRI to examine the influence of physical activity and dementia on three group ICA outcome measures: (a) the spatial map intensity associated with the intra-network connectivity; (b) the power spectra of network time course related to level of coherent activity within networks; and (c) resting-state functional network connectivity (FNC). Imaging data were acquired on eight PD individuals with MCI using a 3T Siemens Trio MRI scanner. MANCOVA was performed using the following covariates: (a) age, (b) composite score from Physical Performance Test (PPT), and (c) total score from the Mattis Dementia Rating Scale-2 (MDRS-2). Neural networks identified included cognitive/attention, cerebellar, motor, and default-mode (DMN) networks. Univariate tests yielded significant effects of PPT composite score on the spatial maps of IC 18 (medial prefrontal cortex), IC 6 (cerebellum), IC 7 (motor network), and IC 38 (DMN). Significant effects of DRS-2 score also found on the spatial maps of IC 18 (medial prefrontal cortex), IC 33 (dorsolateral prefrontal network) and IC 7 (motor network). Univariate test revealed significant effects of PPT composite score on the power spectra of IC 38 (DMN) (and MDRS-2 score on the power spectra of IC 22 (ventral attention network mainly in the right hemisphere). Our results provide preliminary evidence that physical activity in PD-MCI patients modulates the properties of neural networks, in particular the cognitive/attention, motor, and default-mode networks. Investigations of the effect of exercise in PD patients with MCI can provide a useful tool for understanding the role of exercise in PD for improving both motor and cognitive function.

Title: Does impaired reaction time cause rest tremor in Parkinson's Disease?

Authors: *V. V. SHAH[1], T. HOMAYOUNI[2], S. GOYAL[3], H. PALANTHANDALAM-MADAPUSI[1];
[1]SysIDEA Lab, Mechanical Engin., Indian Inst. of Technol. Gandhinagar, Gandhinagar, India; [2]Mechanical Engin., Univ. of California, Merced, Merced, CA; [3]SysIDEA Lab. IIT-GN, Mechanical Engin., Univ. of California Merced, Merced, CA

Abstract: Rest tremor is one of the most common motor symptoms of Parkinson's disease (PD). It occurs at a frequency of 4-6 Hertz in the extremities, such as hand, and characteristically disappears with action and during mental concentration or sleep. The patients suffering from PD are also known to have impairment in their reaction time (RT). For example, Wilson (1925) measured an average RT of 0.36 seconds in patients compared to 0.24 seconds in healthy individuals for a muscle response to single visual stimulus. Although the deterioration in motor control of human body can be intuitively attributed to the increased reaction time, how the increased reaction time is related to such biomechanical symptoms of PD as tremor is not yet understood. The prevailing dogma has been that the tremor originates from oscillations in the central neuronal activity. By contrast, a recent perspective based on feedback control theory (Palanthandalam-Madapusi et al., 2011) suggests that the increased reaction time, which contributes to transport delay in the sensorimotor loop involving extremities, triggers instability driven limit-cycle oscillations observed as rest tremor. This perspective attributes the tremor to the patient's intent to sense and stop it. In this work, we correlate several speculations of the recent perspective with clinical facts using arguments based on feedback control theory along with simple numerical and experimental examples. We contrast it with the prevailing dogma of central oscillator and analyze if any clinical facts can be used to comment further on the mechanism of rest tremors.

Title: Multivariate pattern analysis of fMRI data reveals the discrete neural signature of target-specific deep brain stimulation in the pigs

Authors: *S. CHO, P. TESTINI, M. SETTELL, H. JO, H.-K. MIN, K. H. LEE;
Mayo Clin., Rochester, MN

Abstract: Subthalamic nucleus (STN) DBS is known to evoke non-motor effects such as psychiatric adverse effect (e.g., mania). However, it has been poorly understood the underlying neural mechanism on such non-motor neuromodulatory effect. Previous studies have shown that NAc/IC DBS evokes non-motor effect, which has been applied to treat psychiatric disorder (e.g., obsessive-compulsive disorder). Here we compared functional magnetic resonance images elicited by STN- and NAc/IC-DBS in order to figure out to what extent of similar and dissimilar neuronal activation patterns presents within a large-scale neural network.
We performed STN (n=7) and NAc/IC (n=7) DBS-fMRI experiments in a swine population. Multivariate pattern analysis was adapted to compare the correlational activation pattern of multiple brain regions induced between each DBS target. We trained the machine learning classifier (LDA) and tested whether the classifier can discriminate activation patterns evoked by each different DBS target. The analysis included whole-brain classification (25 ROIs), cortex-based classification (5 clusters), and principle feature set classification (5 ROIs).
The results showed that whole-brain classification (25 ROIs) yielded over 90% mean classification accuracy, and cluster-based classification (5 clusters; association, limbic, sensorimotor, and insular cortices, and thalamus) reached 75% mean accuracy for each cluster. We found that discrete neural signatures of STN and NAc/IC DBS were mainly represented in the three neuronal networks (association, thalamus, and sensorimotor system); however, similar activation patterns were also observed within limbic ROIs.
We conclude that STN- and NAc/IC-DBS evoked discrete neural patterns; nevertheless they also elicited similar neuromodulatory effect in non-motor circuitry. Furthermore, multivariate pattern analysis could possibly discriminate the different brain activation patterns in specific to different DBS-target. Our data suggests that both STN- and NAc/IC DBS shared common neuromodulatory mechanism for non-motor therapeutic and/or adverse effects. This study shows that fMRI with MVPA approach can be used to predict the presence of psychiatric therapeutic and adverse effects in Parkinson's patient who were implanted STN-DBS.

Title: Region-specific transcriptomics of SCA1 mouse models highlight biological pathways underlying tissue vulnerability

Authors: ***T. DRIESSEN**, J. LIM;
Yale Univ., New Haven, CT

Abstract: Spinocerebellar ataxia type 1 (SCA1) is a progressive neurodegenerative disease caused by an expanded polyglutamine repeat in Ataxin-1 (*ATXN1*), and results in progressive ataxia, cognitive impairments, dysarthria, and subsequent respiratory failure. Degeneration of neurons, specifically in the cerebellum and brain stem is a hallmark of SCA1, though the underlying mechanisms dictating cell-type and tissue vulnerability remain largely unknown. In this study, we utilized high throughput transcriptomics to identify pathways unique to vulnerable tissues over the course of disease progression. We first utilized an $Atxn1^{154Q/2Q}$ knock-in mouse model that expresses polyglutamine expanded *Atxn1* throughout the CNS, and compared highly vulnerable tissues, such as the cerebellum and inferior olive, with relatively unaffected regions, such as cortex. Measuring transcriptional changes at the beginning and intermediate stages of tissue pathology allowed us to further elucidate how the transcriptional landscape in vulnerable tissues change over the course of the disease. In addition, transcriptional changes in a second ATXN1 [82Q] mouse expressing the human polyglutamine-expanded mutant ATXN1 in Purkinje cells was assessed at multiple ages and in different tissues to identify meaningful gene clusters common to the two mouse models. RNA-seq data analysis using a variety of bioinformatic tools identified multiple pathways associated with up- or down-regulated gene expression, including inflammatory response, synaptic transmission, and developmental pathways, all of which may be contributing factors in tissue vulnerability. A cluster of genes linked to other SCAs were also significantly altered in the ATXN1 [82Q] cerebellum, providing preliminary evidence that mutant ATXN1 may be an upstream regulator of a portion of SCA genes in affected tissue. In summary, we utilized large scale transcriptomics to identify gene expression changes that are unique to SCA1 affected tissues, paving the way for subsequent

studies to investigate which of these gene clusters predispose the cerebellum and other affected tissues to SCA1 pathology.

Title: Generation of a marmoset model of spinocerebellar ataxia type 3 via AAV9 vector-mediated gene transfer

Authors: ***A. KONNO**, Y. MATSUZAKI, H. HIRAI;
Dept. of Neurophysiol. & Neural Repair, Gunma Univ., Maebashi, Japan

Abstract: Spinocerebellar ataxia type 3 (SCA3) is a genetic disease caused by the expansion of CAG repeat in ataxin-3 (ATXN3) gene. Although there are many researches about possible therapies for SCA3 using a mouse model of SCA3, no therapy has proceeded to the clinic. One of the main reasons may be absence of non-human primate (NHP) model of SCA3, by which scientists can evaluate the effectiveness of possible therapies for future clinical use. In this study, we aimed to generate the marmoset model of SCA3 via adeno-associated virus serotype 9 (AAV9) vector-mediated gene transfer. The marmoset is a small NHP that has attracted remarkable attention as a potential experimental animal link between rodents and humans. Firstly, we used mice to assess the feasibility of the AAV9-mediated production of a SCA3 model, because the assessment of behavioral phenotypes for mice has been already well established. The ATXN3 gene having an expanded CAG repeat (ATXN3[Q89]) was used as the pathogenic gene for SCA3. Rotarod and beam-walking tests revealed progressive ataxia in mice

injected with AAV9 vectors expressing mutant ATXN3[Q89], whereas mice treated with AAV9 expressing ATXN3[Q15], which has the normal length of CAG repeat, were almost indistinguishable from PBS-injected control mice. Then, we proceeded to generate marmoset models by cerebellar injection of the same AAV9 vectors. The behavior of injected-marmosets was monitored and compared with pre-injection levels every two weeks using a tower-descending test and an upper-limb reaching test. In a tower-descending test, marmoset virally expressing ATXN3[Q89] initiated to show significantly worse performance at 4 weeks post-injection and continued to decline thereafter. In an upper-limb reaching test, the marmoset showed poorer performance similarly at 4 weeks after injection, restored to a level similar to the pre-injection period, and again became significantly worse at 14 weeks post-injection. In contrast, marmoset treated with AAV9 expressing ATXN3[Q15] remained almost unchanged in performances in both tests. About 1 year post-injection, immunohistochemical analysis of the marmosets was done. Notably, many large projection neurons in the deep cerebellar nuclei were lost, which was characteristic of SCA3 patients. Thus, we successfully generated SCA3 model of marmoset showing progressive ataxia with characteristic cerebellar pathology.

Title: Analysis of glucose metabolism during the pathogenesis of Spinocerebellar Ataxia Type 1

Authors: ***J. DIAZ**[1], A. PEREZ[1], M. GALLEGO[1], Y.-W. WAN[1], T. INOUE[1], A. CHAI[2], M. MALETIC-SAVATIC[1], H. ORR[3], M. GABER[1], Z. LIU[1], R. SAMACO[1], J. BOTAS[1]; [1]Mol. and Human Genet., Baylor Col. of Med., Houston, TX; [2]King's Col. London, London, United Kingdom; [3]Univ. of Minnesota, Minneapolis, MN

Abstract: Spinocerebellar ataxia type 1 (SCA1) is one of nine Polyglutamine Diseases caused by CAG expansion in the coding region of the corresponding gene. In SCA1, CAG expanded repeats cause an abnormally long glutamine tract in ATXN1 protein and trigger a gain of function pathogenic mechanism that leads to a progressive neurodegenerative disorder. The brain regions primarily affected are the cerebellum and the brainstem. Previous study reported that insulin sensitivity and insulin secretion are abnormal in SCA1 patients. We hypothesize that expression of mutant ATXN1 impairs glucose metabolism and use multiple approaches to test this hypothesis using mice and *Drosophila* disease models. Gene expression analyses in SCA1

mice and flies suggest glucose uptake deficiency in neuronal cells. Confirming these results, positron emission tomography imaging suggests lower glucose level in the cerebellum of SCA1 transgenic mice. Metabolomic analyses in SCA1 fly neurons reveal a decrease in glucose metabolism metabolites. We carried out a genetic screen in *Drosophila* of all genes encoding glycolytic enzymes for potential modifier genes of SCA1 pathogenesis. We found that knocking down glycolytic genes ameliorates neurodegeneration by reducing steady-state levels of mutant ATXN1 protein. Together these data suggest that glucose metabolism impairments contribute to SCA1 pathogenesis and reveal new therapeutic approaches to decrease ATXN1 neurotoxicity.

Title: Pathogenic polyglutamine expansion length correlates with polarity of the flanking sequences

Authors: M. KIM, I. BEZPROZVANNY;
UT southwestern Med. Ctr., Dallas, TX

Abstract: Polyglutamine (polyQ) repeat expansion within coding sequence of a soluble protein is responsible for eight autosomal-dominant genetic neurodegenerative disorders. These disorders affect cerebellum, striatum, basal ganglia and other brain regions. The pathogenic polyQ-expansion threshold in these proteins varies from 32Q to 54Q. Understanding the reasons for variability in pathogenic polyQ threshold may provide insights into pathogenic mechanisms responsible for development of these disorders.
Here we established a quantitative correlation between the polarity of the flanking sequences and pathogenic polyQ-expansion threshold in this protein family. We introduced an "edge polarity index" (^{E}PI) to quantify polarity effects of the flanking regions and established a strong correlation between ^{E}PI index and critical polyQ expansion length in this protein family. Based

on this analysis we subdivided polyQ-expanded proteins into 2 groups - with strong and weak dependence of polyQ threshold on ^{E}PI index. The main difference between members of the first and the second group is a polarity profile of these proteins outside of polyQ and flanking regions. PolyQ proteins are known substrates for proteasome and most likely mechanistic explanation for the observed correlation is that proteasome may have an impaired ability to process continuous non-polar regions of proteins, resulting in release of undigested products.
The proposed hypothesis provides a quantitative explanation for variability in pathogenic threshold among polyQ-expansion disorders, which we establish to correlate with polarity of flanking regions. Most likely mechanistic explanation of these results is that proteasome is not efficient in processing continuous non-polar regions of proteins. If supported experimentally, our hypothesis may have wide implications for further understanding the pathogensis of polyglutamine expansion disorders.

Title: Upregulation of glial GLT1 glutamate transporter corrects Purkinje cell dysfunction and cerebellum-dependent motor incoordination in a mouse model of myotonic dystrophy

Authors: ***M. GOMES-PEREIRA**[1], D. M. DINCA[1], G. SICOT[1], S. O. BRAZ[1], A. LEROY[2], F. MEDJA[1], A. HUGUET[1], A. NICOLE[1], N. GUERIBA[1], C. CHHUON[3], C. PRIGOGINE[2], C. GUERRERA[3], G. CHERON[2], L. SERVAIS[4], G. GOURDON[1];
[1]Imagine Inst., Paris, France; [2]Université Libre de Bruxelles, Brussels, Belgium; [3]Paris Descartes Univ., Paris, France; [4]I-Motion Inst., Paris, France

Abstract: Myotonic dystrophy type 1 (DM1) is a multisystemic condition that affects many tissues as well as age groups. Compelling clinical evidence clearly demonstrates the impairment of the central nervous system (CNS), through cognitive/attention deficits, problems with

executive function, prevalent hypersomnia, behavioral changes and intellectual disability in the most severe cases. The neurological manifestations are highly debilitating and distressing for patients and their relatives, and there is no cure for this devastating condition. However, important gaps exist in our understanding of the disease mechanisms in the brain, which delay the design of rational therapies in the CNS. DM1 is caused by the abnormal expansion of a non-coding trinucleotide CTG repeat, which results in the toxic accumulation of expanded transcripts in the nucleus and changes in the activity of RNA-binding proteins, such as MBNL and CELF proteins. Nonetheless, we do not know the cell populations, the neuronal circuits or the molecular pathways primarily affected by the repeat expansion in the CNS. Using a transgenic mouse model of DM1, we found fine motor incoordination and abnormal Purkinje cell firing with fast oscillatory field potential, indicative of cerebellar dysfunction. This finding was unexpected since cerebellum is not typically associated with DM1 brain pathology. To investigate the mechanisms behind Purkinje cell dysfunction we looked for signs of RNA toxicity. Interestingly, RNA foci and misspliging were not detected in Purkinje cells, but were prevalent in the neighboring Bergmann glia. To find how defective astrocytes affect the physiology of Purkinje cells, we used a global proteomics approach and found significant downregulation of the glia-specific GLT1 glutamate transporter in DM1 mice and human patients. Further analysis revealed that MBNL1 inactivation through sequestration into CUG RNA foci was sufficient to downregulate GLT1. GLT1 abnormalities suggest glutamate missignaling and neuronal hyperexcitability in DM1. Pharmacological upregulation of GLT1 in DM1 mice by ß-lactam injection corrected Purkinje cell electrophysiology and motor deficits, indicating that cerebellar dysfunction is mediated by reduced GLT1 and suggesting that glutamate transport activation in glia may be beneficial in DM1 and other related disorders. Our results strongly suggest a role for cerebellum and glia dysfunction in DM1 brain disease and open avenues for future therapies.

Title: Deficient nuclear export of polyglutamine-expanded androgen receptor contributes to toxicity in a cell model of spinal and bulbar muscular atrophy

Authors: *F. ARNOLD, D. MERRY;
Thomas Jefferson Univ., Philadelphia, PA

Abstract: Spinal and bulbar muscular atrophy (SBMA) is an X-linked neurodegenerative disease caused by a polyglutamine (polyQ) expansion in the androgen receptor (AR). Upon ligand binding of testosterone or dihydrotestosterone (DHT) the AR undergoes a conformational change, inducing nuclear localization and transcription of target genes. In SBMA, both the presence of hormone and the nuclear localization of the AR are necessary for toxicity, with the formation of intranuclear inclusions of aggregated AR a hallmark of the disease state. Given the importance of nuclear localization in disease-mediated toxicity, we sought to determine if the nuclear export of polyQ-expanded AR is disrupted, and, if so, whether enhancing the nuclear export of polyQ-expanded AR is protective in cell models of SBMA. Heterokaryon analysis of cells inducibly expressing human AR reveals that polyQ-expanded AR is deficient in nuclear export compared to wildtype AR, even prior to the formation of intranuclear inclusions. Additionally, tagging the mutant AR with a nuclear export signal (NES) enhanced its nuclear export and reduced both inclusion formation and hormone-dependent toxicity. Moreover, the stabilization of polyQ-expanded AR that occurs upon hormone binding was substantially reduced when AR nuclear export was enhanced. All together, these experiments provide us with a new understanding of the role of nuclear export in SBMA pathogenesis and new insights into the effect of the polyQ-expansion on nuclear export.

Title: TFEB and Hikeshi influence the degradation of the disease-causative proteins in cellular models of neurodegenerative diseases

Authors: *H. ADACHI[1,2], Z. HUANG[1], K. OKADA[1], K. OHNARI[1], T. HASHIMOTO[1], T. TOYOTA[1], Y. IWANAKA[1], R. KATSUMATA[1], G. SOBUE[2];
[1]Dept of Neurol., Univ. of Occup. and Envrn. Hlth., Kitakyushu-Shi, Japan; [2]Dept. of Neurol., Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan

Abstract: A common characteristic of neurodegenerative diseases such as polyglutamine diseases is the abnormal accumulation of disease-causing proteins in the nervous system. The formation of nuclear and cytoplasmic inclusions is commonly observed. Under pathologic conditions, the accumulated level of such misfolded and toxic proteins may exceed the protective ability of the proteolytic machinery; the inability to either maintain misfolded proteins in a soluble form or degrade them results in their accumulation and the formation of inclusions. Autophagy refers to self-phagocytosis and is a process by which cells remove a large amount of proteins with long half-lives as well as damaged organelles. The degradation of proteins with long half-lives, organelles, and aggregated proteins is crucial for the maintenance of cell homeostasis. The transcription factor EB (TFEB) has been reported to regulate autophagy by upregulating genes that belong to the coordinated lysosomal expression and regulation (CLEAR) network, thereby controlling lysosomal biogenesis. Hikeshi is essential for the entry of the Hsc70/Hsp70 (Hsp70s) to the nucleus under stress condition. Hsp70s are rapidly and transiently relocated from the cytoplasm into the nucleus and nucleolus in response to heat shock. Inside the nucleus, Hsp70s dissociate from Hikeshi and bind native or non-native client proteins and function as a molecular chaperone, likely reversing and attenuating the multiple heat shock-induced nuclear phenotypes and therefore protecting the cells from heat shock damage. Homozygous missense mutations in the human Hikeshi gene cause congenital leukodystrophy associated with early onset spastic paraparesis, acquired microcephaly and optic atrophy. We examined the effects of the overexpression of TFEB and Hikeshi in cultured cell models of neurodegenerative diseases. Neuronal cells were transfected using Lipofectamine 2000 with plasmids encoding mutant androgen receptor, huntingtin, ataxin-1, ataxin-3, Hikeshi and TFEB. The overexpression of TFEB and Hikeshi decreased the expression of each causative protein in the neuronal cell models. On the other hand, reduction of TFEB and Hikeshi slows the turnover of mutant proteins. These findings demonstrated that TFEB and Hikeshi influence the degradation of the disease-causative proteins.

Abstract: Among non-human primates, common marmoset offers advantages for reproductive technology compared with the macaque species. Their characters such as shorter pregnancy, faster sexual maturation, and higher fecundity permit rapid establishment of a disease model line after the birth of the first transgenic animal. We have previously developed seven transgenic polyglutamine disease model marmosets carrying human SCA3 disease gene (*ATXN3*) with 120 CAG repeats (Tomioka et al 2016). Recently, we have succeeded to establish the disease model line by generating F1 animals by collecting sperm from a symptomatic male animal in the founder generation. Because of its lower motility, we have used a reproductive technique of intracytoplasmic sperm injection for generating Tg embryos and the embryos were transferred into surrogate mothers. Until now, 46 embryos were transferred into 19 surrogate mothers and 5 animals became pregnant. Among them, 4 offspring were delivered from 2 surrogate mothers and the transgene was detected from 2 infant ear tissues and a placenta from another recipient whose infant is too small for biopsy at current stage. These results show germline transmission of the transgene occurred. Since these F1 animals are too young to perform behavioral analysis, we have attempted to develop phenotyping strategies by using one F0 male animal who has seemed to exhibit disease onset by showing the decline of daily activities and muscle weakness. Behavioral profile was analyzed by capturing them by video images and the infra-red sensors equipped in their home cage. Forelimb grip strength was measured by bar grip test, and their locomotor function was evaluated by both foot print analysis and ladder climbing test. Results suggest that some of these evaluation are sensitive to movement disorder that is characteristic of the PolyQ disease, i.e. lower daily motility detected by the motion analysis as well as infra-red

measurement (Tg :0.621×10^7 a.u. vs WT :$1.49\pm0.26\times10^7$ a.u. as mean±SEM, $p< 0.05$), weaker force by voluntary muscle contraction detected by bar-grip test (Tg: 3.63 Kg/kg-BW vs WT :5.20±0.56 Kg/kg-BW as mean±SEM, $p<0.05$). In contrast, no difference was detected throughout measurement period so far (i.e. foot print analysis) suggesting that these motor functions may altered later in its life span and that this line could be a model for late-onset disease. It is likely that applying these test battery on the F1 marmoset line will successfully characterize their phenotype that is crucial for this model to be used in the translational research.

Title: Expression of the novel polyglutamine protein FAM171B in the developing and adult mouse brain.

Authors: A. K. SUDASINGHE, D. S. SHARLIN, *G. M. GOELLNER;
Biol., Minnesota State Univ- Mankato, Mankato, MN

Abstract: Proteins containing polyglutamine (polyQ) tracts within their primary amino acid sequence are particularly interesting because expansion mutation within them has been shown to underlie a growing list of severe neurodegenerative disorders such as Huntington's Disease and several types of Spinocerebellar Ataxias. FAM171B is a novel polyQ protein, originally identified via large scale sequencing efforts, of which very little is known regarding its normal cellular function and expression pattern. In this study, we utilize both in situ hybridization and immunohistochemistry to assay whether FAM171B is expressed in the developing (postnatal

days 7, 21, 42) and adult mouse brain. Our experiments suggest that FAM171B is indeed expressed in brain with pronounced expression in the hippocampus, Purkinje cells of the cerebellum, and cerebral cortex. Considering these observations, FAM171B can be considered a candidate gene for an as yet molecularly uncharacterized neurodegenerative disease.

Title: Protein interaction networks in the pathogenicity of spinal and bulbar muscular atrophy

Authors: ***A. PLUCIENNIK**[1], T. BERGER[1], S. FINKBEINER[2], D. MERRY[1];
[1]Thomas Jefferson Univ., Philadelphia, PA; [2]Gladstone Inst. of Neurolog. Dis. and the Univ. of California, San Francisco, CA

Abstract: Spinal and bulbar muscular atrophy is caused by a loss of brainstem and spinal cord motor neurons (and of the associated innervated muscles). The genetic basis of this disease is an expansion of a polyglutamine (polyQ)-encoding CAG repeat within the androgen receptor (AR) gene. Several hypotheses have been put forward to explain the cytotoxic consequences of polyQ expansion at the molecular level, including aberrant protein-protein interactions, altered post-translational modifications, and perturbations to global protein folding homeostasis. Here, we have employed a quantitative proteomics approach involving stable isotope labeling of amino acids in cell culture (SILAC) to identify alterations in the AR interactome due to polyQ expansion. Rat neuronal PC12 cells expressing polyQ-expanded AR or wild type AR were used in this study. Protein interaction partners of AR or polyQ-expanded AR were immunoprecipiated using an AR-specific antibody or the expanded polyQ- and conformation-specific antibody 3B5H10. Our approach has identified several promising protein candidates whose interactions with AR are altered by the polyQ expansion; one of these is Usp7 (ubiquitin specific protease 7). This protein preferentially interacts with soluble AR and does not colocalize with AR nuclear inclusions. Overexpression of human Usp7 in PC12 cells enhanced polyQ-expanded AR

aggregation and toxicity. Reduction of Usp7 levels by shRNA-mediated gene silencing in polyQ-expanded AR-expressing cells decreased the frequency of nuclear inclusions. The functional role of Usp7 in spinal motor neurons that express polyQ-expanded AR is currently being evaluated.

Title: Behavioral characterization of Zip14 knockout mice; a potential model of manganism

Authors: ***C. G. JANUS**[1], S. JENKITKASEMWONG[2], H. KHAN[1], B. GIASSON[1], M. KNUTSON[2];
[1]CTRND and Dept. of Neurosci., [2]Dept. of Food Sci. and Human Nutr., Univ. of Florida, Gainesville, FL

Abstract: ZIP14 (SLC39A14) is a transmembrane metal-ion transport protein that can mediate the cellular uptake of a number of metals including zinc, iron, and manganese. Studies of *Zip14* knockout (*Zip14*$^{-/-}$) mice have demonstrated that ZIP14 participates among others in the hepatic uptake of zinc during inflammation. We have recently found that *Zip14*$^{-/-}$ mice display dramatic alterations in manganese metabolism. Most notably, *Zip14*$^{-/-}$ mice exhibit reduced concentrations of manganese in liver and massively elevated manganese concentrations in the brain and bone (10- and 65-fold higher than control). Concentrations of other metals (e.g., zinc, iron, copper) in the brain are unaffected, indicating that the defect is specific for manganese. We hypothesize that the absence of ZIP14 prevents the uptake of manganese in the plasma by the liver, causing subsequent increase of manganese in the blood and accumulation in peripheral tissues, bones, and the brain. In humans, manganese accumulation in the brain deposits in regions of the basal ganglia and can lead to a Parkinsonian-like disorder known as manganism. To define where manganese accumulates in the brain of *Zip14*$^{-/-}$ mice, we used laser-ablation inductively coupled plasma mass spectrometry, which provides a quantitative and detailed image of the distribution of manganese and other metals. We found that *Zip14*$^{-/-}$ mice accumulated manganese in a number of brain areas including the globus pallidus, a region that preferentially loads manganese in humans with manganism. We hypothesized that the accumulation of manganese in the basal ganglia of *Zip14*$^{-/-}$ mice is associated with neuropathological changes leading to alterations in motor behavior. The evaluation of *Zip14*$^{-/-}$, *Zip*$^{+/-}$, and wild type mice in a standard battery of tests of physical development and locomotor phenotype revealed lower body weight of *Zip14*$^{-/-}$

mice, and impairment in both spontaneous locomotor activity as well as motor coordination when the mice were challenged on accelerated rod. *Zip14*$^{-/-}$ mice also showed abnormal species specific spontaneous home cage behavior. The motor deficits of *Zip14*$^{-/-}$ mice were detected as early as 2.5 months and persisted at least until 10 months of age. Overall, our data suggest that *Zip14*$^{-/-}$ mice show impairments in multiple motor systems, whereas hemizygous *Zip14*$^{+/-}$ mice do not compared to WT mice.

Title: Cas9 lipid nanoparticles as an efficient delivery tool for primary neural cultures

Authors: *E. RAMSAY[1], J. SINGH[1], G. THARMARAJAH[1], R. DESOUZA[1], E. OUELLET[1], A. THOMAS[1], S. GARG[1], T. LEAVER[1], A. WILD[1], A. WHITE[2], C. HANSEN[2], J. TAYLOR[1]; [1]Precision Nanosystems Inc., Vancouver, BC, Canada; [2]Physics and Astronomy, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: In recent years, the demand for an efficient delivery tool capable of facilitating the use of RNA for modulating gene expression in the mammalian central nervous system has been a subject of many discussions. Furthermore, progress in the CRISPR-Cas9 gene editing arena has pushed the demand even further as more research programs are now poised in utilizing the technology for establishing new treatment strategies. Of the tools available, developments in the field of lipid nanoparticles (LNPs) has enabled significant gains for the reliable and efficient delivery of these precious payloads both in research and clinical settings. Here, we bridge that gap by describing the development of an LNP delivery system for Cas9, robustly manufactured with clinical-grade materials using microfluidic technology at suitable scales for screening applications. Cas9 LNPs of a defined diameter were engineered by modulating the lipid contents and parameters, such as mixing ratio and flow rate, associated with their manufacture via a proprietary microfluidic platform. The physicochemical characteristics of these novel nanoparticles was determined and correlated with their in vitro performance to guide rational design and optimization. Specifically, the particle size and encapsulation efficiency of Cas9 mRNA and Cas9 ribonucleoprotein (RNP) complexes into electron-dense lipid nanoparticles was determined using dynamic light scattering (DLS) and molecular assays. The performance of

these LNP delivery systems was initially characterized by manufacturing nanoparticles of about 80-100 nm harboring a reporter GFP mRNA. Initial studies demonstrated highly efficient particle uptake and minimal cellular toxicity in primary rat cortical astrocytes. Direct observations of the GFP fluorescence confirmed highly efficient gene expression 48h after a single-dose treatment. Looking at the effect of LNPs on individual cells, further studies facilitated by the use of a microfluidic device capable of high-throughput single-cell digital PCR provided insight into the response seen in a bulk population.These validation studies were paramount in providing suitable insights in establishing strategies for efficiently delivering Cas9 mRNA and/or Cas9 RNP LNP by administering them directly into E18 primary rat astrocyte cell cultures. The editing potential of those formulations was tested in cultures for HPRT target-gene editing.

Title: Micro-RNA351 alleviates denervation-induced skeletal muscle astrophy by targeting tumor necrosis factor receptor-associated factor 6

Authors: ***F. DING**, M. SHEN, J. QIU, Q. CHENG, Q. HE;
Nantong University, China, Jiangsu, China

Abstract: Denervation-induced skeletal muscle atrophy is one of the challenges of peripheral nerve regeneration. We have identified the differentially expressed proteins in the tibialis anterior (TA) muscles after sciatic nerve transection by the isobaric tags for relative and absolute quantification (iTRAQ) coupled with two-dimensional liquid chromatography-tandem mass spectrometry (2D LC-MS/MS), and showed that tumor necrosis factor receptor-associated factor 6 (TRAF6) was up-regulated in denervated TA muscle as the elapse of time. On the other hand, knockdown of TRAF6 could significantly inhibited glucocorticoid-induced C2C12 myotube atrophy *in vitro* and attenuated denevation-induced TA muscles atrophy after sciatic nerve injury *in vivo*. MicroRNAs (miRNAs, miRs) are involved in modulation of various physiopathological processes, but the impacts of miRNAs on muscle atrophy have not been fully investigated. We observed that the expression of miR-351 was differentially expressed in the tibialis anterior (TA) muscle at different time points after sciatic nerve transection, and the time-dependent expression profile of miR-351 was inversely correlated with that of TRAF6 at the mRNA and protein levels. The dual luciferase reporter assay indicated that miR-351 could dramatically down-regulate the expression of TRAF6 by directly targeting the 3'-UTR of TRAF6. Overexpression of miR-351 inhibited a significant decrease in the wet weight ratio or cross-sectional area of the TA muscle after sciatic nerve transection. Western blot analysis showed that the protein expression of TRAF6, muscle ring-finger protein 1 (MuRF1) and muscle atrophy F-box (MAFbx) in denervated TA muscle was respectively suppressed by overexpression of miR-351. In conclusion, miR-351 allivates denervation-induced atrophy of TA muscle after sciatic nerve transection at least partially through negative regulation of TRAF6 as well as MuRF1 and MAFbx, the two muscle-specific ubiquitin ligases, and two downstream signaling molecules of TRAF6.

Title: Prominent phase-amplitude cross-frequency coupling between alpha and gamma oscillations underlies motor-tic encoding in cerebro-basal ganglia-cerebellar networks

Authors: *T. NINOMIYA[1], Y. NAGAI[2], T. SUHARA[2], T. MINAMIMOTO[2], M. TAKADA[1], M. MATSUMOTO[3], M. ISODA[4], K. W. MCCAIRN[1];

Abstract: Tourette syndrome (TS) is a complex hyperkinetic motor and neuropsychiatric disorder. While TS has traditionally been believed to arise from abnormalities within the cortico-basal ganglia-thalamo-cortical network (CBTC), recent studies suggest an involvement of the cerebellum (Cb). Utilizing our nonhuman primate model of motor tics, based on selective bicuculline-mediated disinhibition of functional territories of the striatum (dorsolateral putamen), we investigated how intrinsic and extrinsic networks of the CBTC encode tics in the spectral domain. Positron emission tomography (PET) imaging was initially undertaken to identify areas of activation associated with motor tics. Not only brain regions in the CBTC, but also Cb were found to be activated during the presence of motor tics. We then performed simultaneous multi-site electrophysiological recordings of local field potentials (LFPs) in the primary motor cortex (MI), the basal ganglia, and Cb, and compared them with signals derived from normal movement. The LFP data were subjected to phase-amplitude cross-frequency coupling analysis. Both normal and tic states were associated with increased coupling between the phase of alpha-band activity (7-14 Hz) of any recording sites and the amplitude of gamma-band activity (>50 Hz) of the striatum and MI. However, the strength of alpha-gamma coupling in the tic state was greatly accentuated relative to that in the normal state. The present investigation demonstrates that tic encoding is a global network phenomenon beyond the CBTC, associated with abnormally high and complex, long-range, spectral-domain interactions in the alpha and gamma bands.

Title: Combined malonic and methylmalonic aciduria (CMAMMA) presenting as myelopathy in eighth decade.

Authors: *D. NARENDRA[1,2], N. ATASSI[1], K. LINDGREN[1], F. EICHLER[1];
[1]MGH, Boston, MA; [2]NINDS Intramural Program, Bethesda, MD

Abstract: Mutations in the mitochondrial protein acetyl-CoA synthase 3 (ACSF3) were recently identified as a cause of combined malonic and methylmalonic aciduria (CMAMMA). To date 15 cases with confirmed homozygous or compound heterozygous mutations in ACSF3 have been reported. These have typically presented with vomiting, encephalopathy, and seizures in childhood or neuropsychiatric symptoms in adulthood. The full phenotypic spectrum of disease associated with ACSF3 mutations, however, is unknown. In particular, although myelopathy is a common presentation of elevated methylmalonic acid (MMA) and homocysteine levels in the setting of vitamin B12 deficiency and some forms of methylmalonic aciduria, it has not been associated with mutations in ACSF3 or other causes of elevated MMA with normal homocysteine levels. We identified homozygous ACSF3 missense mutations (c.1672C>T; p.Arg558Trp) in a 77 year-old woman who presented with subacute lower extremity weakness, numbness, and spasticity, consistent with myelopathy. She had no history of seizures or psychiatric disorder. Serum testing revealed highly elevated MMA (12.04; nlm <=0.40) in the setting of normal B12 (>2000; nlm >250). Subsequent urine organic acid analysis was notable for highly elevated methylmalonic acid and malonic acid, establishing the diagnosis of CMAMMA. Her homocyteine level was initially mildly elevated at 14.3 (nlm 0-14.2) and was within normal range at 13.4 on repeat testing. To our knowledge this is the first case of CMAMMA due to ACSF3 mutations presenting as a myelopathy in humans, and the first case to present after the age of 75. It expands the known phenotype of ACSF3 mutations and suggests that patients with myelopathy and high MMA and B12 levels should be screened for CMAMMA and ACSF3 mutations. More fundamentally, it suggests that elevated MMA (with near normal homocysteine levels) may be sufficient to cause myelopathy in humans.

Abstract: Dexmedetomidine(Dex) is a highly specific, potent and selective a2-adrenoceptor agonist. However, it remains unclear whether dex affects neurons in injured central nervous system. This study was performed in order to investigate if dex has effects on motoneurons in injured spinal cord and via which intracellular signaling pathway does it work. Forty female adult Sprague-Dawley rats underwent unilateral brachial plexus roots avulsion were randomly subdivided into the dex(20ug/kg, 0.1ml) and saline(0.1ml) treated groups by intraperitoneal injection following injury. Three days later, the treated rats were sacrificed and the cryostat sections of the spinal cord of the 7th and 8th cervical segments were stained by nertral red(NR), prepared for the immunohistochemistry reactions with CaMKII, p-CaMKII, PKA and nNOS antibodies. The number of survived motoneurons were counted and shown as the ratio of the ipsilateral to contralateral sides of C7 and C8 spinal cord. The results showed that the survival ratio of the motoneurons was significantly higher in the dex group when compared to that of the saline group. Meanwhile, the ventral horn motoneurons were p-CaMKII, PKA and nNOS positive in the ipsilateral but negative in the contralateral spinal cord. Since a2-adrenoceptor agonist can active glycine (gly) receptor via AC-cAMP-PKA pathway and glycine has a protective effect on cells, we think that dex may protect motoneurons in this way. The mechanism of the signaling pathway of the AC, cAMP, gly, p-CaMKII, PKA, and nNOS should be detected further to see whether the dex be used as a neuronal protective drug in the treatment of spinal cord injury.

Title: Altered resting-state functional connectivity in patients with essential tremor

Authors: *A. E. MORRIS[1], S. A. NORRIS[2], A. Z. SNYDER[3], J. M. KOLLER[2], J. W. MINK[1], J. S. PERLMUTTER[2];
[1]Neurol., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Neurol., [3]Radiology, Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Essential tremor (ET) is the most common movement disorder in adults. Yet, its pathophysiology is poorly understood. Deep brain stimulation (DBS) of the ventral intermediate nucleus of the thalamus (VIM) is an effective treatment for medically-refractory ET, but the therapeutic mechanism of action remains unknown. Neuroimaging studies have implicated cerebello-thalamo-cortical pathways in the pathogenesis of ET. However, most of these studies are motor task-based and therefore subject to chicken-egg interpretive ambiguities: do observed response abnormalities reflect abnormal performance, e.g., enhanced tremor, or do observed response abnormalities reflect primary pathology? Resting-state functional connectivity magnetic resonance imaging (rs-fcMRI) offers a means of interrogating brain function without the problem of performance confounds.
Subjects with ET were recruited from the Washington University Movement Disorders Center prior to receiving VIM DBS. Each subject had resting-state scans (2-5 x 6 min BOLD fMRI runs) with eyes closed and were observed for movement during scan acquisition. Tremor rating scale (TRS) severity was assessed pre-operatively. Age and sex-matched control data were previously obtained. fMRI data preprocessing minimized the effects of head motion during scanning. The present results represent 21 ET patients (out of an original sample of 33) and 41 control participants who passed rigorous data quality assurance criteria. Seed regions were defined within the cerebellum, striatum, sensorimotor cortex, anteroventral thalamus, and supplementary motor area (SMA), as well as in multiple cortical areas representing major resting state networks (RSNs). Composite within-RSN functional connectivity (FC) scores were evaluated and correlated with TRS scores.
In comparison to controls, ET patients showed weaker FC between anteroventral thalamus and primary motor cortex, SMA, and brainstem and between cerebellar right crus I and bilateral thalamus. Brainstem-thalamus FC correlated with pre-operative tremor severity. Composite

network strength in sensorimotor, default mode, dorsal attention, control, and salience networks did not differ between groups.
These results support the hypothesis that dysfunction in subcortical cerebello-thalamo-cortical circuits underlies the pathophysiology of ET. Sparing of cortical FC further supports the idea that ET is a disorder of subcortical origin. Finally, these findings support the concept that ET reflects dysfunction at the network level rather than focal dysfunction within a single structure.

Title: Lack of ABCD1 primes microglia for phagocytosis and axonal degeneration

Authors: ***Y. GONG**[1], N. SASIDHARAN[2], P. MUSOLINO[3], J. EL KHOURY[4], F. EICHLER[4]; [1]Massachusetts Gen. Hosp. Ctr. For Comparat, Boston, MA; [2]Massachusettes Gen. hospital, Boston, MA; [3]Massachusetts Gen. hospital, Boston, MA; [4]Massachusetts Gen. hispital, Boston, MA

Abstract: Mutations in ABCD1 cause the neurodegenerative disease adrenoleukodystrophy that most commonly manifests as spinal cord axonopathy. Microglial dysfunction has long been implicated in pathogenesis. We examined spinal cord microglia in ABCD1-deficient mice displaying axonal degeneration and investigated the role of ABCD1 in microglia activity toward neuronal phagocytosis in cell culture. In a mouse model deficient in ABCD1, microglia activation characterized by CD68 and IBA1 expression was found proceeding neurodegeneration. We also demonstrated upregulation of several phagocytosis related markers within the spinal cord. Interestingly this occurs in the absence of overt inflammation. In addition, primary microglia isolated from Abcd1-/- mice didn't show distinct proinflammatory gene expression but revealed significant upregulation in phagocytosis related molecules including

Bai1, Gas6, mfgE8 and TREM2, indicating that microglia lacking ABCD1 are primed for phagocytosis, affecting neurons stressed by the metabolic milieu. Blocking phagocytosis or specific phagocytic receptors may alleviate axonal degeneration and be therapeutically beneficial.

Title: Extraction of motor spatial patterns in children with movement disorders via joint decomposition of brain and muscle activity

Authors: *A. BARACHANT[1,2], J. B. CARMEL[1,2,3], K. M. FRIEL[1,2,3], A. M. GORDON[4], D. GUPTA[1,2];
[1]Burke Med. Res. Inst., White Plains, NY; [2]Weill cornell medical college, Cornell Univ., New York, NY; [3]Blythedale Children's Hosp., Valhalla, NY; [4]Teachers College, Columbia Univ., New York, NY

Abstract: In children with neuromotor disorders such as in cerebral palsy (CP), electroencephalography (EEG) based motor spatial patterns can provide valuable information for functional motor connectivity assessment. However, conducting cue-based EEG motor paradigms in people with CP has 3 main challenges: First, they can have difficulty initiating, maintaining and stopping a movement, which means movement is not time-locked to cue stimuli, which is essential for extracting invariant spatial patterns. Second, their EEG motor patterns maybe weaker than background noise, which requires many more trials than healthy subjects, which can be challenging especially for children. Third, the brain injury that leads to CP causes reorganization of the cortical control signals, leading to atypical motor spatial patterns that are

not trivial to interpret. To overcome these challenges, we describe here a novel semi-supervised method that does not rely on cue based data epoching, but jointly decomposes the brain (EEG) and muscle (EMG) signals in the Riemannian space. It has the advantage of being objective, simpler and generalizable to signals of varying complexity, as compared to other recent methods such as SPoC and mSPoC that are quite complex and designed to handle a specific type of input signal. We demonstrate the method with the analysis of EEG and EMG data from 23 children with CP, to ascertain their reorganized functional motor connectivity. Subjects participated in an EMG-feedback based videogame experiment, where they controlled the lateral movement of a spaceship by pinching the index finger of either hand. In this way, the subject was engaged and focused and rewarded for being calm, while synchronized EEG and EMG was being acquired from hundreds of movement trials. The cue in this case was continuous rather than discrete. EEG and EMG covariance matrices were estimated and projected in their respective Riemannian tangent space and vectorized.Then a Canonical Partial Least Square was applied to find vector rotations in the tangent space to extract a latent variable that explains the maximum variation between EEG and EMG. Rotation coefficients were back-projected and diagonalized to produce a set of spatial patterns ranked by their importance. This method can enable the use of EEG based neurophysiological assessment of functional motor connectivity in people, especially children, with neuromotor disorders. A better understanding of brain physiology can help guide the development of more effective therapies. (Software implementation of this method is made available as an open-source python toolbox called *pyRiemann*)

Title: Closing the loop in essential tremor treatment: an adaptive approach to deep brain stimulation

Authors: *E. OPRI[1], J. SHUTE[2], R. MOLINA[3], K. FOOTE[4], M. OKUN[4], A. GUNDUZ[2]; [2]Biomed. Engin., [3]Electrical and Computer Engin., [4]Ctr. for Movement Disorders & Neurorestoration, [1]Univ. of Florida, Gainesville, FL

Abstract: Essential Tremor (ET) is one of the most common motor disorders, and it is characterized by the presence of a rhythmical, involuntary slow oscillatory movement of the

limbs (~5-10 Hz). Intention tremor occurs generally in the upper limbs, and it manifests during initiation and execution of target-aimed movements. Even though the pathophysiological basis of ET is still not well known, it is suggested that there is a synergic involvement of the cerebellum, ventral intermediate nucleus (Vim), premotor (PM) and primary motor (M1) cortex in the generation of tremor oscillations. Deep Brain Stimulation (DBS) is used to suppress this synergic involvement by targeting "tremor cells" in the Vim region. The aim of the study is to understand the effect of DBS on the Vim, PM and M1 regions, and to develop a closed loop stimulation delivery system that can activate based on specific neuromarkers in the Vim, PM and M1, such as presence of tremor and/or movement. In addition, coherence analysis between PM, M1 and Vim shed light on the relationship and network between the regions involved in the tremor generation. The closed loop system will be implemented in a Medronic Activa PC+S neurostimulator with Nexus E software to achieve a completely standalone solution, together with Nexus D to enable the interfacing with external sensing sources. Hence, the stimulation can be modulated by using neuromarkers together with other sources used as input features, such as accelerometers or gyroscopes, allowing to achieve better performance in detecting when stimulation is necessary. The fusion between internal neuromarkers and external sensor inputs can lead to the creation of "context aware" closed loop systems (e.g. knowing whether the patient is reaching out for a cup of coffee or driving a car) and increasing the quality of life of the patients. Our results suggest that with the adoption of an embedded closed loop DBS solution would be feasible to avoid side effects of stimulation, such as balance and speech impairment, while delivering an equally effective treatment and slowing battery depletion.

Title: Functional correlates of the therapeutic and adverse effects evoked by thalamic stimulation for essential tremor

Authors: *H. JO[1], W. S. GIBSON[1], P. TESTINI[1], S. CHO[1], K. R. GORNY[2], J. P. FELMLEE[2], K. M. WELKER[2], B. T. KLASSEN[3], H.-K. MIN[1,2], K. H. LEE[1];
[1]Dept. of Neurosurg., [2]Dept. of Radiology, [3]Dept. of Neurol., Mayo Clin., Rochester, MN

Abstract: Deep brain stimulation (DBS) is an established neurosurgical therapy for movement disorders including essential tremor and Parkinson's disease. While typically highly effective, DBS can sometimes yield sub-optimal therapeutic benefit and can cause adverse effects. In this study, we tested the hypothesis that intraoperative functional magnetic resonance imaging could be used to detect DBS-evoked changes in functional and effective connectivity that would correlate with the therapeutic and adverse effects of stimulation. Ten patients receiving DBS of the ventralis intermedius thalamic nucleus for essential tremor underwent functional magnetic resonance imaging during DBS stimulation applied at a series of different electrode sites, followed by evaluation of DBS-evoked therapeutic and adverse effects. Correlations between the therapeutic effectiveness of DBS (three months post-operatively) and DBS-evoked changes in functional and effective connectivity were assessed using region of interest-based correlation analysis and dynamic causal modeling, respectively. Further, we investigated whether brain regions might exist in which activation resulting from DBS might correlate with the presence of paresthesias, the most common DBS-evoked adverse effect. Thalamic DBS resulted in activation within established nodes of the tremor circuit: sensorimotor cortex, thalamus, contralateral cerebellar cortex and deep cerebellar nuclei (FDR $q<0.05$). Stimulation-evoked activation in all these regions of interest, as well as activation within supplementary motor area, brainstem, and inferior frontal gyrus, exhibited significant correlations with the long-term therapeutic effectiveness of DBS ($p<0.05$), with the strongest correlation ($p<0.001$) observed within the contralateral cerebellum. Dynamic causal modeling revealed a correlation between therapeutic effectiveness and attenuated within-region inhibitory connectivity in cerebellum. Finally, specific sub-regions of sensorimotor cortex were identified in which DBS-evoked activation correlated with the presence of unwanted paresthesias. These results suggest that thalamic DBS in tremor likely exerts its effects through modulation of both olivocerebellar and thalamocortical circuits. In addition, our findings indicate that DBS-evoked functional activation maps obtained intraoperatively may contain predictive information pertaining to the therapeutic and adverse effects induced by DBS.

[1]Sch. of Electrical and Computer Engin., [2]Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA; [3]Dept. of Neurol., Emory Univ., Atlanta, GA

Abstract: Kinetic tremors in conditions such as essential tremor affect patient movements that require high degrees of dexterity and precision. Common methods of treatment are medications (primidone, beta-blockers) and thalamic deep brain stimulation. Peripheral nerve stimulation has also been tried in patients with treatment-resistant tremor (Prochazka et al. 1992; Hao et al. 2002), but this technique has not been extensively used in patients because of the bulkiness of the stimulation systems used in these experiments, and the perceived lack of efficacy of this treatment modality. To re-evaluate the usefulness of this technique, we developed a wireless wearable stimulation system that uses 3-D accelerometric measurements of arm tremor characteristics for closed-loop optimization of stimulation parameters. The motion sensor data are wirelessly sent to a PC or smartphone that then analyzes tremor movements. The stimulator (constant voltage mode) is powered by a 3.7 V rechargeable Li-ion battery, and can generate pulses up to ± 25 V in amplitude. All custom designed electronics (18 x 28 mm^2) are enclosed in a wrist-watch sized container.
Two subjects (19 and 20 years old) with kinetic tremor participated in this study. Round surface electrodes (1” diameter) were placed on two sites over the radial and ulnar nerves. We initially adjusted stimulation amplitudes so that they were noticeable, but not uncomfortable, using 200 μs wide biphasic stimuli. We then changed the amplitudes, frequency, and duty cycle of the stimuli, as well as the duration of the inter-pulse train interval while observing the amplitude of the kinetic tremor when subjects moved a small object from one cup to another with a spoon. The frequency, amplitude, and phase shift of the tremor were analyzed before and during the stimulation were compared. We found that the tremor amplitude was reduced by up to 63% when 5 stimuli (100 Hz) were applied with 500 ms inter-stimulation intervals. The placement of the electrodes and skin impedance differed between subjects, so that the stimulation parameters may have to be individualized for each patient. In future studies, we will develop an automated method of optimization of electrode positions and stimulation parameters, based on tremor characteristics.

Title: Modeling Progressive Supranuclear Palsy by viral-mediated tau seeding in the cholinergic neurons of the pedunculopontine

Authors: ***D. A. MACLAREN**[1], M. E. GRIFFIN[2], S. D. CLARK[3];
[1]Sch. of Med. and Biomed. Sci., Univ. At Buffalo, State Univ. of New York, Buffalo, NY;
[2]Pharmacol. and Toxicology, Univ. at Buffalo, State Univ. of New York, Buffalo, NY;
[3]Pharmacol. and Toxicology, Univ. at Buffalo, SUNY, Buffalo, NY

Abstract: Progressive Supranuclear Palsy (PSP) is the most common atypical Parkinsonism. Early stages of PSP closely match Parkinson's Disease (PD) to the point that many with PSP are initially diagnosed as PD and prescribed dopaminergic therapies, to which PSP patients respond poorly. The underlying etiology of PSP is pervasive and progressive tau protein aggregation resulting in neurodegeneration of multiple brain areas. Currently there is no preclinical model of PSP that combines 1) the isoform of tau that is prominent in PSP (1N4R), 2) tau aggregation in clinically relevant brain areas, and 3) clinically relevant behavioral deficits. However, our recent data in rats suggest that the targeted viral-mediated over-expression of tau in the cholinergic neurons of the pedunculopontine tegmentum (PPT) may be useful in understanding PSP.
The PPT projects to many brain regions implicated in PSP (e.g. SN, thalamus, globus pallidus) and undergoes considerable degeneration, with early and selective degeneration of the cholinergic subpopulation of neurons. The selective lesion of cholinergic PPT neurons produces deficits similar to that seen in PSP (e.g. deficits in motor performance, attention, and acoustic startle reflex). Therefore, to simultaneously ablate cholinergic neurons (to produce the behavioral effects) and introduce tau protein (to seed pathological tau) we stereotaxically injected an adeno-associated virus (AAV) encapsulated floxed double-inverse ORF wildtype 4-repeat tau vector into the PPT of a transgenic rat line expressing CRE recombinase in cholinergic neurons. At 12 weeks post-infection we see pathology consistent with early PSP: i) the loss of cholinergic neurons, ii) phosphorylated tau, and iii) spread of phosphorylated tau to the SN. Results to date suggest that targeting the over-expression of tau to specific neuronal populations in rats can produce progressive tauopathy not typically seen in other animal models.

Title: Ligand for cell adhesion molecule PTPRD: Illudalic acid derivatives inhibit recombinant PTPRD phosphatase and are tolerated *In vivo*

Authors: ***G. R. UHL**[1], P. PAIK[2], M. MARTINEZ[4], A. SULIMA[5], K. RICE[3];
[1]Mol. Neurobio., NMVAHCS, BRINM and NIH/NIDA, Albuquerque, NM; [2]Mol. Neurobio., NIDA-IRP NIH, Baltimore, MD; [3]Medication development program, NIDA-IRP NIH, Rockville, MD; [4]Res., NMVAHCS/BRINM, Albuquerque, NM; [5]Medications development program, NIDA-IRP, NIH, Rockville, MD

Abstract: PTPRD is a receptor type protein tyrosine phosphatase with human variants that provide oligogenic contributions to risk for restless leg syndrome (RLS, WIlis-Ekbom disorder) and polygenic contributions to vulnerability to addiction. We have recently identified association between RLS-associated PTPRD SNPs and levels of PTPRD mRNA expression in postmortem human brain. Data from work by Hart and colleagues implicated PTPRD in individual differences in rewarding human responses to amphetamine. We have found that mice with altered levels of PTPRD expression display altered sleep onset as well as marked differences in preference for places previously paired with cocaine (CPP). Each of these features increases interest in drugs that could modify PTPRD activities. We have targeted ligands for PTPRD's phosphatase domains, and identified illudalic acid analogs as active at related phosphatases. Recombinant human PTPRD phosphatase domain fusion protein can be produced in E Coli strains in ways that allow it to be active in spectrophotometric phosphatase assays. Illudalic acid analogs, including a 6-butoxy analog, can be synthesized *via* an improved method. The 6 butoxy illudalic acid analog, but not three related compounds, provides micromolar potency inhibition of recombinant PTPRD phosphatase . This inhibition develops during preincubations up to 16 mins in ways that are consistent with pseudoirreversible kinetics and with models for interactions between related compounds and other phosphatases. Mice injected with 6 butoxy illudalic acid analog doses up to solubility limits display no gross alterations in behavior nor any signs of

systemic toxicity. 6 butoxy illudalic acid analogs provide potential lead compounds for inhibition of PTPRD phosphatase activity in ways that should contribute to understanding of the pathways whereby alteration of PTPRD activity influences addiction and RLS phenotypes and to development of drugs that may be useful treatments for these often-poorly-treated disorders.

Title: The role of ABCD1 in dorsal root ganglia in adrenomyeloneuropathy

Authors: *F. EICHLER, R. KOK, Y. GONG, N. SASIDHARAN;
Massachusetts Gen. Hosptial | Harvard Med. Sch., Boston, MA

Abstract: Mutations in ABCD1 cause the neurodegenerative disease adrenomyeloneuropathy (AMN) that manifests as spinal cord axonopathy. It has been reported that ABCD1 is highly expressed in DRG (sensory) neurons. Yet the role of ABCD1 in DRG has not been elucidated. Performing immunfluorescent experiments in wild type mice, we found expression not to be present in DRG neurons themselves but localized around them. Further containing experiments revealed ABCD1 expression in satellite cells as demonstrated by co-localization of ABCD1 and the satellite cell marker S-100. ABCD1 expression localized to peroxisomes that were abundant in satellite cells but sparse in neurons. A lack of costaining between ABCD1 and MBP excluded the possibility that Schwann cells are responsible for the strong expression of ABCD1 at the periphery of the neurons. The strong expression of ABCD1 observed in dorsal root ganglia satellite cells suggests an important role for ABCD1 in this cell type. To investigate this further, we inhibited the growth of satellite cells, using the mitotoxin 1β-arabinofuranosylcytosine (ARAC). After three days of growth we observed a strong reduction in neurite outgrowth and density. Finally we examined DRG explants from both wild type and ABCD1 knockout mice. After three weeks of culturing, a reduction in the neurite density of dorsal root ganglia lacking ABCD1 was observed (81% of WT explants vs. 56% of KO explants with dense outgrowth, paired two-tailed T-test $P<0.05$), accompanied by a lesser but significant (paired two-tailed T-test $P<0.05$) reduction in neurite length. In conclusion, peroxisomes are abundant in satellite cells

in mouse DRG but not their neurons. ABCD1 is a peroxisomal half-transporter and therefore found in DRG satellite cells and to a lesser extent in DRG neurons. Furthermore, satellite cells are important for neurite outgrowth in dorsal root ganglia explant cultures, and this appears to depend on a healthy and functional ABCD1. These insights provide a first anatomic and pathogenic link between the availability of the functional ABCD1 protein and the sensory neuropathy in AMN.

Title: Harmaline-induced tremor in large animals

Authors: *J. LEE[1], I. KIM[1], L. CHENG[2], S.-Y. CHANG[1];
[1]Mayo Clin., Rochester, MN; [2]The affiliated hospital of Gingdao Univ., Gingdao, China

Abstract: Essential Tremor (ET) is the most common adult on-set movement disorder, which affects around 10 million Americans and millions more worldwide. However, underlying mechanisms of ET has not been fully understood. This lack of our understanding also limited to develop novel treatment method and/or strategy. It is important and necessary to develop an animal model of ET to investigate underlying mechanisms and pathophysiology of ET and screen novel drugs. B-carboline alkaloids (BACs), including norharman, harmane, harmine, harmaline, and ibogaine, are well known to induce action and postural tremor in mice, rats, rabbits, cats, and monkeys. However, a drug-induced tremor has not been tested in pig, even though the pig brain, which is gyrencephalic, resembles the human brain more in anatomy, growth and development than do the brains of commonly used small laboratory animals. Thus, we developed a pig tremor and analyzed the drug-induced tremor. Yucatan and domestic pigs were used to develop drug-induced tremor. Under general anesthesia, intravenous catheter and wireless three-dimensional accelerometers were placed on the ear and the limb, respectively. Once the animal was fully awake and its ambulatory behavior was stable, tremor started to be monitored. Video monitoring was performed simultaneously with a tremor monitoring. Harmaline (2.5 and 5mg/kg) was intravenously administered after 30 minutes of baseline recording. Recording session maintained for 3 hours. Harmaline was administsered once a day,

and this was repeated three times with 48 hours interval. Accelerometer data were obtained along three axis; x-,y-,z-, and fast Fourier transformation was used to yield power spectra. In pigs, harmaline could induce tremor with 10-15 Hz and the drug-induced tremor maintained for one and half hours. The amplitude of drug-induced tremor was significantly different with dose. In the 5mg/kg harmaline-injected animal, the amplitude was decreased according to repeated injection, while there was no significant difference in the 2.5mg/kg harmaline-injected animal. Also, the maintained duration of tremor showed a positive correlation with the dose. Our results suggest that harmaline-induced tremor model in pig can be useful as a preclinical animal model to identify the physiological and pathological mechanism for ET and test a novel treatment method.

Title: Psychoactive compounds induce distinctive fine motor deficits and gait disturbance in mice

Authors: *T. HEIKKINEN, T. BRAGGE, T. TURKIA, A. NURMI, R. HODGSON; Charles River Discovery, Kuopio, Finland

Abstract: While many pharmacological treatments with multiple mechanisms of action have been shown to induce motor impairment in mice, more traditional measures for assessing these impairments tend to evaluate gross motor function and not fine movements. Moreover, the clinical utility of the traditional assays has been questioned, which increases the need to create novel assays that are more sensitive to subtle deficits in motor function. In the high precision kinematic assay, a mouse is placed on a runway and allowed to walk from one end to the other. The movement of the animal is recorded with a high speed camera assess multiple body parts from three angles allowing for a comprehensive analysis of the motor function. The analysis provides detailed information of e.g. changes in joint angles, trajectories and the acceleration rates of selected body points and their relation to each other, interlimb coordination etc. Previously, we have demonstrated preliminary data with some known psychoactive compounds that the kinematic analysis is more sensitive than traditional motor assays to the subtle motor deficits. In addition, by breaking the behavior into components, we have been able to provide a much richer characterization of the motor changes. The purpose of the present research was to

apply the kinematic analysis methodology to the assessment of pharmacologically induced impairments in motor function. In this study we assessed drugs with three different mechanisms of action, amphetamine, morphine, pregabalin in the kinematic analysis assay. Doses were selected to be below, at and above doses that have been shown previously to induce robust hyperactivity or anti-allodynia effects by using open field test or von Frey test, respectively. As an example, we observed expected increase in amphetamine induced hyperactivity in dose response manner and at highest doses, but kinematic analysis data revealed changes in the gait at lowest but not highest doses tested. Also, some parameters were only affected at lowest or highest amphetamine doses. Pregabaline, on the other hand did not induce clear locomotor changes in open field test but showed distinct changes in the kinematic analysis. Taken together, data in this presentation highlight the need to use of sensitive assays in vivo to examine therapeutics and their effects not only for their expected efficacy but also for their possible side effect profiles which may implicate unwanted motor impairments, coordination problems and/or sedation.

Title: Identifying cannabis strains for treatment of epilepsy

Authors: *G. M. LEWITUS[1], P. BERMAN[2], K. FUTORAN[3], D. MEIRI[3];
[1]Fac. of biology, Technion, Haifa, Israel; [2]Technion, Hifa, Israel; [3]Technion, Haifa, Israel

Abstract: Epilepsy is the most common serious brain disorder worldwide with no age, racial, social class, national or geographic boundaries. Epilepsy's co-morbidities include cognitive decline, depressive disorders and schizophrenia which are worsened by poorly controlled seizures. There are many treatments available. However, 30% of the cases remain pharmaco-resistant, resulting in poorly controlled seizures. In the last years, the use of Cannabis as anticonvulsants was reintroduced to the clinic and is used as the last line of defense before brain surgeries in pharmaco-resistant children suffering from epilepsy. Cannabis oil extracts contain more than 100 different cannabinoids which have different pharmacology properties. The aims of this research are to identify the cannabinoids in different strains of cannabis grown in Israel and to evaluate their potential use as anticonvulsants. For this propose, we are utilizing mass-

spectrometry, coupled to liquid chromatography (LC-MS) to comprehensively profile the cannabinoid composition for a variety of cannabis strains that are clinically used in Israel. After profiling the cannabinoids, we are evaluating their anticonvulsant effects in the pentylenetetrazol (PTZ) test, which is a validated model to identify drug treatments that are effective in the treatment of epilepsy in humans.

Title: Neural connectivity and cortical activation in chronic tic disorders

Authors: *K. TUNG[1], M. MIYAKOSHI[3], S. MAKEIG[3], S. CHANG[1], J. PIACENTINI[1], S. LOO[2];
[2]Psychiatry, [1]UCLA Semel Inst., Los Angeles, CA; [3]SCCN UCSD, San Diego, CA

Abstract: Background: The etiology and pathophysiology of Chronic Tic Disorders (CTDs) remains poorly understood.One challenge in studying cortical activity in CTDs is involuntary movement that prevents the use of brain imaging due to motion artifacts. The necessity to remain still confounds true pathophysiological underpinnings with compensatory mechanisms. We propose the use of Mobile Brain-Body Imaging methods to study EEG during voluntary movements among children with and without CTDs. Both temporally resolved cortical activation as well as functional connectivity will be examined to test the hypothesis that although both groups will utilize a similar brain network in generating the voluntary movement, differing levels of activation and patterns of connectivity will be observed.
Methods: Participants included 44 children (27 with CTD, 17 healthy controls (HC)), between the ages of 8-12 years old. Diagnosis was made using the Anxiety Disorder Interview Schedule and tic severity was evaluated using Yale Global Tic Severity Scale. All EEG data were recorded using MoBI methods, which allows integration of multiple data sources within a single interface. EEG was recorded during the Voluntary Movement (VM) task in which all children were presented with a visual cue every 2 seconds and instructed to make an exaggerated blink. EEG data was processed and analyzed in EEGLAB.
Results: EEG data recorded during the voluntary movement condition were examined in order to characterize brain dynamics of effortful control over voluntary movement. Although CTD and HC subjects exhibited similar neural activation patterns, group differences emerged primarily in

the medial prefrontal, supplemental motor (SMA) and parietal areas. The HC group exhibited stronger alpha (8-12 Hz) event-related desynchronization before the VM cue whereas the CTD group shows higher gamma (40-50 Hz) activation immediately after the cue in medial frontal, parietal and left SMA.. Additionally, CTD children showed significantly stronger effective connectivity relative to HC ($p<0.01$) in connections to and from posterior regions and right insular cortex whereas HC children exhibited stronger connectivity in fronto-frontal and fronto-temporal connections ($p<0.01$).
Conclusion: CTD group exhibited altered activation and connectivity in frontal, parietal, and motor regions. Group differences in cortical dynamics and associated clinical characteristics such as tic severity and urge strength suggest the importance of multiple networks in generating voluntary movement and highlight the importance of examining both activation and connectivity for models of movement in CTD.

Title: Detailed genetic analysis of healthy and diseased CSMN reveals molecular determinants of vulnerability and progressive degeneration

Authors: *L. LABOISSONNIERE[1], B. GENC[2], J. TRIMARCHI[1], P. OZDINLER[2];
[1]Iowa State Univ., Ames, IA; [2]Northwestern Univ., Chicago, IL

Abstract: ALS is characterized by progressive degeneration of both spinal and corticospinal motor neurons (CSMN). However, the underlying causes for their selective vulnerability and progressive degeneration are not fully understood. The limitations for detailed cellular analysis are the complexity and the heterogeneity of the cerebral cortex, and the limited numbers of CSMN. To overcome these challenges, we generated and characterized UCHL1-eGFP mice, in which CSMN are genetically labeled with eGFP expression that is stable and long-lasting, allowing visualization and isolation of pure populations of CSMN from the motor cortex. By

crossbreeding this CSMN reporter line with mouse models that display CSMN vulnerability, such as the hSOD1^{G93A} mice, we generated hSOD1^{G93A}-UeGFP mice, in which the diseased upper motor neurons express eGFP and thus are purified by fluorescent activated cell sorting (FACS). We generated cDNA libraries from FACS-purified healthy and diseased CSMN at postnatal day (P)16, P30, P60, and P90, and performed microarray analysis to reveal global changes of gene expression at different stages of disease initiation and progression. Our preliminary results suggest the presence of signature events that occur at different stages, as well as the activation and/or inhibition of unique canonical pathways. These findings are important for suggesting novel drug targets for distinct stages of the disease. In addition, our findings will help determine potential early detection markers as well as biomarkers that would suggest the timing and extent of CSMN vulnerability and degeneration in ALS with upper motor neuron involvement.

Title: Altered ceramide generation in charcot marie tooth 2f

Authors: *N. SCHWARTZ[1], C. E. SENKAL[1], L. M. OBEID[2,1];
[1]Stony Brook Univ., Stony Brook, NY; [2]Northport VA Med. Ctr., Northport, NY

Abstract: Charcot-Marie-Tooth (CMT) disease is the most commonly inherited neurological disorder, resulting in motor and sensory dysfunction that typically commences at middle age and progressively worsens throughout life. Nevertheless, the exact molecular mechanisms underlying CMT are unclear, limiting progress in developing potential therapeutics. As sphingolipids serve as bioactive signaling molecules in a plethora of pathways and have been implicated in neurodegenerative diseases including Alzheimer's, Parkinson's, and ALS, we sought to determine if changes in sphingolipid metabolism may mediate CMT phenotypes. One variant of CMT, CMT2F, is characterized by the presence of mutations in heat shock protein 27 (Hsp27), a member of the class of small heat shock proteins that serves many cellular functions. Using liquid chromatography/mass spectrometry, we have determined that peripheral nerve, but not brain nor spinal cord, tissue from mutant Hsp27 mice displays decreased ceramide levels compared to wild-type Hsp27 tissue, suggesting that these mutants suppress ceramide

generation. Mutant cell lines demonstrate decreased mitochondrial respiratory function, paralleling changes induced by blocking ceramide generation pharmacologically, suggesting decreased production of ceramide reduces mitochondrial respiratory function. Furthermore, autophagy is slightly upregulated in mutant cell lines. Taken together, these results suggest that CMT2F mutations in Hsp27 alter sphingolipid metabolism by dysregulating ceramide levels, producing cellular pathology that ultimately leads to neuronal degeneration in CMT2F. We seek to further characterize the role and regulation of sphingolipid signaling and biology in CMT2F. By understanding the effects of sphingolipids on the development of CMT2F, we will be able to identify targets that can be used in the development of novel treatments to prevent or reduce the severity of CMT2F or other neuropathies with similar mechanisms.

Title: ALS and artificial intelligence: IBM watson suggests additional RNA binding proteins linked to ALS

Authors: ***R. P. BOWSER**[1], E. ARGENTINIS[2], R. SATTLER[1], M. COLLINS[1], A. BOEHRINGER[1], I. LORENZINI[1], P. FERRANTE[1], A. LACOSTE[2], S. SPANGLER[3], N. BAKKAR[1];
[1]Barrow Neurolog. Inst., Phoenix, AZ; [2]IBM Watson Hlth., New York, NY; [3]IBM Res. - Almaden, San Jose, CA

Abstract: A number of RNA binding proteins (RNPs) are linked to amyotrophic lateral sclerosis (ALS), with known mutations in 11 RNPs that are causative in familial ALS and another 5 RNPs associated with ALS pathology but with no known genetic mutations. There are over 1,450 RNPs in the human genome, and therefore other RNPs may also be linked to ALS. We sought to identify additional RNPs associated with ALS using methodologies that analyze prior published information to suggest new RNPs with a connection to ALS. The cognitive capabilities of IBM Watson enable it to extract domain specific text features from published literature to identify new connections between entities of interest, such as genes, proteins, drugs, and diseases. This approach has been successfully applied to gain new insights into oncology, but has not been

applied to the neurosciences. We used IBM Watson to identify additional RNPs linked to ALS. IBM Watson analyzed published abstracts to learn the text patterns of a set of known RNPs related to ALS, and then applied that learning to a candidate set of proteins and ranked their similarity to the known RNP "training set". To test IBM Watson's predictive performance, we first restricted its knowledge to information prior to 2012 (known mutations in 8 RNPs linked to ALS). IBM Watson then rank ordered all other 1,445 RNPs with a probability to be linked to ALS. Since that time, mutations in three RNPs (Matrin 3, GLE1, and ARHGEF28) have been linked to familial ALS. Matrin 3 was the top candidate in this retrospective analysis, with both ARHGEF28 and GLE1 within the top 10% of all RNPs. Having shown that such analysis can successfully predict ALS-associated genes, we then applied a training set consisting of all known RNPs with mutations causative of ALS to predict other RNPs linked to ALS. Of the top 50-ranked genes, 5 have already been associated with ALS, even though no disease-causing mutations are known (RBM45, MTHFSD, SMN2, EWSR1 and hnRNPA3). Also included within the top 10 predicted genes were hnRNPU, hnRNPH2, SRSF2, SYNCRIP and CAPRIN1. To validate Watson's predictions, we examined the subcellular distribution of these RNPs in post-mortem tissue samples from ALS and control subjects. We identified reduced levels of SYNCRIP in ALS patients, but no changes in hnRNPH2. SYNCRIP functions in multiple steps of mRNA maturation and transport, and interacts with TDP-43, FUS, and SMN. CAPRIN1 binds G3BP and TDP-43 and accumulates in stress granules. SRSF2 is localized to antisense RNA foci in C9 patients. Overall, our approach using IBM Watson to mine scientific literature to find new ALS-linked RNPs is promising and may aid basic research efforts to understand mechanisms of disease.

Biol., Ctr. of Animal Biotech. and Gene Therapy, Univ. Autonoma de Barcelona, Bellaterra, Spain; [4]Ctr. for Biol. Sciences, Univ. of Southampton, Southampton, United Kingdom

Abstract: The death of motoneurons in Amyotrophic Lateral Sclerosis (ALS) is preceded by failure of neuromuscular junctions (NMJs) and axonal retraction, dependent upon deffective interaction of motor axons with terminal Schwann cells and skeletal muscle fibers. Neuregulin 1 (Nrg1) is a neurotrophic factor highly expressed in motoneurons and NMJs that supports axonal and neuromuscular development and maintenance. Interestingly, Nrg1 expression has been previously found reduced in both ALS patients and SOD1G93A mice. We have characterized the expression of Nrg1 isoforms and ErbB receptors in spinal cord and skeletal muscles of SOD1G93A mice and ALS patients. In SOD1G93A mice skeletal muscles we found a significant reduction of ErbB4 mRNA levels, correlating with the degree of muscle denervation. Skeletal muscles from sporadic and familial ALS patients also showed reduced levels of ErbB4 receptor at protein and mRNA levels. We confirmed that in the spinal cord of the ALS mice, Nrg1 type I mRNA levels increased along the progression of the disease, whereas Nrg1 type III mRNA levels were reduced. We also observed progressively reduced levels of ErbB4 receptor in the motoneurons of ALS mice with age. In conclusion, the abnormalities observed in the Nrg1-ErbB pathway suggest that it is an potential therapeutic target for improving motoneuron survival and/or NMJ maintenance in ALS.

Title: MAPK signaling mediates neurodegeneration in Spinal muscular atrophy

Authors: *S. AHMAD, N. GENABAI, X. JIANG, K. BHATIA, L. GANGWANI;
Texas Tech. Univ. Hlth. Sci. Ctr., El Paso, TX

Abstract: Spinal muscular atrophy (SMA) is the most common genetic cause of infant mortality. The deletion of the *survival motor neuron 1* (*SMN1*) gene causes low expression levels of full-length survival motor neuron (SMN) protein that results motor neuron loss in the spinal cord in SMA. The molecular mechanisms involved in degeneration of motor neurons in SMA are largely unknown. Recently, we have shown that JNK pathway mediates neurodegeneration in SMA. To further understand mechanism of motor neuron degeneration in SMA, we investigated the upstream MAP Kinase signaling that may regulate JNK activation. We examined G-protein mediated signaling, such as Rac1/Cdc42 (G-protein) and p21-activated kinase (PAK), a target of activated Rac1/Cdc42 kinases in WT and SMA mice as well as non-SMA and SMA type-1 patient spinal cord. We show that Rac1/Cdc42 and PAK/4/5/6 were activated in the spinal cords of SMA mice as well as in SMA patients. Protein tyrosine kinase 2 (PYK2), a brain specific isoform, and protein kinase C (PKC), which are known to activate Rac1 were also activated in SMA. Increased Ca^{2+} accumulation was found in neurons that may cause activation of PKC and PYK2 module. Together, these data suggest that the upstream signaling Rac1/Cdc42-PAK4/5/6 and PYK2/PKC kinase modules may activate JNK cascade that mediates neurodegeneration in SMA.

Title: A novel Optineurin truncation mutation identified in an adult onset consanguineous Palestinian family with amyotrophic lateral sclerosis

Authors: *M. DE MAJO[1], M. GOTKINE[2], C. WONG[1], S. TOPP[1], R. MICHAELSON-COHEN[3], S. EPSZTEJN-LITMAN[4], R. EIGESS[4], A. NISHIMURA[1], B. SMITH[1], C. SHAW[1]; [1]Dept. of Basic and Clin. Shaare Zedek Med. Ctr., Jerusalem, Israel; [4]Stem Cell Res. Lab., Med. Genet. Institute, Shaare Zedek Med. Ctr., Jerusalem, Israel

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease with an average survival of 3 years from diagnosis. A clear genetic component is apparent in approximately 10% of cases, and mutations in four major genes: *SOD1*, *TDP43*, *FUS* and *C9ORF72* account for approximately 50% of familial and 15% of sporadic cases. The genetic factors involved in the majority of ALS cases remain to be elucidated. Optineurin (*OPTN*) mutations have been described in open angle glaucoma and more recently, in ALS. Here we describe, for the first time, the genetic and functional characterisation of a novel recessive mutation in *OPTN* found in a consanguineous Palestinian family with an aggressive, adult form of ALS. Furthermore, this study is the first to characterise endogenous OPTN from primary fibroblast lines cultured from carriers of OPTN mutations.

OPTN is a 577 amino acid protein involved in a variety of cellular pathways, including autophagy. OPTN acts as autophagy receptor and it is involved in the clearance of protein aggregates through the autophagy-lysosome pathway. Within the same pathway OPTN is phosphorylated on Ser177 by tank binding kinase 1 (TBK1), a protein also linked to ALS.

A novel homozygous truncation mutation in OPTN (S174X) was identified in this family, via exome sequencing from DNA of affected family members; this results in removal of both the UBAN domain and the TBK1 phosphorylation site. Notably, the truncated protein retains the TBK1 binding region of OPTN. The unaffected mother was confirmed to be a heterozygous carrier, and sequencing of three unaffected siblings of the proband showed two of them to be heterozygous carriers and one to harbour a homozygous S174X change.Fibroblast primary lines were obtained from the unaffected mother and three siblings. Interestingly, Western blot analysis of fibroblast lysates, probing for endogenous OPTN, revealed OPTN expression for the wild type and heterozygous carriers but no expression of the truncated S174X OPTN allele. These observations support the hypothesis that early truncation results in an unstable protein. However, transcript analysis revealed that full length and truncated *OPTN* message was produced from both the heterozygous and homozygous carriers.

The absence of the mutated copy of OPTN suggests that the pathogenic mechanism could be associated with a loss of function, which could result in a knock on effect abolishing interaction with TBK1. Further research will aim to characterise the mechanism behind the pathogenicity of this truncation mutation in *OPTN* and how this affects its interaction with TBK1. The understanding of this mechanism could pave the way to gene replacement therapy approaches.

Title: Disease specific changes in sirtuin 3 levels in a mouse model of amyotrophic lateral sclerosis and Huntington's disease

Authors: E. BARTH[1], H. BAYER[1], J. HANSELMANN[1], P. WEYDT[1], K. LINDENBERG[1], *A. WITTING[2];
[1]Ulm Univ., Ulm, Germany; [2]Univ. Ulm, Ulm, Germany

Abstract: The loss of upper and lower motor neurons characterizes the progressive and fatal neurodegenerative disease amyotrophic lateral sclerosis (ALS), also known as Lou-Gehrig's disease. Weight loss in patients and early changes in mitochondria indicate dysregulation of energy metabolism. These signs are also present in Huntington's disease (HD) patients. In mitochondria there are three members of the seven mammalian sirtuins, regulating energy metabolism. Of these mainly the NAD+ dependent sirtuin 3 (SIRT3) deacetylates proteins and is majorly involved in regulating ROS defense. Furthermore SIRT3 is a sirtuin implicated in human aging, a risk factor for neurodegenerative diseases. We therefore investigated the expression and function of mitochondrial sirtuins in ALS and HD mouse models. For this we quantified *Sirt3*, *Sirt4* and *Sirt5* during the course of disease in male ALS ($SOD1^{G93A}$) and HD (R6/2) mice on mRNA level. We found a specific reduction of *Sirt3* mRNA levels in the disease-affected areas cervical spinal cord and brain stem of end-stage ALS mice. Whereas in HD mice a tendency to increased *Sirt3* mRNA levels was found. Furthermore, the activity of SIRT3 was reduced in the spinal cord of the $SOD1^{G93A}$ mice, which was determined by analyzing the acetylation status of the SIRT3 target superoxide dismutase 2 (SOD2). The cell type specific analysis of cultured primary cells showed the highest levels of mitochondrial sirtuins (Sirt3, Sirt4, Sirt5) in neurons compared to microglia, astrocytes and oligodendrocytes. Surprisingly a cell-type comparison of knock-out cells for the peroxisome proliferative activated receptor gamma, coactivator 1 alpha (PGC-1α), a genetic disease modifier in ALS and HD, showed a shift of the highest *Sirt3* mRNA levels form the neurons to the astrocyte population. In summary our findings support opposite roles of SIRT3 in disease modifying processes related to PGC-1α during the course of ALS and HD.

Title: Apical dendrite degeneration of Betz cells, a new cellular pathology in ALS

Authors: ***P. OZDINLER**[1,2], B. GENC[1], J. H. JARA[1], P. PAYTEL[3], R. ROOS[3], M. MESULAM[2], C. GEULA[2], E. BIGIO[2];

Abstract: Upper motor neurons [a.k.a. corticospinal motor neurons (CSMN) in mice and Betz cells in humans] are important components of motor neuron circuitry because of their unique ability to initiate and modulate voluntary movement by receiving, integrating and conveying cerebral cortex input into spinal cord targets. Degeneration of Betz cells in ALS was documented as early as 1885. Even though this pathology was accepted as a defining characteristic distinguishing ALS from other motor neuron diseases, the timing and the extent of Betz cell degeneration has been actively debated. There is now evidence to suggest that upper motor neuron death is an early event and a significant contributor to disease pathology. Increased cortical hyperexcitability is observed prior to the manifestation of disease symptoms in ALS patients, as detected by transcranial magnetic stimulation. In addition, ALS mouse models display CSMN abnormalities manifested by spine loss and apical dendrite degeneration early in disease. Although large vacuoles are present in apical dendrites of CSMN that become diseased in mouse models of ALS, the health and integrity of apical dendrites of Betz cells in ALS patients have not been assessed. We investigated motor cortex from 11 normal control subjects with no neurologic disease, 5 fALS patients with mutations in *SOD1*, 10 sALS patients without a family history of ALS, and 6 AD patients. We find profound apical dendrite degeneration with large vacuoles in both familial and sporadic ALS patients. In contrast, Alzheimer's disease patients and normal controls retain cellular integrity in the motor cortex. These results suggest apical dendrite degeneration of Betz cells as a potential contributor to upper motor neuron pathology observed selectively in ALS.

Title: SMN functions as a chaperone for the assembly of mRNP transport complexes.

Authors: *P. G. DONLIN-ASP[1], C. FALLINI[1], M. E. MERRITT[1,2], H. C. PHAN[3,4], G. J. BASSELL[1,2,5,3], W. ROSSOLL[1,2,5];

Abstract: Spinal muscular atrophy (SMA) is a neuromuscular disease characterized by a specific degeneration of motor neurons. SMA results from a reduction in the survival of motor neuron (SMN) protein, which is ubiquitously expressed with a well characterized role in promoting the assembly of spliceosomal small nuclear ribonucleoproteins (snRNPs).
We have previously shown specific defects in the axonal localization of poly A mRNA (including *β-actin* and *Gap43*) and mRNA-binding proteins (HuD, IMP1) in axons and growth cones of SMN-deficient motor neurons. We have also reported that overexpression of both HuD and IMP1 can restore axon outgrowth and *Gap43* mRNA and protein levels in growth cones of SMA motor neurons. Our findings led us to hypothesize that SMN plays an additional critical role in the assembly of messenger ribonucleoproteins (mRNPs), and that failure to assemble RNA transport complexes leads to the reported mRNA localization defects in SMA motor neurons.

To test our hypothesis, we have established a trimolecular fluorescence complementation (TriFC) assay as a sensor for the association of mRNAs with RBPs. TriFC performs consistently in cell lines, primary fibroblasts and motor neuron cultures. In motor neurons isolated from a severe SMA mouse model, as well as primary human fibroblasts from SMA patients, we readily detect a severe defect in the assembly of complexes containing IMP1 protein and *β-actin* mRNA, with no reduction in steady state expression. Furthermore, RNA immunoprecipitation experiments also show impairments in the association of IMP1 protein with *β-actin* mRNA. Adapting a novel biochemical method for size fractionation of RNP granules over a density gradient, we observe a consistent shift of IMP1-containing mRNPs toward smaller granules in SMA human fibroblasts. In addition, we have employed super resolution microscopy to compare the size of endogenous IMP1 granules. In SMA patient derived fibroblasts, IMP1 granules are consistently reduced in their volume relative to control lines, a phenotype consistent with both our TriFC and fractionation results. Finally, we can show a defect in the association of IMP1 mRNPs with both actin filaments and microtubules in the SMA patient fibroblasts, suggesting a mechanism to explain reduced mRNA localization reported in SMA motor neurons.
In summary, our results show that SMN plays a more general role in RNP assembly beyond the canonical role in snRNP assembly. Here, we demonstrate that SMN acts as a chaperone for the formation of transport-competent RNA granules, providing a mechanism for mRNA localization defects that may contribute to the motor neuron degeneration observed in SMA.

Title: Adenovirus-induced TDP-43 and FUS aggregates in cultured neuronal and glial cells demonstrated by time-lapse imaging

Authors: *K. WATABE[1], T. ISHII[2], H. MISAWA[2];
[1]Dept. of Med. Technol. (Neuropathology), Kyorin Univ. Fac. of Hlth. Sci., Tokyo, Japan; [2]Dept. of Pharmacol., Keio Univ. Fac. of Pharm., Tokyo, Japan

Abstract: Formation of TDP-43- or FUS-positive cytoplasmic aggregates in neuronal and glial cells is one of the pathological hallmarks of amyotrophic lateral sclerosis (ALS). We have previously demonstrated that proteasome inhibition enhanced adenovirus-induced neuronal cytoplasmic aggregate formation of TDP-43 and FUS in vitro and in vivo, suggesting that impairment of protein degradation pathways accelerates formation of TDP-43 and FUS-positive aggregates in ALS. However, the relationship between the cytoplasmic aggregate formation and the cell death remains unclear. In this study, we performed time-lapse imaging analysis of neuronal and glial cells infected with adenoviruses encoding TDP-43 and FUS cDNAs under conditions of proteasome inhibition. Rat neural stem cell lines stably transfected with EGFP or Sirius under the control of tubulin beta III (TBB3p), GFAP or cyclic nucleotide phosphodiesterase (CNP) promoter were differentiated into neurons, astrocytes and oligodendrocytes, respectively, in the presence of retinoic acid. The differentiated neuronal and glial cells expressing EGFP or Sirius were then infected with adenoviruses encoding DsRed-tagged human wild type and C-terminal fragment (CTF) TDP-43 or mutant P525L FUS in the presence of proteasome inhibitor MG-132 or an adenovirus encoding shRNA for proteasome PSMC1. Time lapse imaging analysis revealed growing DsRed-positive cytoplasmic aggregates in the infected neuronal and glial cells followed by the cell collapse within 72 hours. Released cytoplasmic aggregates composed of WT and CTF TDP-43 remained insoluble in the culture media over 30 hours of the time course. These aggregates consisted of sarkosyl-insoluble granular materials and contained phosphorylated TDP-43. We are also attempting to develop time lapse imaging of cell to cell spreading of these cytoplasmic aggregates.

Title: Methylmercury exposure alters fluo-4 fluorescence in spinal cord slices of mice expressing the human Cu^{2+}/Zn^{2+} superoxide dismutase 1 (hSOD1) gene mutation

Authors: *J. M. BAILEY, Y. YUAN, W. ATCHISON;
Pharmacol. and Toxicology, Michigan State Univ., East Lansing, MI

Abstract: Mice expressing the human Cu^{2+}/Zn^{2+} superoxide dismutase 1 (hSOD1) gene mutation ($hSOD1^{G93A}$) are used to model Amyotrophic Lateral Sclerosis (ALS), as these mice reliably exhibit an ALS-like phenotype as they age. This model has been used to describe the role of gene X environment interactions in the onset and progression of ALS. Previous work has shown that the environmental neurotoxicant methylmercury (MeHg) can hasten the onset of the ALS-like phenotype in these mice, on endpoints of motor function as well as intracellular calcium homeostasis in brain stem and cerebellum. However, ALS is associated with dysfunction and death of motor neurons and the spinal cord is a target of particular interest in understanding this disease's etiology. Here, we describe the effects on intracellular calcium regulation (tracked via fluo-4 epiflorescence) following acute 20 uM MeHg exposure in spinal cord slice taken from $SOD1^{G93A}$, $SOD1^{hWT}$ and wild type mice of both sexes and two age groups (PND 21-30 "adolescent" and 2-4 months old "young adult"). Both dorsal and ventral regions of the spinal cord were prepared. As a function of exposure time, acute MeHg exposure caused a greater increase in fluo-4 fluorescence in the dorsal spinal cord tissue of $SOD1^{G93A}$ mice compared to wild type animals. Spinal cord tissue from $SOD1^{G93A}$ mice was not only generally associated with greater relative fluorescence following acute MeHg exposure, but the time to peak fluorescence was also delayed among these animals compared to wild type controls. These data suggest that MeHg interacts with the $SOD1^{G93A}$ mutation to enhance neuronal dysfunction. This likely demonstrates evidence of a gene X environment interaction relevant to the etiology of ALS and points to a relevant mechanism of action (i.e. calcium dysregulation among neurons of the spinal cord).

Title: Long-term systemic adipose-derived stem cell-conditioned medium therapy in a mouse model of amyotrophic lateral sclerosis

Authors: *C. L. WALKER[1], F. M. KENNEDY[1], C. M. E. FRY[1], A. K. IYER[1], Y. DU[2], K. MARCH[3,4], K. J. JONES[1,4];

[1]Anat. & Cell Biol., [2]Neurol., [3]Med., Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Roudebush VA Med. Ctr., Indianapolis, IN

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating progressive disease involving the loss of motor neurons (MN), resulting in paralysis and death. The superoxide dismutase 1 (SOD1) transgenic mouse model of ALS exhibits is the gold standard animal model, exhibiting similar clinical pathological progression through pre-symptomatic, symptomatic, and end stages of disease. We, and others, have observed that disease onset occurs pre-symptomatically by 47 days of age $SOD1^{G93A}$ mutant mice. Previous research indicates initial hindlimb muscle denervation, with progressive neuromuscular junction (NMJ) loss over time. Our previous data indicate systemic daily therapy of adipose-derived stem cell conditioned medium (ASC-CM), beginning at symptom onset, delayed functional progression and extended survival in $SOD1^{G93A}$ mice, suggesting a central mechanism of action. In addition, we found that daily ASC-CM therapy beginning at 35 days of age, when NMJ innervation is similar to non-diseased mice, significantly attenuated NMJ loss by day 47 in $SOD1^{G93A}$ mice. We then hypothesized that long-term systemic ASC-CM therapy could provide functional and survival benefits, potentially through both peripheral and central mechanisms beyond that observed from post-symptom onset therapy. We began treating sixteen $SOD1^{G93A}$ and sixteen wild-type (WT) mice with either daily ASC-CM or vehicle control medium at 35 days of age until day 63, followed by a twice-weekly treatment schedule until animal end stage. At this time, we also began a battery of behavioral assessments testing gait, grip endurance, tail elevation, and rearing, among other behaviors, to identify any therapeutic effects on symptom onset and progression. The study is currently underway. Based on our previous pre-symptomatic and symptomatic treatment data, we hypothesize that the systemic ASC-CM therapeutic paradigm could prevent hindlimb muscle denervation and act centrally to ameliorate functional decline and impart survival benefits in the $SOD1^{G93A}$ ALS mouse model.

Title: The functional role of AMPK activation in amyotrophic lateral sclerosis.

Authors: *Y. CHERN, Y.-J. LIU, C.-C. LEE, H. PEI;
Inst. Biomed Sci., Taipei, Taiwan

Abstract: Many major neurodegenerative disorders (including Alzheimer's disease, Huntington's disease, and amyotrophic lateral sclerosis (ALS)) with distinct clinical features are protein-misfolding diseases. Regardless the remarkable efforts devoted to the development of therapeutic intervention, no effective treatment for these degenerative diseases is currently available. ALS is a late-onset and progressive motor neuron disease with the hallmark of TDP43 inclusions in the brain and spinal cord. Most of the ALS cases are sporadic (~90%), while only ~10% are caused by mutations of ALS-associated genes (e.g., TDP-43). The prevalence of ALS in Taiwan is 1.97 cases per 100,000. The clinical presentation includes muscle weakness and impaired voluntary movement resulted from degeneration of motor neurons. In addition to the formation of TDP43 inclusions, the mislocalization of TDP43 from nucleus to cytoplasm is considered an early event of ALS, because the mislocalized TDP-43 may form pathological oligomers and inclusions, and subsequently causes degeneration of motor neurons. We have previously demonstrated that abnormal localization of two RNA binding proteins (TDP-43 and human antigen R (HuR)) was associated with elevated AMP-activated protein kinase (AMPK) activity in the motor neurons of ALS patients. Molecular and pharmacological approaches demonstrated that activation of AMPK altered the location of TDP-43 and HuR in mouse motor neurons and in a motor neuron cell line (NSC34) via phosphorylation of importin-α1. Elevation of the cAMP/PKA-dependent pathway using different reagents effectively normalized the AMPK-evoked redistribution of TDP-43, HuR, and several other substrates of importin-α1. Collectively, our findings suggest that a therapeutic strategy focusing on the proper regulation of AMPK activity in motor neurons may produce beneficial effect for patients with ALS.

Abstract: Amyotrophic lateral sclerosis (ALS) is a severe neurodegenerative disease, which affects upper and lower motor neurons, causing progressive muscle paralysis and death. The majority of ALS cases are sporadic with unknown causes, but mutations in numerous genes have been identified in familial cases, which account for approximately 10% of all ALS. Familial ALS genes include Cu, Zn, superoxide dismutase (SOD1), C9orf72, Fused in osteosarcoma (FUS), and many others. It is widely accepted that in ALS non-cell autonomous contribution from astrocytes plays a significant role in the demise of motor neurons. Mitochondrial bioenergetics abnormalities have been widely reported in cultured neurons, in patient-derived fibroblasts, and in animal models of ALS. Mitochondrial defects have also been identified in ALS mouse primary astrocytes. Furthermore, we have described abnormal intracellular calcium signaling in spinal cord astrocytes of ALS mice. However, mitochondrial bioenergetic function and intracellular calcium signaling have not yet been investigated in human ALS astrocytes. Bioenergetic abnormalities can underlie the involvement of astrocytes in ALS, since they could cause energy depletion, but also alter cell secretion processes, calcium signaling, and metabolism of glutamate, lactate, and other substrates necessary for neuronal physiology. In this study, we examined cellular bioenergetics and intracellular calcium signaling in induced pluripotent derived cells (iPSC) derived astrocytes from patients affected by sporadic and familial ALS (mutant SOD1 and FUS, C9orf72), as well as healthy controls. Mitochondrial respiration and glycolytic lactate production were assessed by Seahorse flux analysis. Mitochondrial membrane potential was determined by tetra-methyl-rhodamine-ester (TMRM) accumulation. ATP content was measured by luminometry with and without the addition of specific inhibitors of mitochondrial oxidative phosphorylation (oligomycin) or glycolysis (2-deoxyglucose). ER calcium release and dynamics were assessed by live cell imaging with cytosolic fluorescent calcium reporters (Fluo4). Differences in several bioenergetic and calcium parameters were observed between ALS and control astrocytes, but also among different forms of ALS. These results suggest that primary alterations of bioenergetics exist in ALS astrocytes, which could underlie the involvement of astrocytes in ALS pathogenesis.

Title: Hud regulation of sod1 and fus mrnas in sporadic als

Authors: M. DELL'ORCO[1,2], A. S. GARDINER[1], C. CEREDA[2], *N. PERRONE-BIZZOZERO[1];
[1]Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM; [2]Ctr. of Genomics and Post-Genomics, "C. Mondino" Natl. Inst. of Neurol. Foundation, IRCCS, Pavia, Italy

Abstract: Altered RNA metabolism due to mutations in RNA-binding proteins (RBPs) or their dysregulation has been defined as a central pathogenic mechanism in motor neuron degeneration, such as Amyotrophic Lateral Sclerosis (ALS). Neuronal ELAV proteins, in particular HuD, have been previously associated with neurodegenerative diseases (NDs) (Amadio et al., JAD, 2009; 16:409-19), and *in vitro* and *in vivo* studies demonstrated the involvement of HuR in the regulation of SOD1 (Milani et al., Neurobiol Dis, 2013; 60:51-60), FUS and TARDBP (Lu et al., J Biol Chem, 2014 ; 289:31792-8042014) mRNAs. RBP accumulation in stress granules (SGs) and processing bodies (P-bodies) is a hallmark of ALS pathology. Using human neuroblastoma SH-SY5Y cells as an *in vitro* model of ALS pathophysiology, we found that HuD co-localization with SG and P-body markers is increased after H_2O_2 treatment. By immunoprecitation, we confirmed that HuD interacts with Argonaute and GW182 proteins. Bioinformatics analysis of human SOD1, FUS and TARDBP 3'UTRs demonstrated the presence of HuD consensus binding sequences in these mRNAs (Bolognani et al., Nucleic Acids Res., 2010; 38:117-30; Wang & Tanaka, Nat Struct Biol, 2001; 8:141-5). In our cellular model, the induction of a neuronal-like phenotype by 12-O-tetradecanoyl-phorbol-13-acetate (TPA) differentiation triggers a significant increase in HuD mRNA levels and an oxidative stress-dependent overexpression of SOD1 and FUS mRNAs. Correspondingly, the overexpression of HuD in the *in vitro* cellular model leads to increased SOD1 and FUS mRNA levels. The increase in target mRNA levels is likely due to the binding of HuD to their 3'UTRs and consequent stabilization, as demonstrated by the significant reduction of SOD1 and FUS mRNAs after the overexpression of a dominant negative HuD mutant protein lacking the RNA Recognition Motif 3 (RRM3) required for target stabilization. By *in vitro* RNA immunoprecipitation (RIP) assays, we demonstrated that HuD binds and stabilizes SOD1 and FUS mRNAs leading to increased mRNA levels. By Immunohistochemistry (IHC) experiments in *post-mortem* tissues from sporadic ALS patients we found that HuD

protein levels were increased in the motor cortex compared to healthy controls. We also found increased HuD mRNA levels in the posterior frontal cortex and cerebellum from ALS patients, along with increases in SOD1 and FUS mRNAs. Uncovering HuD post-transcriptional regulation of SOD1 and FUS mRNAs and defining the potential involvement of additional intracellular pathways and trans-acting molecules will open novel perspectives for ALS research and the identification of new therapeutic targets.

Title: Arginine-rich DPRs perturb nucleocytoplasmic transport and RNA metabolism in the pathogenesis of C9orf72 ALS and FTLD

Authors: S. BOEYNAEMS, E. BOGAERT, P. VAN DAMME, W. ROBBERECHT, *L. M. VAN DEN BOSCH;
Lab. of Neurobiology, Vesalius Res. Center, VIB, Leuven, Belgium, Leuven, Belgium

Abstract: Neurodegenerative diseases are characterized by the presence of protein inclusions with a different protein content depending on the type of disease. Amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD) are no exceptions to this common theme. In most ALS and FTLD cases, the predominant species of aggregated proteins are RNA-binding proteins (RBPs). Interestingly, these proteins are both depleted from their normal nuclear localization and aggregated in the cytoplasm. This key pathological feature suggests a potential dual mechanism with both a nuclear loss of function and cytoplasmic gain of function. The aim

of this study is to get a better insight into the mechanisms underlying these specific pathological events. We focused on hexanucleotide repeat expansions in *C9orf72* which are the most common genetic cause of the disease. Unconventional translation of these repeats yields five potentially toxic dipeptide repeat proteins (DPRs). We performed a targeted genetic screen in *Drosophila* model of DPR toxicity. We only observed toxicity of arginine-rich DPRs (GR and PR) and PR toxicity could be modified by silencing importins, exportins, Ran-GTP cycle regulators, nuclear pore components and arginine methylases. These data point at a key role for nucleocytoplasmic in PR toxicity. More recently, we found additional evidence as we observed a strong overlap in the genetic modifiers of our previous PR screen and a new screen in GR flies. In general, we identified several key transport factors which are potent modifiers of both PR and GR phenotypes. Bioinformatic analyses of the cargo sets of these transport factors strongly indicate that problems in nucleocytoplasmic transport could affect processes implicated in the disease, especially centering on RNA metabolism. Moreover, these cargo sets show a striking enrichment for proteins already implicated in ALS and FTLD, suggesting that defects in nuclear transport could indeed initiate pathogenic cascades. This implies that a defective nucleocytoplasmic transport could be a prime suspect as an initiating event in ALS and FTLD pathology and it could become a new therapeutic target. In recent work we are now investigating whether arginine-rich DPRs have additional roles in the initiation of RBP pathology.

Title: Analysis and comparison of WT and mSOD1^{G93A} immune-mediated neuroprotection mechanisms in immunodeficient mice after facial nerve axotomy

Authors: *D. O. SETTER[1,2], E. M. RUNGE[1,2], N. A. MESNARD-HOAGLIN[3,4], M. M. HAULCOMB[1,2], R. J. BATKA[1,2], N. D. SCHARTZ[1], V. M. SANDERS[5], K. J. JONES[1,2]; [1]Anat. and Cell Biol., Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Res. and Develop. Services, Richard L. Roudebush VAMC, Indianapolis, IN; [3]Neurosci. Program, Loyola Univ. Med. Ctr., Maywood, IL; [4]Res. and Develop. Services, Edward Hines, Jr. VA Hosp., Hines, IL; [5]Mol. Virology, Immunol. and Med. Genet., The Ohio State Univ. Col. of Med., Columbus, OH

Abstract: When a facial nerve axotomy (FNA) is performed on recombinase activating gene-2 knockout (RAG-$2^{-/-}$) mice lacking the adaptive arm of the immune system, there is significantly greater motoneuron (MN) death relative to wild type (WT) mice. Reconstituting RAG-$2^{-/-}$ mice with whole splenocytes restores MN survival to WT levels, and further studies indicate that CD4+ T cells are specifically responsible for immune-mediated neuroprotection. In the mouse model of ALS, (mSOD1^{G93A}), there is also significantly decreased MN survival after FNA. Relevant to these findings, recent studies have found evidence for immune dysregulation in both human ALS patients and the mouse ALS model. Reconstituting RAG-$2^{-/-}$ mice with mSOD1^{G93A} whole splenocytes fails to rescue MN survival, whereas reconstitution with isolated mSOD1^{G93A} CD4+ T cells does confer neuroprotection. These results indicate that an inhibitory factor in the mSOD1^{G93A} peripheral immune system prevents CD4+ T cell-mediated neuroprotection. To characterize this inhibitory mechanism, gene expression profiles of the axotomized facial motor nucleus were gathered from the following 6 experimental groups of mice: WT, RAG-$2^{-/-}$, RAG-$2^{-/-}$ + WT whole splenocytes, RAG-$2^{-/-}$ + WT CD4+ T cells, RAG-$2^{-/-}$ + mSOD1^{G93A} whole splenocytes, and RAG-$2^{-/-}$ + mSOD1^{G93A} CD4+ T cells. Genes associated with MN regeneration, glial activation, inflammatory cytokines, and cell death pathways were examined. While immunodeficiency in the RAG-$2^{-/-}$ group did not affect the MN regeneration response or cell death pathway gene expression, both glial activation and cytokine production in the neuropil of the facial motor nucleus that surrounds the MN cell body were significantly altered. Transfer of WT whole splenocytes or WT CD4+ T cells into RAG-$2^{-/-}$ mice restored glial activation and cytokine production to WT levels. These data suggest that the mechanism of immune-mediated neuroprotection involves CD4+ T cell-mediated regulation of the microenvironment surrounding injured MN, and not the MN directly. Future studies based upon these results are expected to provide direction in the development of therapeutic strategies targeting immune-derived inhibitory factors as a new treatment approach for MN disease.

Title: Pathology and functional implications of the C9orf72 repeat expansion in ALS/FTD iPS astrocytes

Authors: *J. T. PHAM[1], J. C. GRIMA[1,2], L. HAYES[1], X. TANG[1], W. ZHOU[1], S. VIDENSKY[1], T. GENDRON[3], J. D. ROTHSTEIN[1,4];
[1]Neurol., [2]Neurosci., The Johns Hopkins Sch. of Med., Baltimore, MD; [3]Neurosci., Mayo Clin., Jacksonville, FL; [4]Brain Sci. Inst., Baltimore, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease resulting from progressive, irrevocable loss of upper and lower motor neurons as well as associated interneurons. Glial cells, especially astroglia, also play important roles in modulating disease progression by secreting neurotrophic factors as well as promoting excitotoxic and/or neuroinflammatory cellular environments. In 2010, a GGGGCC hexanucleotide repeat expansion (HRE) in the first intron of *chromosome 9 open reading frame 72* (*C9orf72*) was identified as the most common genetic cause of familial and sporadic ALS as well as also frontotemporal dementia (FTD), suggesting that the two disparate diseases may share common pathogenic mechanisms. While much of ALS and FTD research has focused on neurons, understanding of ALS and FTD pathogenesis is increasingly extending beyond neuronal death to encompass dysfunction in multiple cell types and differential cellular mechanisms, such as RNA metabolism and protein homeostasis in astroglia. We chose to investigate the astroglial contribution to c9ALS by differentiating patient fibroblast-derived induced pluripotent stem cells (iPSCs) into astroglia (iPSA). The HRE did not affect astroglial differentiation or maturation as evidenced by robust expression of astroglial markers such as GFAP, Aldh1L1, CD44, and S100β. In the presence of primary mouse cortical neurons, c9ALS iPSA also appropriately increased mRNA expression of excitatory amino acid transporter 2 (EAAT2), the principal glutamate transporter in the CNS found predominantly in astroglia, and demonstrated functional glutamate transport from the extracellular space. Total *C9orf72* transcripts were reduced in c9ALS iPSA as measured by qRT-PCR, and RNA foci containing the HRE were detected in c9ALS iPSA by RNA fluorescent in situ hybridization. The level of poly-glutamine-proline dipeptide repeats, a protein product of non-canonical translation of the HRE, was assessed in c9ALS iPSA cell lysates by immunoassay. New studies from our group and others have identified nucleocytoplasmic transport defects as fundamental to *C9orf72* pathophysiology. Ongoing studies are elucidating the composition of nuclear pore complexes and the nuclear proteome in c9ALS iPSA. Lastly, control human iPS motor neurons co-cultured with c9ALS iPSA exhibited decreased viability compared to co-culturing with control iPSA as measured by propidium iodide uptake. These

early studies suggest that *C9orf72* HRE can disrupt normal astroglial function and support of neurons, thereby contributing to c9ALS disease progression.

Hlth., Bloomington, IN; [4]Virology, Immunology, and Med. Genet., The Ohio State Univ. Col. of Med., Columbus, OH

Abstract: Locomotion analysis is a prominent method for the characterization of ALS pathology, identification of symptom onset, and surveillance of disease progression. Previous work in our laboratory has established the interdependent relationship between speed and nearly all locomotion variables. Furthermore, we also illustrated how discrepancies in speed alone are sufficient to account for statistical differences in outcome measures. We present here a large-sample, high-resolution, comprehensive, longitudinal locomotion analysis using the CatWalk XT system. To our knowledge, this is the first study that incorporates the unique speed-variable relationships as they pertain to ALS mice. Sixteen wild-type (WT) mice (B6SJLF1/J) and 24 SOD1^{G93A} mice were allowed to run on the CatWalk apparatus on alternate days, beginning at postnatal day (PND) 38 as described previously. Data acquisition began at PND 45 through end-stage at PND 150. A minimum of 3 crossings up to a maximum of 20 crossings per animal per testing day was acquired. Each crossing from an individual animal produced means for 210 variables, 106 of which were used here. Two variables were significantly different throughout the time course between SOD1 and WT: Speed and Print Area of the Front Paws. Fifteen variables were never different between SOD1 and WT. Most variables were equivalent initially

and only diverged at or after conventional symptom onset (~PND 80-90). Five variables exhibited early (i.e., pre-symptomatic) differences, while four variables displayed unusual relationships. Electromyographic studies have established subclinical neuromuscular pathology as early as PND 40, with fast-twitch muscles being particularly susceptible. Progressive decrease in motor unit number estimation (MUNE) is the primary manifestation of ALS pathology. Muscle contraction force is unchanged until >50% MUNE loss, which coincides with detectable symptom onset. Compensatory mechanisms including collateral reinnervation, increased motoneuron excitability, and increased motor unit area account for the lack of overt symptoms. This remarkable compensatory ability was evidenced in this study by the maintenance of normal locomotion characteristics until symptom onset. We hypothesize that complex alterations in a few key variables help temporarily offset underlying pathology.

Title: Early and androgen-dependent loss of neuromuscular transmission in two SBMA mouse models

Authors: *Y. XU[1], M. KATSUNO[2], H. ADACHI[3], G. SOBUE[2], M. BREEDLOVE[1], C. L. JORDAN[1];
[1]Michigan State Univ., East Lansing, MI; [2]Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [3]Univ. of Occup. and Envrn. Hlth. Sch. of Med., Fukuoka, Japan

Abstract: Spinal bulbar muscular atrophy (SBMA) is an androgen-dependent neuromuscular disease caused by CAG/glutamine tract expansion in the androgen receptor (AR). We find multiple defects in neuromuscular transmission in chronically diseased males of three different SBMA mouse models (Xu et al., J. Neurosci. 36(18):5094, 2016), but whether such defects are androgen-dependent has not been established. Thus, we examined the function of neuromuscular junctions (NMJs) in the EDL muscle from diseased transgenic (tg) females treated with testosterone (T) in the myogenic (overexpression of wild-type AR receptor exclusively in muscle) and AR97Q (global expression of human AR gene with 97 glutamines) models. We also

examined synaptic function in young, pre-symptomatic AR97Q males (33-40 days) and castrated adult AR97Q males in which motor function is normal. Diseased AR97Q and myogenic females show significant impairments in synaptic function. Presynaptically, synapses are weak with significant deficits in quantal content (QC), similar to chronically diseased tg males of these same models. Postsynaptically, fibers in diseased females are depolarized (by 15-25 mV) at rest and have end plate potentials with prolonged decay times, comparable to diseased fibers in males, suggesting comparable changes in chloride channels and acetylcholine receptors to immature states. Interestingly, control asymptomatic females show similar but milder defects. Pre-symptomatic juvenile AR97Q males also show defects in the resting membrane potential (RMP) and QC of comparable magnitude to that of chronically diseased adult AR97Q males. Several other measures of neurotransmission were less severely affected, suggesting that the growing severity of deficits critically mediates the emergence of motor dysfunction. Castration largely rescues synaptic function in behaviorally-intact AR97Q males, with a phenotype similar to asymptomatic control-treated tg females. RMP and QC were each rescued by half whereas other deficits were completely reversed. These data indicate that AR toxicity occurs well before symptom onset and raises the question of whether subclinical toxic effects of AR are androgen-dependent. Together, these data show that deficits in neuromuscular transmission that correlate with motor dysfunction are androgen-dependent. We hypothesize that the depolarized state of muscle fibers in asymptomatic SBMA mice could be a primary trigger for late-stage motor dysfunction and early presynaptic defects. Postsynaptic ion channels and ion transports that control the resting voltage of muscle fibers are likely early molecular targets of AR toxicity.

Title: Novel principle component analysis (PCA) to assess gait in chronically exercised vs unexercised mice shows both exacerbation and amelioration of the underlying phenotype the MDX mouse model for Duchenne's muscular dystrophy (DMD)

Authors: ***P. J. SWEENEY**[1], T. BRAGGE[1], A. NURMI[1], T. HEIKKINEN[1], T. AHTONIEMI[1], J. PUOLIVÄLI[1], D. J. WELLS[2];
[1]Charles River Dicovery Services, Kuopio, Finland; [2]Royal Vet. Col., London, United Kingdom

Abstract: Duchenne muscular dystrophy (DMD) is a progressive disease that is caused by X linked mutation in the dystrophin gene. In DMD patients, the lack of dystrophin causes muscle damage including necrosis, fibrosis and fat infiltration which leads to a progressive decrease in mobility and eventual death. The MDX mouse, a mutant mouse model widely used for the preclinical study of DMD, displays the dystrophin deficiency from the early age of 3 weeks and the process of muscular degeneration and regeneration occurs the age of 8 to 10 weeks. During this "critical period", the process in these mice largely mimics that of DMD boys. The symptoms in these animals are largely subclinical and not evident in traditional functional tests, such as rotarod or open field. Even with chronic exercise regimes, it has been hard to discern changes in these mice without using more advanced technologies. Therefore, typical assays/analyses in this preclinical model are post mortem histopathology of muscles as well as biochemical analysis of serum creatine kinase and occasionally MRI studies.
In our study, we subjected a total 15 MDX animals to a 3 X 30 minutes per week 9 month intensive treadmill exercise regime in an attempt to exacerbate the underlying dystrophic phenotype and compared exercised animals to another group of 15 MDX mice without exercise. As controls, in both groups there were equal numbers of wild type (WT) exercised and unexercised mice. Treadmill speeds were gradually increased up to the level of 14M/min – animals were removed according to a predefined exhaustion criteria. In addition to treadmill exercise, all animals underwent fine motor kinematic gait analysis at the 3, 6, 9 and 12 month time points using kinematic analysis that involves a novel algorithm for Principle Component Analysis (PCA) and yields almost 100 distinct gait related parameters from each mouse.
Results showed that in general exercised MDX mice had to be removed more often, and sooner, from the treadmill - especially at later time points. Interestingly, although certain gait parameters were discernibly impaired according to kinematic analysis, it was also found that some aspects of gait in chronically exercised MDX mice showed marked improvement at various time points, almost approaching wild type mice performance. This suggests that kinematic analysis allows to identify certain gait parameters distinct for the MDX model, especially since deficits with traditional functional tests were found mild or absent. Kinematic analysis may provide a tool to examine efficacy of novel therapeutics alleviating animal models of neuromuscular diseases.

Title: High field (11.7) MRI reflects cyclic changes in muscle damage in chronically exercised vs unexercised MDX model of Duchenne's muscular dystrophy and can be confirmed by novel fine motor kinematic analysis *In vivo*

Authors: P. J. SWEENEY[1], A. SHATILLO[1], A. NURMI[1], A. HARTIKAINEN[1], *T. D. WOLINSKY[2], K. LEHTIMÄKI[1], T. AHTONIEMI[1], O. KONTKANEN[1], M. V. KOPANITSA[1], J. PUOLIVÄLI[1], D. J. WELLS[3];
[1]Charles River Discovery Services, Kuopio, Finland; [2]Discovery from Charles River, Wilmington, MA; [3]Royal Vet. Col., London, United Kingdom

Abstract: Duchenne muscular dystrophy (DMD) is a progressive disease that is caused by X linked mutation in the dystrophin gene. In human DMD patients, the lack of dystrophin progressive paralysis and death eventually results from cardiac or, more commonly, respiratory complications as the primary muscle involved in respiration - the diaphragm – is also severely damaged. The MDX mouse, a mutant mouse model widely used for the preclinical study of DMD, shows underlying DMD-like pathology primarily during the period of 3 – 10 weeks after birth. During this period muscle damage, the cycling of degeneration and regeneration that results in incomplete muscle fiber development and sustained injury, is over and little further damage extends beyond this phase. We have previously shown that with a chronic exercise regime this "critical period" may be extended and muscle damage, albeit less severe, can occur at later stages and can be evidenced by subjecting the animals to examination with high field MRI. However, recent evidence from chronically exercised MDX mice in our labs show that the continued damage is transient and, in fact, the exercise regime at some time points even ameliorates the effects of dystrophin deficiency at later ages. In this study we attempted to longitudinally correlate the deficiencies in gait with the exacerbation of muscle damage as evidenced by high field MRI.
In the study we subjected a total 15 MDX and 10 WT animals to a 3 X 30 minutes per week 9 month intensive treadmill exercise regime and compared these animals to another group of 15 MDX animals and 10 WT animals that did not undergo the treadmill training regime. In both groups there were equal numbers of wild type (WT) exercised and unexercised groups. All animals were subjected to baseline MRI and again at 3months, 6 months and 9 months. The unexercised age matched groups were added post hoc for comparison and subjected to kinematic gait analysis at the same time points as the exercised groups and Principle component Analysis (PCA) was performed on all animals at similar time-points.
Results showed that in general exercised MDX mice had a higher number of hyperintensity (indicating muscle damage) than both WT mice and unexercised MDX mice. However, at certain time points the exercise regime seemed to ameliorate the effects of exercise and this can be seen both in T2 MRI and the level of hyperintensity in certain areas of hind-leg musculature as well as in coincidental kinematic gait analysis. Therefore, the use of these these non-invasive techniques in tandem can be used to better gauge the therapeutic window and the preclinical efficacy of aimed at alleviating neuromusculoskeletal disease.

Title: Genetic rescue of spinal muscular atrophy by zinc finger protein ZPR1

Authors: X. N. JIANG, S. AHMAD, *L. D. GANGWANI;
Biomed. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., El Paso, TX

Abstract: Spinal muscular atrophy (SMA) is caused by mutation of the *survival motor neuron 1* (*SMN1*) gene that result in low levels of full-length SMN produced by *SMN2* gene in humans. The zinc finger protein ZPR1 interacts with SMN and is required for accumulation of SMN in sub-nuclear bodies, including gems and Cajal bodies. Interaction of ZPR1 with SMN is disrupted in cells derived from SMA patient. SMA patients express low levels of ZPR1. ZPR1 down-regulation in mice with SMA-like disease results in increased loss of motor neurons that increases disease severity and reduces the lifespan of SMA.

We have shown previously that the *in vitro* ZPR1 overexpression increases nuclear accumulation and levels of SMN in SMA patient cells. ZPR1 corrects axonal growth defects in spinal motor neurons from SMA mice. These findings suggest that ZPR1 is a modifier of SMA disease severity. To test whether ZPR1 is a protective modifier of SMA, we examined the effect of ZPR1 overexpression in mice with SMA. To examine the effect of overexpression of ZPR1 *in vivo* on SMA phenotype, we created transgenic mice overexpressing Flag-ZPR1 protein. ZPR1 transgenic mice [*Zpr1* (+/+); tg-*Flag-Zpr1* (+)] and [*Zpr1* (+/+); tg-*Flag-Zpr1* (+/+)] breed well and live normal lifespan without any obvious phenotype. We first tested *in vivo* functionality of the recombinant Flag-ZPR1 protein by crossing transgenic mice *Zpr1-tg* with *Zpr1* (-/+) knockout mice. Transgenic expression of Flag-ZPR1 protein was able to fully complement and rescue embryonic lethality of *Zpr1* (-/-) mice and transgenic mice [*Zpr1* (-/-); *Flag-Zpr1* (+)] displayed normal phenotype.

To test whether ZPR1 overexpression will help ameliorate severity of SMA disease, we examined the effect of ZPR1 overexpression in two SMA mouse models, severe SMA [*Smn* (-/-); *SMN2* (+/+)] and SMA delta 7 [*Smn* (-/-); *SMN2* (+/+); *SMN2D7* (+/+)] models. The phenotype of littermates, including growth and survival was examined. We report that the increase in ZPR1 expression improves overall growth and motor function, decreases severity of disease, and prolongs the lifespan of SMA mice in both severe and delta 7 SMA models. These data suggest that the increase in ZPR1 levels reduces severity of disease and improves SMA phenotype.

Therefore, ZPR1 may be a protective modifier of SMA. The ZPR1 represents a new therapeutic target to reduce the severity of SMA disease.

Title: Acetylcholine receptor fragmentation is correlated with the extent of muscle fiber damage in a mouse model of muscular dystrophy

Authors: *R. MASSOPUST, W. J. THOMPSON;
Biol., Texas A&M Univ., College Station, TX

Abstract: The mouse neuromuscular junction (NMJ) is a tripartite synapse consisting of the motor axon terminal, muscle fiber, and surrounding terminal Schwann cells. The NMJ is a cholinergic synapse, which signals to an aggregate of acetylcholine receptors (AChRs) on the muscle fiber surface that resembles a “pretzel”. During the course of normal aging, AChR aggregates undergo a morphological change from pretzel-like shapes into fragmented and punctate structures. It has been proposed that these changes accrue slowly throughout the aging process. However, evidence from our lab suggests that this change is abrupt, on the time scale of days. In the *mdx* mouse model of Duchenne muscular dystrophy, AChR aggregates begin to change from continuous pretzels to fragmented structures at a much younger age than in aging wild-type (WT) mice. It is believed that these changes in *mdx* NMJs occur during a crisis period from 3 to 12 weeks of age. During this time, their muscle fibers undergo structural damage, necrosis and repair. Upon repair, *mdx* muscle fibers contain chains of central myonuclei aligned in the center of the muscle fiber. In normal, healthy muscles, myonuclei are found on the periphery of the muscle fiber, directly under the sarcolemma. Previous evidence suggests that central myonuclei in *mdx* animals remain central for at least 6 months. Central myonuclei are indicators of local damage and repair. In the present work, single muscle fibers were isolated from 2, 6, 12 and 24-week-old *mdx* and WT mice. Individual muscle fibers demonstrate two distinct morphological phenotypes. All muscle fibers with continuous AChR aggregates have central myonuclear chains running throughout less than 50% of the length of the muscle fiber. All muscle fibers with fragmented AChR aggregates have central myonuclear chains running

throughout more than 75% of the length of the muscle fiber. As central myonuclei are an indication of recent muscle fiber regeneration following damage, this suggests that a there is a damage-based threshold for AChR aggregate fragmentation.

Title: Postsynaptic participation in synapse elimination at the developing neuromuscular junction.

Authors: *I. W. SMITH[1], W. J. THOMPSON[2];
[1]Biology/Neuroscience, Inst. For Neurosci., College Station, TX; [2]Biol. / Neurosci., Texas A&M Univ., College Station, TX

Abstract: During development of mature neuromuscular synapses, the innervation of skeletal muscles is extensively remodeled: each muscle fiber transitions from receiving innervation by multiple axons at birth to a singly innervated state in the adult. Termed synapse elimination, this process of loss of redundant motor inputs has typically been characterized as an activity-dependent competition amongst the individual inputs for sole occupation of each muscle fiber endplate. Evidence from our lab indicates an “axo-centric” perspective is an oversimplified explanation for how neuromuscular synapses ultimately become singly innervated. Using light and electron microscopy to investigate mouse neuromuscular junctions (NMJs) during early postnatal development we have found evidence that terminal Schwann cells (tSCs) are capable of altering the competitive balance between inputs. Previously, we have shown how tSCs promote the elimination of inputs, acting as a to drive competition. Additionally, in a series of ongoing experiments we have observed marked differences in the ultrastructure of postsynaptic areas covered by nerve as opposed to tSCs. Our observations indicate muscle fibers undergo extensive remodeling and/or growth, evidenced by pocket-like invaginations in the muscle fiber membrane that appear to be a mechanism for postsynaptic membrane trafficking. Interestingly, pockets appear to contain acetylcholine receptors and are not observed beyond the endplate region at

birth. Moreover, within the endplate region pockets are almost exclusively located beneath areas of nerve terminal contact, suggesting a mode of reinforcement through focal expansion of synaptic contact areas. Interestingly, pockets are not distributed evenly amongst the presynaptic inputs, suggesting selective expansion beneath individual inputs. Collectively our observations and analysis indicate a role for the muscle fiber during the early stages of synaptic competition. We propose that the muscle fibers assess the relative firing patterns and levels of activity of individual inputs and respond through differential distribution of newly synthesized and recycled receptors.

Title: Interaction of age and myostatin in neuromuscular function.

Authors: D. TAVOIAN[1], W. D. ARNOLD[2], *S. DE LACALLE[3];
[1]Ohio Univ., Athens, OH; [2]Neurosci., Ohio State Univ., Columbus, OH; [3]Biomed. Sci., Heritage Col. of Osteo. Med., Athens, OH

Abstract: In our increasingly aging society, finding ways to slow and reverse loss of muscle mass (sarcopenia) and strength (dynapenia) has become an urgent task. Sarcopenia begins in mid-life and accelerates significantly by age 70. The accompanying decrease in strength leads to serious health problems from falls, poor posture, and limited muscular endurance. The causes of sarcopenia are multifactorial but nerve degeneration and a decrease in muscle fiber size play a prominent role. In the last 20 years, the muscle hypertrophy that follows constitutive deletion of the myostatin gene (MSTN) has sparked a wealth of research to investigate its role in muscle mass and strength maintenance in aging. We have tested the effects of deleting MSTN in adulthood and throughout aging in a conditional knockout mouse model. We used 24 adult female mice genetically modified to contain an inducible Cre recombinase transgene and a critical segment of MSTN (exon 3) flanked by loxP sites. At age 12 months, half of the mice were treated with doxycycline in the chow, which rendered MSTN non-functional by excising the DNA flanked by the LoxP sequences. Motor behavior, electromyographic analysis and measurements of muscle strength were collected at baseline (age 11 mo.) and after one year of treatment.
Age alone had an impact in multiple measures of motor function. Compared to baseline, 24

months-old mice showed a slight (4.5%) increase in lean mass and total weight (12.5%), impairment in rotorod performance (33% decrease), a reduction in the number of motor units (by 30%) and an increase in motor unit size (45%). When doxycycline was administered in the diet (MSTN KO), the effects of aging were ameliorated, as indicated by a more pronounced (9%) increase in lean mass, an attenuation in the impairment in rotorod performance (20%), and the slight improvement in motor unit number (a smaller reduction of 28%) and size (an increase of 26%), as well as some improvement in front grip strength (25% increase). A direct comparison of MSTN KO with littermate controls at 24 months of age also suggested a slight beneficial effect of deleting MSTN (albeit not as pronounced as has been shown in constitutive KO male mice) with better performance in motor behavior tests (rotorod) and in front limb strength tests. Our results agree with our previous studies (Williams, PLoS ONE 10(8): e0134854, 2015) reporting a sexual dimorphism in the role of MSTN, and suggest that further evaluation of the potential advantageous effects of inhibiting or counteracting the actions of MSTN in muscle must address sex differences. Ongoing work by our group is also seeking to characterize the neurological changes that we find associated with MSTN deletion.

Title: Mechanically patterned extracellular matrix improves neuromuscular junction formation *In vitro*

Authors: *C. L. WEAVER, A. VU, L. FIJANY, G. YEO, A. ENGLER;
Bioengineering, Univ. of California San Diego, La Jolla, CA

Abstract: Motorneuron diseases (MND) are progressive, debilitating disorders resulting from the loss of muscle innervation from MN degeneration. *In vitro* models of the neuromuscular junction (NMJ), the connection between MNs and muscle fibers, have been developed to isolate and examine cellular dysfunctions associated with MN diseases; however these co-culture models with myotubes and MNs have randomly oriented myotubes with immature synapses that

contract asynchronously. Mechanically patterned (MP) extracellular matrix with alternating soft and stiff stripes improve current *in vitro* NMJ models by inducing mouse myoblast durotaxis to stripes where they aligned and differentiated to form patterned myotubes. MP substrates supported increased differentiation, fusion, significantly larger acetylcholine receptor (AchR) clusters, and increased expression and localization of MuSK and Lrp4, two cell surface receptors required for NMJ formation. Primary mouse MNs cultured with patterned myotubes formed functional synapses that more faithfully recapitulate mature *in vivo* NMJs by supporting extensive neurite outgrowth with processes that co-localized with myotube AchRs. Most importantly, robust spontaneous contractions were observed, indicating that functional synapses were developing. Co-cultures containing myotubes and human embryonic stem cell-derived motorneurons expressing channelrhodopsin were optically stimulated to demonstrate NMJ functional connectivity. The mechanically patterned NMJ platform described here represents a significant improvement over current *in vitro* NMJ systems by creating a model that more accurately recapitulates *in vivo* physiology. Future work adapting the model to include MND patient-derived cells will elucide disease pathology and advance drug discovery, potentially leading to new treatments for this class of debilitating disorders.

Title: Assessment of TrkB receptor expression and function at the neuromuscular junction and sciatic nerve retrograde transport complexes in mice missing muscle-synthesized BDNF

Authors: L. A. VANOSDOL[1], R. L. DANGREMOND[1], A. M. VANDERPLOW[1], B. WILMOT[1], A. L. JUDKINS[1], *E. N. OTTEM[2];
[2]Biol., [1]Northern Michigan Univ., Marquette, MI

Abstract: Neuromuscular diseases (NMDs) are characterized by degeneration and atrophy of motoneurons and muscles they innervate. To determine the importance of muscle-synthesized BDNF to the health of the motor unit, we utilized a transgenic mouse model lacking the BDNF gene only in muscle. Assessment of pathological phenotype of mice revealed adult-onset,

progressive motoneuron pathology and muscle degeneration. We observed somal atrophy of gastrocnemius (gastroc)-associated motoneurons in 120 day-old mice lacking muscle-synthesized BDNF. Gastroc myofibers and motoneurons in transgenic animals are particularly susceptible to progressive pathology when compared to other muscle groups. At the NMJ, we observed significant fragmentation at both the presynapse and postsynapse of knockout animals. Evidence indicated transgenic mice have disrupted retrograde transport processes as phosphorylated-neurofilament-H (p-NF-H) was significantly accumulated in the presynapse NMJ of gastroc-associated NMJs. We found after sciatic nerve ligation there was a significant decrease in accumulating p-NF-H at the distal ligation site. We assessed the distribution of tyrosine receptor kinase B (TrkB), the BDNF receptor, at the NMJ of transgenic and control mice. To assess pathology of the NMJ we labeled presynaptic vesicular acetylcholine transporters, postsynaptic acetylcholine receptors, and the non-phosphorylated (inactive; TrkB) and phosphorylated (active; p-TrkB) isoforms of the TrkB receptor. Preliminary data from confocal microscopy and image analysis suggests mice missing muscle-synthesized BDNF (homozygous knockouts) have much reduced pre- and postsynaptic TrkB expression when compared to control mice or mice with reduced muscle-synthesized BDNF (heterozygous knockouts). Data suggest control and heterozygous animals have similar TrkB receptor expression at both the pre- and postsynapse of the NMJ. Presynaptic BDNF-TrkB signaling has been implicated in initiating retrograde transport, continuing studies will address whether there is a difference in expression of p-TrkB in the pre- and postsynapse of the gastroc NMJ in control and transgenic animals. We will address whether there are differences in p-TrkB inclusion in retrograde transport complexes in control and transgenic mice using a sciatic nerve ligation protocol. Because both homozygous and heterozygous mice with missing or reduced muscle-synthesized BDNF display retrograde transport deficits, but seem to display different levels of pre- and postsynaptic NMJ TrkB expression, determining the levels of p-TrkB expression in the NMJ and retrograde transport complexes is important.

Title: Increased BDNF expression in muscle slows disease in a mouse model of spinal bulbar muscular atrophy

Authors: *K. HALIEVSKI[1], M. KATSUNO[2], H. ADACHI[3], G. SOBUE[2], S. M. BREEDLOVE[1], C. L. JORDAN[1];
[1]Neurosci., Michigan State Univ., East Lansing, MI; [2]Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [3]Univ. of Occup. and Envrn. Hlth., Fukuoka, Japan

Abstract: Muscle-supplied neurotrophic factors are crucial for the normal development and maintenance of the neuromuscular system and have also been implicated in neurodegenerative disease. Notably, such factors become depleted in diseased muscles, such as in spinal bulbar muscular atrophy (SBMA), an androgen-dependent, slowly progressive neuromuscular disease that occurs in men with an expanded CAG (glutamine/Q) tract in the *androgen receptor* (*AR*) gene. Muscles in SBMA mouse models are deficient in brain-derived neurotrophic factor (BDNF) mRNA and this loss correlates with muscle weakness. To determine whether remedying this loss can ameliorate disease symptoms, we experimentally increased muscle BDNF expression in an SBMA mouse model that globally overexpresses a human AR with 97 CAG repeats. We used a floxed stop model that in presence of a muscle-specific Cre (controlled by the human skeletal actin promoter, HSA-Cre) expresses a human BDNF transgene only in skeletal muscles. Such "BDNF-muscle-overexpressors" were then crossed to the SBMA model (HSA-Cre/BDNF^{stop}lox/97Q combination referred to as "Triple"), resulting in overexpression of human BDNF only in muscles of diseased SBMA mice. Controls were 97Q mice with either the BDNF^{stop}lox or the HSA-Cre transgene, or neither, but not both ("Non-triples"), expected to express normal levels of muscle BDNF. We examined motor function (latency to hang up to 120sec) and bodyweight, and monitored disease progression from the day of onset (defined as two consecutive days of reduced hang time). Criterion for endstage was when animal hang time dropped to below 30sec. We found that increased muscle BDNF slows disease progression, doubling the time to endstage, with Triples reaching endstage ~20days after symptom onset compared to ~11 days when transgenic BDNF is lacking in diseased muscle. Age at symptom onset and maximum weight did not differ between groups. Ongoing studies ask what cellular (neurotransmission at the neuromuscular junction) and/or molecular (gene expression) underpinnings may be responsible for this improved phenotype. Understanding mechanisms muscle BDNF acts upon to slow disease progression may suggest therapeutic targets for improving motor function of men affected by SBMA.

Title: Vital imaging of aging neuromuscular junctions

Authors: *R. HASTINGS, W. J. THOMPSON;
Biol., Texas A&M Univ., College Station, TX

Abstract: Neuromuscular junctions (NMJs) are relatively stable structures that appear to change little during the majority of an animal's life. Changes do occur, however, during "old age". These changes are rapid and increase in frequency with age. The phenotype of these changes is remarkably similar to the changes that occur at NMJs present on muscle fibers that have been damaged and underwent degeneration/regeneration. Therefore, we hypothesize that the changes seen at NMJs in aging are the result of muscle fiber damage. To observe these changes, we have used repeated vital imaging to investigate NMJs in the mouse sternomastoid (STM) muscle. Mice used for vital imaging express transgenic cyan fluorescent protein (CFP) in axons and transgenic green fluorescent protein (GFP) in Schwann Cells. This allows the visualization of the axonal and glial components of each NMJ of living mice. In order to visualize the acetylcholine receptors (AChR), a non-saturating dose of α-bungarotoxin (BTX) conjugated to Alexa Fluor 555 was applied to the muscle. The mice were anesthetized using a ketamine/xylazine cocktail. A depilatory cream was used to remove the hair, and a midline incision was made along the neck of the animal to expose the STM. The mouse was secured on a metal platform in a supine position and intubated in order to control its respiration with a ventilator. A small metal stage was positioned underneath the STM and the mouse was placed under an epifluorescence microscope to be imaged. Over the course of the repeated vital imaging sessions, the majority of NMJs changed very little. There were instances, however, of drastic changes to individual NMJs that happened rapidly, i.e. between two imaging sessions. Furthermore, these changes at the NMJ were accompanied by central myonuclei underneath the endplate and smaller cross-sectional area than those whose NMJs appeared normal. Central nuclei and decreased myofiber cross-sectional area are hallmarks of muscle fibers that have undergone damage. These phenomena correlated with the drastic changes at the NMJ, and therefore we conclude that these changes are the result of the muscle fiber undergoing degeneration/regeneration.

Title: Neuromuscular acetylcholine receptor dynamics in dystrophic mice.

Authors: *S. HADDIX[1], W. J. THOMPSON[2];
[1]Inst. for Neurosci., [2]Texas A&M Univ., College Station, TX

Abstract: Duchenne muscular dystrophy (DMD) is a fatal disease that has no cure. While it is characterized as a myopathy, there are also abnormalities of the neuromuscular junction (NMJ) in animal models of DMD, which include fragmentation and expansion of the acetylcholine receptor (AChR) endplate, increased axon branching, and an increased number of terminal Schwann cells. The remodeling is likely initiated by muscle fiber necrosis and regeneration at the junction, as in muscle damage models. However, it is difficult to prove such an event causes the rearrangement in dystrophy. To investigate the events underlying the restructuring of dystrophic NMJs, we utilize a technique to visualize the dynamics of AChRs in *mdx* mice, a murine model of DMD. A low concentration of bungarotoxin (BTX) conjugated to Alexa Fluor® 555 is applied to the sternomastoid muscle of an *mdx* mouse to label junctions *in vivo*. This first dose of BTX labels AChR at the synapse, identifying the endplate morphology at the time of application. Following a 10-day recovery period, which also allows for natural myofiber degeneration and regeneration, the animal is sacrificed and labeled with BTX conjugated to a different fluorophore (Alexa Fluor® 647). We hypothesize that if a necrotic event occurs at the endplate region during the 10-day period the first color BTX will be lost or remodeled. The second color BTX will stain robustly, as receptors must be inserted into the sarcolemma for transmission to resume or as a result of the ongoing AChR turnover. In control animals the first and second BTX applications label the same population of receptors and show no difference in morphology. These we interpret to be fibers that have not undergone a necrotic event at the junction during the 10-day interval. However, in a significant number of the *mdx* synapses the first color BTX has mostly disappeared and the second color of BTX labels a fragmented endplate. This indicates that receptor turnover is higher in dystrophic muscles and corresponds to synaptic remodeling. Often the muscle fibers of these remodeled junctions contain central nuclei, a marker of myofiber regeneration. We suggest that the cause of increased receptor dynamics is necrosis and subsequent regeneration of the muscle fiber at the endplate region. The proportion of these “first color weak, second color strong” junctions is elevated and constant in *mdx* mice from 5 to 9 weeks of age. These time points were chosen as they represent the commonly cited “crisis”

period of myofiber damage in this model. Our results indicate that muscle fiber degeneration and regeneration is occurring at a consistent rate during this period and contributes to synaptic remodeling in dystrophy.

Title: Androgen receptor p160 co-activators in spinal and bulbar muscular atrophy

Authors: *J. ZENCHAK[1], J. JOHANSEN[2];
[2]Col. of Med., [1]Central Michigan Univ., Mount Pleasant, MI

Abstract: Spinal bulbar muscular atrophy (SBMA) is a neurodegenerative disorder that exhibits myopathic and neuropathic characteristics, including muscular weakness and atrophy, and lower motor neuron loss in the brainstem and spinal cord. The molecular basis of the disease is a polyglutamine (CAG) expansion in the *androgen receptor* (AR) gene, resulting in a misfolded and dysfunctional protein.
The AR protein is a major transcription factor, responsible for driving gene transcription that regulates development and maintenance of male reproductive functions and phenotype, and other sexually dimorphic processes. Coregulator proteins aid in this process by binding to AR and altering the topology of chromatin to allow or prevent transcription. Coregulators bind to the amino-terminal of AR, the site of mutation in SBMA, and their recruitment can be affected by the length of the polyQ tract in the AR. The p160 family of coactivators, which includes steroid receptor coactivators 1, 2, and 3, is well-characterized and known to interact with and enhance the activity of AR. Identifying changes in coregulator proteins associated with disease progression may offer a novel therapeutic approach to SBMA.
The AR113Q mouse is one popular model used to study SBMA. The AR113Q knock-in (KI) mouse has 113 CAG repeats inserted in the AR gene, and shows decreased motor function and survival. In AR113Q-KI SBMA mouse skeletal muscle, we examined the p160 co-activator family: steroid receptor co-activators-1, -2, and -3 (SRC-1-3). We used western blotting and immunohistochemistry to detect differences in SRC protein levels in skeletal muscle from SBMA mice. Preliminary data suggests an increase in protein expression of all of the SRC

coactivators, though this difference was only significant for SRC-2. Understanding how the AR interacts with co-regulatory proteins in diseased muscles may provide a tissue-specific therapy for SBMA.

Title: Deletion of pre-B-cell colony-enhancing factor in neurons results in motor dysfunction and paralysis of adult mice

Authors: *X. WANG[1], Q. ZHANG[1], R. BAO[1], N. ZHANG[2], S. DING[1];
[1]Univ. of Missouri Columbia Dalton Cardiovasc. Res. Ctr., Columbia, MO; [2]Dalton Cardiovasc. Res. Ctr., Columbia, MO

Abstract: Pre-B-cell colony-enhancing factor (PBEF), also known as Nicotinamide phosphoribosyl transferase (Nampt), is the rate-limiting enzyme in the salvage pathway of mammalian Nicotinamide adenine dinucleotide (NAD^+) biosynthesis through conversion of nicotinamide (NAM) to nicotinamide mononucleotide (NMN). NAD^+ is an important co-factor as well as a cosubstrate for many biochemical reactions. Our previous study showed that global deletion of PBEF using heterozygous knockout mice exacerbates neuronal death and brain damage after ischemic stroke. Here we found that inducible and neuronal specific deletion of NAMPT results in motor dysfunction and paralysis of adult mice. We generated homozygous inducible and neuron-specific PBEF conditional knockout (cKO) mice, i.e., Thy1-$Pbef^{-/-}$ cKO mice, by crossing $Pbef^{f/f}$ mice with Thy1-Cre-ERT2 mice. The deletion of neuronal PBEF in mice can be achieved by tamoxifen administration. We show that after tamoxifen administration, PBEF expression levels in Thy1-$Pbef^{-/-}$ cKO mice significantly decreased as compared to the control $Pbef^{f/f}$ mice; consistent with the role of PBEF as a rate-limiting enzyme in the NAD^+ salvage pathway, Thy1-$Pbef^{-/-}$ cKO mice exhibited significant lower levels of NAD^+ and NADPH. Moreover, conditional deletion of PBEF in neurons following tamoxifen administration resulted in progressive decrease of body weight, paralysis and died within three weeks.

Meanwhile, the cKO mice exhibited impairments in general motor ability, muscle strength, locomotor activity, motor coordination as shown by different behavioral tests. Administration of NMN, an immediate enzymatic product of PBEF in the NAD^+ biosynthesis salvage pathway, significantly delayed the onset of motor deficits, body weight reduction, paralysis and death induced by PBEF deletion in neurons in the knockout mice. Furthermore, Thy1-Pbef$^{-/-}$ mice exhibited abnormality of neuronal muscular junction. In summary, our results suggest that PBEF-mediated NAD^+ biosynthesis is essential for motor function and survival and PBEF-NAD^+ cascade might be a potential therapeutic target in motor neuron degenerative disorders.

Title: Activation of Schwann cells in a rat model of "Critical Illness Myopathy"

Authors: *Y. LEE[1], L. LARSSON[2], W. J. THOMPSON[1];
[1]Dept. of Biol., Texas A&M Univ., College Station, TX; [2]Karolinksa Institutet, Stockholm, Sweden

Abstract: Patients with “Critical Illness Myopathy” (CIM) are characterized by general paralysis of all limb and trunk muscles but have intact cognitive and sensory function. CIM is observed in intensive care unit patients who have been mechanically ventilated and immobilized for long durations and is considered a consequence of modern intensive care. The weakness is manifest in changes in the contractile proteins in muscles, but we have been investigating whether there are changes in the innervation of the muscles. The Larsson lab has developed a rat model in which normal, adult rats are anesthetized, given paralytics, and respired by mechanical ventilation. We have examined neuromuscular junctions (NMJs) in the soleus muscles of such rats paralyzed for 4 and 8 days by fluorescently staining the muscles for postsynaptic acetylcholine receptors, presynaptic nerve terminals, and Schwann cells (SCs). We find the nerve terminals begin to sprout short processes that follow SC processes extended from the synapses. The most profound changes and the initial changes we see involve extension of numerous processes from the terminal Schwann cells. Observations of NMJs in the rat CIM model are, therefore, consistent

with previous studies that show SC involvement in synaptic remodeling in cases of partial denervation or toxin-induced paralysis.

Title: Reduced corpus callosum and somatosensory pathway function in a CCUG mouse model of myotonic dystrophy type 2: an autofluorescence optical imaging and electrophysiological study

Authors: ***G. CHEN**[1], R. E. CARTER[1], J. D. CLEARY[3], J. M. MARGOLIS[2], Y.-L. KANG[2], C. M. CHAMBERLAIN[3], L. P. W. RANUM[3], T. J. EBNER[1];
[1]Dept. of Neurosci., [2]Dept. of Genetics, Cell Biol. and Develop., Univ. of Minnesota, Minneapolis, MN; [3]Dept. of Mol. Genet. & Microbiology, Univ. of Florida, Gainesville, FL

Abstract: Myotonic dystrophy (DM) is a progressive, multisystem disorder with widespread effects on skeletal muscle, heart and the central nervous system including cognitive deficits. In DM1/DM2, CUG/CCUG expansion transcripts sequester muscleblind-like proteins leading to alternative splicing abnormalities that contribute to the symptoms in multiple systems. Anatomical and diffusion tensor imaging documents widespread changes in the cerebral cortical white matter in DM patients including in the corpus callosum. In this study, we use autofluorescence imaging and electrophysiology *in vivo* to assess cerebral cortical circuit and corpus callosum function in a CCUG transgenic mouse model of DM2.
The CCUG mice express tet-responsive (TRE) (CCUG)300 transcripts under the control of the tet-transactivator (tTA) driven by the *Camk2a* promoter. These mice express CCUG expansion transcripts in the forebrain and show molecular CNS features of DM2, including RNA foci and repeat-associated non-ATG (RAN) protein expression. In anesthetized mice, the cerebral cortex was exposed bilaterally and intracortical microstimulation (ICMS) delivered with a tungsten microelectrode. Field potentials evoked by paired-pulse ICMS were recorded from the contralateral hemisphere to assess presynaptic circuit function. Paired-pulse facilitation (PPF) was completely lacking in the double-positive transgenic mice (tTA[+];TRE[+]) compared to singly transgenic control mice (tTA[+] or TRE[+]) and wild type littermates. Furthermore,

paired-pulse depression at short time intervals was accentuated in double-positive mice. Additionally, the corpus callosum conduction velocity as measured from the time of stimulation to the arrival of fiber volley was significantly slower in the double-positive mice, with a 11-18% reduction compared to control lines. Using flavoprotein imaging, we also evaluated the responses evoked in the somatosensory cortex by air puff stimulation of the contralateral C3 whisker. Compared to the control lines, the responses in the double-positive transgenic mice were reduced from 18-30%. Similar results were obtained from a second line of CCUG mice, but additional experiments are needed to determine significance.
Together the findings of compromised PPF and reduced conduction velocity demonstrate impaired corpus callosum function in the CCUG mice. Importantly, many studies of both DM1 and DM2 suggest abnormalities in the white matter tracts including the corpus callosum. The decrease in the responses to air puff stimulation evoked in the primary somatosensory cortex suggests that other major neuronal pathways are also affected in this DM2 mouse model.

Title: Zebrafish models to validate mutations in CAPN1 causing hereditary spastic paraplegia

Authors: *A. LISSOUBA[1,2], M. LIAO[1], P. DRAPEAU[1,3];
[1]CRCHUM, Montreal, QC, Canada; [2]Pathologie et biologie cellulaire, [3]Neurosciences, Univ. de Montreal, Montreal, QC, Canada

Abstract: Hereditary spastic paraplegia (HSP) is a genetically and clinically heterogeneous disease characterized by spasticity and weakness of the lower limbs with or without additional neurological symptoms, due to the degeneration of upper motor neurons. Although more than 70 genes and genetic loci have been implicated in HSP, many families remain genetically undiagnosed, suggesting that other genetic causes of HSP are still to be identified.Our collaborators performed whole-exome sequencing to analyze a total of nine affected individuals

in three families with autosomal-recessive HSP. Rare homozygous and compound-heterozygous nonsense, missense, frameshift, and splice-site mutations in *CAPN1* were identified in all affected individuals, and sequencing in additional family members confirmed the segregation of these mutations with the disease (spastic paraplegia 76 [SPG76], Ziv et al., AJHG 98:1038-46, 2016). *CAPN1* encodes calpain 1, a protease that is widely present in the CNS. Calpain 1 is involved in synaptic plasticity, synaptic restructuring, and axon maturation and maintenance. We validated calpain 1 deficiency using zebrafish. Antisense morpholino knockdown of *calpain 1a*, a *CAPN1* paralog in *Danio rerio*, resulted in several developmental defects visible at 2 days postfertilization (dpf), and a moderate to severe phenotype was exhibited by 78% of injected embryos at 5 dpf, indicating that these defects are long lasting. The *capn1a* Mo was also injected in the Islet1::GFP transgenic fish expressing GFP in the motor neurons, including the upper branchiomotor neurons. We observed a disorganization of these motor neurons in comparison to those of the control, as well as migration defects of the nV trigeminal nuclei and of the VII facial branchiomotor neuronal cell bodies. Furthermore, the vagal motor neurons had an aberrant positioning and spacing, probably because of a defect in cell motility. Additionally, reduced acetylated-tubulin staining could be observed at the level of the optic tectum and cerebellum and strikingly, clusters of acetylated tubulin could be observed in some cells in the dorsal-most part of the brain. In order to further study calpain 1a defiency in the zebrafish, we generated CRISPR/Cas9 knockout lines of both paralogs of *CAPN1*, *calpain 1a* and *calpain 1b*, and crossed these lines together to obtain a complete calpain 1 knockout in the zebrafish. The identification of mutations in *CAPN1* in HSP and the study of the resulting defiency in the zebrafish expand our understanding of the disease causes and potential mechanisms, opening the door for new therapeutic avenues by high-throughput screening.

Title: Improved motor performance in spastic cerebral palsy children after repetitive transcranial magnetic stimulation

Authors: ***D. BHATIA**[1], B. L. RAJAK[1], M. GUPTA[1], S. PAUL[1], A. MUKHERJEE[2], T. K. SINHA[1];

[1]Dept. of Biomed. Engin., North - Eastern Hill Univ., Shillong, India; [2]UDAAN-for the differently abled, Lajpat Nagar, New Delhi, India

Abstract: Spastic cerebral palsy (SCP) is a non-progressive neuromuscular disorder caused due to brain injury affecting motor ability in children during birth or at an early age. An important treatment approach being employed for SCP is standard therapy (ST) comprising of stretching, positioning and weight bearing exercises. However, recently brain stimulation techniques such as repetitive Transcranial magnetic stimulation (r-TMS) have been explored for the benefit of these patients. This study evaluated the motor performance of spastic CP children after r-TMS therapy using universally accepted scales - gross motor function measure (GMFM) and quality of upper extremity skill test (QUEST) along with EEG analysis. 30 subjects were recruited for this study, out of which 20 were spastic CP children and 10 were normal healthy children. The age, height and weight were matched in selected SCP subjects and then divided into interventional group (IG) and reference group (RG). Subjects in IG were administered 5Hz and 10Hz r-TMS therapy of 15 minutes duration followed by ST of 30 minutes daily for 20 days. The other 10 subjects in RG were provided only ST for 30 minutes daily for 20 days. Statistical analysis of pre versus post scores of both assessment scales (GMFM and QUEST) between different groups (IG and RG) showed significant improvement ($p<0.05$). The GMFM mean change was 2.2% in IG as compared to 0.4% in RG. Similarly, QUEST mean change was 2.3% in IG as compared to 0.6% in RG. Additionally, further analysis of pre and post r-TMS effect was performed using power spectrum density (PSD) analysis of electroencephalogram (EEG) signals of SCP subjects and compared with EEG of normal subjects. EEG recording was performed on all subjects using four electrodes placed on pathway known for motor control and planning, namely C3, C4, F3 and F4. The artifact-free EEG signals of fifteen (15) minutes duration was selected for spectral analysis using Fast Fourier Transformation (FFT) algorithm in MATLAB platform and PSD (power versus frequency) was plotted. The PSD revealed significant peak at frequency of 50Hz and smaller or none at 100Hz, for all healthy subjects; but in case of SCP children, peak at 100Hz were prominent and at 50Hz it was found to be quite low, prior to r-TMS. After 20 sessions of r-TMS therapy; a shift in the PSD frequency peak in SCP was observed in all SCP children at 50Hz similar to that of normal children and at 100Hz the peak was smaller in magnitude. The result of this study demonstrates that r-TMS combined with ST enhances motor ability in SCP children over ST alone in limited number of sessions by stimulating the motor neurons of the brain as evident from the PSD of EEG signal post r-TMS.

Title: Establishment of TDP-43 cryptic exon as a new ante-mortem functional biomarker for Inclusion Body Myositis

Authors: *K. E. BRAUNSTEIN[1], J. P. LING[1], T. E. LLOYD[2], P. C. WONG[1];
[1]Div. Neuropathology, Dept. of Pathology, [2]Dept. of Neurol., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Inclusion body myositis (IBM) is the most common acquired myopathy occurring in adults aged older than 50 years. Abnormal cytoplasmic accumulations of TDP-43, a heterogenous ribonucleoprotein first linked to ALS and FTD, have been also consistently described in myofibers in cases of IBM. We previously reported that TDP-43 represses nonconserved cryptic exons, a critical role that is compromised in ALS and FTD. We hypothesized that such loss of TDP-43 function could underlie degeneration of skeletal muscle in cases of IBM exhibiting TDP-43 pathology. Using RNA-sequencing analysis, we show in myoblast cell culture lacking TDP-43 the incorporation of nonconserved cryptic exons within a series of RNA targets that are flanked by UG-rich elements. Using reverse transcription-polymerase chain reaction analysis, we further reveal the presence of cryptic exons in IBM myofibers exhibiting mislocalization of TDP-43, but not in those of control cases. Thus, these results establish TDP-43 cryptic exon as a novel functional ante-mortem biomarker for the diagnosis of IBM, information that will be critical for assessing target engagement and following efficacy of therapeutic strategy in clinical trials.

Title: High-throughput automated time-lapse imaging of neuron degeneration within a live animal using robotic microscopy

Authors: *J. LINSLEY[1,2], S. FINKBEINER[1,2];
[1]GIND, Gladstone Inst., San Francisco, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Understanding the cellular changes that destine a neuron to live or to die is a fundamental challenge to understanding neurodegenerative disease. Robotic microscopy, an imaging platform that uses automated identification and tracking of millions of individual neurons over set time intervals provides the ability to quantitatively relate intermediate changes within a neuron to it's fate. Yet, while robotic microscopy facilitates longitudinal single cell analysis of neurons in culture, it has not yet been adapted for use in intact tissue, limiting the ability to study neurodegenerative diseases that have cell non-autonomous phenotypes. Taking advantage of the ability to perform time lapse imaging on immobilized zebrafish larvae, we have created a high-throughput, time-lapse, confocal imaging platform combined with automated image analysis software for single cell analysis of genetically defined subsets of neurons within larvae. To demonstrate this technology, genetically encoded nitroreductase was selectively expressed in sensory neurons or motor neurons, and time-lapse imaging was performed before and after exposure to the prodrug Metronidazole. We believe this technology will be easily adaptable to current zebrafish models of neurodegenerative disease, providing both longitudinal single cell analysis as well as a potential drug screen platform.

Abstract: Introduction: This study is aimed at finding means of reducing the increasing incidents of neurological conditions caused by cassava's cyanide poisoning. The studied legend, Manihot Esculenta (Cassava) is a major staple food in Africa, high in Carbohydrates and contains Linamarin (cyanogenic glycoside) which causes Cerebellar Ataxia, Tropical Ataxic Neuropathy and konzo paralytic conditions among the consumers. Netfussion is our innovated device that extracts this toxic cyanide from the raw or poorly processed manihot esculenta (Cassava) and serves as a therapeutic for reducing human systemic and tuber raw food cyanide. Method: 80 known consumers (20 per group) were selected as control and Netfussion test groups. Divided into four groups namely Control (Non net fussed),and three Net fussed test groups; Raw, Fermented & Dry. All groups were neurologically diagnosed & showed acute cyanide poisoning signs of Stomachaches,diarrhea,vomiting,irregular blood pressure,rapid pulse & respiration,headache,twitching,convulsion,mental confusion,etc and differential symptoms of cerebellar ataxia, tropical ataxic neuropathy or Konzo paralysis respectively which affirmed the cyanogenic glycoside poisoning, clinically. Test: Netfussion was employed to extract the Linamarin (cyanogenic glycoside) from the raw cassava tuber, water fermented grade (Fufu), and the dried granule (Gari) before consumption..All groups were subjected to their drug prescriptions, physical therapy and net fussed meals daily except the Control mixed group that were not netfussed. 90 days per batch study was recorded, though still ongoing. Result:Netfussion processed cassava meals administered three groups,(Raw, Fermented and Dry) showed significant improvements more than the non net fussed Control mixed group. Within the net fussed test groups, the Fermented and Dry groups showed excellent improvements more than the raw group. Conclusion: Combination of medical, physical therapies and the novel netfussion toxic cyanide extracting device can reduce the incidents of cerebellar ataxia, tropical ataxic neuropathy and konzo neurological disorders in Africa. This advises against the consumption of poorly processed & raw cassava,and also shows that Netfussion mechanism of extracting bitter cassava's content of Linamarin (cyanogenic glycoside) is very effective and efficient in producing cyanide free & safe cassava meals.

Title: Aggregation of the disease-causing mutants of cysteine string protein-alpha via Fe-S cluster binding

Authors: *N. NASERI[1], B. ERGEL[1], Q. HUANG[2], R. HUANG[2], G. A. PETSKO[1], M. SHARMA[1];
[1]Neurosci., Weill Cornell Med. Col., New York City, NY; [2]Cornell Univ., Ithaca, NY

Abstract: Disease-causing point mutations in cysteine string protein-α (CSPα) lead to aggregation of the protein in adult onset neuronal ceroid lipofuscinosis (ANCL), a lysosomal storage disease that accompanies neurodegeneration. However, the mechanism of aggregate formation remains unclear. Here we show that the cysteine-string region of CSPα, which is normally palmitoylated, lacks efficient palmitoylation in ANCL mutants, allowing oligomerization via Fe-S cluster interaction. In primary mouse neurons, oligomers of mutant CSPα incorporate wild-type CSPα molecules, suggesting a dominant-negative mechanism for ANCL pathogenesis. This aggregation is significantly rescued by pharmacologically chelating iron in primary neurons.

Politecnico Nacional, Mexico city, Mexico; [7]Patologìa Exptl., Inst. Nacional de Neurologìa y Neurocirugìa, Mexico city, Mexico

Abstract: Background. Muscular dystrophies are genetic disorders in which muscle strength is progressively lost with replacement of muscle tissue by fibroadipose tissue. Dysferlinopathies are underdiagnosed muscular disorders caused by mutations in dysferlin encoding gene. Three main phenotypes have been reported: Miyoshi Myopathy (MM); Limb Girdle Muscular Dystrophy type 2B (LGMD 2B), and Distal Myopathy with Anterior Tibial onset (DMAT), among other clinical variants. It is the second most frequent cause of muscular dystrophy in different parts of the world including Mexico. Whole Blood Flow Cytometry (WBFC) has been proposed as a new specific, suitable, and fast alternative for dysferlinopathies prior to molecular diagnosis. This work aimed to make a quantitative analysis of the expression of dysferlin in peripheral blood monocytes (PBM) by calculating the Mean Fluorescence Intensity (MFI) by flow cytometry. **Objective.** To establish a simplified algorithm based on likelihood ratios of dysferlin MIF to allow us to classify individuals with a clinical suspicion of dysferlinopathy prior genetic analysis. **Material and Methods.** We obtained blood samples from 183 healthy individuals and 29 patients diagnosed with dysferlinopathy on the basis of clinical study and skeletal muscle immunofluorescence. PBM were doubled immunolabeled using anti-dysferlin and anti-CD14 monoclonal antibodies. Samples were run on a FACSCalibur™ Flow Cytometer, and analyzed by FlowJo software. We screened cDNA for *DYSF* gene mutations. The relative quantity of dysferlin was expressed as MFI. Performance of WBFC diagnostic test was assessed by calculating likelihood ratios at different MFI cut-off points **Results.** We reported quantitative levels of dysferlin in CD14+ PBM of healthy individuals and compared these with the levels expressed in patients with dysferlinopathy. We established a simplified algorithm based on likelihood ratios that allowed us to classify individuals with a clinical suspicion of the disease into four groups. We found 4 mutations in the *DYSF* gene that were reported previously in our population and two novel mutations. **Conclusion.** The algorithm established give us a range of diagnostic probability a) to guide the physician in applying molecular confirmation by sequencing the *DYSF* gene, b) to distinguish primary dysferlin deficiency from a secondary decrease in other muscular dystrophies and c) to be able to conduct clinical re-evaluation of a case that is not a dysferlinopathy.

Title: Translational profiling of motor neurons in two mouse models of Charcot-Marie-Tooth disease Type 2D

Authors: *E. L. SPAULDING[1,2], R. W. BURGESS[1];
[1]The Jackson Lab., Bar Harbor, ME; [2]Grad. Sch. of Biomed. Sci. and Engineering, Univ. of Maine, Orono, ME

Abstract: Charcot-Marie-Tooth disease (CMT) is a collection of debilitating peripheral neuropathies caused by mutations in over 80 genes. The heterogeneity of the disease, as well as the technical challenge of studying the mammalian peripheral axon *in vivo*, both contribute to the lack of a cure. Dominant mutations in glycyl tRNA synthetase (*GARS*), cause an axonal form of the disease, Charcot-Marie-Tooth Type 2D (CMT2D). How mutations in *GARS* cause CMT2D is unclear, but a toxic gain-of-function is suspected. We are using an *in vivo*, cell type- and compartment-specific approach to profile translation in motor neurons of two mouse models of CMT2D. Impaired translation has recently emerged as a potential gain-of-function mechanism based on work with *Drosophila* models of CMT2D. Because five other tRNA synthetases are also linked to CMT, impaired translation is an attractive disease mechanism to test in a mammalian system. To profile translation in motor neurons we are using two *in vivo*, cell type-specific techniques; non-canonical amino acid-tagging (NCAT) provides the location, identity, and quantity of newly translated proteins, and ribosome-tagging catalogs ribosome-associated RNA. We are separately profiling motor neuron cell bodies from the spinal cord and axons from the sciatic nerve, providing additional cell compartment-specificity. Although local translation in adult, mammalian axons is not established, our preliminary data show that ribosomes are present and associated with mRNA in motor axons of the sciatic nerve. Local translation in axons also occurs during regeneration after injury and our initial studies using NCAT suggest that CMT2D motor axons show a regenerative phenotype. Therefore, we are also profiling regenerating wild-type motor neurons after sciatic nerve crush for comparison against mutant *Gars* samples. Our approach will create translational profiles of CMT2D, healthy wild-type, and regenerating wild-type motor neuron cell bodies and axons. These data will uncover new motor neuron biology that can be used for future study of other peripheral neuropathies or motor neuron diseases. In addition, our study will help to elucidate the disease mechanism of CMT2D and possibly other tRNA synthetase-linked forms of peripheral neuropathy.

Title: Progranulin overexpression attenuates TDP-43^{A315T} mediated neurodegeneration

Authors: **S. BEEL**[1], S. HERDEWYN[2], L. VAN DEN BOSCH[1], W. ROBBERECHT[1], *P. VAN DAMME[2,1];
[1]Lab. of Neurobiology, KU Leuven, Vesalius Res. Center, VIB, Leuven, Belgium; [2]Neurol. Department, UZ Leuven, Leuven, Belgium

Abstract: TAR DNA binding protein 43 (TDP-43) positive inclusions are the main pathological hallmark of both amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). Up to 40% of the patients with FTLD show a familial history for neurodegenerative disease, but only in very rare cases a mutation in the *tardbp* gene can be identified. Much more frequent are mutations in *progranulin* that explain approximately 20% of familial FTLD patients. Interestingly, these patients have neuronal ubiquitin positive inclusions that are most of the time also TDP-43 positive. In total, about 50% of all FTLD patients show similar TPD-43 pathology. While mutations in the *tardbp* gene explain only 3 - 5% of familial ALS cases, a loss of nuclear TDP-43 and cytoplasmic TDP-43 positive aggregates are found in the upper and lower motor neurons and glial cells of most ALS patients. Modeling this TDP-43 pathology in rodents has been a great challenge over the years. Several knockout and (mutant) overexpression models have been generated, but the first mouse model that expresses a mutant human TDP-43 (A315T) protein under control of the mouse prion protein (Prp) promoter has been studied the most. We and others have observed that these Prp-TDP43^{A315T} mice die a sudden death due to gastrointestinal complications. We recently showed that upon prevention of this intestinal obstruction, Prp-TDP43^{A315T} mice show a progressive neurodegenerative phenotype. In the present study, we investigated whether the overexpression of human progranulin (hPGRN) could attenuate their neurodegenerative phenotype. To this end, we crossed the Prp-TDP43^{A315T} mice with hPGRN overexpressing mice and compared them to Prp-TDP43^{A315T} and non-transgenic mice that were all put on the easy to digest gel food diet to prevent intestinal obstructions. Follow up analysis showed that hPGRN overexpression significantly increases the survival and disease duration in Prp-TDP43^{A315T} mice. On a pathological level, we could also find an

increased number of large upper motor neuron axons in the lateral horn of the spinal cord of TDP-43^{A315T}xhPGRN mice compared to TDP-43^{A315T} littermate controls. These findings suggest an important role of hPGRN in attenuating the toxic effect of mutant TDP-43 overexpression in mice. The mechanism by which hPGRN mediates these effects still needs to be elucidated and will help us gain insight in the interplay between TDP-43 and PGRN.

Title: Decrease of rate dependent depression of H-reflex in newborns with muscle hypertonia after antenatal hypoxia-ischemia in rabbit cerebral palsy model

Authors: *A. DROBYSHEVSKY[1], K. QUINLAN[2];
[1]Pediatrics, Northshore Univ. Hlth. Syst. Res. Inst., Evanston, IL; [2]Physiol., Northwestern Univ., Chicago, IL

Abstract: Newborn rabbit kits after global antenatal hypoxic-ischemic (H-I) injury exhibit motor deficits similar to human infants with cerebral palsy, including muscle hypertonia. Loss of supraspinal presynaptic inhibition has been implicated as a mechanism leading to the development of hypertonia and spasticity in cerebral palsy. We hypothesized that a decrease of descending corticospinal motor projections, observed in this rabbit model, will affect the rate dependent depression (RDD) of H-reflex as a measure of supraspinal inhibitory control. The secondary objective was to examine developmental changes in H-reflex during postnatal maturation. H-reflex was elicited in lightly anesthetized P1, P5, P11, P18 and adult rabbits using needle electrodes for stimulation and thin wire electrodes placed in m. flexor carpi radialis in forelimbs and m. gastrocnemius in hind limbs for recording. In some experiments H-reflex was measured on exposed nerve preparation with subsequent nerve cutting to confirm the origin of H-wave. RDD was measured as a ratio of H-wave magnitudes in control and test stimuli pairs, presented every 10 sec with 5, 2, 1, 0.5, 0.15, 0.08, 0.03 sec inter-stimulus intervals (ISI). In addition, maxH/maxM amplitude ratio was measured by varying stimulation amplitude. Newborns of naïve control and rabbit dams that underwent global fetal H-I at E25 for 40 min

were used. We were able to elicit H-reflex 85% in forelimbs and 65% hind limbs at P1, and in almost all kits at later ages. The magnitude of the test pulse decreased from 82% to 53% to 21%, at 5 ,0.5, 0.03 sec ISI respectively. There was no significant difference in RDD during postnatal development between P1 and P11 in either forelimb or hind limbs. There was also no significant difference in RDD between forelimbs and hind limbs at corresponding ages. Significant reduction of RDD was found in hypertonic kits after H-I, both in fore- and hind limbs at P1 and P11, at 0.3, 0.15.008 sec ISI: Significant increase in hypertonic kits in maxH/maxM from 0.24 to 0.42 was found only in hind limbs at P1 but not at P11.We conclude that the significant reduction of RDD in hypertonic kits suggests a decreased supraspinal inhibitory control that might be mediated by the loss of descending motor projections after fetal H-I. An increase of maxH/maxM may indicate that stronger afferent synaptic connection is retained in hypertonic kits due to delayed arrival of corticospinal projections. Subsequent decrease of maxH/maxM at later ages may indicate continued degeneration of the spinal circuit in hypertonic kits.

Title: Serotonin sensitivity of spinal motor neurons from hypoxia-ischemia rabbit model of cerebral palsy

Authors: *K. A. QUINLAN[1], A. DROBYSHEVSKY[2];
[1]Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Northshore Univ. Hlth. Syst., Evanston, IL

Abstract: Spinal motor neurons show profoundly increased excitability in the presence of 5HT. This excitability has been shown in previously published studies to underlie muscle spasms after spinal cord injury. More recently, an increased presence of serotonin in the spinal cord has been shown in the rabbit hypoxia-ischemia (H-I) model of cerebral palsy as well. Increased hypertonicity of the limb muscles was correlated with increases in serotonin immuno-positive fibers and serotonin concentration (determined by HPLC). Blocking serotonin receptors with intrathecal methysergide *in vivo* was shown to decrease the muscle stiffness of the rabbit kits affected by H-I. However, changes in gene expression levels of 5HT2 receptors and the 5HT

transporter suggest H-I affected spinal cords could be less responsive to serotonin. Thus, this work aimed to determine whether spinal motor neurons are equally responsive to serotonin (specifically 5HT2 receptor agonists) in control and H-I affected rabbit kits. Spinal motoneurons were targeted for whole cell patch clamp in transverse spinal cord slices from control (sham operated and unaffected kits) and H-I affected rabbit kits between birth and 5 days of age. Lumbar motor neurons from H-I affected kits have higher input resistance (suggestive of smaller cell size), a larger amplitude after-spike after hyperpolarization (AHP), and a smaller current amplitude at firing onset (I-on) than the lumbar motor neurons of control rabbits. Motor neurons respond to bath perfusion of 0.3 uM alpha-methyl 5HT (a 5HT2 receptor agonist) and 10 uM citalopram (a selective serotonin reuptake inhibitor) with an increase in input resistance, a reduction of I-on and an increased AHP duration. Our preliminary results show H-I affected motor neurons are less responsive to 5HT2 receptor activation than controls. However, since these properties (input resistance, I-on and AHP) are all altered in the baseline measurements of control vs H-I motor neurons, this suggests H-I motor neurons are influenced by higher basal levels of serotonin. Thus lumbar motor neurons from H-I affected rabbits show baseline properties that align with increased serotonergic tone. In conclusion, lumbar motoneurons from H-I affected rabbits show baseline properties that align with increased serotonergic tone, and are less responsive to exogenous 5HT2 agonist application. Future work will verify current results and test sensitivity of H-I affected motoneurons to inhibition of serotonergic receptors.

Title: Inositol polyphosphate multikinase is a regulator of transsulfuration pathway

Authors: *R. TYAGI, S. H. SNYDER, B. D. PAUL;
The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Inositol polyphosphate multikinase (IPMK) is one of the members of inositol phosphate kinase family that generates inositol polyphosphates. IPMK possesses inositol phosphate kinase (IP3-kinase) as well as phosphatidylinositol kinase (PI3-kinase) activities. IPMK is a pleiotropic protein and non-catalytically regulates mammalian target of rapamycin

complex 1 (mTORC1), serum response factor, p300, and tumor suppressor protein p53. We report that IPMK regulates expression of cystathionine γ- lyase (CSE) and 3-mercaptopyruvate sulfurtransferase (3-MST), enzymes involved in Hydrogen sulfide production. Protein levels of CSE and MST are increased in IPMK null fibroblasts as compared to wild type fibroblast cells. Regulation of CSE and MST is independent of catalytic activity of IPMK. IPMK regulates CSE expression at the transcriptional level. Since cystathionine β-synthase (CBS) is expressed at relatively lower levels as compare to CSE in fibroblasts, CSE is the major source of cysteine generation from cystathionine in mouse fibroblasts. Lysates prepared from IPMK null fibroblasts produced more cysteine as compared to wild type cells. Hydrogen sulfide levels are also increased in IPMK null fibroblasts. Expression of CSE is inducible upon condition such as lipopolysaccharides (LPS), and inflammation mediated by tumor necrosis factor α (TNF-α). We propose that IPMK acts as a repressor of CSE expression.

Title: Investigating the function of TLDc proteins in the oxidative stress response and neurodegeneration

Authors: ***P. L. OLIVER**, M. J. FINELLI, K. X. LIU, Y. WU, K. E. DAVIES;
Univ. of Oxford, Oxford, United Kingdom

Abstract: Oxidative stress is a pathological feature of many neurological disorders; therefore, utilizing proteins that are protective against such cellular insults is a potentially valuable therapeutic approach. Oxidation resistance 1 (OXR1) has been shown previously to be critical for oxidative stress resistance in neuronal cells; deletion of this gene causes neurodegeneration in mice, yet conversely, overexpression of OXR1 is protective in cellular and mouse models of amyotrophic lateral sclerosis (ALS). Interestingly, specific isoforms of OXR1 are located to the mitochondrial membrane; however, the molecular function of this protein is unclear. OXR1 contains the Tre2/Bub2/Cdc16 (TBC), lysin motif (LysM), domain catalytic (TLDc) domain, a

motif present in a family of proteins including TBC1 domain family member 24 (TBC1D24), a protein mutated in a range of disorders characterized by epilepsy, hearing loss, and neurodegeneration. The TLDc domain is highly conserved across species, although the structure-function relationship is unknown. To understand the role of this domain in the stress response, we have carried out systematic analysis of all mammalian TLDc domain-containing proteins, investigating their expression and neuroprotective properties in parallel. In addition, we have performed a detailed structural and functional study of this domain in which we identified key residues required for its activity. Our data demonstrate that the integrity of the TLDc domain is essential for conferring neuroprotection, an important step in understanding the functional significance of all TLDc domain-containing proteins in the cellular stress response and disease. We are currently investigating novel interactors common to all TLDc domain-containing proteins to understand how they regulate oxidative stress.

Title: N-Acetyl-L-Cysteine attenuates Porphyromonas gingivalis-induced inflammatory response and cell death in murine brain endothelial cells

Authors: *V. CHAROENSAENSUK[1], K.-L. OU[1,2,3], L.-Y. YANG[4];
[1]Sch. of Dentistry, Col. of Oral Med., [2]Res. Ctr. for Biomed. Devices and Prototyping Production, [3]Res. Ctr. for Biomed. Implants and Microsurgery Devices, Taipei Med. Univ., Taipei, Taiwan; [4]Sch. of Medicine, Col. of Med., China Med. Univ., Taichung, Taiwan

Abstract: Several epidemiologic studies have reported that *Porphyromonas gingivalis* (*P.gingivalis*), a major pathogen of periodontal diseases, increases the risk of having cardiovascular and cerebrovascular diseases including stroke. However, the cellular and molecular mechanisms underlying the *P.gingivalis*-induced inflammatory response as well as death of endothelial cells and the relation between the periodontal diseases and the cerebrovascular diseases remain poorly understood. In this study, we investigated the effect of *P.gingivalis* infection on the inflammatory response and cell death in murine brain endothelial cells. Live *P.gingivalis* of different multiplicity of infection (MOI) was used to infect bEnd.3 mouse brain endothelial cells for 90 minutes. Twenty-four hours after the infection, cell viability

was assessed by MTT assay and Trypan Blue Dye staining. Nuclear condensation of cells was also examined by DAPI staining and the cytokine expression of cells was evaluated by Western Blot analysis. In separate experiments, bEnd.3 cells were pretreated with N-Acetyl-L-Cysteine (NAC), an antioxidant, at different concentrations for 2 hours before the *P.gingivalis* infection. Our results indicated that live *P.gingivalis* caused the death of bEnd.3 cells in an MOI-dependent manner. The DAPI staining experiment showed that brain endothelial cells after *P.gingivalis* infection underwent apoptotic cell death, manifested by the nuclear condensation following DAPI staining. *P.gingivalis* infection induced an increased expression of interleukin-1 beta (IL-1β) in an MOI-dependent manner. Pre-treatment with NAC significantly attenuated *P.gingivalis*-induced cell death, which was accompanied by the decreased expression of IL-1β. Our findings demonstrate that *P.gingivalis* causes cell death and promotes the expression of IL-1β in murine brain endothelial cells. Furthermore, antioxidant NAC attenuates the *P.gingivalis*-induced cell death and expression of IL-1β, strongly suggesting that *P.gingivalis* causes the inflammatory response and cell death through an oxidative stress pathway.

Title: Sevoflurane-induced changes in gene expression in developing monkey brain

Authors: ***F. LIU**, T. A. PATTERSON, M. G. PAULE, W. SLIKKER, Jr., C. WANG;
Natl. Ctr. For Toxicological Research/FDA, Jefferson, AR

Abstract: Sevoflurane, a volatile anesthetic, is frequently used during general anesthesia. However, its safety in pediatric use is of growing concern. The present study evaluated whether prolonged exposure of infant monkeys to a clinical concentration of sevoflurane is associated with any adverse effects on the developing brain using DNA microarray analysis. Infant monkeys were exposed to 2.5% sevoflurane (a concentration which produces anesthesia) for 9 hours. Afterwards, brain frontal cortex was collected and RNA was extracted from the tissue. Gene expression profiling was performed using the Agilent M. Mulatta (Rhesus) Oligo Microarray platform containing 43,663 probes. The gene expression data from 4 sevoflurane-exposed and 4 control monkeys were analyzed using GeneSpring GX with quantile

normalization. Using the inclusion criteria of greater than a 1.5 fold-change in expression (either up or down) and a *p*-value<0.05, 576 differentially expressed genes (DEGs) were identified: 303 genes were up-regulated and 273 genes were down-regulated in the sevoflurane-exposed monkey brains. These genes were loaded into an Ingenuity Pathway Analysis database for pathway, disease and biological function, and network analyses. The results indicated that the DEGs contributed significantly to nervous system development and functions; neurological diseases; cell death and survival; and cell cycling. Moreover, a considerable number of DEGs were associated with networks of lipid metabolism, molecular transport and small molecule biochemistry. Findings from the microarray analysis have provided evidence to further evaluate the mechanisms that underlie sevoflurane-induced neural damage during development (Supported by NCTR/FDA and CDER/FDA).

Title: Participation of MAPK signaling pathway in a model of neuronal degeneration in rat striatal

Authors: *R. A. SANTANA MARTINEZ[1], D. BARRERA OVIEDO[2], P. D. MALDONADO JIMÉNEZ[1];
[1]Natl. Inst. of Neurol. and Neurosurg., Mexico, Mexico; [2]Pharmacol., Facultad de Medicina, Mexico City, UNAM, Mexico

Abstract: Quinolinic acid (QUIN) is an endogenous metabolite from kynurenine pathway, which acts as a competitive agonist on NMDAr and its intrastriatal administration to rats has been used to reproduce some biochemical, behavioral and morphological alterations similar to those observed in some chronic-degenerative disorders. QUIN induces selective neuronal death on medium spiny neurons in the striatum, which has been related to an oxidative microenvironment. It has been checked that alterations of oxidative stress-depended signaling pathway are related with the physiopathology of some brain diseases. Oxidative stress activates in some cases MAPK signaling to further the survival cell, but also the activation of the same

pathway, promotes cell death. MAPK activation must be finely regulated in time and intensity, but its study in vivo is scarce. MAPK activation- dependent survival cell has been related to suitable levels of neurotrophic, whose post-mortem deficit has been associated to death cell in the striatum. In this study, we evaluate the participation of MAPK activation in the cell death in the striatum induced with QUIN. Animals were intrastriatally infused with QUIN (30, 60, 120 and 240 nmol/µl). Right striatum was dissected at 2 h, 24 h and 7 days after QUIN injection. MAPK levels were detected by western blot and IHC. Histological analysis was done by H&E and FJ-B at 7 days after QUIN injection. Motor evaluation was done 6 days after operation. In all experiments SSI was used as vehicle in the control group. We found that QUIN (120 and 240 nmol/µl) significantly increased the activation of pathways related to death cell (p-JNK y p-p38) at 7 days. Also, QUIN decreased the activation of pathways that promote survival cell (p-ERK1/2). The sustained activation of p-JNK with QUIN 120 nmol from 2 h to 7 days could be involved in the onset of morphological alterations observed up to 7 days. Moreover, cell death in the striatum could also be due to decreased levels of BDNF, which regulates the function of adult neurons. The decrease of preserved cells may be the cause of the deficit in motor evaluation with higher doses with QUIN. These data suggest that activation of MAPK related to cellular death could be participating in the mechanism of damage of QUIN in the striatal cells of rats.

Title: NADPH oxidase-2 and inflammasomes after traumatic brain injury

Authors: *M. W. MA[1,3], J. WANG[1,3], K. M. DHANDAPANI[2,3], D. W. BRANN[1,3]; [1]Neurosci. and Regenerative Med., [2]Neurosurg., Med. Col. of Georgia - Augusta Univ., Augusta, GA; [3]Charlie Norwood VA Med. Ctr., Augusta, GA

Abstract: Traumatic brain injury (TBI) is the leading cause of death in young adults and contributes to nearly a third of all injury related deaths. Oxidative stress and inflammation both play key roles in the pathology following TBI. The membrane enzyme NADPH oxidase (NOX) is a major contributor to the oxidative stress, and inflammasomes have been linked to the development of inflammatory events following brain injury. Though NOX inhibition reduces injury severity post-TBI, its protective mechanism is still unclear. Our current study evaluates the role of the major NOX isoform, NOX2, in inflammasome activation after TBI. Wild type and NOX2 knockout mice underwent focal TBI. The expression of Nod-like receptor 3 (NLRP3), apoptosis-associated speck-like protein containing a CARD (ASC), and inflammasome products cleaved caspase-1 and interleukin-1β (IL-1β) were assessed in the cerebral cortex at various time points after TBI. We found that ASC protein expression increased significantly at 4 days post-TBI in the WT mice. This increased ASC expression was attenuated in NOX2 KO mice and with NOX2 inhibitor (apocynin) treatment. Furthermore, ASC and IL-1β mRNA expression was also significantly reduced in the NOX2 KO mice as compared to WT mice. Immunostaining of injured WT mice also showed increased cleaved caspase-1 and NLRP3 expression, which was attenuated in NOX2 KO mice. These results suggest a key role for NOX2-dependent oxidative stress in the induction of inflammasomes after TBI.

Title: Effect of diferuloylmethane on egg-laying behaviour in hydrogen peroxide-exposed *Caenorhabditis elegans*

Authors: M. MENDOZA-MAGAÑA, M. MALDONADO-RUBIO, M. GALLEGOS-SAUCEDO, S. NERY-FLORES, A. CASTILLO-ROMERO, M. RAMIREZ-HERRERA, G. CAMARGO, *L. HERNANDEZ;
CUCS-Universidad de Guadalajara, Guadalajara, Mexico

Abstract: Background. High levels of reactive oxygen species (ROS) produces Oxidative stress (OS) which cause injuries in cell components (lipids, proteins and DNA). Thus, the OS has been associated with several diseases, including neurodegenerative and psychological diseases. Particularly, depression and anxiety disorders, linked to Serotonin and Dopamine levels, could

be associated with OS. It has been proposed that the damage associated with ROS, might be improved by interventions that increase resistance to OS. The use of naturally occurring substances, such as vitamins, phenols and essential oils, might be a cost-effective option. In this sense, a useful approach could be the phytochemical Diferuloylmethane (DFM), a polyphenolic compound with well documented antioxidant properties against certain reactive oxygen species such as hydroxyl groups, peroxides and superoxide radicals. Several studies in relation to oxidative stress have been conducted in the nematode *Caenorhabditis elegans* (*C. elegans*). The *C. elegans* is one of the simplest organisms with a nervous system that performs many functions featured by the nervous systems of more complex organisms and often is used as a model to help understand the basic mechanisms which complex behaviours are built. Particularly, *C. elegans* has the components of the serotonergic and dopaminergic systems and their activity can be studied through the stereotyped egg-laying behavior. Additionally, the *C. elegans* possess cellular and molecular mechanisms of oxidative stress response similar to those existing in humans. **Objective.** We investigated the effect of hydrogen peroxide on Serotoninergic and Dopaminergic system through egg-laying behavior, and we evaluated if this noxious effect could be counteracted by DFM. **Methodology:** WT (Bristol N2) strain of *C. elegans*, adult age synchronized and cultured in NMG-agar plates seeded with E. coli OP50, were used in this study. They were transferred to 12-well plates and were exposed to different concentrations of H_2O_2. Then, worms were relocated to Agar-NMG plates with food, and after 1 hour, the eggs laid were counted in each group of worms. This protocol was repeated by adding DFM as antioxidant. **Preliminary Results and Conclusion:** H_2O_2 exposure decreased the egg-laying in C. elegans, so probably the oxidative damage by H_2O_2 caused a dysfunction of serotonergic activity. For its part, DFM partially reverted the damage caused by the H_2O_2 exposure. These results suggest that DFM, at least in part, protected against damage oxidative induced to neurotransmission systems involved in *C. elegans* egg-laying, mainly the serotonergic pathway.

Title: Crispr/Cas9 knockout demonstrates a key role for Bid as a molecular link between paradigms of ferroptosis and mitochondrial death pathways in neuronal cells

Authors: *A. JELINEK, S. NEITEMEIER, L. HOFFMANN, G. GANJAM, C. CULMSEE; Inst. of Pharmacol. and Clin. Pharm., Philipps-University of Marburg, Marburg, Germany

Abstract: Targeted genome engineering by CRISPR/Cas9 is an evolving tool for generating specific knockout cell lines by DNA cleavage and introduction of indel mutations. In this study, we exploited this tool to generate a Bid (BH3-interacting domain death agonist) knockout cell line in neuronal HT-22 cells. Bid determines regulated cell death in paradigms of oxidative glutamate toxicity (oxytosis) in neurons, where its activation and mitochondrial translocation mediates mitochondrial damage, subsequent release of Apoptosis inducing factor (AIF) and cell death. In the present study we generated a Bid CRISPR/Cas9-knockout cell line to elucidate the potential role of Bid in a model of ferroptosis in HT-22 cells. Ferroptosis has recently been characterized as an iron-dependent form of oxidative stress induced cell death and involves cystine/glutamate antiporter (X_c^-) inhibition, impairment of GpX4 (glutathione peroxidase 4) activity and subsequently increased lipid peroxidation. Until today, however, the key mechanisms mediating cell death as a consequence of ROS accumulation and potential involvement of mitochondrial death pathways in paradigms of ferroptosis remain to be investigated.

We induced ferroptosis with erastin in wild-type cells and analyzed the effects of the established inhibitors ferrostatin-1, liproxstatin-1 and the Bid inhibitor BI-6c9 on paradigms of mitochondrial parameters compared to the effects in Bid-knockout cells. BI-6c9 inhibited erastin-induced morphological changes and also prevented cell death. Similar protective effects were achieved in a concentration-dependent manner with ferrostatin-1 and liproxstatin-1. FACS analysis demonstrated that the applied inhibitors abolished lipid peroxide formation and reduced mitochondrial ROS production in conditions of erastin-induced ferroptosis and glutamate-induced oxytosis. Confocal imaging of dsRed-Bid and mito-GFP transfected cells further demonstrated the inhibitory effect of both, BI-6c9 and ferrostatin-1 on Bid translocation to the mitochondria in this model system. Investigating the CRISPR/Cas9-Bid-knockout HT-22 cell line revealed that Bid knockout prevented lipid peroxidation and the impaired mitochondrial respiration as well as mitochondrial ROS formation and loss of mitochondrial membrane potential, and cell death upon X_c^--inhibition by erastin.

In conclusion, the present study exposes the mitochondrial transactivation of Bid as a key molecular link between oxidative stress and mitochondrial pathology in the model of ferroptosis considerably resembling major characteristics of cell death in paradigms of oxytosis in neuronal cells.

Univ., Taipei, Taiwan; [7]Bioinformatics and Biosignal Transduction, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: The accumulation of reactive oxygen species (ROS) is associated with several diseases such as neurodegenerative disorders, traumatic brain injury and stroke. For this reason, reducing the accumulation of ROS in neurons is crucial in the treatment of those diseases. This study aimed to investigate the neuro-protective functions of sigma-1 receptor (Sig-1R), a chaperon residing at the endoplasmic reticulum, and the zinc finger 179 (Znf179), a brain protein whose function is mostly unknown. We established the model in which the ROS accumulation was triggered by hydrogen peroxide (H_2O_2) and the resultant apoptosis signaling pathway initiated by H_2O_2 was also verified. We found that the Sig-1R agonists, dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS), greatly reduced the activation of apoptotic pathways. By performing protein-protein interaction assays and shRNA knock-down of Sig-1R, we identified that the Znf179 is a downstream target of Sig-1R. Further, overexpression of Znf179 produced a neuroprotective effect just like that caused by DHEA and likewise being mediated the antioxidant mechanism. Henceforth, we examined the amount of peroxiredoxin 3 (Prx3) and superoxide dismutase 2 (SOD2) in the hippocampi of wild-type and Znf179 knockout mice, and found that both enzymes are reduced in the knockout when compared to wild-type mice. In conclusion, this study demonstrated a novel role of Znf179 as a downstream mediator of the neuro-protective action of Sig-1R against neurodegenerative and neuro-traumatic diseases.

Title: Evaluation of the Nrf2 activation in a no canonical pathway. Participation of DPP3 protein

Authors: *C. A. SILVA[1], P. D. MALDONADO[2];
[1]Natl. Inst. of Neurol. and Neurosurg., Mexico City, Mexico; [2]Patología Vascular Cerebral, Inst. Nacional de Neurología y Neurocirugía, Mexico, Mexico

Abstract: The transcription factor Nrf2 is the master regulator of the cellular antioxidant responses and the cells counteract the oxidative stress by activation of Nrf2. The canonical pathway of Nrf2 activation involves the oxidation of the some Keap1 cysteins residues (protein that negative regulates Nrf2 by retains Nrf2 in the cytoplasm), phosphorylation of serine 40 in Nrf2, subsequent dissociation of the complex Keap1-Nrf2 and the Nrf2 translocation to the nucleus. However, a not canonical pathway has been reported in vitro recently. This pathway involves the disruption of Keap1-Nrf2 complex by direct interaction of some proteins with Keap1 or Nrf2, like p62, DPP3, p21 and others; however, there have been few studies *in vivo*. It has been reported that quinolinic acid (QUIN) is a selective agonist of NMDAr is capable to induce an oxidative/nitrosative state in the cell, so its intrastriatal administration has been used as an excitotoxic/pro-oxidant model to study both events. Unexpectedly, we found that QUIN administration increase the Nrf2 activation 30 min after to injury without increase of ROS production. In this work we propose to evaluate the effect of different doses of QUIN on Nrf2/Keap1 interaction, and study the participation of some proteins DPP3 and p62 on this interaction, in the rat striatum in an in vivo model. We administrated 1 μL of isotonic saline or QUIN (15, 30, 60, 120 and 240 nmol) in the right striatum of male Wistar rats (260-300 g) and then we sacrificed the animals at 30 min after injection. The Nrf2, Keap1, p62 and DPP3 levels was measured by western blot, the oxidative stress level was evaluated by the GSH/GSSG ratio finally we evaluated the Keap1 and DPP3 protein interaction by IP. The total amount of p62 and DPP3 proteins shows no change with all doses of QUIN, whereas total Keap1 increased 30 min after the QUIN administration in a dose-response manner. The GSH/GSSG ratio showed not changes with all doses of QUIN however the interaction of Keap1 and DPP3 increases in a dose-response manner. These results suggest that at 30 min, the activation of Nrf2 could be associated with the Keap1-Nrf2 disruption by DPP3 and oxidative stress independent.

Title: Manganese induced toxicity can be attenuated by VIP in NE 4C cell line

Authors: *T. DAGCI[1], G. ARMAGAN[2], S. BORA[3], A. ERDOGAN[3];
[1]Ege Univ. Sch. of Med. Physiol. Dept., Izmir, Turkey; [2]Dept. of Biochemistry, Fac. of Pharm., [3]Dept. of Physiology, Sch. of Med., Ege Univ., Izmir, Turkey

Abstract: Vasoactive intestinal peptide (VIP), a peptide neurotransmitter released by GABAergic interneurons in the dentate gyrus, has a role in modulating neural stem/progenitor cells. VIP has beneficial effects in murine models of inflammatory diseases including septic shock, rheumatoid arthritis, multiple sclerosis and Crohn's disease. Manganese (Mn) is an essential metal in the organism. It has many roles in metabolic processes in the biological system. Increased concentration of Manganese in the brain is known to be associated with excitotoxicity and neuroinflammation.
The aim of this study was to examine the effects of VIP against manganese toxicity in NE-4C cell line. Neural stem cells are considered to be an appropriate study model to assess toxic effects of various agents since they are cells present in both developing nervous systems and also in the adult brain. The cytotoxicity was measured by lactate dehydrogenase assay and apoptotic/antiapoptotic protein levels were analyzed using Western Blot techniques following treatments.
In this study, significant reduction in LDH release was observed following VIP treatments when compared with Mn-treated cells. Similarly, proapoptotic protein bax and ROS production significantly decreased in cells after incubation with VIP in the presence of Mn ($p<0.001$). However, an increase in bcl-2 levels that was not statistically significant was observed in the group that was treated with Mn and VIP. Our study provides the evidence that VIP may exert protective effects via modulating oxidative stress in Mn induced neurodegeneration in NE-4C cells. The assessment of the impact of potential neuroprotective compounds against Mn toxicity would be important for novel drug discovery.

Title: Genetic loss of CYLD exerts neuroprotective effects against RIP-1 mediated necroptosis *In vitro* and after experimental traumatic brain injury

Authors: *N. A. TERPOLILLI[1,2], G. K. GANJAM[3], S. DIEMERT[3], I. EISENBACH[3], L. HOFFMANN[3], C. REUTHER[3], N. PLESNILA[2], C. CULMSEE[3];
[1]Univ. of Munich, Dept. of Neurosurg., Munich, Germany; [2]Inst. for Stroke and Dementia Res., Univ. of Munich, Munich, Germany; [3]Inst. für Klinische Pharmakologie und Klinische Pharmazie, Philipps-Universitaet, Marburg, Germany

Abstract: Background
The tumor suppressor deubiquitinase CYLD is as a key regulator of NF-kB activity, a transcription factor that promotes neuronal survival after brain injury. In addition, CYLD was recently linked to pathways of death receptor-mediated necroptosis, a form of programmed cell death. In the present study we sought investigated the role of CYLD in a model of glutamate-induced oxidative damage *in vitro* and in an model of experimental traumatic brain injury (TBI) *in-vivo*.
Results
CYLD depletion enhances receptor interacting protein 1 (RIP1)-ubiquitination after induction of oxidative stress in HT 22-cells and primary cultured neurons thereby preventing the formation of the RIP1-RIP3 necroptosome formation. mitochondrial damage andcell death. In vivo, genetic loss of CYLD significantly attenuated secondary lesion expansion and intracranial hypertension 24h after trauma. Brain water content was significantly reduced by 39% in the traumatized hemisphere of CYLD knock-out animals as compared to wild type littermates at this time point. 7 days after trauma lesion volume was reduced by trend in CYLD transgenic mice, neurological outcome, however, was not altered.
Summary and conclusion
Our results suggest that CYLD is a mediator of RIP1/RIP3-dependent necroptosis in paradigms of oxidative stress, acting upstream of mitochondrial demise. The present findings imply that detrimental CYLD activation occurs independently of death receptor stimulation thus suggesting a novel pathway of CYLD-dependent necroptosis triggered by oxidative stress. As genetic loss of CYLD resulted in a significant reduction of posttraumatic brain damage, CYLD dependent RIB1/RIP3 dependent necroptosis seems to play an important role after TBI; CYLD may therefore represent a novel target for the development of neuroprotective strategies applicable in acute brain trauma.

Abstract: Copper is a heavy metal and an integral component of various enzymes. It is necessary for some biological functions and mitochondrial respiration; however, excess copper is neurotoxic and has been implicated in neurodegenerative diseases as Alzheimer. This metal has consequences in cellular state, for example modifies the cellular redox environment which in turn, influences various cellular functions. On another hand, tryptophan degradation through kynurenine pathway (KP) is also modulated by the redox environment and some KP metabolites possess redox properties as L-kynurenine (L-KYN), kynurenic acid (KYNA) and 3-hydroxykynurenine (3-HK) which are produced by indolamine 2-3 dioxigenasa (IDO), kinurenine aminotransferase (KAT) and kynurenine 3-monoxygenase (KMO), respectively. The imbalance in the production of these kynurenines is related with aging and some pathologies. The aim of this study was to evaluate the effect of copper on IDO, KAT and KMO activities and its correlation with oxidative stress parameters. To accomplish these objectives, we first evaluated copper toxicity (0-500 uM) through MTT reduction, reactive oxidative species (ROS) production, lipid peroxidation (LP) and cell death on rat cortex slices. Then, IDO, KAT and KMO activities were evaluated in rat cortex slices after 2h of incubation with copper (0-500 uM). Our results showed that $CuSO_4$ decreased MTT reduction in a concentration-dependent manner, increased ROS, LP and cell death. After 2 h of incubation, $CuSO_4$ drastically abolished IDO activity, and KAT activity also was reduced; while increased KMO activity. Our data suggest that copper affects redox balance and alters KP metabolism, which is very significant in diseases with common factors as copper, KP metabolites and oxidative damage.

Title: Pro-inflammatory and oxidative stress mechanisms elicited by Aβ in astrocytic/glial cells: their impact for the integrity of the neurovascular unit

Authors: *A. A. ROSTAGNO, S. COCKLIN, J. GHISO;
New York Univ. Sch. of Med., New York, NY

Abstract: Vascular deposition of amyloid (cerebral amyloid angiopathy, CAA) is an almost universal feature in Alzheimer's disease and the primary cause of cerebral haemorrhage in early onset familial cases bearing specific mutations in the Aβ peptide. CAA narrows vessel lumen and changes vessel architecture, impairing cerebral blood flow and generating hypoxic/ischemic conditions that negatively impact in the metabolic regulation and function of the neurovascular unit. In this line, current findings highlight a previously unrecognized functional and pathogenic synergy between neurons, glia and vascular cells, providing a new framework to reevaluate how alterations in cerebral blood vessels contribute to the neuronal dysfunction. The complexity of the cellular mechanisms elicited by amyloid in astrocytic/glial cells as well as their relationship to the induction of pro-inflammatory conditions capable of affecting microvessel function/permeability remain to be fully elucidated. We aimed to provide insight into the compromised molecular pathways and identify potential new targets for therapeutic intervention. Astrocytic/glial cells were challenged with wild-type Aβ and the AβE22Q Dutch vasculotropic variant associated with cerebrovascular deposition and a hemorrhagic clinical phenotype. A combination of FACs-analyzed bead arrays, ELISA, zymography, and confocal studies were employed to evaluate the production of pro-inflammatory cytokines, activation of MMPs, and ROS generation whereas the vitamin-E analog Trolox was tested for prevention/amelioration of these detrimental cellular pathways. Oligomeric Aβ triggered elevated production of the pro-inflammatory mediators IL-6, IL-8, and IFN-γ, enhanced activation of MMP-2, exacerbated ROS production, and cell death. In all cases, challenge with AβE22Q translated into a more pronounced response, in agreement with the high oligomerization tendency of the variant and the

aggressiveness and early onset of the clinical phenotype. Trolox not only inhibited ROS production and MMP-2 activation, but also preserved cellular integrity and viability, highlighting the primary role of ROS in the initiation of amyloid-induced cell death pathways. Our data emphasizes the detrimental role of astrocyte/glia-initiated Aβ-mediated pro-inflammatory pathways and suggests that targeting oxidative stress is a potential complementary therapeutic strategy to preserve the integrity of the neurovascular unit.

Title: Anti-oxidant effects of Curcumin following spinal cord injury in rats

Authors: Y. A. ABDULLAH, S. A. EL SAYED, S. W. AZIZ, *A. A. ABDELLATIF; Biology, SSE, American Univ. in Cairo, New Cairo, Egypt

Abstract: Spinal Cord Injury (SCI) is considered a major challenge to healthcare systems. Primary mechanical injury initiates a "cascade of biological events" which constitutes the secondary injury which contributes to neurological damage and dysfunction. Lipid peroxidation is a critical process in the pathogenesis of secondary damage following SCI. In the process of lipid peroxidation, reactive oxygen species scavenge electrons from lipids. This process causes great damage to the cells as lipids are a main component of the plasma membranes, and therefore results in extensive cell damage.
Curcuma longa commonly known as Turmeric is a spice widely used in India in Ayurvedic medicine as a treatment for inflammatory conditions. The main primary active constituent of the plant is curcumin which gives it its characteristic yellow color. Curcumin has been studied for multiple potential medical uses such as, anti-cancer, antioxidant, antibacterial and anti-inflammatory (Aggrawal, 2007).
The aim of this work is to explore the antioxidant activities of Curcumin and its therapeutic potential in reducing oxidative stress in SCI model in rats.
Material & Methods: All experiments were performed in accordance with the NIH guidelines for the care and use of laboratory animals. Adult female Sprague-Dawly rats weighing approx. 150 grams were divided into the following groups: normal, sham control receiving only skin and

muscle incision with no injury to the cord tissue, an injury group that received right side hemi-section of the spinal cord at T 9-10 level, and treatment groups receiving SCI at T 9-10 level followed by the treatment with Curcumin either orally mixed with food or locally at the injury site or systemic injection of increasing doses of 50-300 mg/kg.
Total Antioxidant Capacity (TAC) & Malondialdehyde (MDA) were estimated in the cord tissue at 1 and 2 weeks post injury.
Results: Treatment with Curcumin showed a dose dependent increase in the Total Antioxidant Capacity (TAC) as well as reduction in Malondialdehyde (MDA) activity in the treatment groups when compared with control groups.

Title: An expanded palette of redox-sensitive fluorescent proteins with enhanced sensitivity and brightness

Authors: *B. CAMPBELL, C. LIU, G. PETSKO;
Neurosci., Weill Cornell Med. Col., New York, NY

Abstract: Oxidative stress is a ubiquitous and chronic pathological feature of neurodegenerative diseases (NDDs), but the technology available for visualizing this process is limited. Redox-sensitive fluorescent proteins (roFPs) are the most promising tools available for quantitative, long-term, and compartment-specific reporting of the intracellular redox state. However, after more than a decade since their inception, they are still restricted primarily to the green emission channel and exhibit poor photostability and low brightness. To advance this technology, we used rational and semi-random mutagenesis to produce novel cyan, green, and yellow redox sensors that surpass the capabilities of roGFP, the current gold standard. Our genetically encoded biosensors display the largest dynamic range yet reported for a roFP and exhibit enhanced maturation, brightness, and photostability. Because they are ratiometric by excitation, they can be used for quantitative analysis in living cells independent of probe expression levels, illumination intensity, and bleaching. We are currently developing orange and red variants to complement this palette, and are using these sensors to investigate the role of mitochondrial dysfunction in NDDs using multiplex imaging.

Title: Effect of pyrophosphate thiamine on the nerve conduction speed in patients with diabetic polyneuropathy

Authors: *I. IBARRA VALDOVINOS[1], R. G. RESENDIZ GUTIERREZ[1], B. UGALDE VILLANUEVA[1], J. C. SOLIS SAINZ[1], P. GARCIA SOLIS[1], M. RAMOS GOMEZ[2], L. S. GALLARDO VIDAL[3], H. L. HERNANDEZ-MONTIEL[1];
[1]Facultad de Medicina, [2]Facultad de Quimica, Univ. Autonoma De Queretaro, Santiago de Querétaro, Mexico; [3]Medicina familiar, Inst. Mexicano del Seguro Social, Santiago de Querétaro, Mexico

Abstract: Diabetic polyneuropathy pathophysiology is multifactorial and largely caused by the alteration of metabolic pathways that compromise the structural and functional integrity of peripheral nerves. These metabolic pathways include glycosylation of proteins with accumulation of advanced glycosylation products, sorbitol and hexosamines pathways, and protein kinase C. Chronic hyperglycemia increases the production of superoxide radicals, causing tissue damage. Although different drugs have been employed to inhibit pathways involved in this damage, a true benefit for this pathology has not been shown. Therefore, a good control of blood glycose is still a key factor to prevent or delay tissue damage. This work aims to evaluate the use of thiamine pyrophosphate to prevent the damage associated to diabetic polyneuropathy. Thiamine pyrophosphate belongs to a new group of powerful therapeutic agents that activate the enzyme transketolase, thus decreasing the activation of pathophysiologic metabolical pathways. The studied population will be adult patients between (30 to 60 years of age) with type 2 diabetes mellitus (5 to 10 years of evolution) with a diagnosis of diabetic polyneuropathy in lower limbs clinically determined by The Michigan Neuropathy Screening Instrument. Our hypothesis is that thiamine pyrophosphate will improve the nerve conduction velocity (NCV) by improving metabolic glycemic control as well as oxidative balance. Thus, the NCV in the same patient before the treatment will be its own control. Only patients treated with oral hypoglycemic agents that agree to participate in the project. This project has been approved by the Committee of Bioethics of the Autonomous University of Queretaro, and follows the guidelines of Helsinki. Patients will be assessed before and after the treatment by monitoring blood glycose, thiamine pyrophosphate, thiamine, fructosamine, insulin, glycosylated hemoglobin, C-peptide, endogenous antioxidant enzymes (SOD, CAT and GSH), pro-inflammatory cytokines and NCV in lower limbs. NCV will be analyzed with the international Kimura standards, by determining the change for each patient before and after treatment; thus using each subject as its own control.

Title: Effect of an endogenous interferon inducer and a promoter of energetic metabolism on the viability of a islets of langerhans hepatic portal graft in a murine model of type 1 diabetes mellitus: a new approach to neurodegeneration?

Authors: *B. UGALDE VILLANUEVA[1], I. IBARRA VALDOVINOS[1], R. G. RESÉNDIZ GUTIÉRREZ[1], E. A. LÓPEZ ARVIZU[1], M. D. ABURTO FERNÁNDEZ[1], M. RAMOS GÓMEZ[2], H. L. HERNÁNDEZ MONTIEL[3];
[1]Facultad de Medicina, [2]Facultad de Química, [3]Investigación Biomédica, Facultad de Medicina, Univ. Autónoma De Querétaro, Querétaro, Mexico

Abstract: Type 1 diabetes mellitus (T1D) is a metabolic disease caused by an autoimmune reaction that destroys the pancreatic beta cells, gradually decreasing the ability to produce insulin, leading to the development of hyperglycemia. It is estimated that in 2015, around the world 542,000 children under 15 were suffering from T1D, and it is estimated an incidence of 86,000 new cases per year. In Mexico, the reported incidence up to 2010 was 6.2%, and according to the International Diabetes Federation, in our country around 13,500 children under 15 were suffering T1D in 2015. T1D treatment is based on exogenous insulin administration; however, glycemic control is often difficult due to the constant dose adjustment based on weight, making it difficult to prevent chronic complications. This has led to the constant search for new treatments to afford a better control of glycemia. One of the most promising alternatives is the graft of islets of Langerhans. This approach is used in humans, and patients have achieved independence of exogenous insulin administration for up to 5 years. However, the use of these techniques have some technical limitations as the process of islet isolation, insufficient amount of islets available for grafting, the adverse effect on the use of immunosuppressive agents and gradual loss of function as well as destruction of grafted islets, all of which limit their efficiency. In this project we will analyze the beneficial effect on the functionality of the islets of Langerhans graft by using thiamine pyrophosphate as a promoter of energetic metabolism, and an inducer of endogenous interferon in a model of T1D induced with streptozotocin (STZ). The graft will be applied through the portal hepatic vein, and our hypothesis is that the treatment will induce an improvement in the glycemic metabolic control and in the graft survival. The graft of islets will be obtained from non-treated rats through a Ficoll separation column, and the islets will be grafted into diabetic rats via hepatic portal vein. In order to confirm the induction of diabetes, glycose and C-peptide will be measured in STZ-treated rats before grafting. To determine the degree of functionality of the islets of Langerhans graft, glycose, C-peptide, antioxidant enzymes (CAT, SOD, GSH) and a histological and immunohistochemical evaluations will be performed. The use of adjuvant treatments could have a future impact on the use of grafted islets in the cerebral ventricular system in models of neurodegeneration such as Alzheimer's disease to determine the effect of insulin central administration.

Abstract: Metabolic syndrome (MS) has showed an increased incidence in Mexican adult population, positioning itself as a serious health problem. According to the International Diabetes Federation (IDF), affects at least a quarter of the world's population. In Mexico, according to the latest National Health and Nutrition Survey of 2012 (ENSANUT), the prevalence of MS was 45%. At present, it is considered that insulin resistance is perceived like the main cause of MS pathophysiology, which is related to the progression and development of subsequent metabolic diseases. Other related factors are obesity, hypertension, hyperglycemia and dyslipidemia. At a cellular level, it has been shown that chronic low-grade inflammation and oxidative stress participate as risk factors in the development of MS, diabetes and several neurodegenerative disorders. This has highlighted the relationship between MS and neurodegenerative disorders, especially implicating hipoinsulinemia and insulin resistance within the nervous system. Conditions such as Alzheimer's disease, Parkinson's disease and depression have been shown to share pathophysiological disturbances with MS. Considering the increase in MS prevalence, this relationship implies a parallel increase in the number of new cases of neurodegenerative diseases. The aim of this project is to determine the presence of risk factors for neurodegenerative diseases in adult patients with MS (according to NCEP ATP III criteria), in addition to the measurement of anthropometric assessment, proinflammatory cytokines (TNF-alpha, IL-6) and endogenous antioxidant enzymes (CAT, SOD and GSH). This project will be developed according to the guidelines of the Bioethics Committee of our University and the Helsinki declaration. Our purpose is to develop a neurodegenerative disease risk profile in the MS population.

Title: Quinolinic acid toxicity involves mitochondrial dysfunction as an independent manner of NMDA receptor activation in astrocytes primary cultures

Authors: *J. G. REYES OCAMPO[1], A. SALAZAR-RAMIRO[2], D. GONZÁLEZ-ESQUIVEL[3], B. PINEDA[2], C. RIOS[3], V. PÉREZ-DE LA CRUZ[3];
[2]Neuroinmunología, [3]Neuroquímica, [1]Inst. Nacional de Neurología y Neurocirugía, Mexico, D.F., Mexico

Abstract: Quinolinic acid (QUIN), a neuroactive metabolite of the kynurenine pathway, is normally present in nanomolar concentrations in human brain and cerebrospinal fluid (CSF) and is often implicated in the pathogenesis of a variety of human neurological diseases. QUIN is an agonist of NMDA receptor and is able to produce oxidative stress leading to cell death. The aim of this study was to evaluate whether the mitochondrial dysfunction induced by QUIN was depending of ROS production or NMDA receptor activation. We evaluated ROS levels, mitochondrial membrane potential and cellular function in astrocytes primary culture exposed to QUIN (100 μM) and/or MK-801 (1mM). QUIN induced intracellular ROS production in a time- and concentration dependent manner in astrocytes cultures. The pre-incubation with MK-801 abolished the ROS production induced by QUIN. QUIN decreases both mitochondrial membrane potential, evaluated by JC-1, and mitochondrial function evaluated by MTT reduction. However, MK-801 does not have any effect on these parameters. Considering the results obtained in astrocytes primary cultures, we evaluated the effect of QUIN on succinate dehydrogenase (SDH) activity on isolated mitochondria from different brain regions. After 1 h of incubation, QUIN (100 and 500 μM) decreased almost 50% of SDH activity in mitochondria from all regions. Our data showed that QUIN affects SDH activity, which can be related with the mitochondrial dysfunction observed in astrocytes and it is independent of NMDA receptor activation. All these evidence suggests that mitochondrion is an important target of QUIN toxicity and could be that

QUIN has a transport mechanism by which enter into cell and directly interacts with the mitochondrion.

Abstract: Mitochondrial dysfunction and protein aggregation have been suggested as major contributors to midbrain dopaminergic (DA) neuron degeneration in Parkinson's disease, but the underlying mechanism remains largely unknown. In this study, we investigated a novel gene expression program controlled by DA neuron-specific transcription factor Foxa2 in regulating mitochondrial oxidative stress and protein degradation. In a mouse genetic model of Parkinson's disease, we found that loss of Foxa2 transcription factor activity contributes to DA neuron degeneration and mitochondria functional impairment. To further investigate intracellular functions modulated by Foxa2 in DA neurons, we performed ChIP-Seq analysis using induced pluripotent stem cell (iPSC)-derived DA neurons and identified novel targets of Foxa2 transcriptional regulation in mature DA neurons. Our ChIP-seq study revealed a novel gene expression program that regulates mitochondrial reactive oxygen species (ROS) production, autolysosome formation, lysosome biogenesis, and ubiquitin-mediated protein degradation. These findings suggested a critical role of Foxa2 in regulating mitochondrial function and protein degradation, two of the most critical pathways associated with the pathogenesis of Parkinson's disease.

Title: Neuron releases α-synuclein during hypoxia causes neuroinflammation and exacerbate neurodegeneration through Mac1/NOX2 pathway.

Authors: ***V. JAIN**[1], S. B. SINGH[2];
[2]Neurobio., [1]Defence Inst. of Physiol. and Allied Sci., North Delhi, India

Abstract: Cellular responses to hypoxia can be acute or chronic. Acute responses mainly depend on oxygen-sensitive ion channels, whereas chronic responses rely on the transcription factors, which up-regulate the expression of enzymes, transporters, and growth factors. Chronic hypoxia known to causes neuronal cell death in mixed neuronal culture but the role of glial cells in this pathology is still an enigma. To better understand the pathogenic mechanisms and role of glial cell, we evaluated neuronal damage, calcium homeostasis, neuroinflammation and possible signalling involved. Results from present study revealed that hypoxia exposure resulted in a delayed accumulation of intracellular calcium coupled to a decrease in the rate of calcium clearance from the cell which further causes neurodegeneration. Additionally these neurodegenerative cells exacerbate microglial activation and damage-associated molecular patterns (DAMPs) level as evident from increases level of α-synuclein level. This increased DAMPs further enhance level of integrin receptor Mac1 (also known as CD11b/CD18, complement receptor 3 [CR3], or aMb2) its downstream effector NADPH oxidase (NOX2) which further contribute to maintaining chronic neuroinflammation. This study revealed the crucial role of Mac1/NOX2 signaling in maintaining neuroinflammation and progressive neurodegeneration during chronic hypoxia stress.

Title: Inhibition of palmitic acid-induced cell death by blocking apoptosis, necroptosis and inducing autophagy

Authors: *M. L. MONTERO[1,2], J.-W. LIU[3], M. DE LEON[3];
[2]Physiol. Dept., [3]Ctr. for Hlth. Disparities and Mol. Med., [1]Loma Linda Univ., Loma Linda, CA

Abstract: Lipotoxicity (LTx) is triggered by lipid overload that leads to oxidative stress, cellular dysfunction and cell death. This cellular phenomenon has been associated with metabolic syndrome, obesity, and type II diabetes. Nerve growth factor differentiated pheochromocytoma 12 (NGFDPC12) cells serve as a neuronal model to study this process. Autophagy is a survival mechanism induced by starvation, growth factor deprivation, hypoxia and oxidative stress by which the cell rids itself of protein aggregates, oxidized lipids, carbohydrates and even dysfunctional organelles with the intent to maintain adequate energy levels contributing to cellular homeostasis. Previous work in our laboratory showed that high concentrations of Palmitic Acid (PA) induces cell death mainly by apoptosis. When apoptosis is inhibited by caspases inhibitor, cell death still goes on in a caspase independent manner known as necroptosis. In this study, we found that PA-LTx also decreased the expression and activation of the vesicle docking protein LC3 (Atg8) that is crucial for autophagosome formation during autophagy. Therefore, using a caspase inhibitor, ZVAD-fmk, in conjunction to a necroptosis inhibitor, Necrostatin-1, and an autophagy inducer, Rapamycin, we are able to increase cell viability during PA-LTx. The apoptotic process can be measured using the split pattern of nuclear proteins Topoisomerase I (Topo I, 100kDa) and Poly (ADP-ribose) polymerase (PARP, 110kDa) by Western blots. There is a specific cleavage product catalyzed by caspases of 70kDa and 85 kDa for Topo I and PARP, respectively. On the other hand, there are specific cleavage products catalyzed by cathepsins; 70 and 45 kDa for TopoI and 50 kDa for PARP. Using these markers we identify the cell death mechanism taking place in our experimental conditions. Our laboratory has also demonstrated that docosahexaenoic acid (DHA) reverses PA-LTx-induced cell death in NGFDPC12 cells. Our results show that DHA inhibits caspases activation and the 70kDa and 85kDa split products of Topo I and PARP respectively. Moreover, DHA activated the autophagy cascade. We found increase mRNA levels of autophagy related genes like Atg7 and Atg12. Also DHA increased the active form of LC3 as measured by Western blot. Our data suggest that DHA rescuing of PA-LTx-induced cell death is through inhibition of apoptosis

and/or necroptosis. At the same time induction of autophagy gives the cell the capacity to cope with excess formation of ROS, lipid peroxidation and protein malfunction and provides energy sources for ATP formation.

Title: Multiple sources contribute to extracellular H_2O_2 dynamics in the striatum

Authors: ***S. PANDA**, L. R. WILSON, A. C. SCHMIDT, L. A. SOMBERS;
Chem., North Carolina State Univ., Raleigh, NC

Abstract: Oxidative stress has been implicated as a key player in various neuropathologies such as Parkinson's disease and Alzheimer's disease. A variety of cellular processes are involved in the generation and accumulation of extracellular reactive oxygen species, such as hydrogen peroxide (H_2O_2), in the striatum; however, the extent to which each of these sources contributes to extracellular H_2O_2 dynamics in striatal tissue remains unknown. Potential sources of H_2O_2 in the striatum include mitochondrial activity, and the biosynthesis and metabolism of dopamine (DA). The goal of this project is to quantitatively investigate key contributors to striatal H_2O_2 fluctuations using fast-scan cyclic voltammetry coupled with carbon-fiber microelectrodes. Pharmacological agents are used to manipulate (1) DA synthesis (L-DOPA, 100 mg/kg), (2) DA metabolism (pargyline, 75 mg/kg), and (3) the mitochondrial electron transport chain (local infusion of rotenone, 197 pg; or sodium succinate, 243 pg). Striatal H_2O_2 dynamics are voltammetrically quantified in real time using a dual microelectrode device. This device consists of two carbon fiber microelectrodes, one of which is coated with an m-phenylenediamine (mPD) membrane - a size exclusion membrane that enables selective detection of H_2O_2. The uncoated microelectrode is used to simultaneously monitor the effects of these drugs on local dopamine dynamics. The results indicate that each of these processes is contributing to the generation of extracellular H_2O_2 in the striatum. Overall, this work sheds light on the potential for these pathways to contribute to oxidative stress in this critical brain region.

Abstract: Epidermal fatty acid-binding protein (E-FABP/FABP5/DA11) binds and transports long-chain fatty acids in the cytoplasm and protects neuronal cells from reactive oxygen species (ROS) and cell death after palmitic acid-induced lipotoxic injury (PAM-LTx). However, the mechanism of protection from PAM-LTx remains unclear. Current understanding suggests E-FABP functions as an antioxidant protein against ROS through covalent modification of Cys-120 residue. Additionally E-FABP could function by binding free fatty acids in the cytoplasm rendering fatty acids unavailable for lipid peroxidation. The amino acids responsible for binding of fatty acids in EFABP binding pocket are Arg^{109}, Arg^{129}, and Tyr^{131}; furthermore, Arg^{129} forms a salt bridge with the carboxylate group of fatty acids that may be essential for stabilizing fatty acid binding. Therefore, we sought to create a mutant E-FABP that significantly decreased binding affinity to palmitic acid and examine whether the mutant retained protection against ROS in nerve growth factor-differentiated PC12 cells (NGFDPC12 cells). The use of this mutant will allow for the examination of E-FABP antioxidant properties that are dependent or independent of fatty acids binding to E-FABP. We hypothesize mutant E-FABP-R129A will significantly decrease binding affinity to palmitic acid while retaining antioxidant function. Isothermal titration calorimetry demonstrates that recombinant rat E-FABP-R129A clearly exhibits significantly reduced binding to palmitic acid verses wild type E-FABP. Furthermore, we found NGFDPC12 cells are protected against ROS when recombinant E-FABP-R129A is delivered by BioPORTER® QuikEase™ Protein Kit. These findings suggest that E-FABP antioxidant function is not dependent on fatty acid binding, and support roles of this protein beyond functioning as intracellular fatty acid transporter.

Title: Anti-inflammatory actions of heme oxygenase mediated by binding and down- regulating nitric oxide synthase

Authors: *S. CHOWDHURY[1], S. SNYDER[2];
[1]Neurosci., Johns Hopkins Med. Inst., BALTIMORE, MD; [2]JHMI, BALTIMORE, MD

Abstract: Nitric oxide (NO) and carbon monoxide (CO) are synthesized from L-arginine and heme by the catalytic actions of NO synthase (NOS) and heme oxygenase (HO), respectively. NO and CO similarly activate soluble guanylate cyclase but also display notable differences. It is unclear whether the two gasotransmiters converge or exhibit reciprocal feedback regulation. Macrophage-inducible NOS generates NO to kill other cells via nitrosative burst, whereas HO1 synthesizes bilirubin, which exerts antioxidant cytoprotective effects and also provides cytoprotection by facilitating iron extrusion from cells. We observe coordinated reciprocal pro- and anti-inflammatory activity in macrophage cells stimulated by LPS/IFN-γ. A sudden surge of cyclooxygenase 2 activity occurs (as early as 4 h post treatment) followed by inducible NOS expression (6 h post treatment) ultimately activating heme oxygenase 1 (12 h post treatment) to rescue the uncontrolled inflammatory insult. HO1 induced by NO interacts with and inhibits iNOS by 12 h post treatment. While iNOS binds strongly with HO1 in the ectopically expressed HEK cells, the binding is not affected by mutating the substrate binding residue in HO1 (H25A). Ectopically expressed HO1 shuts off iNOS enzymatic action, while its own activity is increased by binding to iNOS. Mapping the binding domain sites for HO1 indicates that its N-terminal 40 amino acids are indispensable for binding with iNOS.

Hosp., Uppsala, Sweden

Abstract: Sleep deprivation (SD) in military leads to often decline in cognitive and higher mental functions. Since a close link between SD and onset of Alzheimer's Disease (AD) is established, it appears that SD may worsen brain pathology in AD. Previously, we showed that 48 or 72 h SD alters serotonin (5-hydroxytryptamine, 5-HT) metabolism and induces brain pathology that is significantly reduced by 5-HT3 receptor antagonist ondansetron. Recent reports suggest that treatment with 5-HT6 receptor antagonists has also beneficial effects in attenuating behavioral and cognitive functions in AD.
We found that Cerebrolsyin, a balanced composition of several neurotrophic factors and active peptide fragments when delivered through TiO2-nanowired-technology results in superior neuroprotective effects on brain pathology in AD. Thus, we examined whether AD brain pathology is aggravated in SD and nanodelivery of 5-HT6 receptor antagonist SB-399885 together with Cerebrolsyin may have synergistic enhanced therapeutic effects in AD in combination with SD.
Male Wistar rats (age 20 to 25 weeks) were subjected to 72 h SD using an inverted flowerpot model placed in a pool of water maintained at 1 cm below the surface so that animals are deprived of restful sleep. After 72 h of SD these animals were administered amyloid-beta peptide

(AβP, 250 ng/10 µl, i.c.v.) in the left lateral ventricle once daily for 4 weeks to develop AD like symptoms and brain pathology. Control group received 0.9 % saline instead of AβP.
Our observation shows that AβP infusion in SD rats resulted in marked exacerbation of brain pathology (2 to 3 fold higher) after 4 weeks in terms of AβP deposition in the brain, neuronal damages in cortex, hippocampus and cerebellum, blood-brain barrier (BBB) breakdown and edema formation as compared to identical AβP infusion in control rats. These SD rats also showed much worse behavioral performances on Rota-Rod treadmill, inclined plane angle test, and water maze apparatus.
TiO2-nanowired delivery of 5-HT6 receptor antagonist SB-399885 (3 mg/kg) together with Cerebrolsyin (2.5 ml/kg) intravenously once daily for 2 weeks starting from 1 week after the onset of AβP infusion resulted in marked neuroprotection in AD brain in SD group as compared to tehse drugs either given alone or without nanotechnology under identical conditions. Interestingly, nanowired delivery of drugs in combination also improved behavioral function remarkably in SD rats after AβP infusion. These observations are the first to show that a combination of 5-HT6 receptor antagonist with Cerebrolsyin using nanodelivery has superior neuroprotective effects in AD induced brain pathology in SD, not reported earlier.

Abstract: Alzheimer's disease (AD) inflicts over 40 millions people aged 65 and older Worldwide and roughly 5 million Americans are living with the disease that involves huge burden on the society and families as well. Thus, exploration of novel therapeutic measures is needed to contain the disease and improve the quality of life of the victims.
Previous reports from our laboratory showed that amyloid beta peptide ($A\beta P_{1-40}$) infusion induced AD like symptoms developed in rats with regard to brain pathology is significantly reduced by drugs modulating histamine receptors. Thus, histamine H3 receptor inverse agonist BF 2649 hydrochloride and one selective H3 receptors antagonist with partial H4 agonist properties Clobenpropit dihydrobromide when given after 1 week of AβP infusion for 3 weeks resulted in significant reduction in AβP deposits in the brain along with neuronal damage and glial activation. These drug treatments also attenuated breakdown of the BBB to Evans blue albumin and radioiodine in cortex, hippocampus, hypothalamus and cerebellum. Interestingly, Clobenpropit showed superior effects than BF2649 in reducing brain pathologies in AD. However, when these drugs were administered 2 weeks after the onset of AβP for 2 weeks, the magnitude of neuroprotection was severely diminished. This suggests that histamine receptor modulation could reduce AD pathology in a narrow therapeutic window. Since TiO2-nanowired delivery of cerebrolysin- a multimodal drug comprising a balanced composition of several neurotrophic facto and active peptide fragments administered (2.5 ml/kg, i.v.) after 1 week of AβP infusion for 3 weeks also induced neuroprotection, in this investigation we studied the co-administration of cerebrolysin and histaminergic drugs in our AD model on brain pathology. AD like pathology was induced by intraventricular administration of ($A\beta P_{1-40}$, 250 ng/10 µl) once daily for 4 weeks. In separate group of rats BF 2649 (1 mg/kg, i.p.) or Clobenpropit (1 mg/kg, i.p.) was administered once daily for 2 weeks after onset of βbP administration accompanied with TiO2 nanowired cerebrolysin (2.5 ml/kg, i.v.). Our results showed a significant reduction in AbP deposits in the brain along with neuronal damage and glial activation. Breakdown of the BBB and brain edema formation was also absent in these treated AD rats. Interestingly, a combination of cerebrolysin and Clobenpropit showed superior effects in reducing brain pathology in AD. Taken together, our observations are the first to show that

cerebrolysin potentiate the neuroprotective effects of H3 receptor blocker and stimulation of H4 receptors is in AD pathology even initiated 2 weeks after AβP infusion.

Title: Impact of cellular stress produced by acidic pH and growth factor withdrawal on neuronal differentiation of human hippocampal neural precursor cells (hHippNPCs): implications in neurodegenerative diseases.

Authors: *M. CARDENAS-AGUAYO[1,2], L. GOMEZ-VIRGILIO[3], G. LOPEZ-TOLEDO[4], U. GARCIA[4];
[1]Physiol., UNAM, Ciudad DE Mexico, Mexico; [2]Physiol., Sch. of Medicine, Natl. Autonomous Univ. of Mexico, Mexico, Mexico; [3]Mol. Biomedicine, [4]Physiology, Biophysics and Neurosci., Ctr. for Res. and Advanced Studies of the Natl. Polytechnic Inst. (CINVESTAV-IPN), Mexico, Mexico

Abstract: Background: NPCs are the most primordial and less committed and pluripotent cells of the nervous system. They give rise to three principal phenotypes in CNS: neurons, glia and oligodendrocytes. Neurotrophic factors had a crucial role in proliferation; differentiation and survival of NPCs. Alzheimer's disease is characterized by alterations in growth factor levels and a stress environment. It is known that chemical stimulus could reprogram somatic cells. Neurodegenerative diseases are characterized by a reduction in neurogenesis and by impairment in protein recycling by autophagy or proteasome, that results in protein aggregation. **Methods**: To elucidate the impact of stress on neural differentiation, recycling systems and tau protein, we cultured embryonic hHippNPCs in the presence or absence of 5 ng/ml FGF-2 for 2 to 7 days or treat them for 25 minutes at pH5.7 and subsequently culture them in the presence of FGF-2 for 2 to 7 days. We analyze by Western blot and immunocytochemistry the expression of NPCs, proliferation, glial, neuronal and synaptic markers and total, phosphorylated and oligomeric tau. We evaluate cell viability, autophagy and proteasome activation and electrophysiological properties. **Results:** We found significant decrease in Nestin, Sox-2, Lin28, PCNA and GFAP expression at 7 days in cells cultured in absence of FGF-2 and in cells exposed to pH5.7 in the

presence or absence of FGF-2. Synaptic markers: PSD95, Arc and neuronal differentiation markers: DCX, NF and NeuN, were increased. Tau expression was significantly increased in cells cultured in the absence of growth factors for 2 and 7 days or in acidic conditions for 7 days. Tau oligomers were significantly increased at 2 days without growth factors or pH5.7 in the presence of FGF-2. Tau phosphorylation, autophagy and proteasome markers were significantly increased at 7 days in the absence of growth factors and in acidic conditions. At 2 days in acidic conditions with or without FGF-2, ROS where significantly increased and Nrf-2 activated. hHippNPCs cultured in the absence of FGF-2 or in acidic conditions showed outward potassium currents and action potentials when differentiate for 28 days. **Conclusions**: We conclude that both growth factor withdrawal and acidic environment induce neuronal differentiation of hHippNPCs, promote tau expression, phosphorylation and aggregation and induce activation of major recycling systems as a response to cellular stress that activates signal transduction and regulates gene expression. Both growth factor withdrawal and acidic environment constitute a stress condition similar to a neuropathology where growth factors are scarce and acidosis could exist.

Title: Prion protein suppresses seizure-induced c-fos expression, a marker for neural activity in zebrafish

Authors: *R. KANYO, P. L. A. LEIGHTON, W. T. ALLISON;
Biol. Sci., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Introduction: Prion protein (PrP) has been linked to Alzheimer’s disease (AD), the most prevalent dementia. PrP directly interacts with amyloid-β oligomers, and PrP-knockout mice are more susceptible to seizures and excitotoxicity, compelling PrP as a promising target for drug therapy. Zebrafish enable potent high-throughput drug screening platforms that

faithfully represent the complexity of the central nervous system. Using our engineered mutants, two PrP homologues expressed in zebrafish are investigated here to identify screenable phenotypes related to neuroprotection.
Methods: *Prp1, Prp2* and compound mutant (*Prp1/2*; *prp1* and *prp2* are disrupted) fish were engineered by targeted mutagenesis. Seizure susceptibility was compared in mutant and wild type (WT) embryos via treatment with convulsant pentylenetetrazol (PTZ). Neural activity was measured using *c-fos* expression as a proxy, and quantified using real-time PCR. mRNA expressing zebrafish *prp1*, *prp2* or mouse homologue *prnp* were injected to query specificity of the knockout phenotype and to investigate the conserved role of PrP.
Results: Neural activity (*c-fos* mRNA levels) was increased in *Prp* mutants compared to WT when treated with PTZ. *Prp1* had 2.2-fold higher *c-fos* mRNA levels than WT, *Prp2* 1.68-fold, and *Prp1/2* 2.61-fold. In *Prp1/2* mutants, the knockout-mediated enhancement of *c-fos* expression was suppressed/rescued by delivery of mRNA expressing *prp* variants. Mouse *prnp* mRNA suppressed *c-fos* expression by 51 % almost down to WT levels. Zebrafish paralogs of *prp* moderately supressed *c-fos* expression, but were less effective than mouse *prnp.* Further experiments will titrate the dose of the rescuing mRNA.
Conclusion: A seizure-susceptibility phenotype previously established using behaviour and electrophysiology in our *Prp2* mutant (Fleisch *et al.* 2013) was confirmed here using molecular phenotyping, and exacerbated in compound mutants when *prp1* was also disrupted. Our findings provide a route towards a screenable phenotype and support that PrP is neuroprotective, including during seizure, by regulating neuron excitability (channels). Differences amongst zebrafish and mouse PrP revealed herein prompt new hypotheses regarding which protein domains mediate the ancient protective function of PrP. Disrupting PrP is emerging as a therapeutic target in AD, thus identifying modulators of PrP neuroprotective activity is expected to have an impact beyond the socioeconomic consequences of prion diseases in cattle and cervids.

Title: Neuroprotection against Alzheimer's disease-related amyloid-β toxicity: sigma-1 receptor modulation of VDAC-1 channels

Authors: *C. FERNÁNDEZ ECHEVARRÍA, T. MEDIAVILLA, D. MARCELLINO;
Integrative Med. Biol., Umeå Univ., Umeå, Sweden

Abstract: Investigation into the mechanisms underlying neurodegenerative disease has been one of the fastest growing areas of research in recent decades. This is especially true in the case of Alzheimer's disease (AD), whose revalence continues to increase dramatically. Recent research has revealed proteins, such as plasmalemmal VDAC-1, to contribute to the toxicity of amyloid-β, the main component of amyloid plaques found in the brains of Alzheimer patients. Furthermore, sigma-1 receptors (SIG1R) have been proposed as putative targets to offer neuroprotection against neurodegenerative disease. We propose that one of the neuroprotective mechanisms of SIG1R activation may involve the regulation of VDAC-1 related toxicity. Establishing a link between SIG1R and VDAC-1 is a matter of great importance for the development of novel pharmacological strategies to treat disease. We have specifically investigated the possible modulation of VDAC-1 by SIG1R in cellular models of Alzheimer-related toxicity. In addition, the putative neuroprotective effects of sigma-1 receptor ligands were evaluated with regard to its ability to reduce Aβ-induced neuronal toxicity.

Title: Neuroprotection by a N-terminal fragment and hexapeptide core sequence of beta amyloid

Authors: *N. ALFULAIJ;
Dept. of Biol., Univ. of Hawai'i at Manoa Dept. of Biol., Honolulu, HI

Abstract: Amyloid-beta (Aβ) is the primary component of plaques associated with Alzheimer’s disease (AD). We previously demonstrated that the presence of nicotinic receptors (nAChRs), an identified neuromodulatory target for Aβ, sensitizes neurons to Aβ neurotoxicity. A N-terminal

Aβ fragment, $A\beta_{1-15}$, also has neuromodulatory activity but is not toxic. We showed specifically that picomolar levels of $A\beta_{1-15}$ enhances Ca^{2+} signaling, fear memory and long-term potentiation (LTP). Within $A\beta_{1-15}$, we further identified a hexapeptide core sequence ($A\beta_{core: 10-15}$), YEVHHQ, which is as or more effective as $A\beta_{1-15}$.
In view of the absence of neurotoxicity, we conjectured that $A\beta_{1-15}$ and $A\beta_{core}$ would be neuroprotective against full-length Aβ toxicity. Using a reactive oxygen species (ROS) assay as a measure of toxicity, we demonstrated that $A\beta_{1-15}$ or $A\beta_{core}$ blocks full-length Aβ neurotoxicity (100nM – 3 days) in a neuroblastoma cell line expressing nAChRs. Combination treatments were done using different timing and dosages of the peptide fragments to evaluate their action and potency. With co-incubation, both $A\beta_{core}$ and $A\beta_{1-15}$ blocked full-length Aβ-induced ROS and nuclear disintegration in cultures expressing nAChRs, while rescue (post Aβ treatment) with the peptides was partially effective.
To confirm our findings in a physiologically relevant model, we have utilized primary hippocampal neuron cultures and slice cultures subjected to full-length Aβ compared to combination treatment of $A\beta_{1-42}$ and $A\beta_{1-15}$ or $A\beta_{core}$ with various timing and dosage regimens. To further elucidate the molecular pathways affected by Aβ, $A\beta_{1-15}$, $A\beta_{core}$ or combinations, cell and slice cultures were treated with the aforementioned peptides and then changes in pJNK and pERK were examined, as both of these MAP kinases have been implicated in Aβ toxicity. Based on our previous work showing $A\beta_{1-15}$ to be protective against full-length Aβ-induced LTP inhibition in wild-type acute hippocampal slices, we are also examining the impact of $A\beta_{core}$ in synaptotoxicity. These studies include testing the $A\beta_{core}$ as well as $A\beta_{1-15}$ against acute full-length Aβ application in wild-type hippocampal slices as well as slices from 5xFAD (APP/PS1 expressing transgenic mouse model) mice which rapidly accumulate Aβ.
The action of the N-terminal fragment $A\beta_{1-15}$ and the $A\beta_{core}$ indicates that they may serve a competitive, neuroprotective role at the synapse in the context of accumulating Aβ in AD. Furthermore, the neuroprotective action of the $A\beta_{core}$ suggests the possibility of using this core sequence as a scaffold for optimization of a potential biologic for protection against Aβ-induced toxicity.

Title: Extensive axonal damage is observed in $Gas6^{-/-}Axl^{-/-}$ double-knockout (DKO) mice following exposure to cuprizone.

Authors: *B. SHAFIT-ZAGARDO[1], A. RAY[1], R. C. GRUBER[2], J. WILLIAMSON[1], J. DUBOIS[1];
[2]Pathology, [1]Albert Einstein Col. Med., Bronx, NY

Abstract: Multiple sclerosis (MS) is characterized by inflammation, axonal damage and demyelination. Growth arrest-specific protein 6 (Gas6) and members of the Axl, Tyro3 and MerTK (TAM) family of receptor tyrosine kinases important for the innate immune response, efferocytosis and homeostasis are aberrantly expressed in MS lesions. Both Gas6 and ProS1 signal through the TAMs but only Gas6 directly activates Axl. We generated $Gas6^{-/-}Axl^{-/-}$ DKO mice to ensure complete deletion of the Gas6/Axl signaling axis while leaving ProS1/Tyro3/Mertk signaling intact. This eliminates the possibility that ProS1 can activate Axl via receptor heterodimerization with Tyro3 or MerTK in the absence of Gas6. Naïve DKO and WT mice have equivalent numbers of Olig2+ and Olig1+ oligodendrocytes, normal-appearing myelin, and equivalent numbers of myelinated axons in the corpus callosum as determined by electron microscopy. DKO mice show significantly fewer Olig2+ oligodendrocytes in the corpus callosum at 5 weeks cuprizone treatment, and little to no remyelination apparent at 6 weeks, indicating a lag in remyelination, while WT mice begin to remyelinate by 6 weeks. After 6-week-cuprizone exposure and 3-week withdrawal, female and male DKO mice had significant axonal damage including swollen axons with autophagolysosomes and multivesicular bodies, and fewer myelinated axons relative to WT mice. There was no difference in the number of $Iba1^{+}/4D4^{+}$ microglia between both groups of mice. These data demonstrate an important role of Gas6/Axl signaling in maintaining axonal integrity and remyelination. This warrants further studies for therapeutic intervention in mouse models and perhaps individuals with MS.

Title: *In vivo* tracking confirms dendritic cell exosomes enter the brain and may travel along CSF pathways

Authors: *A. D. PUSIC, D. DUKALA, R. P. KRAIG;
Univ. of Chicago, Chicago, IL

Abstract: Exosomes from IFNγ-stimulated dendritic cells (SDC-Exos) contain miRNAs which promote myelination, reduce oxidative stress (OS), and preferentially enter oligodendrocytes in brain slice cultures (1). When nasally administered to naïve animals, SDC-Exos improve remyelination following lysolecithin-induced demyelination (an *in vivo* model of multiple sclerosis) and inhibit spreading depression (SD) (2). SD is the likely cause of migraine with aura, and a well-established experimental model of migraine that triggers increased OS and transient demyelination (3). Collectively, these experiments show that nasal administration of SDC-Exos effectively improve brain function. However, little is known about the route of entry, timing and distribution of nasally delivered SDC-Exos. We nasally administered mCLING-labelled SDC-Exos and tracked their entry into brain. mCLING (membrane-binding fluorophore-cysteine-lysine-palmitoyl group) labels plasma membranes and is taken up by endocytosis (4), making it ideal for organelle tracking. The dye remains detectable in membranes after fixation and exhibits switching between bright and dark states under continuous excitation (flickering), allowing for its use in ground-state depletion microscopy (GSD; with ~20 nm resolution). Using wide field, confocal and GSD microscopy, we showed that exosomes enter and widely distribute throughout the brain. They appear to follow interstitial pathways from the olfactory bulb, with a gradient from the pial surface into the parenchyma consistent with CSF initial distribution. A rostral-caudal gradient was also noted. Preliminary data suggest nasally delivered exosomes travel along perivascular spaces. GSD images confirm fluorophore flickering was only seen with labelled exosomes (using a running median filter; 5). Our results provide evidence that SDC-Exos enter brain, distribute throughout the parenchyma, and have a functional impact. This data further supports use of SDC-Exos as a novel therapeutic for neurodegenerative disorders.

Abstract: Axonal pathology is a key regulator to long-term disability in multiple sclerosis (MS), an inflammatory demyelinating disease of the central nervous system, but the mechanisms that underlie axonal pathology in MS remain elusive. Evidence suggests that axonal pathology is a direct consequence of demyelination, as we and others have shown using animal model (EAE) of MS.7, 8-Dihydroxyflavone (DHF), a TrkB agonist, is a neuro-protective agent used for different animal models of neurodegenerative diseases.We recently reported (Makar.et.al. 2016 journal of Neuroimmunology 292 : 9-20) that axonal protection is enhanced when we treated the EAE mice from the onset of the disease. Furthermore, treatment with DHF (5mg/kg, I.P, daily for 30 days) in EAE mice inhibited clinical severity and inflammation when we treated the EAE mice from the onset of disease. Treatment with DHF increased TrkB activation after EAE. Improvement in EAE, suggests a pivotal role of TrkB signaling in anti-inflammatory performance after EAE. A potential action of DHF on delayed treatment is still active or not is not clear because delayed treatment is more effective for MS patients. Now we treated EAE mice with the same dose of DHF at the severity of the disease and interestingly we found that delayed treatment is also effective to inhibit the clinical severity, axonal damage, demyelination and inflammation. Since progressiveness of MS is associated with axonal degeneration associated with demyelination, which is an important factor for the development of neurodegeneration in MS/EAE. These results set a precedent for the therapeutic use of DHF in EAE and perhaps MS during progressive stages.

Title: Neuronal hemoglobin expression and its relevance to multiple sclerosis neuropathology

Authors: *K. ALKHAYER, N. K. SINGHAL, J. MCDONOUGH;
biological sciences and school of biomedical sciences, Kent State Univ., Kent, OH

Abstract: Multiple sclerosis (MS) is characterized by demyelination and progressive neurological disability. Previous studies have reported defects to mitochondria in MS including decreased expression of nuclear encoded electron transport chain subunit genes and inhibition of respiratory complexes. We previously reported increased levels of the hemoglobin β subunit (Hbb) in mitochondrial fractions isolated from postmortem MS cortex compared to controls. In the present study, we performed immunohistochemistry to determine the distribution of Hbb in postmortem MS cortex and identified proteins which interact with Hbb by liquid chromatography tandem mass spectrometry (LC-MS/MS). We found that Hbb was enriched in pyramidal neurons in internal layers of the cortex and interacts with subunits of ATP synthase, histones, and a histone lysine demethylase. We also found that Hbb is present in the nucleus and that expression of Hbb in SH-SY5Y neuroblastoma cells increased trimethylation of histone H3 on lysine 4 (H3K4me3), a histone mark that regulates cellular metabolism. These data suggest that Hbb may be a part of a mechanism linking neuronal energetics with epigenetic changes to histones in the nucleus and may provide neuroprotection in MS by supporting neuronal metabolism.

Title: Estriol preserves axonal integrity and cortical volume in experimental autoimmune encephalomyelitis

Authors: *C. E. MEYER[1], H. JOHNSONBAUGH[2], S. LEPORE[2], N. ITO[2], R. VOSKUHL[2], A. MACKENZIE-GRAHAM[1];

Abstract: Despite wide symptomatic variability in multiple sclerosis (MS), grey matter atrophy has consistently emerged as a strong indicator of clinical disability. In fact, evidence suggests progressive loss of grey matter correlates with physical and cognitive dysfunction better than many other commonly occurring hallmarks of MS, including enhancing lesions and lesion burden. Current treatment options are primarily designed to reduce inflammation and have had only modest success at slowing grey matter atrophy. Treatment with the sex hormone, estriol, has been shown to both reduce relapses and preserve grey matter in MS and in its most commonly used mouse model, experimental autoimmune encephalomyelitis (EAE). In this study, we sought to elucidate the mechanism by which estriol treatment preserves grey matter. Our investigation involved implanting either an estriol or placebo pellet subcutaneously in female THY1-YFP+ mice prior to EAE induction with myelin oligodendrocyte glycoprotein (MOG) peptide. *In vivo* Magnetic Resonance Images were collected 20 days after disease induction. Following image acquisition, the mice were sacrificed and Clear Lipid-exchanged Acrylamide-hybridized Rigid Imaging-compatible Tissue-hYdrogel (CLARITY) was performed on the brain and spinal cord. Volumetry analysis revealed preservation of cortical volume in estriol-treated mice with EAE when compared to vehicle-treated mice with EAE. CLARITY images demonstrated that estriol treatment resulted in preservation of cortical layer V pyramidal neurons and reduced formation of axonal ovoids and end bulbs in the spinal cord. Through cross-modality analysis, our results shed light on the relationship between cortical atrophy and axonal transection while also suggesting a mechanism by which estriol treatment preserves grey matter in EAE.

Title: Sensitivity of mri measures to axonal and/or myelin repair in the presence of inflammation: a quantitative assessment of *In vivo* mtr, dti, and post-mortem immunohistochemistry in a rodent model of spontaneous remyelination

Authors: *B. A. HOOKER, R. RAJAGOVINDAN, M. J. VOORBACH, C. H. SCHROEDER, J. D. BEAVER;
ZR13, AbbVie, North Chicago, IL

Abstract: Background: Magnetization Transfer (MT) imaging and Diffusion Tensor Imaging (DTI) are increasingly utilized in clinical trials of novel multiple sclerosis therapies. While measures derived from these techniques are sensitive to changes in white matter pathophysiology, they are also believed to be influenced by confounding factors such as changes in edema, typical in MS lesions, and thus limited in specificity. We investigated the sensitivity and specificity of *in vivo* MT ratio (MTR) and DTI measures to quantitative changes in myelin and axonal density in the presence of inflammation and edema assessed by immunohistochemistry (IHC).
Methods: Focal demyelination was induced in Sprague Dawley rats (n=24) using stereotactic injection of 3uL of 1% lysophosphotidylcholine into the corpus callosum. DTI (380x380x500 μm, b~700 s/mm^2, 30 directions) and MTR (250x250x500 μm, 9 μT Gaussian RF pulse, 2 kHz off-resonance) at 4.7T were acquired in three cross-sectional cohorts of animals at 14, 28, 56 days post injection (dpi), and sacrificed following image acquisition. Fractional anisotropy (FA), axial (AD), radial (RD), mean diffusivity (MD), T2 signal intensity and MTR maps were derived from the MR images. Brains were serially-sectioned and stained to assess myelin density (MBP), axonal density (NF1), inflammation (Iba1) and edema (IgG). Quantitative endpoints were derived from lesions manually delineated on MRI and IHC.
Results: Focal lesions were detected in all animals. Myelin and axonal pathology were highest at 14 dpi followed by spontaneous repair evidenced by improvement in MBP and NF1 staining ($p<0.05$) by 56 dpi. In line with the IHC findings, increase in MTR, FA and reduction in MD, RD and T2 were observed 56 dpi relative to 14 and 28 dpi ($p<0.05$). MTR and FA increased by 3 and 30%; MD, RD and T2 decreased by 4, 10 and 17% at 56 dpi relative to 14 dpi. The outcome of univariate and multivariate analysis to elucidate the magnitude of influence each underlying aspect of pathophysiology (myelin, axon, inflammation and edema) had on each MRI outcome measure will be reported along with strategies to minimize the influence of confounding factors in the interpretation of MRI outcome measures.

Conclusions: The findings provide improved understanding of the pathophysiological sensitivity and specificity of MRI measures, aiding in the choice of optimal measures and their precise interpretation in clinical trials of remyelinating agents.

Title: Delayed treatment of experimental autoimmune encephalomyelitis with glibenclamide promotes M2 polarization of macrophages and reduces neuroinflammation

Authors: *T. K. MAKAR[1,2,3], V. GERZANICH[4], V. NIMMAGADDA[1,2], P. R. GUDA[1], A. B. MORRIS[1], D. TRISLER[1,2,3], C. T. BEVER, Jr[1,2,3], M. SIMARD[4];

Abstract: We studied therapeutic effect and anti-inflammatory mechanisms of glibenclamide in experimental autoimmune encephalomyelitis (EAE), an animal model of multiple sclerosis (MS). Recently, we showed that treatment with Sur1 antagonist glibenclamide (Glib) starting from the onset EAE attenuates neuroinflammation and clinical severity of disease (Makar.et.al. 2015 Neuroinflammation Vol: 12 P-210.). Here we report new data with delayed Glib treatment during chronic stage of EAE. Treatment (20 μg Glib/day/mouse) starting at 12 and 24 days after onset of the disease significantly improved clinical symptoms and reduced inflammation in lumbar spinal cords. Similar to the reported findings with treatment at the onset of EAE, delayed treatment with Glib inhibited infiltration of the CD45+ leukocyte cells and CD11b+ macrophages. Additionally, Glib treatment significantly reduced expression ($p<0.02$) of Endothelin-1 (ET-1). Progression of the EAE was associated with significant infiltration into the

parenchyma of spinal cords macrophages with M1 activation state. Treatment with Glib reduced the number of M1 and increased the number of M2 activation state macrophages. This resulted in increased labeling for M2 markers CD163 and IL-10. The polarization of macrophages towards M2 active state in Glib treated mice was associated with decrease of the pro- inflammatory molecules IFN-γ, TNF-α, MCP-1 and ET-1. The results of the study revealed novel cellular mechanisms involved in anti-inflammatory effects of Glib. The beneficial effect of Glib observed in EAE strongly indicates that treatment with Sur1 antagonists have promising therapeutic potential as disease modifying approach at chronic stages of MS.

Hosp., Uppsala, Sweden

Abstract: Military personnel are highly vulnerable to concussive head injury (CHI) during combat operation either at ground level or at high altitude mountains. High altitude induced l

brain edema development and alterations in cognitive dysfunctions are well known. However, effects of head injury at high altitude as compared to sea level are still not known. In this investigation we examined CHI at laboratory-simulated condition of high altitude and compared the results on identical head injury at normal laboratory conditions.
Rats were exposed to simulated high altitude (HA) equivalent of 5000 m in an Altitude chamber (Hypobaric chamber) 11.2 % O2 at 0.53 Atm for 6 h daily for 1 week. The temperature of the hypobaric chamber was maintained at 21±1 °C. The humidity (45 to 50%) and airflow was maintained at 4 liter per hour. Control rats kept at room temperature at standard laboratory conditions. Control or HA arts were provided food and water ad libitum before experiment. CHI was inflicted in control and HA rats under Equithesin anesthesia (3 ml/kg, i.p.) by dropping an Iron tapered cylinder (114.6 g) through a guide tube from 20 cm height over the exposed right parietal skull inducing an impact of 0.224 N over the skull surface without making any fracture. The method simulates counter coup injury and results in profound cellular damage in the left uninjured hemisphere as compared to the injured side 12 to 24 h after the primary insult. In these rats blood-brain barrier (BBB) breakdown to Evans blue albumin and radioiodine was examined together with edema formation using brain water content. Nissl stain on paraffin sections was used to evaluate neuronal injuries. Our results showed that CHI in HA rats resulted in 250 % exacerbation of BBB breakdown, 3-to 4- fold higher brain edema development and 2- to 2.5 fold greater neuronal injuries in the cerebral cortex, hippocampus and cerebellum as compared to rats kept at room temperature.
Co-administration of Cerebrolsyin 2.5 or 5 ml/kg, i.v. with mesenchymal stem cells (MSCs, 1 million) 4 to 6 h after trauma was able to induce profound neuroprotection in CHI arts at room temperature. However, this dose was only slightly effective in reducing brain pathology following CHI in HA rats. On the other hand when TiO2 nanowired cerebrolysin (2.5 ml) was co-administered with 10^6 MSCs 4 or 6 h after trauma significant reduction in the BBB breakdown, edema formation and neuronal injuries were seen in HA rats. Taken together our observations are the first to point out that CHI in HA results in exacerbation of brain pathology and under such situations nanodelivery of suitable drugs are needed to achieve better neuroprotection, not reported earlier.

Abstract: Nicotine exposure in military is associated with mental dysfunction. Whether stress related to combat or trauma results in more nicotine consumption is still unclear. Thus, further investigations on nicotine use in TBI are needed to explore outcome of brain pathology. Since substance abuse is affected by hot and cold environment, in present investigation nicotine exposure at hot environment was examined in relation to TBI in model experiments.
Previous reports from our laboratory showed that nicotine administration (9 mg/kg/day s.c. for 1 week) in rats resulted in breakdown of the blood-brain barrier (BBB) permeability, brain edema formation and neuronal injury that was exacerbated by cold environment (+8 °C). Thus, it would be interesting to see whether subthreshold dose of nicotine (4 mg/kg, s.c. per day for 1 week) could aggravate TBI induced brain pathology at normal room temperature or at hot environment (38 °C). Since closed head injury (CHI) is quite common in military personnel during combat related TBI, we examined effects of CHI in nicotine treated groups.
Male Wistar rats (age 16 to 18 weeks of age) were administered nicotine (4 mg/kg, s.c.) per day either at room temperature (21±1°C) or reared at cold ambient temperature (8 °C) for 1 week. In a separate group rats exposed to nicotine at room or cold temperatures CHI was produced by inflicting 0.224 N impact on the exposed right parietal skull under Equithesin anesthesia using a an iron cylinder tapered towards impact side (weight 114.6 g) dropped from 20 cm height using a guide tube. Control CHI group were administered 0.9 % saline instead of nicotine. After 24 h of CHI, BBB breakdown to Evans blue albumin (EBA) and radioiodine ($^{[131]}$-Iodine) was examined together with brain edema formation using brain water content. Neuronal injuries were evaluated

on paraffin sections (3-µm) with Nissl or Haematoxylin and Eosin (H&E) staining.
Our results showed that CHI in nicotine exposed rats exacerbated BBB breakdown by 150 to 200 % with 2-3 fold higher brain edema formation and 2- to 4-fold greater neuronal injuries at room temperature. Interestingly, CHI in nicotine treated rats at hot environment further exacerbated brain pathology by 250 to 300 % as compared to identical CHI in nicotine treated animals at room temperature.
Taken together our observations are the first to point out that nicotine exposure prior to TBI results in greater brain pathology and these effects are further aggravated when CHI was inflicted at hot environment with nicotine intoxication, not reported earlier.

Abstract: Blast brain injury (bBT) is a serious problem in military personnel during combat or peacekeeping operations. The primary and secondary pressure waves created by the blast induces intense brain damage depending on the magnitude and severity and the distance between blast and the victim. Few reports using compressed-air or gas induced blast in the shock tube in the magnitude of 150 to 250 kPa showed unilateral brain damage e.g., neuronal loss, activation of astrocytes and distortion of axonal and synaptic connections after 2 to 12 h bBT. However, studies on drugs modifying bBT induced brain pathology are still lacking.

Previously we have shown that cerebrolysin- a multimodal drug when given alone or using TiO2 nanowired delivery induces marked neuroprotection following brain injury caused by trauma, hyperthermia or concussion. Thus, we examined effects of cerebrolysin following bBT in a rat model.

Equithesin anesthetized Male Wistar rats (age 25 to 30 weeks) were placed in a compressed air driven blast shock tube with head facing. The torso was wrapped to protect from the blast waves. Rats were exposed to blast waves of either 150±5 kPa or 250±8 kPa (measured using a pressure transducer fixed into the shock tube) and allowed to survive 8 or 24 h. Brain edema, blood-brain barrier (BBB) breakdown and cellular injuries were examined using standard protocol.

Our results showed breakdown of the BBB to Evans blue albumin and radioiodine ([131]-I) in the cerebral cortex, hippocampus and cerebellum by 4 to 8-fold from the normal control rats depending on the magnitude of the blast waves. The contralateral side also showed 2 to 4 folds higher BBB leakage after 150 or 250 kPa shock waves, respectively. The brain water content elevated by 6 to 10 fold on the right hemisphere, whereas 4 to 6-fold increase in water content was seen on the left side. Nissl staining showed pronounced neuronal loss, damage and cell death in the above brain areas that was most prominent on the right side.

Cerebrolysin (2.5 or 5 ml/kg, i.v.) administered 2 and 4 h after bBT (250 kPa) significantly reduced brain pathology following 8 h. However, multiple injections of high doses of cerebrolysin (5 ml/kg, 2,4,6,8 and 10 h after injury) are needed to induce neuroprotection 12 h after bBT. TiO2 nanowired delivery of cerebrolysin (2, 4 and 8 h after bBT) significantly reduced brain pathology at 12 h. These results for the first time show that cerebrolysin if given in multiple doses is able to thwart bBT induced brain pathology and TiO2-nanowired cerebrolysin has superior neuroprotective effects, not reported earlier.

Title: Concussive head injury induced brain ischemia and oxidative stress are thwarted by nanodelivery of Chinese traditional medicine DL-3-n-butylphthalide (DL-NBP)

Authors: *L. FENG[1], A. SHARMA[2], A. NOZARI[3], D. F. MURESANU[4], J. V. LAFUENTE[5], A. OZKIZILCIK[6], R. TIAN[7], H. S. SHARMA[2];

Neurosciences, Univ. of Med. & Pharm., Cluj-Napoca, Romania; [5]Neurosciences, Univ. of Basque Country, Bilbao, Spain; [6]Biomed. Engin., [7]Chem. & Biochem., Univ. of Arkansas, Fayetteville, AR

Abstract: Concussive head injury (CHI) often known as closed head injury is the most prominent traumatic brain injuries in military personnel during combat operation resulting in life time disabilities. Thus, exploration of suitable therapeutic measures to improve the quality of life and rehabilitation of CHI victims is the need of the hour. Our laboratory is engaged in exploring novel therapeutic measures for the treatment of CHI to reduce brain pathology at the cellular and molecular levels using a variety of drugs using nanotechnology. Previously, we reported nanodelivery of traditional Chinese medicine DL-3-n-butylphthalide (DL-NBP) in CHI that was most effective in reducing brain pathology in CHI if given 2 and 4 h after an 8 h injury or 8 and 12 h after 24 h trauma. Since CHI induces severe brain ischemia and oxidative stress, in this investigation we examined the effects of TiO2-DL-NBP on regional cerebral blood flow (CBF) and oxidative stress in our rat model of CHI.

The CHI was induced by dropping a weight of 114.6 g on the right parietal skull bone over a distance of 20 cm in anesthetized rats resulting an impact of 0.224 N on the skull surface. This impact induces severe brain pathology over 4 h to 24 h. In separate groups of CHI we administered TiO2-nanowired-NBP (40 or 60 mg/kg, i.p.) 2h and 4 h after injury in 8 h survival group and 8 h and 12 h after trauma in 24 h survival group. In tehse untreated and treated groups regional CBF (rCBF) in the cerebral cortex, hippocampus, thalamus, hypothalamus, cerebellum and brainstem was examined using [125]-Iodine labeled microspheres (15±0.6 μm o.d.). We also measured Luminol, Malondialdehyde, Myeloperoxidase, and Glutathione in the above brain regions using standard biochemical procedures. Untreated CHI resulted in a progressive increase in brain Luminol, Malondialdehyde and Myeloperoxidase (+20 to 50 %), and a decrease in Glutathione levels (-25 to -40 %) after 8 h and 24 h CHI respectively. These changes in oxidative parameters correlated well with the reduction in the rCBF (-30 to -50 %) and development of brain edema formation. TiO2-NBP resulted in significant improvement in rCBF in all brain areas examined and thwarted the oxidative stress in CHI in all brain regions. Interestingly, normal NBP requires 80 to 100 mg/kg, dose to have comparable reduction in rCBF and oxidative stress in CHI. These observations clearly suggests that nanodelivery of NBP has superior neuroprotective effects in CHI due to its anti-ischemic and antioxidant properties. Further research is needed to understand the dose and time related neuroprotective effects in CHI, a feature that is currently being investigated in our laboratory.

Title: Treatment with Nrf2 and p53 transcription factor modulators in an *In vitro* mild TBI model

Authors: *W. A. RATLIFF[1,2], J. N. CHANG[1,2], N. H. GREIG[3], B. A. CITRON[1,2];
[1]Lab. of Mol. Biol., Bay Pines VA Healthcare Syst., Bay Pines, FL; [2]Dept. of Mol. Med., Univ. of South Florida Morsani Col. of Med., Tampa, FL; [3]Translational Gerontology Br., Natl. Inst. on Aging, NIH, Baltimore, MD

Abstract: In the United States each year, it is estimated that 1.7 million people sustain a traumatic brain injury (TBI). In our military members and athletes, in particular, TBI remains a major cause of morbidity and mortality. The majority of TBIs are mild and these can result in deleterious cognitive effects for which there is currently no effective treatment. We have demonstrated improved outcomes in both *in vitro* and *in vivo* models of brain injury following treatment with tert-butylhydroquinone (tBHQ). tBHQ is an activator of the inflammatory responsive transcription factor, Nrf2, and has been shown to induce the production of several neuroprotective factors. A recent study has also identified pifithrin-α oxygen (PFT-α (O)), a p53 inactivator, as demonstrating neuroprotective effects in an *in vitro* excitotoxicity model and an *in vivo* open head injury model. Our study utilizes an *in vitro* "injury in a dish" model to evaluate the effects of a repetitive physical injury on a neuronal cell line and evaluate the potential protective effects of treatment. tBHQ plus the sulfur containing inhibitor, PFT-α, produced significantly improved neuronal function measured with an MTS assay (compared to either treatment alone) while tBHQ plus SP600125, a Jun-N terminal kinase inhibitor, was not additionally protective. We have investigated treatment with tBHQ, PFT-α (O) and a combination of the two to determine whether simultaneous activation of Nrf2 and inhibition of p53 would provide a synergistic neuroprotective effect in terms of neuronal survival and neurite health. Observations indicate that treatment with tBHQ plus PFT-α (O) improves overall neuronal survival and neurite health, as measured by neurite length per cell, when compared to vehicle treated cells or those that received only one treatment. This suggests that simultaneous activation of Nrf2 and inhibition of p53 do produce enhanced neuroprotective effects in response to neuronal injury and could represent a novel treatment in response to head injury. Overall, the goal of our group is to help identify therapeutic approaches that would benefit individuals suffering mild traumatic brain injury.

Abstract: Military personnel during combat situations are often prone to traumatic spinal cord injuries (SCI). About 11 % of combat related casualty was reported in US armed forces during 2005 to 2009 due to SCI. Combat stress in armed forces also results in hypertension. Thus, it would of great interest to investigate whether SCI in hypertension aggravates pathophysiological reaction of the cord, and if so do we need additional therapeutic strategies to treat such cases. Accordingly, to deal with these kinds of co-morbidity, exploration of novel therapeutic strategies area required.

Since hypertension alone could result from oxidative stress and SCI induces lipid peroxidation, in this investigation we explored pathophysiology SCI in chronic hypertension. Furthermore used mesenchymal stem cells together with a potent antioxidant compound H-290/51 either alone or using TiO2-nanowired technology to thwart spinal cord pathology in hypertension. Rats were made hypertensive using 2-kidney 1 clip (2K1C) technology where a silver clip was placed on the right renal artery (0.5 mm od) to constrict the vessel for renal hypertension that develops after 4 to 6 weeks (mean arterial blood pressure MABP 180±10 torr). In these hypertensive rats a focal SCI was inflicted under Equithesin anesthesia over the right dorsal horn of the T10-11 segment (1.5 mm deep and 4 mm long). The animals were allowed to survive 24 h after the primary insult.

Our results showed 150 to 230 % increase in the breakdown of the blood-spinal cord barrier

(BSCB) to Evans blue albumin and radioiodine in the T4, T9 and T12 segments in hypertensive group after SCI as compared to normotensive injured rats. Spinal cord edema was 2- to 4 –fold higher in hypertensive rats after SCI than normal injured group. Neuronal injury, activation of glial cells as seen using glial fibrillary acidic protein (GFAP) immunoreactivity and myelin degradation was 120 to 180 % higher in the T9 and T12 segments in hypertensive rats after SCI than injured normotensive animals. Co-administration of TiO2 nanowired commercial mesenchymal stem cells (MSCs, 10^6 cell, i.v.) together with H-290/51 (50 mg/kg, i.p.) 4 to 6 h after trauma significantly attenuated exacerbation of SCI pathophysiology in hypertensive rats and induced remarkable neuroprotection. In normal injured animals co-administration of MSCs and H-290/51 without nanodelivery was also effective when administered 4 to 8 h after SCI. These observations are the first to point out that hypertension exacerbates SCI-induced pathophysiology and in such situations nanodelivery of MSCs and antioxidant compound H-290/51 is needed to achieve neuroprotection, not reported earlier.

Abstract: K. Yang and K. Lee are equally contributed to this work.
Heat Shock Proteins (Hsps), one of the molecular chaperone proteins, are induced by stress or damage such as spinal cord injury (SCI). Recently, Hsps, especially Hsp70 have been found to play an important role for neuroprotection relevance to cell death in SCI but there is a paucity of

study about the role of Hsp27, and 90 in the secondary injury after SCI. In this study, we investigated the change of spinal Hsp27, 70, and 90 expression patterns after SCI. Spinal cord injury was made at T10 level by free-weight dropping a 10 g from a 12.5 mm height using a New York University (NYU) impactor under isoflurane anesthesia. And to assess the temporal changes of Hsp27, 70, and 90 expressions was performed by western blotting in the injured lesion, epicenter at 4h, 8h, 12h, 24h, 3d, and 7d after SCI. Hsp27 expression was significantly increased from 4h to 7days after SCI. Hsp70 was increased immediately after injury but it returned around basal level 7 days after SCI. Interestingly, HSP 90 expression was decreased less than basal level until 7 days after SCI. These results demonstrated that the Hsp27, 70, and 90 were differentially expressed in injured lesion with a different time-course following SCI. This result will be provide a scientific information for further study to explore the role of Hsp27, 70, and 90 on neuroprotection and the secondary injury mechanisms after SCI.

Title: The neuroprotective role of peroxisome proliferator activated receptor-gamma (PPAR-γ) after spinal cord injury in rats

Authors: Y. KIM[1,2], J. OH[1], J. KIM[2,3], *Y. W. YOON[1];
[1]Korea Univ. Col. Med., Seoul, Korea, Republic of; [2]BK21 program, Dept. of Publ. Hlth. Sci., Korea Univ. Grad. Sch., Seoul, Korea, Republic of; [3]Korea Univ. Col. Hlth. Sci., Seoul, Korea, Republic of

Abstract: Traumatic spinal cord injury (SCI) causes deficit of physiological functions below the damaged spinal segment. Pathways in biosynthesis of eicosanoids which result from membrane breakdown extremely increase immediately after SCI. Products of those are the ligands of peroxisome proliferator activated receptors (PPARs), which are a nuclear receptor to regulate gene transcription related to glucose and lipid metabolism. PPARs are classified into three isotype (α, β/δ, γ) in the spinal cord. Above all, PPAR-γ is well studied as regulation of inflammation and neuroprotection in various neurological degenerative diseases. Thus, we

investigated how the PPAR-γ has a neuroprotective role after SCI in rats. The spinal cord of the 10th thoracic vertebra level was contused using NYU device (10 g weight, 12.5mm height) after laminectomy under anesthesia with ketamine/rompun mixture (1:4) in male Sprague-Dawley rats. We examined protein expression of PPAR-γ in the injured epicenter, rostral, caudal and L4-5 region of the spinal cord at various times after SCI (6h, 12h, 24h, 3d, 1w, 3w and 5w). Pioglitazone (PPAR-γ agonist), G3335 (PPAR-γ antagonist) or vehicle (100% DMSO or saline) were administered by intrathecal injection in the early or the late phase after SCI. We assessed locomotor behavior using a BBB rating scale, and analyzed mRNA expression of inflammatory mediators using real-time PCR after the drugs administration. The protein expression of PPAR-γ was excessively increased in all of the spinal segments from 6 hours to 3 days after injury, and then that was gradually returned to basal level. Intrathecal administration of pioglitazone in the early phase improved the joint movement, however, no difference after that. On the other hand, G3335 reduced general locomotion recovery after SCI. mRNA expression of inflammatory mediators and chemoattractant were increased after G3335 treatment in the late phase than in the early phase. These results demonstrated that additionally elevated PPAR-γ may not have benefits to recover motor function anymore, however, deficit of PPAR-γ activity affects to exacerbate it through enhancement of inflammatory reaction.

Title: Role of miR 711 in neuronal cell death after spinal cord injury

Authors: ***J. WU**, B. SABIRZHANOV, B. A. STOICA, J. MATYAS, M. COLL-MIRO, L. YU, A. I. FADEN;
Dept. of Anesthesiol. & Ctr. for Shock, Trauma and Anesthesiol. Resea, Univ. of Maryland, Sch. of Med., Baltimore, MD

Abstract: Spinal cord injury (SCI) triggers secondary injury processes, including neuronal cell death and axonal loss, which contribute to neurological dysfunction. Unfortunately, no current therapeutic strategies are effectively targeting these mechanisms. It is increasingly clear that focusing on one molecule or pathway at a time is unlikely to bring about functionally meaningful neuroprotection and axonal growth. MicroRNAs (miRs) are small (20-23 nucleotide) non-protein-coding RNAs that negatively regulate target gene expression at the posttranscriptional

level by binding to their mRNAs and inducing its degradation and/or inhibiting translation. As single miRs can simultaneously modulate the expression of various proteins in multiple pathways, miRs are attractive candidates as upstream regulators of the secondary SCI progression. Although miRs have been implicated in the pathophysiology of central nervous system (CNS) disorders, few have been directly evaluated at a mechanistic level in traumatic SCI. In the present study, changes in miRs in injured spinal cord after moderate contusion in mice were examined using miR arrays and qPCR. One selected miR (711) was examined with regard to its regulation and relation to neuronal cell death and axonal growth; effects of miR-711 modulation were evaluated after SCI and using *in vitro* primary cortical neurons. Levels of miR-711 were increased in the injured spinal cord early after SCI. Increases coincided with downregulation of the pro-survival protein Akt, a target of miR-711, with sequential activation of glycogen synthase kinase 3 (GSK3)α/β and pro-apoptotic BH3-only molecules PUMA (Bcl2-binding component 3). Central administration of the miR-711 hairpin inhibitor after SCI increased Akt expression and attenuated apoptotic pathways. This treatment increased neuronal survival and axonal myelination, and improved recovery of motor function and coordination. *In vitro*, neurite outgrowth was inhibited in primary cortical neurons transfected with a miR-711 mimic. Together, our data suggest that trauma-induced miR-711 elevation contribute to neuronal cell death after SCI, in part by inhibiting Akt, and may serve as a novel therapeutic target. **Key words:** MicroRNA 711, spinal cord injury, neuroprotection, axonal growth, locomotor function.

Abstract: Central nervous system (CNS) neurons in adult mammals are unable to regenerate their axons after injury. Retinal ganglion cells' (RGCs') intrinsic ability to regenerate and extend their axons is limited after birth. Krüppel-like transcription factor (KLF) family members regulate intrinsic axon growth ability both *in vitro* and *in vivo*, but mechanisms downstream of these transcription factors are not known. Here we identify KLF9 as an axon growth suppressor upregulated 250-fold in RGC development, and find that knocking down KLF9 in adult animals promotes long-distance optic nerve regeneration *in vivo*. By screening genes regulated by KLFs in RGCs that promote (KLF7), inhibit (KLF9 and KLF16) or have no effect in axonal growth (KLF11), we identify dual-specificity phosphatase 14 (Dusp14) as a key player limiting axon growth and regenerative ability downstream of KLF9. We demonstrate the KLF9-Dusp14 pathway inhibits the activation of mitogen-activated protein kinases (MAPK), critical to neurotrophic signaling of RGC axon elongation. Decreasing Dusp14 expression or function in RGCs increased axon growth *in vitro* and survival and regeneration after optic nerve crush *in vivo*. These results link intrinsic and extrinsic regulators of axon growth and shed light into the KLF9-Dusp14 pathway. Targeting this pathway could improve regeneration in the adult CNS after injury.

Title: Neuroprotective properties of BK channel modulators in an acute spinal cord injury model

Authors: M. JACOBSEN, J. BARDEN, K. LETT, M. KARNITSKY, *J. A. BUTTIGIEG; RIC rm 218, Univ. of Regina, Regina, SK, Canada

Abstract: Spinal cord injury results in significant neuronal and glial cell death resulting in impaired neurological and motor function. While there are often surviving axonal tracts, these are frequently dysmyelinated or demyelinated. Key to this pathology is uncontrolled Ca^{2+} entry,

resulting in excitotoxicity and cell death. We propose that by activating mechanisms attenuating global depolarization and limiting Ca^{2+} entry, we can reduce neuronal death and significantly improve neurological and motor function. To this effect, we previously demonstrated that the large-conductance, voltage and Ca^{2+}-activated K^+ (BK or Maxi K^+) channel is altered after SCI, and may play a part in the neuropathology of SCI. In this study, we set out to explore whether the use of a BK channel activator, Isopimaric acid (ISO), is neuroprotective post spinal cord injury. *Wister* rats received a 25-g clip compression injury at the T7 levels for 1 min. One hour post-surgery, they were administered ISO (120 μM), Ibeurotoxin (IbTx; 100nM), or a vehicle control via mini-osmotic pump. Loss of myelination, and cell death were assessed using immunohistochemistry (IHC). Compound Action Potentials (CAP) and high frequency conduction experiments were performed on spinal cords 8 weeks post surgery. Range of motion and joint velocity of knee, ankle and toe joint segments were assessed using two-dimensional motion capture on a weekly basis for 8 weeks. Animals treated with ISO had preservation or re-establishment of axonal tracts and myelination. Compound action potentials of SCI animals treated with ISO were significantly greater than in untreated animals ($p<0.01$), as was the velocity of the CAP ($p<0.001$), however, there were no differences in refractory period or spike train duration, suggesting that there was no difference in function in the surviving neurons. Finally, animals treated with ISO has significantly greater range of motion and joint velocity of their knee and ankle joints, compared to untreated controls ($p<0.001$), and were not significantly different to lamenectomised animals.
In conclusion, activation of the BK channel during acute SCI may be a novel therapeutic target for acute spinal cord injury. Further studies are required to determine if modulation of the BK channel in chronic injury is beneficial for recovery, and to understand the mechanisms by which this ion channel may be working during spinal cord injury repair.

Title: Omega three fatty acids and cooling mitigate altered structural properties of cortical neurons following mechanical injury

Authors: *P. CINTORA[1], Y. J. LEE[1], C. BEST-POPESCU[2];
[1]Neurosci., [2]Bioengineering, Univ. of Illinois At Urbana Champaign, Urbana, IL

Abstract: According to the center for disease control and prevention (the CDC), an estimated 1.7 million brain trauma cases occur each year in the United States (US), and Traumatic Brain Injury (TBI) contributes to a third of all injury-related deaths in the US. Brain trauma can cause immediate, or insidious and persistent, changes in a person's physical, emotional and cognitive functioning. Mild Traumatic Brain Injury (mTBI), or low impact force-induced concussion, is one of the most common causes of brain injury experienced by contact sport athletes and civilians today. In recent years, increasing scientific evidence has emerged strongly suggesting a link between long- term damage of the nervous system and recurrent, low impact force-induced concussions. Concussive forces harm neurons by a variety of mechanisms including: - stretching and shearing of axons; free oxygen radical production; excitotoxic neurotransmitter release; and the release of immune and inflammatory mediators. These consequences of injury may ultimately lead to neuronal degeneration, a break in communication between neurons and subsequent neurodegeneration (i.e. cell death). Using standard cell survival assays, in combination with a novel quantitative form of microscopy Spatial Light Interference Microscopy(SLIM), a cell trauma device (AMScien Instruments) and *in vitro* murine neuronal networks, we characterize and quantify changes in cell survival, neuronal structural integrity, and membrane dynamics after cell culture exposure to mechanical impact (10-14, and 32 psi) and repetitive low force impact. Importantly, we also evaluate how specific physical (e.g. temperature) and chemical reagents (e.g. omega-3 fatty acids and growth factors) modify the impact-induced cellular and network stress response. This *in vitro* injury model promises to broaden our understanding of the injury mechanism of cell- induced trauma and has direct implications in terms of testing effective neuroprotective prevention and treatment strategies.

Engin., Indian Inst. of Technology, Banaras Hindu Univ., Varanasi, India

Abstract: Spinal cord injury (SCI) is a devastating disease causing lifetime disability for which no suitable therapeutic strategies are available except use of high doses of corticoids. Although, corticoids in high dose have serious side effects and improvements in functional and/or pathological outcomes are controversial during long-term treatment. Thus, a possibility exists that a combination of dexamethasone with other potent neuroprotective drugs in SCI will have better therapeutic value.
Our previous studies show that topical application of Acure compound AP173 having affinity to melanocortin-4 receptors that binds to both adrenergic receptors α-2a and I-2 receptors showed pronounce neuroprotective effects in SCI on functional and pathological parameters at 5 h. Thus, the possibility that repeated topical application of Acure compound AP173 either alone or in combination with dexamethasone would enhance the therapeutic value in SCI was examined in a rat model. SCI was produced by making a longitudinal incision into the right dorsal horn of the T10-11 segments under equithesin anesthesia and AP173 (10 µg in 20 µl) was administered topically at 5 min, 60 min or 120 min after injury. The rats were allowed to survive 12 h. In other group, dexamethasone (30 mg/kg) was administered intravenously at 5 min, 60 min and 120 min injury. In addition, a combination of AP173 topically and dexamethasone intravenously were given in another group of rats at identical time periods after SCI. Topical application of AP173 alone 5 min after SCI markedly attenuated behavioral dysfunction following 2 to 4 h after injury that was extended to 5 h if repeated application were made at 60 min and 120 min after trauma. On the other hand, beneficial effects of dexamethasone were seen on Tarlov scale at 9 to 12 h if administered either at 5 min, 60 min and/or 120 min after injury repeatedly. However, a combination of AP173 and dexamethasone either given at 5 min, 60 min or 120 min or their repeated administration (5 min+ 60 min +120 min) did not improve the Tarlov scale after trauma. Likewise, the effects of AP173 on spinal cord edema and BSCB permeability were most

marked when it was administered either at 5 min or repeatedly at 5 min, 60 min and 120 min after injury. Interestingly, identical administration of dexamethasone only slightly reduced the edema formation and BSCB permeability. A combination of dexamethasone and AP173 did not improve the neuroprotective effects of either compound in SCI. These results suggest that AP173 if administered repeatedly during early hours of SCI may have better therapeutic efficacy during early phase of spinal pathology and functional outcome as compared to dexamethasone alone.

Title: Protective effect of the L-type calcium channel on the survival of rat cortical cells

Authors: ***T. TAKADERA**[1], N. OKUMURA[2];
[1]Hokuriku Univ., Kanazawa-Shi, Japan; [2]Fukui Univ., Fukui, Japan

Abstract: Calcium ions mediate a variety of physiological neuronal responses, including cell death or survival. The purpose of this study is to examine whether the L-type calcium channel (LTCC) is involved in the survival of rat cortical cells.
Cultures of rat cortical cells were prepared from an embryonic day 18 rat neocortex. Apoptosis was quantified by scoring the percentage of cells that exhibited an apoptotic nuclear morphology at the single cell level. Intracellular calcium levels were measured using the Ca^{2+}-reactive fluorescent probe Fluo4/AM.
Dihydropyridine-type drugs, such as nifedipine, specifically interact with the LTCC and inhibit calcium influx. After being cultured for 8-10 days, the rat cortical cells were subjected to in vitro nifedipine treatment for 48 h, which induced apoptotic cell death. The cell death was accompanied by caspase-3 activation. *N*-methyl-D-aspartate (NMDA), an agonist of the NMDA receptor, protected the cells from nifedipine-induced apoptosis. Calcium influx via the NMDA receptor contributed to protecting the cells from nifedipine-induced apoptosis. On the other hand, inhibitors of the NMDA receptor, such as MK801, ketamine, alcohol, and memantine, induced apoptosis in the rat cortical cells. LTCC agonists, such as FPL64176, protected the cells from NMDA antagonist-induced apoptosis. FPL64176 increased the cortical cells' calcium levels, whereas nifedipine reduced their calcium levels.

Treating the cells with LY294002, an inhibitor of phosphatidylinositol-3 kinase (PI-3K), also induced apoptosis. The addition of NMDA or FPL64176 to the cells protected them from LY294002-induced apoptosis. Insulin-like growth factor I (IGF-I) acts via PI-3K to protect neurons from apoptosis. IGF-I inhibited NMDA receptor inhibitor- and LTCC inhibitor-induced apoptosis. In addition, the neural caspase-dependent apoptosis induced by MK801, nifedipine, and LY294002 was abrogated by glycogen synthase kinase-3 inhibitors. It is suggested that the LTCC and the NMDA receptor both contribute to the survival of cortical neurons, and hence, ensure that neurogenesis progresses normally.

Title: Antidepressants protect mouse HT22 hippocampal cells from apoptosis through activation of the lysophosphatidic acid receptor LPA_1.

Authors: *M. C. OLIANAS, S. DEDONI, P. ONALI;
Biomed. Sciences, Sect. Neurosci., Univ. of Cagliari, Monserrato, Italy

Abstract: Antidepressants have been shown to decrease neuronal vulnerability to a variety of stressors through mechanisms not completely elucidated. The bioactive phospholipid lysophosphatidic acid (LPA) has been shown to modulate neurogenesis, axonal growth, neuronal differentiation and emotional-like behaviour through specific G protein-coupled receptors termed LPA_{1-6}. Recently, we have reported that in CHO fibroblasts different antidepressants trigger growth factor receptor transactivation and cell proliferation by activating LPA_1 receptor. In the present study we show that in immortalized mouse hippocampal HT22 cells ERK1/2 phosphorylation induced by either the tricyclic antidepressant imipramine or the atypical antidepressants mianserin and mirtazapine was antagonized by the selective LPA_1 antagonist AM966 and by Ki16425, which preferentially blocks LPA_1 and LPA_3. ERK1/2 activation induced by either antidepressants or LPA was attenuated by cell treatment with pertussis toxin and blockade of fibroblast growth factor receptor (FGF-R) tyrosine kinase activity with PD173074. Withdrawal of serum induced apoptosis of HT22 hippocampal cells, as indicated by increased annexin V staining, activation of caspase 7 and 3, and stimulation of poly-(ADP

ribose) polymerase cleavage. Both antidepressants and LPA counteracted the apoptotic cell death and this effect was antagonized by blockade of LPA_1 with AM966 and Ki16425 or by inhibition of FGF-R by PD173074. These data indicate that LPA_1 coupled to growth factor receptor transactivation is a novel molecular target of the neuroprotective action of antidepressants

Title: Arundic acid increases the expression and function of human excitatory amino acid transporter 1 (EAAT1) via ERK, Akt and NF-κB pathways

Authors: P. KARKI, *E.-S. Y. LEE;
Physiol., Meharry Med. Col., Nashville, TN

Abstract: Glutamate is the major excitatory neurotransmitter in the brain and excess extracellular glutamate has to be instantly removed from the synapse to prevent excitotoxic neuronal death. Astrocytes play a critical role in maintaining glutamate homeostasis in the brain since two major glutamate transporters- excitatory amino acid transporter (EAAT) 1 and 2 are predominantly expressed in astrocytes. The reduced expression and function of these astrocytic glutamate transporters act as a contributing factor to the pathogenesis of multiple neurological disorders. The dysfunction of EAAT1 has been linked to Alzheimer's disease, ataxia, and traumatic brain injuries, and also to ophthalmic disorders such as glaucoma. Pharmacological compounds that enhance the expression and function of EAAT1 could be potential therapeutics against these diseases. Arundic acid is an astrocyte modulating agent that inhibits the synthesis of neurotoxic astrocytic protein, S100β and with its potent neuroprotective properties this compound is in the process of clinical development for acute ischemic stroke, amyotrophic lateral sclerosis, Alzheimer's and Parkinson's diseases. Interestingly, arundic acid has been shown to increase EAAT1 expression but the mechanism remains to be elucidated. In this report, we investigated the mechanism of arundic acid-induced upregulation of EAAT1 at transcriptional level and found that NF-κB plays a critical role in this process. In human astrocytic H4 cells, arundic acid-induced increase in EAAT1 promoter activity, mRNA/protein levels and glutamate uptake were blocked by QNZ, a pharmacological inhibitor of NF-κB.

Further, the mutation on NF-κB consensus sites of EAAT1 promoter abolished arundic acid-induced EAAT1 expression. Arundic acid also increased NF-κB reporter activity and induced the nuclear translocation as well as bindings of NF-κB to EAAT1 promoter. Arundic acid activated the Akt and ERK signaling pathway and treatment with LY294002, an Akt specific inhibitor, and U0126, an ERK inhibitor blocked arundic acid-induced increase in EAAT1 expression. Arundic acid also increased EAAT1 promotor activity, mRNA and protein levels in human astrocytes via Akt, ERK and NF-κB pathways. Arundic acid attenuated manganese-induced decreases of EAAT1 promoter activity, mRNA/protein levels and glutamate uptake by suppressing Mn-activated Ying Yang 1 (YY1) expression. These results demonstrate that arundic acid increases the expression and function of EAAT1 via the Akt, ERK and NF-κB signaling cascades and also prevents EAAT1 repression caused by neurotoxins such as manganese via repressing YY1 activation.

Abstract: The anticholinesterase paraoxon (Pxn) is related to military nerve agents and, here, was studied in rat hippocampal slice cultures. Low dose treatment (50 μM) caused a slow, time-dependent loss of GluR1 over 3 days, and high dose Pxn (200 μM) resulted in faster decline in synaptic markers. Evidence in the slice cultures indicated the synaptic compromise is transient for low-dose Pxn, but not for the high-dose insult. Pxn was then studied in vivo, and injected adult rats exhibited a pathogenic cascade initiated by seizure events. Subsequent signs of damage were evident by higher levels of brain proteins labeled with an antibody against 4-hydroxynonenal (4-HNE), an indicator of oxidative stress. Loss of synaptic markers was also found in samples of frontal cortex and hippocampus, regions implicated in learning and memory. Next, we tested a fatty acid amide hydrolase (FAAH) inhibitor (AM5206) for protective effects in Pxn rats since such FAAH modulation has been found beneficial for offsetting seizure-related pathology (Naidoo et al. 2011-12: J Mol Neurosci 43:493, Neurotherapeutics 9:801). The ip injected AM5206 reduced Pxn-induced seizure levels by 86% ($p<0.001$), and it improved balance and coordination measured 24 h post-insult ($p<0.01$). In addition to the seizure and functional protection, evidence shows that AM5206 reduced the 4-HNE indicator of oxidative stress, and the results were in conjunction with synaptic protection. These results support the endocannabinoid enhancement pathway for neuroprotection, in which negative modulation of FAAH slows the breakdown of endogenous cannabinoids, thus allowing them to persist, activating CB1 receptors and repair mechanisms linked to the reduction in excitotoxic progression. FAAH inhibition is an area of research focused on exploiting signaling pathways to prevent and treat neurological damage.

Title: Androgen receptor-independent mechanisms for dihydrotestosterone protection in rodent astrocytes

Authors: ***N. K. KUBELKA**, N. RYBALCHENKO, M. SINGH;
Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Dihydrotestosterone (DHT) is known to exert protective effects in the central nervous system through activation of the intracellular androgen receptor (AR). However, recent studies suggest that DHT may also exert protective effects by way of alternate mechanisms that include prior conversion to 5-alpha androstane-3,17 beta diol, (3beta-diol), a metabolite that can bind to and activate estrogen receptors. Using rodent-derived astrocytes, which lack classical androgen receptor expression, we found that DHT protected against the cytotoxic effects of iodoacetic acid (IAA) toxicity, a metabolic and pro-oxidant stressor. The protective effects of DHT, as assessed by the Calcein-AM assay, were blocked by the co-application of the non-selective estrogen receptor (ER) antagonist, ICI-182,780. This finding implicated ERs as mediators of DHT-induced cytoprotection. Using a complementary viability assay, the MTT assay, which is not only a surrogate marker for cell viability/number, but also an index of mitochondrial respiration, we found that 3beta-diol was also protective against IAA. Interestingly, while the effects of 3beta-diol, the presumptive mediator of the effects of DHT, were blocked by ICI-182,780, they were not blocked by the ER isoform-selective antagonists MPP, against ER alpha, and PHTPP, against ER beta. Collectively, these data support our hypothesis that DHT is protective against cytotoxicity in rodent astrocytes, which lack classical androgen receptor expression, and that the metabolite of DHT, 3beta-diol, may be an important mediator of DHT's effects. Our results also implicate the capacity to convert DHT to 3beta-diol as a relevant factor in conferring protection in postmenopausal women, since in the postmenopausal period, circulating estrogen and progesterone levels have diminished, but androgen levels persist.

Title: Knock-down of targets in the rat CNS using Antisense Oligonucleotides: Kinetics of distribution and pharmacodynamics in the CNS after an intrathecal dose

Authors: *F. KAMME[1], B. POWERS[2], C. MAZUR[2], D. A. WOLF[3], J. M. SULLIVAN[4], D. A. NORRIS[2], A. VERMA[3], E. SWAYZE[2];

Abstract: Antisense Oligonucleotides (ASOs) reduce the amount of a target protein by hybridizing to the cognate RNA. The ASO-RNA hybrid is detected by RNAseH1 and leads to scission and subsequent nonsense-mediated decay of the RNA. In turn, this leads to decreased expression of the target protein. ASO drugs are used clinically, and several are in late stage clinical development, for systemic as well as CNS indications. This study was undertaken to characterize distribution and pharmacokinetics of ASOs in the rat CNS after an intrathecal dose. We imaged ASO distribution in rat brain as a function of time and dose. Imaging was performed semi-quantitatively using an ASO-specific antibody, immunofluorescent detection and high-throughput laser scanning. Furthermore, ASO distribution in live rats was measured by ^{125}I-labelled ASO and whole body SPECT/CT. Down regulation of the target mRNA was measured with qRT-PCR and protein downregulation measured with immunofluorescence and laser based scanning. Finally, ASO tissue concentrations were measured using ELISA. SPECT/CT showed rapid distribution of the dosed ASO from the site of injection in the lumbar cord, to the brain. ASO-staining showed early diffusion of ASO from CSF in the subdural space into brain parenchyma. At 6-8 h post dosing, ASO redistributed rapidly from what appeared to be the extracellular space, into cell bodies. At 24 h, ASO staining showed widespread distribution throughout the rat CNS, including hippocampus, striatum and brainstem. After 24h, changes in ASO distribution were subtle, with an overall gradual decrease in staining intensity until the end of the time course, 16 weeks. RNA knock down was maximal at 7 days after dosing, and maintained at >50% mRNA reduction until week 8. Immunostaining showed a concomitant reduction in protein expression throughout the brain. We show widespread distribution of an intrathecally delivered ASO, into rat brain and spinal cord. Target mRNA and protein knock-down was efficient and sustained. ASO technology is a versatile and powerful platform for CNS research that is rapidly translatable into clinical applications.

Title: The dysfunction of glutamate transporters on the endothelial cells induced by A2AR decreases intracranial glutamate efflux across the blood brain barrier

Authors: *W. BAI, N. YANG, X. CHEN, Y.-L. NING, P. LI, Y. PENG, R.-P. XIONG, Y. ZHAO, Y.-G. ZHOU;
Mol. Biol. Center,State Key Lab. of Trauma,Burn and Combined Injury, Res. Inst. of Surgery and Daping Hosp., Chongqing City, China

Abstract: Besides of the re-uptake by nerve cells, the outward transport by endothelial glutamate transporters is an important mechanism to ensure the intracranial glutamate maintaining at a low level. Our previous study found that the increased level of intracranial glutamate after traumatic brain injury (TBI) was associated with the change of blood glutamate level, suggesting that there was an disturbance of glutamate outward transport across the blood brain barrier (BBB). In this study, we found that Adenosine A2A receptor (A2AR) selective agonist CGS21680 significantly decreased the efflux of intracranial H^3-glutamate, thus lead to the increase of intracranial glutamate level. While inhibiting A2AR activity, either by applicating antagonist ZM241385 or A2AR genetic knockout, could recover the reduction of intracranial glutamate outflow caused by TBI. Furthermore, in an oxygen glucose deprivation (OGD) model of monolayer Bend.3 cells ,we found that A2AR activation increased the expression of glutamate transporters (GLAST/GLT-1) but at the same time reduced their transport efficiency from intracellular to extracellular, resulting in a increased glutamate level in culture medium which even higher than the initial level, indicating that A2AR activation might also cause the reverse transport of glutamate with GLAST/GLT-1. We further explored that A2AR activation could decrease the PKA-dependent interaction of Na^+/K^+-ATPase α1 subunit and phospholemman (FXYD1), thus decreasing the Na^+/K^+-ATPase activity and the Na^+/K^+ distribution inside and outside the cells, leading to rapid decreasing of Na^+-dependent GLAST/GLT-1 efficiency. Consistent with these results, these effects were all inhibited by administration of A2AR antagonist ZM241385. Taken together, the above results showed that A2AR may play an important role in regulating intracranial glutamate homeostasis, and the dysfunction of GLAST/GLT-1 induced by A2AR activation contributes significantly for the sharp rise of intracranial glutamate level after TBI and other brain injuries, which provides a potential therapeutic target for the treatment of brain injury.

Title: N-docosahexaenoylethanolamine enables robust optic nerve regeneration after injury

Authors: *H. KWON, H.-Y. KIM;
NIAAA/National Instiutes of Hlth., Rockville, MD

Abstract: *N*-docosahexaenoylethanolamine (synaptamide), a structural analog of the cannabinoid receptor ligand anandamide, is an endogenous metabolite of docosahexaenoic acid (DHA). Our previous studies have shown that synaptamide stimulates neurite growth, neurogenesis and synaptogenesis. In this study, we investigated the effect of synaptamide on axon growth and regeneration after injury. For *in vitro* studies, mouse P0 mouse primary cortical neurons were plated on an axon chamber and axotomy was performed on 7DIV when axons were sufficiently grown into the other side of the axon chamber. To investigate axon regeneration *in vivo*, mice at 12-14 week of age were injected with synaptamide (10-25 mg/kg) intravitreally after optic nerve crush (ONC). Synaptamide at nM concentrations promoted axon outgrowth *in vitro* through the activation of G protein coupled receptor (GPCR) 110/cAMP/ protein kinase A (PKA) signaling. Significant increases in axon growth were observed when synaptamide was added to either soma or axon side of the chamber. Axon growth after axotomy was also promoted by synaptamide addition to either side of the chamber. Using bodipy-synaptamide and GPR110 antibody, direct physical interaction of synaptamide and GPR110 in primary cortical neuron was demonstrated, and this interaction was crucial for the observed axon outgrowth. Knocking out *gpr110* abolished synaptamide effects on axon outgrowth and regeneration, indicating that GPR110 is required for synaptamide-mediated axon regeneration. In the ONC animal model, axon regeneration was promoted after synaptamide injection. Moreover, electroretinogram (ERG) and visual evoked potentials (VEP) measured at 3 months following optic nerve injury indicated significant improvement of visual function with the synapatamide injection. Collectively, these findings suggest synaptamide as a potential therapeutic agent for functional recovery after nerve injury.

Abstract: RNA-guided genome editing triggered by the CRISPR-Cas9 DNA endonuclease has the potential to cure the underlying cause of a genetic disease. This therapeutic strategy will require tissue-specific delivery of the editing molecules *in vivo*, a goal that is particularly challenging in the brain. Here we show the Cas9 ribonucleoprotein (RNP) complexes can be used to edit post-mitotic neurons in the mouse brain. We also show that protein engineering of Cas9 increased the efficiency of *in vivo* neuronal cell editing ten-fold. Cas9 RNPs introduced locally in the brain trigger genome editing in cells including hippocampal, striatal and cortical neurons by a mechanism that involves spreading beyond the immediate site of injection. We also show that Cas9 RNP complexes are stable over 6 hours in blood plasma. These advances provide a robust technology for application of genome-editing in the brain to treat the underlying cause of neurological genetic diseases.

Title: Inhibition of Cdc42 signaling enhances the sensitivity of cerebellar granule neurons to intrinsic apoptosis

Authors: *N. PUNESSEN, A. NGUYEN, D. A. LINSEMAN;
Univ. of Denver, Denver, CO

Abstract: Neurodegenerative diseases such as amyotrophic lateral sclerosis, Alzheimer's disease, and Parkinson's disease are caused by loss of specific populations of neurons in the brain, brainstem, or spinal cord. Many of these diseases lack highly effective treatments, as most current therapeutics only provide symptom relief but do not alter the underlying cell death mechanisms that contribute to disease progression. One of the most significant contributors to neurodegeneration is excessive programmed cell death, also known as apoptosis. Rho family GTPases, including Rho, Rac and Cdc42, are critical regulators of neuronal growth cone dynamics, axonal outgrowth, and dendritic spine morphogenesis. In addition, these GTPases are also key modulators of neuronal survival and apoptosis. A substantial body of literature has demonstrated a largely pro-apoptotic role for Rho in neurons, while Rac typically plays a pro-survival role. In contrast to the well described antagonistic roles of Rac and Rho in regulating neuronal survival, relatively little is known regarding the effects of Cdc42 on this process. Here, we investigated the role of Cdc42 in cerebellar granule neuron (CGN) survival by testing specific inhibitors of Cdc42 function or one of its downstream effectors. CGNs require serum and depolarizing extracellular potassium (25K healthy medium) for their survival in culture and removal of these survival signals (5K apoptotic medium) leads to intrinsic apoptosis of approximately 50% of the cells after 24 hours. Inhibition of Cdc42 with two dissimilarly structured compounds, ZCL278 and ML141, had no effect on CGN survival in 25K healthy medium but markedly potentiated apoptosis in 5K apoptotic medium. Inhibitors of the downstream Cdc42 effectors, PAK (FRAX486), ACK (AIM100), and N-WASP (Wiskostatin), each produced similar enhancement of CGN apoptosis in 5K apoptotic medium without inducing overt apoptosis in 25K healthy medium. We are currently utilizing molecular approaches (siRNA and dominant negative constructs) to confirm the results obtained with these chemical inhibitors. Overall, the data suggest that Cdc42 signaling to multiple downstream effector proteins plays a pro-survival role in CGNs. Interruption of these Cdc42 pathways is not sufficient on its own to trigger CGN apoptosis in the presence of strong survival signals like serum and depolarizing potassium. However, inhibition of Cdc42 signaling does significantly sensitize CGNs to intrinsic

apoptosis. It will be of interest in the future to determine if Cdc42 pro-survival signals are compromised in various types of neurodegenerative disease.

Title: Identification of proteins that bind to LDL Receptor-related Protein-1 (LRP1) in Schwann cells and activate c-Jun *In vitro* and *In vivo*.

Authors: *A. FLÜTSCH[1], A. GILDER[2], K. HENRY[1], E. MANTUANO[2], S. L. GONIAS[2], W. M. CAMPANA[1];
[1]Dept. of Anesthesiol., [2]Departments of Pathology, UCSD, La Jolla, CA

Abstract: After injury, Schwann cells (SCs) serve as "first responders" by transdifferentiating into a repair phenotype that supports proliferation, cell migration, secretion of growth factors and extracellular matrix proteins and clearance of degraded myelin. These processes are essential for functional nerve regeneration and are referred to as activation of the SC Repair Program (Jessen *et al*. 2015 Dev Cell 34:613-20). LRP1 is up-regulated in SCs after injury and orchestrates many elements of the SC Repair Program (Campana *et al*., 2006 J Neurosci 26(43):1197-207). Cell signaling pathways activated by SC LRP1 include ERK1/2, PI3K, Rac1, and the unfolded protein response (UPR).
The transcription factor c-Jun plays an essential role in the activation of the SC Repair Program (Arthur-Farraj *et al*., 2012 Neuron 75(4):663-47), however SC signaling receptors that regulate c-Jun have not been identified. To address this question, primary SCs were treated with the known LRP1 ligands, tissue-type plasminogen activator (tPA) or the hemopexin domain of MMP-9 (PEX), for 5-30 minutes. Both LRP1 ligands robustly phosphorylated c-Jun and the response was blocked by Receptor-associated Protein (RAP), a known LRP1 antagonist. To confirm that LRP1 activates c-Jun *in vivo*, sciatic nerve injury was induced in Sprague Dawley rats. 24 hours later, when LRP1 is substantially up-regulated in SCs, tPA or PEX was injected directly into the nerves. After 15 min, both ligands significantly increased c-Jun activation as determined by immunoblotting.
To identify novel LRP1 ligands, responsible for activating the SC Repair Program, we applied a proteomics-based discovery approach. Extracts of injured sciatic nerves, prepared so that intact cells are not disrupted, were immunoprecipitated with Fc-fusion proteins containing the

extracellular ligand-binding domains of LRP1 (CCR2 and CCR4). The same samples were incubated with free Fc protein as a control. Tandem mass spectrometry (LC-MS/MS) revealed potential novel LRP1 ligands including Pacsin-1, the axonal protein NFM, and von Willebrand factor. The LRP1-interactome was computationally scored with MiST to exclude false positives and to narrow down candidates for *in vitro* binding validation. Novel LRP1 ligands involved in c-Jun activation may be used therapeutically to augment the SC Repair Program and thus, enhance functional nerve repair.

Title: Immunohistochemistry of selected gene candidates following early life exposure of NMDA and glutamate to hippocampal neurons reveals diversity

Authors: *L. K. FRIEDMAN[1], A. SLOMKO[2];
[2]Cell Biol. and Anat., [1]New York Med. Col., Valhalla, NY

Abstract: Immature neurons can resist neurotoxicity and are capable of generating substantial preconditioning effects in response to seizures or certain excitatory amino acids (EAAs). Our recent transcriptome profiling of hippocampal neurons revealed many up- and down- regulated genes involving distinct Ca^{2+}-binding protein families, G-coupled proteins, growth factors, synaptic vesicle docking factors, neurotransmitter receptors, heat shock, oxidative stress, and anti-apoptotic Bcl-2 gene members that influence neuronal survival. In order to verify regulation of certain candidate genes involved in neuronal preconditioning neuroprotection, we used our prior protocol to expose immature hippocampal neurons to high doses of glutamate (250μM) or NMDA (100μM) for 48 hrs (5DIV), followed by immunohistochemistry with 15 specific antibodies 7 days later when cultured neurons mature (14DIV). A marked decrease in the number of Calb1 and Calm2 positive neurons was observed following NMDA but not after glutamate treatment whereas ryanodine and Cav1.2 voltage gated channel expression was steady under both conditions. A dramatic reduction in the density of $GABA_A\alpha5$ and $GABA_B$ receptor expressing neurons was also observed by prior NMDA exposure but immunodensity measurements of the survivors was unchanged as was expression of the GABA synthesizing enzyme, GAD, suggesting fast inhibitory neurotransmission and response to benzodiazapines

and $GABA_B$-mediated IPSPs may not be reduced in mature survivors despite loss of inhibitory networks. While NR1 mRNA expression was decreased in the microarrays, protein expression revealed selective loss of the NR1 C1 splice variant. Calm2 which can induce inactivation of NMDA receptors by binding tightly to C1 but not C2 regions of its NR1 subunit suggests that the C1 splice variant is co-regulated with Calm2 and that simultaneous loss of these proteins would reduce subsequent NR1 trafficking, phosphorylation, and NMDA currents following early life NMDA exposure. Selective upregulation of Chat after glutamate treatment can lead to persistent increases in cholinergic content. CNRIP mRNA and protein, CB1 interacting, was upregulated under both conditions which can inhibit excitatory neurotransmission and contribute to preconditioning. Diverse changes following overactivation of excitatory receptors of immature neurons appear permanent and are expected to have profound effects on network function and adaptive responses to further insult. Understanding immature defenses may allow translational intervention to improve histopathology and memory and attention tasks deficits that follow neurological insults in adulthood.

Title: The importance of expression of nur family genes on neurite outgrowth through the effect of p300 and histone modification

Authors: *K. SHIMOKE[1], R. YAMAZOE[1], Y. NISHIHATA[1], H. MARUOKA[2];
[1]Kanasai Univ., Suita, Osaka, Japan; [2]KURABO, Kadoma, Osaka, Japan

Abstract: Nerve cells are specialized to transduce an electric signal via the axon, thus it is necessary to construct the neuronal network by the elongation of neurites.In this process, specific genes are expressed during neurite formation. Identification and functional analyses of these genes are important in developing a new strategy for regenerative therapy.We have previously analyzed that valproic acid (VPA), a histone deacetylase inhibitor, promoted neurite outgrowth.

In addition, we have demonstrated that VPA induced the nur family, nur77 and nurr1 genes, in PC12 cells.In present study, we investigated which gene belonging to the nur family, nur77 or nurr1, was important in elongation of the neurites in the presence of VPA by knock-down experiments that suppress nur77 or nurr1 mRNA and p300 mRNA by the specific siRNAs, showing that both genes are important for neurite outgrowth through the function of p300 in the presence of VPA. We also found that epigenetic regulation via histone H3 modification was important for the VPA-induced neurite outgrowth.
These results suggest that up-regulation of nur77 and nurr1 are involved in neurite outgrowth in the presence of VPA through the effect of p300 and acetylation of histone H3 at the specific lysine residue.

Title: Investigation of intracellular signaling and non-coding RNA underlying microglial polarity Induced by neuronal damage.

Authors: S. YACKLEY[1], C. MEYER[1], E. WHITEFORD[1], M. TAPPATA[1], *A. SHIBATA[2]; [1]Biol., [2]Biol. Dept., Creighton Univ., Omaha, NE

Abstract: Activated microglia, the resident immune cells in the CNS, can trigger neurotoxic inflammatory responses or promote neurogenesis and neuronal survival. Microglia exhibit functional polarization becoming pro-inflammatory (M1) or anti-inflammatory (M2) depending upon the activating stimulus. The underlying mechanisms of microglia polarity are still not fully understood. We hypothesize that traumatic injury to cortical neurons polarizes microglia to an M2-like state to promote neurogenesis. We utilize an *in vitro* model system to examine how neuronal damage influences microglial polarization. Immunocytochemical, immunoblot, FLOW and RT-PCR analyses suggest that microglia responding to damaged neurons acquire an M2-like phenotype expressing higher levels of M2 markers CD206 and Arg1 and lower levels of M1

markers CD45 and CD86. A significant decrease in the neurotoxic cytokines IFN-γ and TNF-α and a 23 ± 2.5% increase in the neurogenic cytokine MCP-1 was measured by ELISA in media from microglia co-cultured with damaged neurons as compared to media from microglia co-cultured with undamaged neurons ($p<0.05$). RT-PCR analysis confirms a reduction of IFN-γ and TNF-α mRNA and an increase in MCP-1 mRNA in microglia co-cultured with damaged neurons. Reactive nitrogen species production by microglia co-cultured with damaged neurons was significantly lower (1.26 ±0.09 mM) than that produced by LPS-stimulated M1 microglia (6.05 ±0.06 mM, $p<0.05$). Transition to a neurogenic M2-like microglial phenotype may involve regulation of protein expression via non-coding RNAs. RT-RCR analysis of microRNA (miR) in microglia co-cultured with neurons revealed significant increases in let-7c, miR-124, and miR-9 expression. Co-culture of microglia with undamaged neurons increased let-7c expression by 8.5 fold ± 2.0 ($p=.038$) and miR-124 expression by 9.8 ± 1.3 ($p=.002$) as compared to control microglia. Co-culture of microglia with damaged neurons increased let-7c expression by 12.2 fold ± 3.9 ($p=.009$) and miR-124 expression by 9.9 ± 0.9 ($p=.0001$) as compared to control microglia. MiR-9 expression is specifically increased (4.6± .64 fold) in microglia co-cultured with damaged neurons as compared to microglia co-cultured with undamaged neurons ($p=.037$) suggesting a specific regulatory role for miR-9 in neurogenic microglia. Ongoing immunoblot analysis suggests MAPK pathway and STAT signaling is associated with polarization of microglia following activation by neuronal damage. Understanding the immune mechanisms that drive the neurogenic phenotype of microglia will provide insight into the intrinsic neuroprotective role of immune activity in the CNS.

Title: Drugs that affect dna methylation modulate neuritogenesis in sh-sy5y cells

Authors: *R. A. CANTELMO[1], A. C. SANTOS[2], N. A. G. SANTOS[2], S. R. L. JOCA[3]; [1]Sch. of Pharmaceut. Sci. of Ribeirão Pret, Ribeirao Preto, Brazil; [2]Dept. of Toxicology, [3]Dept. of Pharmacol. Sci., Sch. of Pharmaceut. Sci. of Ribeirão Preto, Ribeirão Preto, Brazil

Abstract: Introduction: DNA methylation is an epigenetic mechanism catalyzed by DNA methyl transferases (DNMT) and associated with gene silencing. Studies suggest that it regulates the expression of genes associated with neural plasticity and might play a role in neurodegenerative diseases. However, little is known about how drugs that target DNA methylation affect neuroplasticity. The present study addresses this issue in SH-SY5Y cells, a widely used neuronal cell model. **Objective:** The aim is to evaluate the effect of two DNMT inhibitors (5-aza-cD, 5-aza-2´-deoxycytidine and RG108, n-phthaloyl-l-tryptophan) and of a metil donor (SAM, S-adenosil-metionine) on neuritogenesis in SH-SY5Y cells stimulated (or not) with retinoic acid (RA), which induces the expression of neurotrophin receptors (trkB and trkC) in these cells. **Materials and Methods:** Growth medium: F12 Ham plus 15% fetal bovine serum (FBS) and 1% antibiotics (PSN). Neurite outgrowth assays: $1x10^5$ cells/well in 24-well plates for 24h; medium was replaced by F12K plus 1% FBS with (or without) 10 μM RA and incubation for 5 days. Additions: RG108 (2000 μM, 100 μM and 4 μM), 5-aza-cD (0.5 μM and 0.005 μM) or SAM (10 nM) and incubation for 72h. Quantitation: inverted-phase-contrast microscopy and Image J open source software. Statistics: one-way ANOVA with Dunnet´s multiple comparisons test or Mann-Whitney t-test for pairs, $P < 0.05$, GraphPad Prism software. **Results:** RG108 (100 μM and 4 μM) 5-aza-cD (0.5 μM) and SAM (10 nM) increased the neuritogenesis of RA-differentiated cells; while RG108 (2000 μM) completely inhibited the neuritogenesis. RG108 (4 μM), 5-aza-cD (0.5 μM and 0.005 μM) and SAM (10 nM) also increased the neuritogenesis of non-RA-differentiated cells; while RG108 (2000 μM) decreased it. **Discussion and Conclusions:** DNA methylation regulators are able to increase the neuritogenesis in SH-SY5Y cells regardless the stimulation by retinoic acid, which suggests their ability not only to activate neurotrophin receptors, but also to induce their expression in this cellular model. Pharmacological modulation of DNA methylation might be an important target to modulate neuroplasticity and the underlying pathways should be investigated.

Title: Pathological stimuli-induced HDAC1 nuclear export is dependent on calcineurin-mediated dephosporylation

Authors: *Y. ZHU, O. G. VIDAURRE, K. P. ADULA, N. KEZUNOVIC, G. HUNTLEY, P. CASACCIA;
Neurosci. Dept., Icahn school of Med. at Mount Sinai, New York, NY

Abstract: Axonal damage is a common pathological feature shared by many distinct neurodegenerative disorders, but its mechanism is only partially understood. Previous work from our lab identified HDAC1 nuclear export as one of the mechanisms contributing to impaired mitochondrial transport and axonal damage. We also reported that inhibition of nuclear export ameliorated the clinical signs related to axonal damage in animal models of demyelination. In our current study, we showed that neuronal-specific ablation of HDAC1 in specific brain regions (by crossing floxed HDAC1 mice to Camk2a-Cre or Grik4-Cre mice) partially protected axons and circuits from excitatory amino acid and cytokine induced damage. In addition, site-directed mutagenesis of serine 421 and 423 to alanine residues promoted the nuclear-cytosolic shuttling of HDAC1, suggesting that dephosphorylation of the serine residues is critical in the process. Importantly, overexpression of dephosphorylated HDAC1 in naïve neurons was sufficient to induce onset of axonal damage. Finally, since our previous studies identified intracellular calcium as an upstream mediator of HDAC1 translocation, we hypothesized that the calcium-dependent phosphatase calcineurin may also play a role in the process. Inhibition of calcineurin activity by the specific inhibitor FK506 prevented HDAC1 nuclear export as well as axonal damage in neurons treated with excitatory amino acid and cytokine. Taken together, our study provides novel insights to the molecular mechanism of HDAC1 translocation and axonal damage under pathological conditions, highlighting HDAC1 as a potential therapeutic target that can promote neuroprotection in a variety of neurodegenerative disorders.

Title: A time course analysis of focused ultrasound mediated glial activation and neuronal stress responses.

Authors: *J. SILBURT[1], K. MARKHAM-COULTES[3], M. A. O'REILLY[4,2], K. HYNYNEN[4,2], I. AUBERT[3,1];

Abstract: Focused ultrasound (FUS) has been used to locally and temporarily permeabilize the blood-brain barrier (BBB), facilitating the non-invasive delivery of therapeutics from the blood to the brain. This technology can be used to deliver genes, stem cells, and therapeutics in animal models. The current safety profile of transcranial FUS-induced BBB permeability led to a clinical trial for the treatment of brain tumors. Clinical applications for neurological conditions such as Alzheimer's disease are being developed and are requiring additional information on the impact of FUS on neural responses. To date, most analysis on safety has focused on gross histology and have not analyzed in depth neuronal stress and glial activation. We have previously shown that in the cortex, following FUS treatment microglia and astrocytes are activated by 4 hours and 4 days respectively, both of which resolve to baseline by 15 days (Jordão et al, 2013). Since this study, the development of new ultrasound transducers and a feedback control system has substantially improved FUS-induced BBB permeability applications. To further assess the impact of FUS-induced BBB permeability on the brain, we evaluated glial cell activation and neuronal stress responses following FUS, up to 10 days post-treatment in a time-course experiment. Using a feedback control system, we applied FUS unilaterally to the hippocampus of C57Bl/6 mice at 3.5 months of age and subsequently analyzed the neuronal stress and glial response using immunohistochemistry. We demonstrate an activation timeline of microglia and astrocytes following FUS. Both astrocytes and microglia display a transient activation, resolving within 10 days. This activation is specific to the focal points of BBB opening. We also investigated whether FUS damages neurons, and show minimal neuronal stress and no neurodegeneration. We conclude that using the feedback control system, FUS induces a mild and transient activation of glial cells. This provides further evidence that FUS-mediated BBB permeability can be applied to the brain in a controlled manner, without inducing damage.

Title: Proteomic analysis of focused ultrasound-induced blood-brain barrier permeability

Authors: *M. LYNCH[1,3], M. KAWAJA[5], J. SILBURT[1,3], S. HEINEN[1], I. AUBERT[1,3], M. O'REILLY[2,4], K. HYNYNEN[2,4];
[1]Biol. Sci., [2]Physical Sci., Sunnybrook Res. Inst., Toronto, ON, Canada; [3]Lab. Med. & Pathobiology, [4]Med. Biophysics, Univ. of Toronto, Toronto, ON, Canada; [5]Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: Focused ultrasound (FUS), in presence of microbubbles, transiently induces blood-brain barrier (BBB) permeability, allowing for the delivery of therapeutics to targeted areas of the brain. FUS has been shown to safely induce BBB permeability without causing edema, hemorrhage or red blood cell extravasation. However, the effect of FUS on the proteomic profile, particularly regarding stress proteins and molecular chaperones, remains unknown. Furthermore, most FUS safety studies have been conducted in healthy models while clinical use includes neurological disorders, such as Alzheimer's disease (AD). As such, the effects of FUS in disease states must also be explored.
Transgenic amyloidosis mice and their non-transgenic littermates underwent unilateral FUS treatment. 24-hours, 2 and 9 days after FUS, mice were sacrificed and treated/untreated hemispheres as well as hippocampal regions were collected for proteomic analysis. Briefly, samples were trypsinized and analyzed using tandem mass tag mass spectrometry. MS/MS samples were analyzed using Sequest and X! Tandem and protein identification was done using Scaffold. Using the untreated contralateral hemisphere as a control we examined the effect of FUS in non-transgenic and transgenic mice both separately and together. We searched specifically for heat shock proteins, molecular chaperones, inflammatory markers, apoptosis, transcription and translation to identify stress and damage related proteomic changes. In addition, using 2D gel electrophoresis we identified upwards of 20 unique proteins modulated by FUS. This study demonstrates that FUS-induced BBB permeability can modulate protein expression in the brain, with minimal impact on stress and damage related proteins, in a mouse model of amyloidosis and their non-transgenic littermates. As FUS is being considered for clinical trial in the treatment of Alzheimer's disease, it is important to know how this method can change protein expression in the brain, in both healthy and pathological conditions.

Title: Induction of osteopontin expression in 3-nitropropionic acid-induced neurotoxicity in rats: potential involvement in striatal neuronal death

Authors: ***T. RIEW**[1,2], Y.-J. SHIN[3], X. JIN[3], J. CHOI[3], M.-Y. LEE[3];
[1]Dept. of Anatomy, Col. of Medicine, The Catholic Univ. of Korea, Seoul/seocho-Gu, Korea, Republic of; [2]Catholic Neurosci. Institute, Col. of Medicine, The Catholic Univ. of Korea, Seoul/seocho-Gu, Korea, Republic of

Abstract: Osteopontin (OPN), an adhesive glycoprotein, has recently been shown to be involved in 3-nitropropionic acid (3-NP)-induced neurotoxicity. The present study explores further the involvement of osteopontin in striatal neuronal death after 3-NP intoxication. Rats were given intraperitoneal injection of 3NP (15mg/kg/day) for 3 days. Double-labeling study using cell death markers such as Fluoro jade-B or TUNEL revealed that OPN expression was induced exclusively in dying neurons as early as 6 hours after the last injection of 3NP. The expression of OPN coincided with a decrease in DARPP-32 expression, marker for medium-sized spiny striatal neurons. OPN expression in dying neuron was evident within 6 hours after last injection of 3NP, peaked at 24 hours, and almost completely disappeared at 7 days. Instead, punctate OPN-positive profiles, most of which were co-labeled with DARPP-32, were absent in the injured striatum until 3 days after the intoxication, but progressively increased in their number and intensity by 7 days. From 3 days and onward, brain macrophages expressing OPN accumulated within the injured striatum. Immunoperoxidase and immuno-gold electron microscopy revealed two different subcellular distribution patterns in degenerating striatal neurons, with OPN protein being diffusely distributed over the somata and specifically localized within swollen mitochondria of degenerating dendrites, which corresponded to punctate profiles in light microscopy. These data suggest that after the 3-NP intoxication OPN is induced exclusively in degenerating neurons, in which OPN was differentially distributed along their somato-dendritic

domains, suggesting that OPN may be involved in the pathogenesis of striatal degeneration.

Laboratories, Inc., Tampa, FL

Abstract: Worldwide, approximately 0.5% of the population suffers a traumatic brain injury each year with most of these injuries classified as mild. Even mild injuries can have long-term consequences that interfere with the life of the patient and impose a burden on our health care system. An improved understanding of the signaling events that are responsible for this neurodegeneration will help to determine necessary treatments to reduce or eliminate neuronal loss. Additionally, while we cannot prevent all injuries, it is important to understand preventative strategies and lifestyle choices, such as cigarette smoking, that could affect the postinjury prognosis. Oxidative damage that results from injury contributes to neuronal loss and an increasing body of evidence suggests that cigarette smoke promotes neurodegeneration. We sought to determine whether exposure to cigarette smoke results in increased neurodegeneration following traumatic brain injury. Additionally, we examined antioxidant therapy that could be

beneficial following injury and could be particularly helpful when the injury is combined with a cigarette smoke insult. We investigated whether tobacco smoke amplifies oxidative stress and accelerates neurodegenerative processes after traumatic brain injury and whether treatment to elevate antioxidant transcription factor activity, Nrf2, could be beneficial with a mouse TBI and tobacco smoke exposure model. We found that postinjury exposure to second hand smoke resulted in less dendritic material in granule cells in the hippocampus. Changes in dendritic complexity in the brain, reactive astrocytosis, and Nrf2 pathway expression may provide a context for the effects of tobacco smoke exposure on traumatic brain injury recovery and whether increasing antioxidant signaling affected plasticity following injury.

Abstract: Cranial radiotherapy is essential in the treatment of malignant pediatric brain tumors, but is unfortunately associated with long-term side effects, including cognitive decline. The underlying cellular mechanisms are only partly known and the relative contribution of, for example, reduced neurogenesis, perturbed myelination, astrogliosis, neuronal cell death, and vascular dysfunction, is a matter of debate. In the current study we investigated the role of the vasculature in cranial radiotherapy. Postnatal day 14 mice received a single absorbed dose of 10 Gy whole brain irradiation (IR) and were sacrificed 6 hours, 24 hours or 7 days post IR. Endothelial cells were isolated from the hippocampus and from the cerebellum using fluorescence-activated cell sorting, followed by cell cycle analysis and gene expression profiling. Flow cytometry revealed that IR increased the percentage of endothelial cells (relative to the whole cell population) in both the hippocampus and the cerebellum, indicating that other cell types were more susceptible to IR-induced cell death. However, IR suppressed proliferation of endothelial cells, as judged by a decreased percentage of cells in S phase and an increased percentage in G0/G1 phase of the cell cycle 6 hours after IR. Genes involved in endothelial cell-specific apoptosis (e.g. ASMase) were not induced at any time point investigated. Inflammation-related genes, on the other hand, were strongly induced, such as CCL2, CCL11 and IL-6. We conclude that endothelial cells do not undergo apoptotic cell death to the same extent as other cell types in the hippocampus and the cerebellum after IR, but that they display reduced cell proliferation. In addition, we demonstrate that endothelial cells play an active, hitherto unknown, role, in the inflammatory response after IR.

Title: Imaging neurodegenerative and glial pathology at single-cell resolution using AAV mediated conditional genetics: A proof of principle in focal cerebral ischemia

Authors: *M. EL-SAADI[1], X. TIAN[1], L. RIVERS[1], H. SUN[2], X. LU[1];
[1]Dept. of Pharmacology, Toxicology, and Neurosci., [2]Dept. of Cell. Biol. & Anat., Lsuhsc-Shreveport, Shreveport, LA

Abstract: A poor mechanistic understanding of neurodegeneration, secondary to the limitations of available biological tools have hindered advancements in this field of research. Developing

biological tools is paramount in the search for novel therapies to stop the onset or halt the progression of ND. Here we describe a simple method- Mosaicism with AAV mediated Genetic Conditionality (MAGiC) for single-cell analysis of neurodegeneration via retro-orbital introduction of AAV for conditional genetic labelling and perturbation in adult mice. MAGiC represents a fast, flexible, less-invasive and easily reproducible method that can be used to reveal detailed morphology and fine structures of genetically defined cell-type specific neurons and glia, allowing for automatic 3D reconstruction and quantification. As proof of principle, we subjected MAGiC mice to middle cerebral artery occlusion (MCAO). Using multi-photon imaging and 3-D reconstruction, we have illustrated the degenerating cortex pyramidal and striatal medium spiny neurons with characteristic features of neurodegeneration. Moreover, we've documented drastic axon degradation consistent with Wallerian pathology while the cell bodies remain intact ("dying back"), opening the possibility of therapeutic intervention. Most notably, this method reveals elaborate morphology of reactive glia and "caught red-handed" the glial engulfment of degenerating neurons and blood vessels. We are employing such "single-neuron degeneration" approach as an in vivo High Throughput Screening (HTS) platform to facilitate translational efforts by improving predicative validity of preclinical assessment of potential efficacy of neuroprotective therapy.

Title: The role of ER stress in Neuropathy Target Esterase-associated disorders

Authors: *E. SUNDERHAUS[1], D. KRETZSCHMAR[2];
[1]Mol. & Med. Genet., [2]Oregon Inst. of Occup. Hlth. Sci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Mutations in Neuropathy Target Esterase (NTE), a phospholipase and regulator of PKA signaling, have been shown to cause a spectrum of disorders. Loss of NTE's ortholog,

Swiss Cheese (SWS), in *Drosophila melanogaster* has been shown to cause an increase in phosphatidylcholine and age-dependent neurodegeneration. SWS is localized to the Endoplasmic Reticulum (ER), and recently, it was shown that perturbing the membrane composition of the ER led to the activation of the ER stress response through the inhibition of the Sarco/Endoplasmic Reticulum Ca^{2+} ATPase (SERCA). To investigate whether ER stress could be causing the neurodegeneration and other symptoms of NTE associated disorders, we are using the *sws*^{1} null mutant line. To determine if *sws*^{1} flies show an activated ER stress response, we analyzed the levels of GRP78, a chaperone known to be elevated in cells undergoing ER stress. Using Western blots, we showed that 7-day-old *sws*^{1} flies had elevated levels of GRP78 when compared to age-matched controls. We next addressed whether manipulating ER stress genetically and chemically can prevent *sws*^{1}-related phenotypes. Overexpressing XBP1, an ER transcription factor, indeed suppressed the degeneration and locomotion defects in *sws*^{1} detected by histology and negative geotaxis assays. Similarly, overexpression of SERCA was able to significantly improve the behavioral defects and neurodegeneration seen in *sws*^{1}. Feeding the flies tauroursodeoxycholic acid (TUDCA), a chemical known to reduce ER stress, significantly improved the neurodegeneration, as well as the gliopathy observed in *sws*^{1}, but did not prevent the locomotion deficits. We will now investigate effects on the ER stress pathways in the *sws*^{1} flies in more detail, and we will determine how different disease-related NTE constructs affect the ER response in the hopes of identifying targets for potential therapies.

Title: Mutation of histidine 547 of human dopamine transporter increases dopamine uptake and attenuates HIV-1 Tat-induced inhibition of dopamine transport

Authors: *J. ZHU[1], P. QUIZON[2], W.-L. SUN[3], Y. YUAN[4], N. M. MIDDE[3], C.-G. ZHAN[4]; [1]Drug Discovery and Biomed. Sci., South Carolina Col. of Pharmacy, Univ. of South Carolina, Columbia, SC; [2]Drug Discovery and Biomed. Sci., Univ. of South Carolina, Columbia, SC; [3]Drug Discovery and Biomed. Sci., Univ. o South Carolina, Columbia, SC; [4]Pharmaceut. Sci., Univ. of Kentucky, Lexington, KY

Abstract: Abnormal dopaminergic transmission has been implicated as a risk determinant of HIV-1-associated neurocognitive disorders (HAND). HIV-1 transactivator of transcription (Tat) protein and cocaine synergistically increase synaptic dopamine (DA) levels by directly inhibiting DA transporter (DAT) activity, ultimately leading to dopaminergic neuron damage. Therefore, an intervention for HIV infection-induced dysfunction of DA systems has the potential to improve neurocognitive function in patients with the early-stage of HAND. Through integrated computational modeling prediction and experimental validation, we have identified key residues in DAT with which Tat interacts, which are critical for Tat-induced inhibition of DAT and transporter conformational transitions. This study investigated the functional influences of mutations of histidine547 (H547A) and its associated residues tyrosine 548 and tyrosine 551 of human DAT in basal DA transport and Tat-induced inhibition of DA transport. Compared to wild type human DAT, H547A-hDAT displayed a 197% increase in the Vmax with no change in the Km. The increased Vmax in H547A was not accompanied by change in DAT surface expression. Results from other substitutions of His547 show that the Vmax was not altered in H547R but decreased by 99% in H547P and 60% in H547D, respectively. Importantly, Tat-induced inhibition of DA transport observed in wild type hDAT was attenuated in H547A, H547R and H547D. PMA, a PKC activator, produced a 40% inhibition of Vmax in wild type DAT and 61% in H547A, whereas BIM, a PKC inhibitor, increased Vmax in WT and H547A by 198% and 142%, respectively. This indicates that H547A-induced increase in DA uptake is dependent on basal PKC activity. These findings demonstrate that His547 plays a crucial role in enhancing basal DA transport and the Tat-DAT interaction. This study may provide novel insights into identifying targets on DAT for therapeutic interventions, improving DAT-mediated DA transmission of HAND in concurrent cocaine abusers.

Title: Genetic ablation of Trpm2 accelerates protein and lipid aggregation in the brain by impaired autophagic clearance

Authors: *B. LEE, J. JUNG, J. LEE, H. KIM, G. HONG, J. WEE, H. LU, U. OH;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: TRPM2, a non-selective cation channel implicated in neurodegenerative diseases is known to work as an enzyme that hydrolyzes highly reactive, neurotoxic ADP-ribose (ADPR). Although ADPR is hydrolyzed by NUT-9 in major organs, these are defective in the brain. The present study questions the role of TRPM2 in the catabolism of ADPR in the brain by assessing the phenotypic response to its dysfunction. Genetic ablation of TRPM2 results in the accumulation of ADPR, disruption of ADPR catabolism, and reduction in autophagic activity in the brain. *Trpm2*$^{-/-}$ mice show aggregations of proteins and lipids in the brain, aberrant structural changes and neuronal connections in synapses, and neuronal degeneration. The TRPM2-deficient mice also exhibit learning and memory impairment, enhanced neuronal intrinsic excitability, imbalanced synaptic transmission, and bilateral spontaneous multifocal epileptiform discharges. The accumulation of ADPR and reduction in AMP in the brain of *Trpm2*$^{-/-}$ mice owing to the loss of TRPM2 catabolizing activity may account for the aggregation of neurotoxic proteins in dendritic spines, which ultimately leads to neuronal dysfunction and degeneration. These results respond to long-unanswered questions regarding the potential role of the enzymatic function of TRPM2 in the brain, whose dysfunction evokes protein/lipid aggregation by autophagic disturbance.

Title: Modulating the lysosomal gene network to identify new therapeutic opportunities for neurodegenerative disorders.

Authors: *V. BOUCHE[1], A. PEREZ ESPINOSA[1], D. MEDINA[2], L. LEONE[3], M. SARDIELLO[1], A. BALLABIO[2], J. BOTAS[1];
[1]Mol. and Human Genet., Baylor Col. of Med. - Neurolog. Res., Houston, TX; [2]Telethon Inst. of Genet. and Med. (TIGEM), Naples, Italy; [3]Inst. of Bimolecular Chemistry, Consiglio Nazionale delle Ricerche, Pozzuoli, Italy

Abstract: Protein and organelle turnover in neurons and in other cell types is controlled by the lysosome-autophagosome system. Increasing evidence shows that the lysosome is strongly involved in the pathogenesis of several neurodegenerative conditions, in which abnormal protein turnover and degradation contribute to the progression of the disease. The evolutionary conserved CLEAR network regulates the expression of genes involved in lysosome biogenesis, autophagy and lipid metabolism. In mammals, the master gene TFEB and other members of the MiTF-TFE family of transcription factors control this network. The genome of *Drosophila melanogaster* includes only one member of the MiTF-TFE family, namely Mitf, who functions as mammalian TFEB. The genetics of the *Drosophila* model system and the absence of redundant MIT transcription factors can be exploited to identify new interacting modulators of TFEB/Mitf function. An important feature of *Drosophila* is their suitability for large genetic screens, which are now possible thanks to the near saturation of their genome with mutations. Therefore, we are conducting an *in vivo* screening using transgenic *Drosophila* strains in which kinases are genetically downregulated. Several assays are being performed in order to evaluate Mitf nuclear translocation and transcriptional activation of target genes. We hypothesize that the genetic screen will identify candidate kinases and pathways involved in TFEB-mediated activation of lysosomal function. Additionally, we will test candidate hits in the context of several *Drosophila* models of proteinopathies, inducing lysosomal-mediated clearance of accumulated toxic protein. We expect that data from the genetic screen will provide novel insight into pathways not previously known to control the lysosomal network through activation of TFEB. Perhaps more importantly, hits from the screen may identify new potential targets for therapeutic intervention in several neurodegenerative disorders.

Title: Effect of nitric oxide synthase inhibitors on methamphetamine-induced hyperthermia and dopaminergic neurotoxicity in mice

Authors: *A. S. DARVESH[1], W. J. GELDENHUYS[2], M. M. HOSSAIN[1], P. SADANA[1], A. J. PRUS[3], S. P. BERGER[4], J. R. RICHARDSON[1];

Abstract: The psychostimulant methamphetamine (MA) produces hyperthermia and long-term nigrostriatal dopaminergic neurotoxicity in both humans and animals. The MA-induced increase in body temperature has been suggested to contribute to dopaminergic neurotoxicity as depletion of striatal dopamine (DA) and reduction of protein levels of tyrosine hydroxylase (TH) was observed following exposure to MA. Oxidative stress, including production of both reactive oxygen and nitrogen species, has been implicated in the neurotoxic effects of MA. Here, we examined the effect of two nitric oxide synthase (NOS) inhibitors on MA-induced hyperthermia and dopaminergic neurotoxicity in adult male CD1 mice. Treatment with a single dose of MA (40 mg/kg, i.p.) exhibited a significant increase in body temperature (+2.2 ^{o}C) up to 2 hr after MA administration. MA-induced hyperthermia was accompanied by induction of heat shock protein 70 (HSP70) (186%), a marker for cellular stress, in the striatum at 16 hr after MA exposure. Mice euthanized six days after MA administration showed significant depletion of cellular DA (47%) and levels of TH protein (52%) in the striatum. Pre-treatment of mice with the non-specific NOS inhibitor NG-nitro-L-arginine methyl ester (L-NAME, 60 mg/kg, i.p.) or the inducible NOS (iNOS) inhibitor aminoguanidine (AG, 100mg/kg, i.p.), 30 min before MA exposure, significantly suppressed the MA-induced elevations of body temperature, and striatal HSP70 expression. Finally, L-NAME and AG pre-treatment prevented the MA-induced reduction of striatal DA and protein levels of TH. Since pre-treatment with both L-NAME and AG also attenuated MA-induced hyperthermia, it is plausible that this effect may contribute to the NOS inhibitor-mediated neuroprotection. Together, these results suggest that NOS mechanisms may contribute to the dopaminergic neurotoxicity of MA and inhibition of oxidative stress could be a potential therapeutic target for reducing MA neurotoxicity.

Title: Impact of stressors on lambda-cyhalothrin induced brain cholinergic dysfunction in rats: Role of mitochondrial bioenergetics

Authors: *R. K. SHUKLA[1], R. GUPTA[1], M. H. SIDDIQUI[2], A. KUMAR[3], A. B. PANT[1], V. K. KHANNA[1];
[1]CSIR – Indian Inst. of Toxicology Res., Lucknow, India; [2]Dept. of Bioengineering, Fac. of Engineering,, [3]Dept. of Biochemistry, Integral Inst. of Med. Sci. & Res., Integral Univ., Lucknow, India

Abstract: Recently, we have found that pre-exposure to immobilization stress (IMS), a psychological stressors and forced swim stress (FSS), a physical stressors exacerbated lambda-cyhalothrin (LCT) induced brain cholinergic dysfunctions in rats. In continuation to this, studies have been carried out to understand the impact of IMS and FSS on LCT induced apoptosis and mitochondrial impairments. No significant change in plasma corticosterone levels, blood brain barrier permeability and expression of anti-apoptotic (Bcl2) and pro-apoptotic (Bax, Caspase-3) proteins was observed in frontal cortex and hippocampus in rats subjected to IMS (one session, placed in plastic restrainer, 15 min/day) or FSS (one session, 3 min/day) for 28 days or exposed to LCT (3.0 mg/kg body weight, p.o.) for 3 days (on days 26, 27 and 28) alone in comparison to controls. Marginal changes in mitochondrial activity, ROS generation and membrane potential both in frontal cortex and hippocampus were evident in rats subjected to IMS or FSS or those exposed to LCT alone as compared to controls. Pre-exposure to IMS or FSS for 28 days followed by LCT treatment for 3 days in rats resulted to increase plasma corticosterone levels, disrupt blood brain barrier permeability and affect the mitochondrial bioenergetics as compared to rats exposed to IMS or FSS or LCT alone. Further, pre-exposure to IMS or FSS caused a marked enhanced ROS generation and decrease in mitochondrial membrane potential associated with alteration in pro and anti-apoptotic proteins in frontal cortex and hippocampus on LCT treatment as compared to rats exposed to IMS or FSS or LCT alone. These changes affect the learning and memory activities on pre exposure to IMS or FSS for 28 days followed by LCT treatment rats. The results clearly exhibit that both psychological and physical stressors contribute in the LCT induced mitochondrial impairments associated with cholinergic dysfunctions. Alterations in behavioural and neurochemical end points were more intense in LCT treated rats pre-exposed to IMS as compared to those pre-exposed to FSS.

Title: Lipidomic analyses identify mitochondrial lipids and omega-3/omega-6 phospholipid decreases in a mouse model of Gulf War Illness

Authors: *U. JOSHI;
Neurosci., Roskamp Inst., Sarasota, FL

Abstract: Introduction: Gulf war illness (GWI) is a multi-symptom illness that affects 25% of veterans from the 1991 Gulf War (GW). Using chemicals implicated in the pathogenesis of GWI (a nerve gas antidote pyridostigmine bromide and a pesticide permethrin), we developed a mouse model of GWI, which presents with cognitive impairment and anxiety, features that are similar to symptoms reported by veterans with GWI. Studies suggest that chronic clinical presentation of GWI accompanies impaired energy utilization in the brain and altered inflammatory parameters in the periphery of ill GW veterans. Therefore, we examined brain lipid profiles in this GWI mouse model at a chronic 16-months post-exposure, a timepoint that is relevant to the current clinical condition of veterans with GWI. Methods: Brain cardiolipin (CL) were extracted using a modified Bligh-Dyer method and analyzed using normal phase high pressure liquid chromatography (HPLC) followed by mass spectrometry (MS) in the fourier transform mass spectrometry (FTMS) mode at 100,000 resolution on a LTQ-Orbitrap mass spectrometer. Following acetonitrile-methanol crash, acylcarnitines were analyzed using hydrophilic interaction liquid chromatography (HILIC) and MS analysis in the FTMS mode at 30,000 resolution on the LTQ-Orbitrap. Lipid extracts obtained using the Folch method were subjected to normal phase LC/MS to separate phospholipid (PL) classes and individual species were identified and quantified with the LipidomeDB software. Lipid extracts were saponified for gas chromatography/mass spectrometry analysis to examine the total fatty acid (FA) content. Results: We observed decreases in acylcarnitine, CL and in PL that contained omega-3 and omega-6 FA in the brains of exposed animals. Total FA analysis also confirmed decreases in omega-3 and omega-6 FA in the brains of GW agent exposed mice. Conclusion: These results indicate that a further examination of mitochondria and biological functions involved in transport and metabolism of omega-3 and omega-6 FA may lead to the development of novel therapies for treating GWI.

Title: Probing the contractility of capillary pericytes *In vivo* with optogenetics

Authors: *D. A. HARTMANN, R. I. GRANT, A. Y. SHIH;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: The cerebrovasculature modulates its resistance to flow in order to match blood supply with the high metabolic demand of the brain. While it is accepted that arterioles ensheathed by vascular smooth muscle cells are capable of modulating blood flow resistance, it is debated whether capillaries lined with pericytes also regulate blood flow. In an attempt to clarify the capacity for pericyte-lined capillaries to regulate blood flow, we examined the contractile ability of cerebral pericytes ~4-9 branch points beyond the penetrating arteriole, which constitutes the middle of the capillary bed. To do this, we generated a transgenic mouse expressing channelrhodopsin-2 in all mural cells (smooth muscle cells and pericytes), and imaged vascular dynamics through an acute skull-removed cranial window using two-photon wavelengths that excite channelrhodopsin-2 primarily in the plane of focus during real-time image collection. In mice lightly anesthetized with isoflurane (0.7% MAC in air), diameters of some capillaries that were 4 or more branch points away from the penetrating arteriole decreased over 20 seconds of excitation, resulting in lumen diameter reductions from baseline averaging ~10%. We only observed diameter changes when using 800 nm two-photon excitation, a stimulation protocol previously used by Hill, et al. (Neuron 87, 2015). The same capillaries exhibited no diameter changes when imaged with 900 nm two-photon excitation, thus making artifacts due to movement of the animal, breathing or heart-beat less likely a contributor to the observed changes. Critically, we did not observe the same extent of capillary constriction using an equivalent stimulation protocol on littermates lacking channelrhodopsin-2 in mural cells. This indicates that channelrhodopsin-2 excitation is the most likely cause of capillary constriction, rather than laser-induced vessel damage. Ongoing studies are being done to ensure that diameter changes are not the result of vessels moving out of the focal plane, and also to examine if these small diameter changes have a meaningful influence on blood flow. Although these are not physiological conditions (i.e. anesthetized with optogenetic stimulation), this work suggests that pericytes deep in the capillary bed are capable of modulating lumen diameter.

Title: The cerebrovascular mural cell continuum: A structural and biochemical characterization of smooth muscle cells, pericytes and intermediary hybrids

Authors: *R. I. GRANT, D. A. HARTMANN, R. G. UNDERLY, A. N. WATSON, A. Y. SHIH;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Vascular smooth muscle cells (VSMCs) and pericytes are the two primary mural cell types that reside on blood vessels of the brain. VSMCs canonically reside on arteries and arterioles, exhibiting ring-like morphology that completely encircles the arteriolar endothelium without any obvious central cell body. In contrast, capillary pericytes have a prominent ovoid cell body and elongated cellular processes that partially cover the capillary endothelium. It is widely accepted that VSMCs regulate blood flow, but whether capillary pericytes possess this ability is a topic of debate. One reason for this debate is a lack of information on how to define mural cells as the cerebral vasculature transitions from arterioles to capillaries. To address this issue, we imaged mural cells in optically-cleared and immunostained mouse cortical tissues with two-photon microscopy. Mural cells were labeled in transgenic mice that expressed tdTomato under control of the PDGFRβ or NG2 promoters. We classified mural cells based on their morphology and expression of the contractile protein, α-smooth muscle actin (α-SMA). These characteristics were then related to subsurface microvessel branch order, defined as the number of branch points between a microvessel of interest and the nearest penetrating arteriole. As arterioles transitioned to capillaries, we found 'hybrid' mural cells with characteristics of both VSMCs and pericytes. These cells possessed protruding, ovoid cell bodies and were oriented longitudinally along their associated vessel, similar to capillary pericytes. However, they also exhibited strong α-SMA expression and completely encircled the endothelium similar to VSMCs. With respect to branch order, VSMCs resided on the penetrating arteriole defined as zero order, hybrid mural cells were typically on 1st to 4th order branches, and capillary pericytes were found on 5th order vessels and beyond. This cellular layout, however, depended upon the size of the branch emerging from the penetrating arteriole. Our data should facilitate a discussion of how to define mural cell types in relation to vessel branch order, a common vascular metric that can be determined both *in vivo* and *ex vivo*.

Title: Chemogenetic modulation of disinhibitory VIP interneuron circuits to enhance recovery from stroke

Authors: ***C. E. BROWN**[1], E. WHITE[2], N. LIANG[2], K. GERROW[2];
[1]Island Med. Program, [2]Univ. of Victoria, Victoria, BC, Canada

Abstract: Functions lost due to stroke such as movement or sensation of the limbs can be partially restored through the rewiring of surviving brain circuits. However, the extent to which neural circuits can regain lost function is limited by excessive inhibitory signalling in the stroke affected hemisphere. One inhibitory circuit that plays a key role in regulating cortical excitability involves those that express vasoactive intestinal peptide (VIP). These VIP interneurons specialize in inhibiting other classes of inhibitory neurons thereby forming a "disinhibitory" network. As such, they are well positioned to modulate post-stroke cortical excitability and recovery of function. In order to first understand how stroke affects these circuits, we performed longitudinal *in* vivo two photon imaging of VIP interneuron structure before and several weeks after focal ischemic stroke in the forelimb somatosensory cortex. Our results show that VIP neurons in the peri-infarct cortex lose a significant number of dendritic spines and axonal boutons in the first week after stroke. This loss of inputs and outputs was followed by a protracted period of growth where new, but generally unstable dendritic spines and axonal boutons formed in the peri-infarct zone. Given the disruptive impact of stroke on VIP circuit structure and presumably function, we hypothesized that chemogenetic enhancement of VIP interneuron excitability could facilitate its disinhibitory role in the stroke affected hemisphere, and help restore lost functions. Our preliminary data show that chemogenetic activation of VIP neurons (expressing excitatory hM3D(Gq) DREADD) enhances normally dampened cortical

responses to forepaw touch after stroke. Furthermore, we have behavioural evidence that chronic chemo-genetic activation of these neurons (from 5 to 42 days post-stroke) significantly enhances the recovery of sensory and motor functions of the affected forepaw. Collectively, these findings suggest that augmenting disinhibitory circuit activity in the stroke affected hemisphere may represent a promising new experimental approach to restoring sensori-motor function.

Title: Whole brain activation dynamics after stroke

Authors: *S. LEVY[1], M. ASWENDT[1], B. HSUEH[2], G. SUN[1], S. ISHIZAKA[1], D. SMERIN[1], M. CHENG[1], K. DEISSEROTH[2], G. STEINBERG[1];
[1]Neurosurg., [2]Stanford Univ., Stanford, CA

Abstract: Recovery following stroke occurs in both animals and humans, and this is attributed in part to rewiring of neural connections in areas adjacent to or remotely connected to the infarct. As stroke causes brain-wide network changes, it is important to investigate brain activity patterns at the cellular level after stroke. In this study we use a high resolution 3D whole brain imaging technique called CLARITY to visualize whole brain/circuit activation at the cellular level during poststroke recovery. An activity reporter mouse line (FosTRAP) was used in this study to visualize cells activated by the immediate early gene Fos. We hypothesize that the CLARITY procedure will provide a more detailed and complete visualization of brain activation patterns in the whole brain.
We used C57Bl6 WT male mice and the activity reporter mouse line (FosTRAP) which utilizes a tamoxifen-dependent Cre recombinase driven under the immediate early gene Fos. Ischemic stroke was induced by transient middle cerebral artery occlusion with an intraluminal suture (30min). Mice were sacrificed at different time points (Post-stroke day 1, 7, 14 and 28) and brains were processed with the CLARITY protocol. Brains were also immunostained with antibodies for neurons and glia.
Stroke brains collected at different post-stroke timepoints became optically transparent after the CLARITY process. Interestingly, the ischemic area turned transparent for all timepoints except

post-stroke day 7 and 28. At these time points the ischemic area remains opaque after the CLARITY process, suggesting that that there may be biphasic physiological processes occurring at these time points that prevented successful clearing. Using Fos-TRAP reporter mice, we observed increased cellular activation in the uncleared infarct and surrounding areas.
Stroke brains can be made optically transparent after the CLARITY process. Using the FosTRAP activity reporter mice, CLARITY provided high resolution visualization of cellular activation patterns during stroke recovery. Ongoing studies include brain maps of activated cells with colocalizations of activated cells using various cellular markers, which may reveal important physiological mechanisms underlying post-stroke recovery.

Abstract: Spontaneous recovery after stroke occurs in both human and animals. A number of events have been described, including changes in extracellular matrix, glia and angiogenesis. However, the underlying neural and molecular mechanisms driving spontaneous recovery are still unclear. We investigated brain/circuit activation patterns in the ipsi- and contralesional hemispheres of spontaneously recovered mice after experimental stroke. In addition, cortical regions from both hemispheres were processed for RNA sequencing to examine the molecular pathways underlying spontaneous recovery. *Method* Ischemic stroke was induced in C57BL/6J adult male mice by transient MCAO for 30 min. Neurological score, vertical pole, and rotating horizontal beam test were performed at baseline and poststroke days 4, 8, and 14 to evaluate recovery. Infarcts were visualized by acquiring T2WI at poststroke day2 using 7-Tesla MR scanner. Mice were sacrificed at poststroke day 15 for immunostaining with antibodies for

astroglial (GFAP), inflammatory (CD68), and chronic neuronal cell activity (FosB). Primary motor cortices were processed for RNAseq. All stroke mice in this study exhibited similar prestroke behavior, poststroke day 4 deficits and cortico-striatal infarct, as verified by MRI and/or histology. These mice were then categorized into spontaneously recovered and non-recovered groups based on their rotating beam performance. *Result* Out of 36 stroke mice with above mentioned similar conditions, 10 (28%) were categorized into spontaneously recovered group and 26 were categorized into non-recovered group. Hierarchical clustering analysis supported this categorization. At poststroke day 14, the recovered group exhibited significantly better beam performance in distance traveled ($p < 0.001$) and speed ($p < 0.001$). FosB immunostaining analysis indicated that higher percentage of the recovered mice exhibited FosB activation in the corresponding contralesional cortex that mirrored the ipsilesional cortical infarct than in non-recovered group (83% and 25%, respectively, $P = 0.05$). *Conclusion* Our study demonstrates that stroke mice with similar cortico-striatal infarct can exhibit significant difference in their behavioral recovery outcome. A higher percentage of spontaneously recovered mice exhibit FosB activation in the contralesional cortex, suggesting that recruitment of contralesional cortex during recovery is beneficial. Current studies include comparison of the RNAseq transcriptome between ipsi- and contra-lesional hemispheres in both groups, which would provide insights into the molecular pathways mediating spontaneous recovery after stroke.

Title: The dramatic alterations of microvascular complexity and oligovascular unit in mice with metabolic syndrome

Authors: *G. XIAO, S. NUNEZ, J. HINMAN;
Neurol., UCLA, Los Angeles, CA

Abstract: Metabolic syndrome (MetS) and obesity are becoming one of the most significant public health problems all over the world, which produce various vascular risk factors and increase the risk of developing chronic vascular disease, particularly cerebral vascular disease. Studies show that patients with MetS have a six-fold increase in the incidence of silent white matter changes and microvascular infarcts, which may lead to dementia, disability and even death. The underlying mechanisms of these changes in white matter are likely involved the interaction of the dominant cell type, oligodendrocyte lineage within white matter. However, the molecular mechanisms that maintain and potentially perturb the oligovascular unit in white matter disease are still poorly understood. To reveal the oligovasuclar changes and molecular mechanisms that mediate disease-activated disruption of the oligovascular unit within white matter, we used cell-specific reporter and RiboTAG transcriptional profiling to identify the structural alteration and molecular signature of the cerebral endothelia damaged by MetS. Transgenic mice (Tie2-Cre:flox-stop tdtomato plus flox-RiboTAG; PDGFRa-CreERT2:RiboTAG) were fed with 60%kCal from fat diet for 12 weeks at 2 months age to induce MetS and 10%kCal from fat diet was used as control. In our findings, MetS alters the cellular and molecular integrity of white matter, which results in an overall loss of nodal-paranodal complexes as well as a decrease in the length of paranodal segments. Electron microscopic analysis reveals a notable change in the density of axons within the white matter of MetS mice. In addition, the myelin profiles of these axons are more prominent in MetS mice compared to controls. Vascular volumes within white matter are significantly decreased in both large and micro vessels in mice with MetS. Surprisingly, the ratio of oligodendrocyte precursor cell increases in MetS mice. Transcriptional profiling of white matter endothelial cells reveals a difference of expression profile between normal mice and mice with MetS. The significant changes in endothelial cell gene expression are associated with the decreased volume of vessels in white matter with MetS through apoptotic signaling pathway. These findings may indicate the loss of vasculature leads to the structural disruption of myelin, alterations of the oligodendrocyte linage and axonal organization. Taken together, our studies suggest a molecular interaction between cerebral microvasculature and the cellular biology of white matter and in doing so create a potential molecular target for diffuse white matter disease.

Title: Vasoconstriction induced by cortical inhibition reduces cerebral blood flow and hemoglobin oxygenation

Authors: *M. DESJARDINS[1,2], K. KILIÇ[3], C. MATEO[4], P. SAISAN[3], C. L. G. FERRI[3], Q. CHENG[3], K. WELDY[3], D. KLEINFELD[4,5,6], A. DALE[2,3], A. DEVOR[3,2,7];

Abstract: Positive Blood Oxygen Level Dependent (BOLD) functional magnetic resonance imaging (fMRI) signal arises in response to neural activity when an increase in cerebral blood flow (CBF) overcompensates for the competing increase in cerebral metabolic rate of oxygen ($CMRO_2$), causing a decrease in deoxyhemoglobin concentration ([HbR]). Yet, the origin of the negative BOLD (nBOLD) signal, arising under certain conditions, is still debated. Using optogenetics and two-photon microscopy *in vivo*, we have previously shown that inhibitory activity elicits a biphasic arteriolar response with a dilation followed by a constriction phase [1]. Arteriolar dilation and constriction lead to increase and decrease in CBF, respectively. However, accompanying changes in blood oxygenation also depend on $CMRO_2$ and thus remain unknown. To address this question, we performed simultaneous measurements of intrinsic optical signals (IOS) and laser speckle contrast (LSC) in response to optogenetic stimulation of inhibitory neurons through thinned skull over the somatosensory cortex of awake, head-fixed VGAT-ChR2(H134R)-EYFP mice. IOS provide measurements of oxy- ([HbO]), deoxy- and total

([HbT] = [HbO]+[HbR]) hemoglobin concentrations. LSC is inversely proportional to CBF. The measured ROI- and group-averaged timecourses of [HbO], [HbR], [HbT] and CBF responses (Fig. 1) show that activation of inhibitory neurons elicits a biphasic hemodynamic response. During the initial CBF increase, [HbO] increases while [HbR] decreases; during the following CBF decrease, [HbO] decreases and [HbR] increases. Therefore, the vasoconstriction phase elicited by neuronal inhibition causes a decrease in both blood flow and oxygenation, which would be reflected as nBOLD in fMRI. [1] Uhlirova H et al. SfN abstr 2014 #352.10. Fig. 1: Average timecourses +/- s.e.m. (N=3, 720 trials total, each trial was a single 100 ms, ~6 mW pulse of 450 nm).

Abstract: Identification of the cellular players that communicate neuronal activity to the vasculature is important for the basic understanding of cerebrovascular regulation. Previously, we reported that arteriolar dilation in response to optogenetic (OG) activation of all cortical inhibitory neurons (INs) started in deep cortical layers [1]. There, we delivered 473 nm-laser light for OG stimulation to the cortical surface via the objective. Since light at this wavelength does not penetrate deep into the tissue, we reasoned that INs that were driving the early dilation onset in deep layers have superficial axons or dendrites. In principle, OG-induced depolarization of superficial axons may trigger antidromic action potentials (APs) that couple OG stimulation at the surface to the release of vasoactive messengers in deep layers. In this case, the vasoactive effect would be abolished by blocking APs and rescued by delivering OG light directly to layer V. To test this hypothesis, we used a tapered optical fiber positioned with its light-emitting tip in layer V for OG stimulation. Under control conditions, OG stimulation through objective and

fiber induced similar arteriolar responses, but upon AP blockade with TTX, the response was lost in both cases (Figure). These results suggest that spiking is required to enable release of vasoactive agents, and that depolarization along dendrites rather than axons may communicate superficial excitation to vasoactive messenger release in deep layers. Supporting this, computational simulations of INs spanning across cortical layers revealed that depolarization of superficial dendrites could drive the soma, located as deep as in layer V, above its firing threshold. Thus, INs mediating dilation may have dendrites, which extend to the surface, and axons that reach into deep layers. One IN type meeting these morphological criteria are which express vasoactive intestinal peptide (VIP). However, further studies with more selective expression of OG actuators are required to test this prediction.

Title: Optical control of blood flow in naive animals

Authors: *R. L. RUNGTA[1], B. OSMANSKI[1], D. BOIDO[1], M. TANTER[2], S. CHARPAK[1]; [1]Neurophysiol. and New Microscopies Lab., INSERM U1128 and Univ. Paris Descartes, Paris, France; [2]Wave Physics for Med. Lab., INSERM U979, Paris, France

Abstract: Abstract:
Over the past decade the use of optogenetics to drive genetically distinct populations of brain cells has profoundly increased our understanding of neural circuitry and brain function in health and disease. Optogenetics is now regularly integrated with functional imaging techniques such as BOLD-fMRI or CBV-fMRI, that rely on neurovascular coupling. However, despite the fact that visible light has been shown to dilate peripheral vessels, the effects of light on cerebral blood flow have not been thoroughly investigated. Here we tested whether light stimulation protocols similar to those commonly used in opto-fMRI or to study neurovascular coupling modulate blood flow in mice that do not express any light sensitive proteins.
Combining two-photon laser scanning microscopy and ultrafast functional ultrasound imaging (fUS), approaches that measure blood flow at the microscopic and macroscopic levels, we report that light per se causes a pronounced pseudo functional hyperemia, of similar magnitude to a sensory stimulation, in the neocortex and the olfactory bulb. Pulses or trains of blue or yellow light (471 or 561nm), shone on the mouse brain across a chronic cranial window, triggered a reversible and reproducible dilation of arterioles. The effect was energy-dependent appearing at a threshold of ~0.5mW-1mW. Two-photon imaging of GCaMP6f in transgenic mouse lines revealed that light caused a decrease of vascular smooth muscle cell calcium that preceded the onset of dilation and occurred in the absence of neuronal excitation.
These results impose careful consideration on the use of photo-activation in studies involving blood flow regulation, as well as in studies requiring prolonged and repetitive stimulations to

correct cellular defects in pathological models. They also suggest that light could be used to locally increase blood flow in a controlled fashion.

Abstract: Non-invasive detection of mild traumatic brain injury (mTBI) is important for evaluation of acute through chronic effects of head injuries, particularly after repetitive impacts. To better detect abnormalities from mTBI, we performed longitudinal studies of magnetic resonance diffusion tensor imaging (DTI) and diffusion kurtosis imaging (DKI) in adult mice after single mTBI (s-mTBI) and repetitive mTBI (r-mTBI; daily x 5), or respective sham procedures. The s-mTBI impact was attenuated for r-mTBI to differentiate whether repetition lowered the impact threshold for pathology. In the corpus callosum, s-mTBI reduced DTI fractional anisotropy (FA) at all post-injury time points (3, 6, 42 days). Conversely, cortical regions were not altered after s-mTBI but r-mTBI reduced cortical axial diffusivity (AD) at all time points with a corresponding increase in axial kurtosis (Ka) at 6 days post-injury. Post-imaging tissue analysis revealed differential pathology in the corpus callosum versus cortex, without detectable microhemorrhages. The corpus callosum exhibited microglial activation, astrogliosis, and demyelination after s-mTBI, with much less robust changes after r-mTBI. However, microglial activation was increased in the cortex after r-mTBI, with a strong correlation (0.7286) to cortical AD values. Studies in Thy1-YFP-16 mice revealed low levels of

axon damage in the cortex in both models, along with marked axon pathology in the corpus callosum. Finally, r-mTBI, but not s-mTBI, produced social deficits consistent with the function of this anterior cingulate region of cortex. Overall, vulnerability of cortical regions is demonstrated after mild repetitive injury, with underlying differences of DTI and DKI, microglial activation, and behavioral deficits.

Title: Neovascularization and functional recovery after intracerebral hemorrhage is conditioned by the Tp53 Arg72Pro single nucleotide polymorphism

Authors: *A. ALMEIDA[1,2], C. RODRÍGUEZ[1], T. SOBRINO[3], M. RAMOS-ARAQUE[1], J. CASTILLO[3], J. P. BOLAÑOS[2];
[1]Inst. of Biomed. Res. of Salamanca, Salamanca, Spain; [2]Univ. of Salamanca, Salamanca, Spain; [3]Hlth. Res. Inst. of Santiago de Compostela, Univ. Clin. Hospital-University of Santiago de Compostela, Santiago de Compostela, Spain

Abstract: Intracerebral hemorrhage (ICH) is a devastating subtype of stroke that lacks effective therapy and reliable prognosis. Neovascularization following ICH is an essential compensatory response that mediates brain repair and modulates the clinical outcome of stroke patients. However, the mechanism that dictates this process is unknown. Bone marrow-derived endothelial progenitor cells (EPC) promote endothelial repair and contribute to ischemia-induced neovascularization. The human *Tp53* gene harbors a common single nucleotide polymorphism (SNP) at codon 72, which yields an arginine to proline aminoacidic substitution *(Arg72Pro*) that modulates the apoptotic activity of the p53 protein. Previously, we found that this SNP controls

neuronal susceptibility to ischemia-induced apoptosis *in vitro*. Here, we evaluated the impact of the *Tp53 Arg72Pro* SNP on vascular repair and functional recovery after ICH. We first analyzed EPC mobilization and functional outcome based on the modified Rankin scale (mRS) scores in a hospital-based cohort of 78 patients with non-traumatic ICH. Patients harboring the *Pro* allele of the *Tp53 Arg72Pro* SNP showed higher levels of circulating EPC-containing $CD34^+$ cells, EPC-mobilizing cytokines -vascular endothelial growth factor (VEGF) and stromal cell-derived factor-1α (SDF-1α)- and good functional outcome following ICH, when compared with the homozygous *Arg* allele patients, which is compatible with increased neovascularization. To directly assess whether *Tp53 Arg72Pro* SNP regulated neovascularization after ICH, we utilized the humanized *Tp53 Arg72Pro* knock-in mice, which were subjected to the collagenase-induced ICH. The brain endothelial cells of the *Pro* allele-carrying mice were highly resistant to ICH-mediated apoptosis, which facilitated cytokine-mediated EPC mobilization and cerebrovascular repair. However, these processes were not observed in the *Arg* allele-carrying mice. These results reveal that the *Tp53 Arg72Pro* SNP determines neovascularization, brain repair and neurological recovery after ICH. This study is the first in which the *Pro* allele of *Tp53* is linked to vascular repair and ability to functionally recover from stroke.

Title: Lysophosphatidic acid receptor 2 contributes to secondary damage after spinal cord injury

Authors: *C. LÓPEZ SERRANO[1], E. SANTOS-NOGUEIRA[1], I. FRANCOS-QUIJORNA[1], M. COLL-MIRÓ[1], J. CHUN[2], R. LOPEZ-VALES[1];
[1]Departament de Biologia Cellular, Fisiologia i Immunologia, Univ. Autonoma De Barcelona, Bellaterra, Spain; [2]Mol. and Cell. Neurosci. Department, Dorris Neurosci. Center. The Scripps Res. Institute, La Jolla, San Diego, CA

Abstract: Lysophosphatidic acid (LPA) is an extracellular lipid mediator involved in many physiological functions by signalling through six known G-protein-coupled receptors (LPA_1-LPA_6). In the central nervous system (CNS), LPA mediates a wide range of effects, including neural progenitor cell physiology, astrocyte and microglia activation, neuronal cell death, axonal retraction, as well as CNS contributions to pain, schizophrenia and hydrocephalus.
We recently reported that LPA contributes to secondary tissue damage after spinal cord injury (SCI). Interestingly, selective blockade of LPA_1 after spinal cord contusion lesion reduced functional deficits and myelin loss, linking LPA_1 signalling to demyelination, which was in part, mediated by microglial cells.
Here, we provide clear evidence on the deleterious contribution of another LPA receptor, LPA_2 (Lpar2, Edg4), to SCI. We found that LPA_2 is constitutively expressed in the spinal cord parenchyma and its transcripts are up-regulated after contusion injury, in part, by microglial cells. To dissect out the role of LPA_2 in this pathology, we induced contusion injuries in LPA_2 deficient mice. Functional and histopathological analysis showed that motor skills, as well as myelin and neuronal sparing, were significantly enhanced in the absence of LPA_2. To gain insights into the detrimental actions of LPA_2 in spinal cord we performed cell culture studies. These experiments revealed that, similar to LPA_1, activation of microglia LPA_2 led to oligodendrocyte cell death. Moreover, we also found that the cytotoxic effects underlying by microglial cells upon LPA_2 stimulation were mediated, in part, by the release of purines. Overall, this study provides new mechanistic insights into how LPA contributes to SCI physiopathology.

Title: Activity of dorsal raphe serotonergic neurons in a spinal cord injury model of depression

Authors: *K. FARRELL[1], M. R. DETLOFF[2], J. D. HOULE[2];
[1]neurology, [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Depression occurs three times more frequently in spinal cord injured (SCI) individuals than in the general population and only a small percentage receives relief with pharmaceutical treatment. The pathology of depression has been attributed to an imbalance in the neurotransmitter serotonin, with the raphe nuclei acting as the primary central source. There also is a suggestion that neuroinflammation may have a prominent role in the development and/or persistence of SCI-depression. In this study we used a battery of behavioral tests (sucrose preference, social exploration, open field, novel object recognition, and forced swim) and hierarchial cluster analysis to identify a depression-like phenotype in approximately 30% of female rats at 4 weeks after a low thoracic, moderate contusion injury. We examined SCI-induced changes in electrophysiological activity of serotonergic dorsal raphe neurons as they relate to long-loop input from pre-frontal cortex glutamatergic neurons to GABAergic interneurons of the dorsal raphe nucleus, using whole cell patch clamp techniques to detect alterations in serotonergic and GABAergic neuron activity in the dorsal raphe at 5 weeks after injury. Further, we used immunocytochemistry to measure changes in levels of GLT1 as an indicator of astrocyte glutamate transport activity. ELISA was used to measure levels of TNFα as evidence of chronic inflammation in higher brain centers (cingulate gyrus, prefrontal cortex and hippocampus) that may contribute to a depressive phenotype and immunocytochemistry identified macrophage-microglial cell activity in the dorsal raphe between non-depressive and depressive phenotypes in SCI rats. Elucidating the role of inflammation in the development of depression after SCI could be instrumental in identifying efficacious treatment strategies for this population.

Abstract: The majority of traumatic spinal cord injuries (SCI) are anatomically incomplete and result in some recovery of function. SCI often leads to oligodendrocyte death and the loss of myelin (demyelination) in the weeks post injury; this impairs impulse conduction and leaves axons vulnerable to degeneration. In rodents, there is robust endogenous myelin repair (remyelination) that correlates temporally with a high rate of oligodendrocyte production and functional recovery. However, a causal link between remyelination and spontaneous motor recovery has not been established. Here, we use an inducible conditional knockout (iCKO) of myelin-gene regulatory factor (Myrf) from oligodendrocyte precursor cells using a PDGFRα-CreER^{T2} driver line. Following chemical demyelination we find that iCKO of Myrf greatly impairs the formation of mature oligodendrocytes, process outgrowth and subsequent remyelination, while leaving oligodendrocyte precursor (OPC) recruitment and undamaged myelin intact. Both Myrf inducible conditional knockout mice (iCKO) and littermate controls (n=23) received a 70 Kdyne thoracic contusion at T9/T10. Tamoxifen was administered between 9 and 5 days prior to injury. Motor behaviour was assessed using the Basso Mouse Scale (BMS) for open field locomotion, gait (footprint) analysis and the horizontal ladder test. There were no significant behavioural differences between iCKO and control mice in any of these behavioural assessments in the first 6 weeks after injury. We also crossed Myrf iCKO mice and controls with an inducible membrane-tethered GFP reporter (PDGFRα-CreER^{T2}::ROSA26mGFP(mT/mG) allowing for the visualization of new myelin following injury. De novo oligodendrocyte production was nearly halted, and little new oligodendrocyte myelin was observed in the Myrf iCKO mice. These data show that oligodendrocyte remyelination is not a major contributor to the recovery of overground locomotion following a moderate thoracic spinal cord contusion.

Title: Dissecting trauma-reactive astrogliosis *In vivo* by cell-type specific analysis of actively translating mRNA

Authors: *J. E. BURDA[1], Y. AO[1], R. KAWAGUCHI[2,3], S. DEVERASETTY[4,5], G. COPPOLA[2,3,5], M. V. SOFRONIEW[1];

Abstract: In addition to upholding normal central nervous system (CNS) function, astrocytes respond to diverse forms of CNS injury with dynamic changes in gene expression, metabolism, morphology, proliferative capacity and function collectively referred to as reactive astrogliosis. Many lines of evidence indicate that astrocytes tune their responses to varying degrees of cell death, axonal injury, vascular disruption and inflammation, resulting in distinct and likely function-specific reactivity profiles that may be informed by differences in molecular expression. Using the transgenically targeted (*J Neurosci 28:7231; 2008*) RiboTag procedure (*PNAS 106:13939; 2009*) and RNA deep sequencing, we have obtained gene translation profiles of reactive astrocytes from the mouse spinal cord after traumatic injury (SCI). Bioinformatics analyses of astrocyte ribosome-associated mRNA (ramRNA) are being used to identify gene expression profiles that define trauma-reactive astrogliosis, and the molecular regulators underlying these dynamic changes in cell state. Importantly, many changes in astrocyte-specific gene expression differ from changes observed for non-astrocyte RNA derived from whole spinal cord tissue after SCI, allowing for the elucidation of reactive astrocyte-specific molecular contributions to the post-injury milieu. Further, we developed a user-friendly database of absolute and relative gene expression profiles of murine scar-forming reactive astrocytes and non-astrocyte cells following SCI to enable searching for individual genes of interest (https://astrocyte.rnaseq.sofroniewlab.neurobio.ucla.edu, *Nature*, 532:195-200; 2016). This study provides a qualitative and quantitative measurement of gene expression by reactive astrocytes after traumatic injury *in vivo*. Further investigation into the genomics of reactive astrogliosis will aid our evolving understanding of mechanisms influencing neuroregeneration and repair. Title: The Aqp4-Trpm4 macromolecular complex mediates astrocyte migration after spinal cord contusion

Authors: *J. A. STOKUM[1], V. GERZANICH[1], J. SIMARD[2];
[1]Neurosurg., [2]Neurosurgery, Pathology, Physiol., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Glial scar formation, a downstream consequence of spinal cord injury (SCI), maintains BBB integrity after SCI, yet strongly inhibits neuronal regeneration and functional recovery. Astrocytes, which migrate to the site of injury after SCI, contribute to glial scar formation. Recently, it was shown that transmembrane water flux mediated by aquaporin-4 (Aqp4), a passive astrocyte transmembrane water channel, is essential for astrocyte migration and glial scar formation. However, the mediators of ion (osmolyte) flux that drive Aqp4 activity during astrocyte migration are unknown. We hypothesized that Trpm4, a Ca^{2+} activated monovalent cation channel that is de novo upregulated by astrocytes after SCI, drives Aqp4 water flux during astrocyte migration after SCI. We used co-immunoprecipitation (CoIP) and Forester resonance energy transfer (FRET) to determine if Aqp4 and Trpm4 co-associate in astrocytes after SCI. To study the functional interaction of Aqp4 and Trpm4 in astrocyte migration, we used calcein fluorescence imaging, immunocytochemistry, and the xCELLigence migration assay. CoIP and FRET data indicate that Aqp4 and Trpm4 form an integral membrane channel complex in astrocytes following SCI. Calcein imaging data indicates that Trpm4 osmotically drives Aqp4 water flux in response to raised intracellular Ca^{2+}. Immunocytochemistry indicates that Aqp4 and Trpm4 localize to the astrocytic lamellipodia with PIP_2, an enhancer of Trpm4 activity. Migration assays indicate that expression of Aqp4 and Trpm4 are necessary for proper migration of primary astrocytes. In conclusion, transmembrane water transport mediated by the Aqp4-Trpm4 complex is necessary for proper astrocyte migration. Thus, the Aqp4-Trpm4 complex represents a new therapeutic target to modulate glial scar formation after SCI.

Title: The effects of distinct spared nerve injury models on spinal synaptic plasticity following spinal cord injury

Authors: *J. HUIE[1], K. MORIOKA[1], C. OMONDI[1], J. HAEFELI[1], J. SACRAMENTO[1], A. FERGUSON[1,2];
[1]Brain and Spinal Injury Ctr., UCSF, San Francisco, CA; [2]San Francisco Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: Spinal cord injury (SCI) is often accompanied by concomitant peripheral injuries, yet little is known about the effect of these injuries on central nervous system (CNS) recovery. Pain research suggests that peripheral nociceptive stimulation may induce maladaptive forms of spinal cord plasticity that could undermine recovery of sensory and motor function. We have recently shown that peripheral electro-nociceptive input after SCI induces maladaptive synaptic plasticity in spinal motor neurons that is AMPA receptor-mediated (Huie et al., 2015). Here we investigate the impact of peripheral nerve injury on spinal synaptic plasticity below a complete SCI.The most widely-used model of nerve injury pain is the spared nerve injury (SNI) model which produces both acute and chronic nociception. SNI models involve cutting 2 branches of the sciatic nerve while sparing the third branch. The ‘spared sensory’ model involves cutting a motor nerve (tibial) and sensory/motor nerve (common peroneal), sparing the sensory sural nerve. An alternative ‘spared motor’ model cuts the sural and common peroneal, sparing the motor tibial nerve. Despite both models being referred to in the literature as ‘spared nerve injury’, the differences in modalities that are interrupted and/or spared in these two SNI models may create

divergent responses in the CNS that are relevant to recovery. To assess how peripheral injury affects spinal synaptic plasticity, we used each SNI model separately in conjunction with a complete thoracic spinal transection to model polytraumatic injury. Lumbar spinal cords were harvested 20 minutes after SCI+SNI, and subcellular fractionation of spinal homogenates was performed to produce a synaptoneurosomal fraction. AMPA receptor subunit (GluA1) expression was assessed using linear fluorescent near-infrared western blot. Preliminary findings suggest a divergent effect of SNI models on AMPA receptor subunit expression, with the 'spared motor' model producing a greater increase in GluA1 expression than the 'spared sensory' model. Work is ongoing to further fully characterize the effects of these SNI models on spinal cord plasticity following SCI.

Title: Nano-based drug delivery systems: Targeting to corticospinal tract neurons for controlled release of therapeutics

Authors: *C. MENGJIE[1], R. VEETTIL[1], D. HYNDS[1], S. GHOSH[2], T. MCALLISTER[2]; [1]BIOLOGY, TEXAS WOMAN'S UNIVERSITY, Denton, TX; [2]Southeast Missouri State Univ., Cape Girardeau, MO

Abstract: Damage to axons of corticospinal tract neurons leads to permanent loss of voluntary fine motor control. Nanoparticle-based systems have seen increasing use in therapeutic fields, where they often serve as a vehicle to deliver drugs to the damaged tissues. We have designed a nano-based drug delivery systems that are capable of being remotely actuated to release an imbibed therapeutic on demand. Furthermore, these biocompatible nanomaterials are encased in a hydrogel that can be derivatized to target the drug delivery system to specific cells. Similar systems can cross the blood brain barrier. In this study, we used nanomaterials with polyethylene glycol-based coats derivatized with -COOH and -NH_2 functionl groups on their surface to study

the mechanism of cell targeting in B35, PC12, and corticospinal tract (CST) neurons. Nanomaterials are taken up more efficiently by neurons, including corticospinal tract neurons. Therapeutic drugs that enhance axon extension (e.g. Y27632, C3 exoenzyme) loaded into nanoparticles are used to study the efficiency of drug release and enhancement of neurite outgrowth. These data suggest that our nanoparticle drug delivery systems are able to target specific neurons and provide on-demand release of a specific drug. Therefore, these systems provide potential therapies for encouraging axon regrowth after spinal cord injury.

Title: Age-associated exacerbation of myelin injury is associated with decreases cholesterol synthesis

Authors: *N. MICHAELS, S. K. JENSEN, K. S. RAWJI, M. B. KEOUGH, J. R. PLEMEL, V. W. YONG;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Age is associated with worse clinical outcomes and delayed recovery in many neurological disorders. Animal models suggest age is associated with increased axonal injury, exaggerated micro- and astro-gliosis, and delayed remyelination. However, the impact of age on the early stages of injury, particularly myelin damage, has not been established. In the current study, we investigated age-associated differences in myelin disruption between young and aging animals. We induced a focal injury in the ventrolateral white matter of female young (1.5 month) and aging (8 month) mice via the injection of 0.5% lysolecithin. Mice were then sacrificed 4, 24, and 72 hours afterwards. Analyses of eriochrome cyanine histochemistry and myelin basic protein immunoreactivity revealed a greater amount of myelin disruption in aging animals 24 and 72 hours post lesion. To investigate potential mechanisms underlying age-associated exacerbation of myelin disruption, we have microdissected naïve and 72-hour post lesion ventrolateral white matter of young and aging mice for RNAseq studies and many transcriptomic differences are apparent. The most pronounced differences occurred in the cholesterol

biosynthesis pathway. Cholesterol in the central nervous system (CNS) is primarily synthesized *de novo* in oligodendrocytes. These cells have been reported to continue to produce cholesterol for the maintenance and synthesis of new myelin throughout the life of an organism. Therefore, its decreased synthesis could indicate oligodendrocyte dysfunction, leaving these cells and myelin more susceptible to injury. Indeed, immunohistochemical analysis of oligodendrocyte lineage cells revealed significantly greater loss 4 hours after injury that persisted into the later time points. These novel results emphasize a greater demyelinating injury in aging compared to young mice in response to lysolecithin and they provide a model to identify mechanisms that contribute to exaggerated myelin disruption with aging so neuroprotective therapeutic strategies can be developed.

Miami Project to Cure Paralysis

Title: Behavioral and histochemical evaluation of phantom limb pain model in rats

Authors: ***S. JERGOVA**, A. LANJEWAR, A. R. NIEDECKEN, C. MARCH, J. SAGEN; Miami Project, Univ. of Miami Sch. of Med., Miami, FL

Abstract: Phantom Limb Pain (PLP) is described as a pain sensation originating from missing body parts. It is very common in amputees (50-70%) and often reported as a severe pain. Therapeutic strategies targeting PLP often provide inadequate pain relief, mostly due to multifactorial features of PLP in terms of origin and mechanism. The goal of this project was to develop a preclinical PLP model in rats to enable evaluation of novel interventive therapies. Animal models of PLP are based on deafferentation injury followed by autotomy behavior. Several clinical studies showed that the presence of pre-amputation pain increase the risk of developing PLP. We used formalin injection prior to axotomy to mimic this scenario and to evaluate development of the behavior in relation to the injection site. Chronic nerve injury prior to axotomy was also evaluated in terms of behavior and expression of various neurotransmitters.

Sprague Dawley males were used in the experiments; their behavior was recorded and scored daily, distinguishing nail biting, distal and proximal digit injury. Animals were perfused within a month and sciatic nerve, dorsal root ganglia (DRGs), spinal cord and brain removed and processed for immunohistochemistry as follows: sciatic nerve was immunostained with NaV 1.7; DRGs with NaV 1.3, 1.7-1.9, CGRP and Substance P; spinal cord with c-Fos, NaV 1.7, CGRP, GAD65/67, NK1 receptor and IBA-1; brain sections were immunostained for c-Fos and GFAP. Results show development of autotomy, as an indicator of disturbed sensory processing, in both models of pre-amputation pain. Animals developed signs of PLP targeting the digits relative to the formalin injection (either lateral or medial side of the hind paw). Control animals (saline injection prior to axotomy) developed delayed and weak or none signs of PLP within the observed period. In the CCI model, the location of the behavior was in correlation with the location of a tactile allodynia at the lateral or medial side of the paw as indicated by Von Frey filaments. The immunohistochemical analysis of the ganglia, spinal cord and brain tissue showed changes in the expression of NaV 1.7 in DRGs and spinal cord related to the development of autotomy. Also, ipsilateral sprouting of CGRP fibers into deeper spinal laminae and enhanced expression of NK1 receptor was observed in animals with PLP behavior compared to animals with the same injury but with mild or no autotomy. The expression pattern of the other neuropeptides was comparable between the different treatment groups. Our results show that the proposed model may be useful in evaluating novel treatment strategies for PLP and suggest possible neurochemical targets for therapy.

Title: Experimental cervical spinal cord injury induces an autoantibody response in the sub-acute phase of the disease

Authors: *A. ULNDREAJ[1], A. TZEKOU[2], E. E. TORLAKOVIC[2,3], M. G. FEHLINGS[4,2]; [1]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada; [2]Univ. Hlth. Network, Toronto, ON, Canada; [3]Dept. of Lab. Hematology, Univ. of Toronto, Toronto, ON, Canada; [4]Inst. of Med. Science, Univ. of Toronto, Toronto, ON, Canada

Abstract: Spinal cord injury (SCI) dysregulates the immune system in an injury level-dependent fashion. The majority of clinical SCI cases occur at the cervical level, which may have a distinct immune signature from thoracic SCI. Autoantibodies against spinal cord and systemic antigens were shown to impair recovery in a mouse model of low thoracic SCI, but whether the development of autoantibodies is induced after cervical SCI remains unknown. Here we explored the development of autoantibody responses in the sub-acute (2 weeks), chronic (10 weeks) and late chronic (20 weeks) phase of cervical SCI in rats. Cervical SCI was induced in female Wistar rats with a 35 g modified aneurysm clip that compressed the spinal cord for 60 sec at the C7-T1 level. Sham animals underwent the same surgical procedure, except for clip compression. Naïve, age-matched rats were also included. We found increased levels of IgG and IgM immunoglobulins in the spinal cord of injured rats at 2 weeks, but not at later time points of this study. Immunohistochemistry and histology revealed increased binding of endogenous IgG and IgM immunoglobulins at the injury epicenter. There, we identified reactive astrocytes surrounding the developing cavity and neurons in the anterior horn as some of the spinal cord cells where endogenous antibodies were primarily located. High antibody levels in the lesioned spinal cord at 2 weeks after cervical SCI were paralleled by a robust autoimmune activation in the spleen. *In vivo*, antibody secreting cells (plasma cells) were significantly expanded after SCI. In an *in vitro* spleen activation paradigm, we found that splenic cells had increased proliferation capacity and produced more immunoglobulins when stimulated with spinal cord homogenate from injured rats, compared to sham controls. This ability was lost after 2 weeks. In conclusion, our results demonstrate that cervical SCI induces an autoantibody response, which is pronounced during the sub-acute phase of injury. This is the first study to characterize the expansion of IgG and IgM immunoglobulin autoimmune responses after cervical SCI and warrants future research that will investigate the mechanisms of autoantibodies and their implication in the progression of cervical SCI.

Title: Promoting targeted reinnervation of phrenic motor neurons and restoration of respiratory function using BDNF after spinal cord injury

Authors: *B. CHARSAR[1], M. URBAN[1], B. GHOSH[1], G. M. SMITH[2], A. C. LEPORE[1]; [1]Thomas Jefferson Univ., Philadelphia, PA; [2]Temple Univ., Philadelphia, PA

Abstract: We are testing a novel approach to promote regrowth of damaged descending bulbospinal respiratory axons and reinnervation of their correct phrenic motor neuron (PhMN) targets after cervical spinal cord injury (SCI). Cervical SCI, which occurs in more than half of all human cases, can be extremely debilitating if the neural circuitry responsible for controlling respiratory function is affected. PhMNs located at cervical levels C3-C5 directly control activation of the diaphragm, which is the major inspiratory muscle. PhMNs are mono-synaptically innervated by bulbospinal projections of respiratory neurons located in a brainstem nucleus called the rostral Ventral Respiratory Group (rVRG). Cervical SCI can result in persistent diaphragm compromise because of damage to these descending rVRG axons, denervation and silencing of spared PhMNs, and consequent paralysis of the hemi-diaphragm. In a rat model of unilateral C2/3 hemisection SCI, we are expressing the axon guidance molecule, brain-derived neurotrophic factor (BDNF), in PhMNs to direct regenerating ipsilateral and/or sprouting contralateral rVRG axons towards PhMNs with the goal of achieving targeted restoration of the critical rVRG-PhMN-diaphragm circuit. Specifically, we are employing anatomically-targeted delivery of adeno-associated virus serotype 2 (AAV2) to the ipsilateral C3-C5 spinal cord to achieve BDNF expression throughout the denervated PhMN pool. Using neuroanatomical tract tracing and *in vivo* electrophysiological approaches, we are exploring the effects of this strategy on rVRG axon regrowth and collateral sprouting, synaptic reconnection with PhMNs, and restoration of ipsilateral hemi-diaphragm activity. Given our findings that rVRG neurons express the BDNF receptor, tropomyosin-related kinase B (TrkB), and that we can efficiently transduce PhMNs using this AAV2-based approach, we hypothesize that BDNF will promote robust PhMN reinnervation by injured rRVG axons and diaphragmatic respiratory recovery.

Title: Pharmacological inhibition of CSPGs receptors LAR and PTPσ positively modulates the inflammatory response and promotes oligodendrocyte replacement following spinal cord injury

Authors: *S. M. DYCK[1], H. KATARIA[1], S. THOMAS[1], B. LANG[2], J. SILVER[2], S. KARIMI-ABDOLREZAEE[1];
[1]Physiol., Univ. of Manitoba, Winnipeg, MB, Canada; [2]Neurosciences, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstract: Traumatic spinal cord injury (SCI) results in significant cell death in oligodendrocytes leading to demyelination and functional deficits. Resident neural precursor cells (NPCs) have a tremendous potential to replace lost oligodendrocytes following SCI. However, the ability of NPCs to proliferate and differentiate into oligodendrocytes is challenged in the post-SCI microenvironment. We previously identified for the first time that injury-induced upregulation of chondroitin sulfate proteoglycans (CSPGs) inhibits several properties of NPCs including their survival, proliferation and differentiation which is meditated through signaling of LAR and PTPσ receptors and activation of downstream Rho/ROCK pathway. In the present study, we evaluated the therapeutic potential of two functionally blocking peptides against LAR (Inhibitory LAR Peptide, ILP) and PTPσ (Inhibitory Sigma Peptide, ISP) in promoting endogenous cell response after SCI. We show that ILP and ISP efficiently block CSPGs inhibitory effects on NPC survival, proliferation, and oligodendrocyte differentiation. In a clinically-relevant model of compressive SCI in rats, we delivered ISP and ILP treatment locally to the injured spinal cord in a sustainable manner for various time-points. Using BrdU incorporation, Western blotting and immunohistochemistry, we identified multiple beneficial effects of ISP and ILP therapy following SCI. Our BrdU studies revealed that ILP and ISP therapy enhances endogenous cell response following SCI by promoting oligodendrocyte preservation and replacement. Conversely, there was a significant decrease in proliferating astrocytes associated with reduced astrocytic scarring. Moreover, ILP and ISP treatment fosters a neuroprotective and anti-inflammatory response in the post-SCI milieu characterized by induced interleukin-10 (IL-10) and arginase-1 expression. Interestingly, ILP/ISP treatment also promoted the phagocytosis ability of microglia which was otherwise reduced upon their activation and by exposure to CSPGs *in vitro*. In conclusion, we demonstrate that CSPGs regulate the response of endogenous precursor cells following SCI by LAR and PTPσ dependent mechanisms. Blocking these receptors by ILP and ISP treatment improves oligodendrocyte differentiation in SCI likely by promoting a pro-regenerative immune response following injury. CSPGs are a key component of the post-SCI milieu with a significant impact on the cell replacement process. Accordingly, our study has identified new clinically relevant therapeutic targets for enhancing cell-based therapies for the treatment of SCI. *Supported by grants from CHN and NSERC.*

Title: Induction of immune tolerance by short-course immunosuppresion after spinal grafting of allogeneic neural precursors in pigs with previous chronic spinal cord traumatic injury.

Authors: *M. MARSALA[1], J. D. CIACCI[2], E. I. CURTIS[2], S. MARSALA[1], M. R. NAVARRO[1], P. CHEN[1], S. JUHAS[3], J. JUHASOVA[3], K. YAMADA[4], K. JOHE[5]; [1]Dept. of Anesthesiol., [2]Dept. of Neurosurg., Univ. of California San Diego, La Jolla, CA; [3]Lab. of Cell Regeneration and Plasticity, Inst. of Animal Physiol. and Genet., Libechov, Czech Republic; [4]Columbia Univ. Med. Ctr., New York, NY; [5]Neuralstem, Germantown, MD

Abstract: *Background:* Current clinical protocols use transient or continuous immunosuppression in patients receiving allogeneic neural precursor grafts for treatment of a variety of neurological diseases, including spinal trauma, stroke or ALS. At present there is no solid evidence, however, that would confirm long-term immune tolerance to allogeneic grafts in a large animal model(s) of chronic spinal cord injury. In our current study, we have tested the engraftment of porcine fetal NPCs after transplantation into the lumbar spinal cord of allogeneic transiently-immunosuppressed spinally-injured recipients. *Material and Methods*: Porcine fetal spinal cord-derived NPCs were isolated from 30-day-old fetuses. NPCs were expanded and characterized by immunofluorescence staining after differentiation in vitro. Clones of UBI-GFP expressing NPCs were then prepared and used in vivo for grafting into the lumbar spinal cord of allogeneic pigs with previous spinal cord L3 contusion injury. Animals (n=4) with fully developed paraplegia were grafted at 5.5 months after spinal injury. All animals received between 30-40 injections of NPCs targeted above, at epicenter and below the injury (10 ul/300,000 cells/injection). After cell grafting, animals were immunosuppressed iv with a combination of Prograf and MFF for 4 weeks. At 4 weeks, immunosuppression was terminated

and animals survived for an additional 3 months (n=1), 6 months (n=1) or 12 months (n=2) without immunosuppression. After survival, animals were perfusion fixed and the presence and differentiation of grafted cells analyzed by immunofluorescence. *Results:* i) In vitro induced NPCs showed expression of neural/neuronal markers, including DCX, NeuN, GABA and GFAP. ii) Analysis of previously injured spinal cord tissue grafted with UBI-GFP+ NPCs showed extensive GFP+ grafts occupying previously injured spinal cord regions. iii) Double staining with neuronal markers (NeuN, SYN, NSE) showed the presence of high density grafted neurons throughout the grafts. iv) Staining with excitatory and inhibitory neurotransmitter markers showed a preferential GABA/glycin-ergic phenotype (VGAT and GAD65 +) in grafted neurons. v) Staining with glial markers showed near complete repopulation of individual grafts with GFAP+ astrocytes and regularly distributed Olig2 positive oligodendrocytes at 12 months after grafting. vi) No signs of cell-mediated rejection were seen at any time point after cell grafting. *Conclusion:* These data demonstrate that short course (4 weeks) immunosuppression is effective in inducing immune tolerance to allogeneic NPCs after grafting into chronically-injured spinal cord in pigs.

Title: Astrocytic morphology altered by glycogen synthase kinase 3β (GSK3β) and chondroitinase ABC in the optic nerve and the spinal cord.

Authors: ***A. KALAM**[1], A. D. RIVERA[1], E. J. BRADBURY[2], A. DIDANGELOS[2], A. M. BUTT[1];
[1]Sch. of Pharm. and Biomed. Sci., Univ. of Portsmouth, Portsmouth, United Kingdom; [2]Wolfson CARD, King's Col. London, London, United Kingdom

Abstract: Astrocytes constitute a major element of the mature glial scar that forms as a result of spinal cord injury (SCI). The glial scar is a physical and chemical barrier for axonal growth and is a key reason why axons do not regenerate. Our aim is to determine whether combinatorial

treatment with GSK3β inhibitors and ChABC has a synergistic effect on regulating the astroglial scar to a more permissive one for axon growth. To test multiple combinatorial treatments with numerous GSK3β inhibitors that have different mode of action we used *in vitro*, *ex vivo* and *in vivo* models to study glia relevant to SCI.
In vitro astrocyte scratch assay was performed using rat primary astrocytes with different GSK3β inhibitors. Since *in vitro* cultures of astrocytes do not reflect the complex three-dimensional multicellular environment of the spinal cord and it is not feasible to test all the drugs *in vivo*, we developed a 'medium throughput' *ex vivo* slice models, using spinal cord and optic nerves from transgenic mice in which the astroglial promoter glial fibrillary acidic protein (GFAP) drives expression of enhanced green fluorescence protein (eGFP). Thoracic spinal cord slices (P10-15) or adult optic nerves from mice were maintained in culture for 3 to 7 days *in vitro* (DIV) and treated with GSK3β inhibitors (lithium chloride, ARA014418, tideglusib or TWS119) or ChABC. Inhibition of GSK3β and treatment with ChABC induced morphological changes in astrocytes in the spinal cord and optic nerve, with the development of a polarised astrocyte phenotype. An equivalent effect of GSK3β inhibition was demonstrated in cultured optic nerves, with a profound effect on astrocyte morphology. To examine this astrocyte phenotype further, we performed a genome wide microarray analysis on the optic nerve following GSK3β inhibition compared to controls. Pathway analysis (IOA, Ingenuity Systems) indicated Axon Guidance Signalling as one of the major pathways significantly altered by GSK3β inhibition, with prominent effects on sema3, which is known to promote axon growth. The results support the possibility that GSK3β inhibition induces an environment permissive for axon growth and that the polarised astrocyte will provide a scaffold for axon growth.
To examine this, we plan to investigate the best GSK3β inhibitors singly or in combination with ChABC *in vivo* using a contusion model of spinal cord injury in adult rats. These experiments will allow us to determine the optimal combinations of GSK3β inhibition and ChABC for regulating the astroglial scar to one that is more permissive for axon growth, prior to determining whether they promote reformation of connections and recovery of function *in vivo* in SCI.

Title: The combined therapy of estradiol and tamoxifen confers neuroprotection after spinal cord injury

Authors: *J. M. SANTIAGO SANTANA[1], W. I. MALDONADO GEORGE[1], D. N. MILLÁN[2], L. A. RODRÍGUEZ[3], S. M. RIVERA[2], L. M. GARCÍA[3], J. COLÓN[3], A. PÉREZ[3], S. AYUSO[2], J. M. COLÓN[4], A. I. TORRADO[4], I. K. SALGADO[4], Y. ARROYO[3], J. D. MIRANDA[4];

Abstract: Spinal cord injury (SCI) is a devastating condition that affects 276,000 people in the U.S. SCI triggers a variety of events at the cellular and molecular level, such as apoptosis, demyelination, inflammation and gliosis, generating a non-permissive environment for axonal regeneration and cell survival. A variety of studies show that Estradiol (E2) has neuroprotective effects after SCI. However, the negative effects that estrogen may generate can raise some concern. Fortunately, Tamoxifen (TAM) is a FDA approved drug that can selectively modulate estrogen receptors, selectively allowing for the beneficial effects of E2. This study shows definitive evidence of the effects of the combined therapy of E2 and TAM administration after injury. Adult female Sprague-Dawley rats received a moderate contusion at the thoracic vertebrae (T_{10}) with the NYU impactor device. Sham animals were treated with an E2 implant (placed subcutaneously, in the *mid*-scapular region; 3 mg) and E2 bolus (intravenously; 100 µg), this project consisted of four groups of SCI animals; the groups were depicted as follows, 1) injured with an empty silastic implant (SE) and sesame bolus, 2) injured with a E2 implant and E2 bolus, 3) injured with SE + E2 bolus and TAM (placed subcutaneously, *mid*-scapular region; 15 mg), 4) injured with E2 implant + E2 bolus + TAM. Behavioral studies were performed weekly over a 35 days post-injury (DPI) period and anatomical studies were performed to assess white matter spare tissue with luxol fast blue staining. Results showed that administration of E2 and TAM administration after SCI significantly enhances functional locomotor recovery at 35 DPI (* = $p<0.05$). Luxol fast blue staining showed a significant increase in white matter preservation after SCI in caudal areas in animals treated with E2 (* = $p <0.05$) and in rostral and caudal areas (*** = $p < 0.001$) in animals treated with the combined therapy (E2 + TAM). Together this data suggests that TAM administration may be a suitable approach to develop a possible therapy for SCI in the near future.

Title: Imaging neural activity in the primary somatosensory cortex using GCaMP transgenic mice

Authors: X. LIN, W. XIONG, W. WU, M. WALKER, X. JIN, *X. M. XU;
Neurolog. Surgery, Indiana Univ., Indianapolis, IN

Abstract: The ability to chronically monitor neuronal activity in the living brain is essential for understanding the organization and function of the nervous system. Two-photon laser scanning microscopy (2P) imaging with genetically encoded calcium indicators (GECIs) permit investigating intracellular calcium transients in vivo. In this study, we described an experimental procedure for measuring calcium transients from single neuron in primary somatosensory cortex or S1 from GCaMPs transgenic mouse using 2P. This GCaMP animal model allows for prolonged and stable calcium imaging in intact adult animals in vivo. Key aspects of the protocol, which can be completed in less than 1h, include the use of a variant of high-speed 2P imaging and minimally invasive surgery procedures for an open-skull window on both sides of the skull. Although we only demonstrate the technique in the S1 area, it allows investigation of activity patterns in defined neuronal populations in the living brain and will greatly facilitate dissecting complex structural and functional relationships of neural networks.

Title: miR-21 correlates with progression of degenerative cervical myelopathy and is a marker of hypoxia-induced inflammation

Authors: *A. M. LALIBERTE[1], S. KARADIMAS[2], K. SATKUNENDRARAJAH[2], P. VIDAL[2], M. G. FEHLINGS[2];
[1]Genet. and Develop., Univ. of Toronto, Toronto, ON, Canada; [2]Genet. and Develop., Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Degenerative Cervical Myelopathy (DCM), the most common cause of adult spinal cord dysfunction, is a compressive non-traumatic form of spinal cord injury resulting from degeneration of the structural elements of the spine. Although the structural compression can be identified, the progression of DCM pathology is highly variable. This unpredictability is largely due to the scarcity of knowledge of the underlying mechanisms. MicroRNA-21 (miR-21) is up-regulated under hypoxia and is associated with pro-inflammatory macrophage activation, both potentially important mechanisms in DCM pathology. Previously, we have found an increase in mir-21 in the spinal cord and plasma of DCM rodents. Further, preliminary data from the ongoing human DCM microRNA biomarker study have identified a correlation between miR-21 and poor 1-year follow-up outcomes. Given miR-21's relationship to both hypoxia and inflammation, it is possible that hypoxia-induced miR-21 exacerbates inflammation and directly promotes neurological deterioration in DCM. Therefore, we hypothesize that miR-21 is up-regulated by the hypoxic/ischemic conditions arising from cord spinal cord compression, and that this increase contributes to DCM progression. Using a novel mouse model of DCM, we examined wild type and miR-21 knockout mice at 3, 6 and 12 weeks after DCM induction (mild, moderate, and severe deficits, respectively) compared to sham. To determine whether miR-21 levels were associated with hypoxia, we performed qPCR for miR-21 and hif1a and found that expression of both were highest in moderate DCM mice (10 fold, $p<0.001$, and 1.5 fold, $p=0.004$, respectively). The cellular localization of miR-21 expression was determined by in situ hybridization of spinal cord cryosections, where there was colocalization of miR-21 with Iba1+ microglial cells. In order to confirm the relationship between hypoxia, miR-21 and microglia, in vitro hypoxia experiments were performed using the HAPI microglial cell line. HAPI cells increased mir-21 under hypoxia (1% O2) (19 fold, $p<0.001$) and with pro-inflammatory LPS stimulation (7.8 fold, $p<0.001$). With respect to the function of miR-21 in DCM animals, loss of miR-21 in knockout mice improved rotarod performance by 70% compared to wild type ($p=0.004$). Based on these findings, hypoxia is associated with increased microglial expression

of miR-21 and progression of DCM. Furthermore, we demonstrate that miR-21 deletion attenuates this locomotor deterioration in DCM mice. These data support the observed correlation between miR-21 and patient outcome, underscoring the potential utility of miR-21 as both predictive marker and therapeutic target in DCM.

Title: Immune modifying microparticles modulate hematogenous monocytes and promote recovery after spinal cord injury

Authors: *J. G. COOPER[1], S. JEONG[1], I. IFERGAN[2], S. B. SHARMA[1], D. XU[2], T. MCGUIRE[1], J. A. KESSLER[1], S. D. MILLER[2];

Abstract: Spinal cord injury (SCI) disrupts the blood-brain/spinal barrier and causes a neuroinflammatory response at the lesion site that ultimately results in a secondary wave of axonal destruction. Many studies have demonstrated that infiltrating hematogenous monocytes are important contributors to secondary tissue damage and fibrotic scar formation after SCI. This suggests that selectively blocking monocyte infiltration during the acute phase after SCI could help limit tissue damage. However, developing a practical and translatable approach to selectively target hematogenous monocytes has been challenging due to their surface marker similarities with resident microglia and other immune cells. In the present work, we demonstrate that hematogenous monocytes can be safely and selectively depleted through intravenous injection of immune modifying microparticles composed of biodegradable poly(lactic-co-glycolic)acid (PLGA-IMPs) to produce therapeutic benefits after contusion SCI in mice. PLGA-IMPs selectively target circulating monocytes by binding to the macrophage receptor MARCO, which is expressed on the cell surface of monocytes. Monocytes bound to PLGA-IMPs no longer

travel to inflamed sites, but instead, they are sequestered to the spleen and undergo apoptosis. We demonstrate that acute PLGA-IMP treatment after severe contusion SCI in mice markedly improves functional recovery up to 12 weeks post injury as assessed by Basso Mouse Scale (BMS) open field scoring. Animals that receive PLGA-IMP treatment after SCI display decreased intralesional expression of inflammatory cytokines, diminished fibrotic scarring, and reduced levels of inhibitory extracellular matrix molecules, hence making the environment more permissive for repair and recovery. We demonstrate that acute IMP treatment results in the preservation of axonal density caudal to the lesion site at chronic time points. These data support that hematogenous monocytes contribute to neuroinflammatory damage and fibrotic scar formation after SCI, and more importantly establish PLGA-IMPs as a promising tool for treating SCI and encourage further optimization of the technology to move it forward into clinical development.

Title: Riluzole prevents functional deficits during mild distraction spinal cord injury

Authors: *E. N. SHIMIZU, K. J. JOHNSON, M. I. ROMERO-ORTEGA;
Bioengineering, Univ. of Texas At Dallas, Dallas, TX

Abstract: Scoliosis, an abnormal curvature of the spine, affects an estimated 6 to 9 million people in the United States. The first treatment involves bracing to mitigate further curvature, however the effectiveness of this approach is limited, leading to 38,000 spinal fusion surgeries annually. During scoliosis corrective surgery significant distraction forces are imparted on the vertebral column, causing spinal cord injury (SCI) in approximately 1-3% of surgeries, reaching as high as 27% in severe deformities where more complex surgical procedures must be used. We previously developed a new SCI model that utilizes linear actuators to apply bilateral distraction forces on the rat spinal cord, resembling those during scoliosis corrective surgery. Characterization of the injury allowed us to define optimal parameters (i.e. distraction length,

and speed). We use a total distraction length of 5mm at 0.5 mm/s and hold distracted for 15 minutes, which does not cause tissue damage as determined by immunocytochemistry. Instead it induced hypoxic damage, possibly by oxidative stress, indicated by significant increase in protein carbonyls 30 minutes post injury. These changes correlate with a mild locomotor deficit, which persisted for the 7 day assessment period. In this study, we investigated the neuroprotective effect of Riluzole, a sodium channel blocker, to mitigate the deficits following a mild distraction SCI. Thirty-two adult female Long Evans rats were randomly divided into four experimental groups in which either Riluzole or vehicle was administered intraperitoneally to each animal prior to undergoing a sham operation or a distraction injury. Behavioral assessment was evaluated using the CleverSys TreadScan kinematic system on post- operative days 1,3,5, and 7. Statistical analysis showed significant deficits ($p<0.05$) in the stride length and stance time in vehicle treated animals after distraction during the 7 day assessment period. This deficit was prevented by Riluzole pre-treatment, as these animals showed comparable stride length compared to sham animals. The data suggests a mechanistic explanation to a mild distraction SCI which involves dysfunction in ion channels creating an excitotoxic environment that can be prevented by Riluzole. These results also support the notion that Riluzole can be used as neuroprotective treatment to reduce the risk of SCI during corrective spine surgery.

Title: Neuroplasticity in the injured spinal cord following Sox9 ablation three weeks post injury

Authors: *N. M. OSSOWSKI, N. M. GEREMIA, T. HRYCIW, K. XU, A. BROWN; Robarts Res. Inst., Univ. of Western Ontario, London, ON, Canada

Abstract: Recovery after spinal cord injury is limited, as neuronal connections lost due to trauma are never fully restored. This poor recovery is due to the molecular environment of the spinal cord that limits neuroplasticity. Perineuronal nets are matrix structures that pose a major impediment to reactive sprouting owing to their high content of chondroitin sulfate

proteoglycans (CSPGs). Our laboratory has shown that conditional *Sox9* ablation prior to spinal cord injury, effectively decreases CSPG levels in the perineuronal nets distal to the lesion. We have also demonstrated that the decrease in perineuronal net CSPG levels improves locomotor recovery after spinal cord injury. In the present study we have set out to determine whether conditional ablation of *Sox9* in the subacute period after spinal cord injury also yields increased neuroplasticity compared to controls. In this study, *Sox9* was ablated in mice 3 weeks after spinal cord injury. Immunohistochemistry and neuronal tracing to assess neuroplasticity and levels of perineuronal nets will be presented.

Title: IL-13 administration favors microglia and macrophages to adopt an M2-like phenotype after spinal cord injury

Authors: *J. AMO-APARICIO, R. LOPEZ-VALES;
Univ. Autonoma De Barcelona, Bellaterra, Spain

Abstract: Spinal cord injury (SCI) elicits an inflammatory response that comprises mainly microglia and peripheral blood-derived macrophages. These cells contribute directly or indirectly to tissue damage and functional loss; however, they can also promote repair. These paradoxically conflicting roles of microglia and macrophages depend on their polarization state: In response to interferon gamma or lipopolysaccharide, macrophages and microglia undergo “classical” M1 polarization. Contrary, upon interleukin 4 (IL-4) or interleukin 13 (IL-13) stimulation, macrophages and microglia acquire “alternative” M2 polarization. M1 macrophages and microglia release high levels of pro-inflammatory cytokines and free radicals. These compounds are crucial for killing microbes and tumor cells, but they also induce damage in healthy

neighboring cells and are associated with cell loss and secondary damage after SCI. Contrary, M2 macrophages release anti-inflammatory cytokines and are involved in parasite containment, tissue repair and remodeling events after injury. Importantly, the finding of this macrophage dichotomy was originally described using *in vitro* systems. *In vivo*, macrophages are influenced by multiple additional factors. This leads to a wide spectrum of intermediate phenotypes, where the M1 and M2 archetypal states are located at the ends of this range. Macrophages and microglia display predominantly M1 markers after SCI, whereas the expression of M2 markers is limited. To get insights into the mechanisms that impede microglia and macrophages to acquire an M2-like phenotype after SCI, we found that the expression of IL-13, one of the most important M2 polarizing factors, is detected at very low levels in the contused spinal cord and only for the first 24 hours post-injury. We therefore hypothesized that inefficient induction of IL-13 expression after SCI favors microglia and macrophages to remain in a M1-like state. We first evaluated the expression of IL-13 receptor (IL-13Rα1) and found it is induced in microglia and macrophages following contusion injury. Interestingly, we observed that microglia and macrophages induce the expression of the M2 marker Arg1 upon IL-13 administration into the lesion site. Moreover, IL-13 administration reduced the expression of the M1 markers, iNOS and CD16/32, in these immune cell subsets. These results provide evidence that low levels of IL-13 after SCI hamper microglia and macrophages to acquire an M2-like activation state. Further studies are needed to elucidate whether the redirection of microglia and macrophages polarization by IL-13 minimize tissue damage and functional deficits after SCI.

Title: A potent anti-spastic effect after intrathecal NK1 antisense oligonucleotide or subpial AAV9-NK1-ShRNA delivery in rats with chronic spinal transection-induced muscle spasticity

Authors: *M. BRAVO HERNANDEZ[1], T. YOSHIOZUMI[1], M. R. NAVARRO[1], K. KAMIZATO[1], T. TADOKORO[1], O. PLATOSHYN[1], S. MARSALA[1], J. D. CIACCI[2], C. MAZUR[3], M. MARSALA[1];
[1]Anesthesiol., [2]Neursurgery, Univ. of California San Diego, LA Jolla, CA; [3]Ionis Pharmaceuticals, Carlsbad, CA

Abstract: BACKGROUND: The spinal NK1 receptor system has been demonstrated to play an important role in the development and maintenance of chronic pain states after peripheral nerve injury. In contrast, its role in the development of spinal hyper-reflexia and muscle spasticity resulting from spinal traumatic injury is not well defined. The goal of the present study was to assess the treatment effect of: i) spinal intrathecal (IT) delivery of NK1 antisense oligonucleotide (NK1-ASO), and ii) subpial (SP) delivery of AAV9-NK1-shRNA in rats with chronic spinal cord transection-induced muscle spasticity. METHODS: Adult Sprague-Dawley (SD) rats (female, 200-300 g) had the Th9 spinal segment transected to induce muscle spasticity. The presence of spasticity was defined as exacerbated EMG response recorded from the gastrocnemius muscle after applying progressively increased paw pressures using von Frey filaments (0.6-26 grams). After baseline spasticity measurement, animals received: i) a single lumbar intrathecal bolus of NK-1-ASO or control antisense oligonucleotide (Cont-ASO), or ii) subpial (SP) AAV9-NK1-shRNA or control AAV9-GFP. Before and after treatment, the presence of spasticity response was measured in 1-week intervals for up to 12 weeks. The effect of each treatment on spinal NK1 expression was evaluated by immunofluorescence and confocal microscopy or by qPCR. RESULTS:In spastic animals receiving IT injection of NK1-ASO, a progressive decrease in measured surface EMG activity after paw tactile stimulation was seen with the maximum effect measured at 2 weeks after injection ($p<0.05$). A significant anti-spastic affect was still present at 10 weeks after treatment. No changes in spasticity response were measured in animals receiving control ASO. In animals injected SP with AAV9-NK1-shRNA, a comparable anti-spasticity effect was seen at 2 weeks after treatment. Histological and qPCR analysis of the lumbar spinal cord showed a 75-85% reduction in NK1 signal with no change in substance P expression. CONCLUSIONS: These data show that NK1-ASO or AAV9-NK1-shRNA-mediated suppression of spinal NK1 receptor expression may represent a novel therapeutic approach for modulation of chronic spinal injury-induced muscle spasticity and hyper-reflexia.

Title: The effects of 10ms pulsed radiofrequency (PRF) treatment on behavioral measures of chronic pain and gene expression changes along the nociceptive pathway

Authors: *J. M. WILLIAMS[1], D. M. TILLEY[2], C. KELLEY[2], D. L. CEDENO[2], R. VALLEJO[2];
[1]Illinois Wesleyan Univ. Dept. of Psychology, Bloomington, IL; [2]Millennium Pain Ctr., Bloomington, IL

Abstract: Pulsed radiofrequency (PRF) therapy is a clinical treatment utilizing electromagnetic energy aimed to relieve chronic pain states such as neuropathic pain. A previous study in our laboratory used a spared nerve injury model (SNI) of chronic pain to investigate the behavioral efficacy of PRF therapy and associated molecular changes in the sciatic nerve, ipsilateral L5 dorsal root ganglia (DRG) and spinal cord of rats using clinically-relevant settings (500 Hz, 45 V and a 20ms pulse burst within 500ms pulse intervals). The previous study found significant pain relief following PRF therapy that was associated with gene expression changes in TNF-α, IL-6, GABAB-R1, NA/K ATPase, 5-HT3R and c-fos. These changes varied depending upon the tissue examined. The present study investigated whether a 10ms pulse burst with 500ms pulse intervals would yield similar behavioral efficacy and similar changes in gene expression. Results show that 10ms PRF therapy produced significant pain relief 24 hours following treatment. Unlike the previous 20ms study, no significant changes in gene expression were observed in the sciatic nerve (site of injury) following 10ms treatment. In the DRG, 10ms PRF treatment resulted in gene expression changes in subP, NA/K ATPase, 5-HT3R, Gal, VIP and GFAP levels. In the spinal cord, gene expression changes following 10ms PRF treatment were observed in subP, NA/K ATPase, 5-HT3R, Gal, NPY, IL-6 and SNAP25 levels. Overall, 10ms PRF treatment was equally efficacious as 20 ms PRF treatment in relieving neuropathic pain induced by SNI lesions of the sciatic nerve and resulted in gene expression changes in the DRG and spinal cord regions, but not the sciatic nerve.

Title: Treatment of postraumatic intraspinal pressure may limit secondary damage in acute rodent spinal cord injury

Authors: *Z. Z. KHAING, L. N. CATES, D. M. DEWEES, Z. BIRJANDIAN, C. P. HOFSTETTER;
Neurolog. Surgery, Univ. of Washington, Seattle, WA

Abstract: Traumatic spinal cord injury (SCI) leads to devastating neurological impairment. Currently, the only clinically effective intervention following traumatic SCI is surgical decompression to remove the impinging bone fragments within 24 hours after injury. Recent data from our lab and others indicate that intraspinal pressure increases significantly (up to five times the normal intraspinal pressure) after a moderate thoracic contusion SCI. Here we examined the histological and behavioral correlates of increased intraspinal pressure after acute SCI. We found that there was an increase in the local edema (spinal cord water content: intact = 64.95 ± 0.80%, 4 hours after post injury = 74.80 ± 0.18%; 7 days after injury = 75.38 ± 2.46%), along a 10-15 mm segment of the injured spinal cord compared to uninjured cord tissue. Next, we examined myelin sparing using the Iorn-Eriochrome Cyanine R method. Preliminary data suggests a trend towards increased myelin sparing in the injury center and in segments rostral to the injury in animals that received surgical decompression by opening the meningeal linings to alleviate increased intraspinal pressure, compared to control animals (injury alone). Importantly, treatment of elevated intraspinal pressure reduced the lesion length (rostrocaudal extent) significantly ($p < 0.005$). There was no significant difference of the spared neurons between injured animals compared to injured animals that received decompression surgery. Intriguingly, decompression by opening the meningeal linings resulted in significant functional recovery after SCI: evaluated using an open-field locomotor test (Basso, Beattie and Breshnahan test), and foot-fault analysis. Results presented here suggest that raised tissue pressure following acute SCI is an important parameter that significantly affects functional recovery in a clinically relevant rodent model. Moreover, elevated pressures may impact the efficacy of experimental therapeutic interventions that are currently evaluated in rodent contusion models of SCI.

Title: Potent & long-lasting suppression of muscle spasticity by spinal subpial AAV9-mediated VGAT and GAD65 gene delivery in a rat thoracic 9 transection model of chronic spasticity.

Authors: *T. YOSHIZUMI[1], K. KAMIZATO[1], A. PLATOSHYN[1], M. R. NAVARRO[1], S. MARSALA[1], J. D. CIACCI[2], M. MARSALA[2];

Abstract: Loss of spinal segmental GABA-ergic inhibition is believed to play an important role in the development of spinal injury-induced muscle spasticity and spinal hyper-reflexia. In our previous studies, we have characterized the anti-spastic potency of spinal parenchymal GAD65 gene delivery once combined with systemic tiagabine (GABA uptake inhibitor) treatment but the overexpression of GAD65 gene alone showed no measurable treatment effect. In our current study, the anti-spastic potency after spinal subpial dual gene delivery, composed of GAD65 & VGAT (vesicular GABA transporter), in a thoracic 9 (T9) complete transection model of chronic spasticity in rats was studied. Adult Sprague-Dawley (SD) rats were used to perform a T8 laminectomy followed by a complete T9 transection of the spinal cord. To measure muscle spasticity, EMG response recorded by surface EMG electrodes from the gastrocnemius was used and analyzed after applying progressively increased paw pressure using von Frey filaments. At 2-3 months after transection and baseline spasticity measurement, animals received a lumbar subpial injection of AAV9 encoding the GAD65 and VGAT under ubiquitin promoter. AAV9-UBI-GFP was used in controls. After AAV9 delivery, the spasticity response was measured in 7-day intervals for 2 months & animals were then perfused with 4% paraformaldehyde. The expression of GAD65, VGAT, VGLUT1 and VGLUT2 was then analyzed in spinal cord sections with immunofluorescence. A potent and time-dependent antispasticity effect was seen in the treatment group. A significant effect was present at 3 weeks and then continued for the duration of the study (i.e., 2 months). No effect was seen in the control group. Immunofluorescence analysis of lumbar spinal cord sections showed a significant upregulation of GAD65 and VGAT and also the presence of those proteins in excitatory VGLUT1 and VGLUT2 terminals. These data demonstrate that dual AAV9-mediated subpial GAD65/VGAT gene delivery leads to a potent and sustained anti-spasticity effect. The use of this treatment approach may represent a novel treatment for modulation of chronic spinal injury-induced muscle spasticity.

Title: Activation of RhoA is contributed to apoptosis of reticulospinal neurons in lamprey brain after spinal cord injury

Authors: *K. G. ZHANG[1], J. HU[1], W. RODEMER[1], M. E. SELZER[1,2];
[1]Shriners Hosp. Pediatric Res. Ctr., [2]Neurol., Lewis Katz Sch. of Medicine, Temple Univ., Philadelphia, PA

Abstract: Disability following spinal cord injury (SCI) is due to failure of axonal regeneration. It is believed that both extrinsic inhibitory factors, e.g., the chondroitin sulfate proteoglycans (CSPG) and the myelin-associated growth inhibitors (ligands for the Nogo receptor), and a developmental loss of intrinsic growth capacity contribute to regeneration failure in CNS axons. The latter is suggested by findings in the lamprey that the 18 pairs of individually identified reticulospinal neurons (RNs) vary greatly in the abilities of their axons to regenerate through the same spinal cord environment. We also found that the same neurons that are bad regenerators undergo very delayed apoptosis, and show common molecular markers. For example, we showed that after SCI, the CSPG receptors PTPσ and LAR are upregulated selectively in the bad-regenerating/bad-surviving neurons. Thus we hypothesize convergence of signaling pathways for cell survival and axon regeneration. In mammals, many of the postulated extrinsic growth-inhibitory factors, including CSPGs, activate intraneuronal signaling pathways that converge on RhoA. Therefore, we cloned lamprey RhoA and studied its role downstream of the CSPG receptors on SCI-induced retrograde neuronal death. RhoA mRNA was expressed widely in normal lamprey brain, but was upregulated by 2 weeks post-SCI selectively in neurons undergoing apoptosis, indicated by labelling with fluorescently labelled inhibitors of caspase activation (FLICA). Thereafter, RhoA mRNA decreased through 9 weeks, the longest time investigated. RhoA mRNA was found in severed axon tips immediately after spinal cord injury, and this was followed by anterograde translocation from the perikaryon down the axon, beginning at 5 days post-SCI. However, RhoA protein was continuously activated in FLICA-

labeled neurons through 9 weeks post-SCI. RhoA activation was correlated with caspase activation, and inversely correlated with the previously-determined regenerative probability of RNs. These findings are consistent with a role for RhoA in signaling apoptosis and restricting axon regeneration.

Title: Surgical decompression for degenerative cervical myelopathy induces activation of the immune system

Authors: *P. VIDAL VERA[1], S. K. KARADIMAS[1], A. ULNDREAJ[3], A. M. LALIBERTE[3], J. WANG[2], M. FEHLINGS[3];

Abstract: Degenerative cervical myelopathy (DCM) is the most common spinal cord impairment. It is caused by the age-related degeneration of the cervical spine, leading to chronic compression of the spinal cord. Surgical decompression is the current treatment for DCM patients, in order to halt disease progression and further neurological deterioration. However, restoration of the spinal cord blood flow can cause ischemia-reperfusion injury (IRI), contributing to the neurological decline observed within the first months after surgical management.
The primary objective of this study was to characterize the inflammation post-decompression and its contribution to IRI and neurological recovery in an experimental rodent model of decompression. A gradual compression of the spinal cord was induced into two groups by inserting a biomaterial underneath the C5-6 lamina. The first group received an early decompression (6 weeks after DCM), whereas in the second group surgery was delayed (12 weeks after DCM). Locomotor assessment of upper and lower limbs was performed using the Catwalk analysis, whereas manual dexterity was assessed using the Capellini handling test. Our results using injection of fluorescent microspheres show that surgical decompression increases spinal cord blood flow compared to DCM animals in the early decompressed group.

This is accompanied with a concomitant increase in the production of inflammatory cytokines in the spinal cord within 24 hours after decompression. When surgery is delayed there is spinal cord reperfusion followed by astrogliosis and an ongoing release of inflammatory blood monocytes and the production of cytokines, without neurological improvement. Moreover, we found that early decompression attenuates inflammation within 24 hours after surgical decompression, resulting in gait improvement in upper and lower limbs together with a significant recovery in manual dexterity.
Our data show that surgical decompression triggers activation of the immune response. When surgical decompression is delayed, spinal cord reperfusion is followed by ongoing activation of the immune system and glial cells. This is associated with a slow or poor neurological recovery observed in our group with delayed surgery

Abstract: The spinal cord injury is a social and economic problem which represents a great burden on the patient and their families as well as for public health systems. Differents strategies have been designed for the treatment of this disease, which have focused on two aspects: the first is neuroprotection, i.e., protect the surviving nerve tissue after primary damage, the second is the neuroregeneration, which is to promote the regeneration of nerve tissue post primary and secondary damage; for this, the materials science, has sought to generate biocompatible materials capable of performing the function as a neuroregenerator and neuroprotective agent, at the same time acting as a substrate or cell scaffold. In this regard, biomaterials polypyrrole synthesized by plasma energy and doped with iodine (PPPY / I), have shown the capacity to help in recovery following traumatic spinal cord injury (TSCI) in sub-acute phase [1]. On the other hand, there are reports of biomolecules such as the albumin serum (SA) in which reference to its function as a neuroprotective versus neurotoxic agents such as hydrogen peroxide (H_2O_2) and high concentrations of calcium (Ca^{+2}) under is conditions in vitro [2,3]. Therefore, in this study, we explored the combined application by microinjection of suspensions of two types PPPy/I in the presence or absence of albumin serum rat (RSA) as a treatment in a TSCI in sub-acute phase in a rat model and while it demonstrates the importance of the surface characteristics of those materials in functional recovery response. The results show there is a significant difference between the TSCI + PPPy/I.1 and TSCI + PPPy/I.2 + RSA groups both with respect to TSCI group, and that the surface chemistry of both polymers is involved directly with the biological response obtained. Yang-Ming Univ., Taipei, Taiwan

Abstract: Cervical root avulsion causes the loss of motor and sensory functions in the upper limb and leads to neuron death in the spinal cord. Avulsion one or multiple nerve roots is commonly observed in severe brachial plexus injuries (BPI), that often causes unbearable neuropathic pain and loss of motor function. Neuroinflammation is involved in development of neuropathic pain. Moreover, inflammation induced oxidative stress is involved in the causes of neuronal death after nerve injury. Since minocycline and acidic fibroblast growth factor (aFGF) has anti-inflammation capability. Herein, we investigated the neuroprotective effects on administration of minocycline and aFGF at acute phase following cervical root injury. After 6th to 8th cervical roots transection (both dorsal and ventral), minocycline was immediately given for one week and aFGF for the following two weeks. Our preliminary data showed that neuroprotective treatment significantly suppressed IBA1 (microglia) and GFAP (astrocyte) expression in the ventral horn in one-week group. Furthermore, the number of survived -motoneurons was significantly elevated after treatment. Our data suggested that neuroprotective treatment at acute phase improved survival of motoneuron and suppressed neuroinflammation in the ventral horn. Since the mechanisms for neuroprotection with cervical root injury model is still unclear, we believe our research will help understand such injuries and provide potential treatment for these patients.

Abstract: Imaging patterns of neural activity using genetically encoded calcium indicators (GECIs) has enabled studies of brain circuit dynamics, but applying these approaches beyond the cortex is difficult. Spinal cord neurons in central pattern generator (CPG) circuits control rhythmic locomotor behaviors but sit below highly optically scattering white matter, making imaging of these cells challenging, even with two-photon microscopy. With longer excitation wavelength and stronger suppression of background fluorescence, three-photon excited fluorescence (3PEF) microscopy enables deeper penetration into tissue. We developed a long-term implantable spinal imaging chamber that provides optical access to the lumbar spinal cord (L2 - L5), which contains a high density of inter- and moto-neurons that drive hindlimb muscles. We designed a treadmill the animal can run on while held by the implanted chamber under the microscope, optimized such that applied forces and motion of the mouse's back relative to the floor during running are as natural as possible. Once trained, animals exhibited a normal running gait and grooming behaviors while spine fixed atop the treadmill. Running activity was similar in spine-fixed and non spine-fixed sessions: average running speed of 0.36 m/s vs. 0.43 m/s, and fraction of time spent running of 21% vs. 18%. The image motion artifact in running mice was ~3 μm. To image neural activity we expressed the GECI RCaMP1h in spinal cord neurons using an AAV1 viral vector. Using 1.7 μm excitation for 3PEF (Fig. a), we observed spontaneous neural activity (normalized change in fluorescence > 50%) in awake, running mice at a depth of 0.5 mm (Fig. b). In neurons expressing RFP (not calcium sensitive), normalized fluorescence changes were less than 5% (Fig. b, bottom trace). When combined with quantitative tracking of limb kinematics and targeting of GECI expression to genetically defined neural populations, this capability for 3PEF imaging of cell-resolved neural activity could enable detailed studies of how activity patterns in CPG circuits coordinate rhythmic locomotion.

Title: Single versus repeated mild blast exposure; the galanin, serotonin and noradrenalin systems

Authors: L. KAWA[1], U. P. ARBORELIUS[1], A. KAMNAKSH[2], T. HOKFELT[1], D. V. AGOSTON[2], *M. G. RISLING[3];
[1]Dept. of Neurosci., Karolinska institutet, Stockholm, Sweden; [2]Dept. of Anatomy, Physiol. and Genet., Uniformed Services Univ., Bethesda, MD; [3]Karolinska Inst., Stockholm S-171 77, Sweden

Abstract: Traumatic brain injury (TBI) as a result of exposure to blast related mechanisms is a spectrum disorder. At the mild end, mild blast TBI (mbTBI), there is significant overlap with mood/anxiety- disorders such as posttraumatic stress disorder. Little is known about the underlying mechanism(s) as the resulting injury is distinct from the TBI literature in the civilian population; not involving rotational acceleration. mbTBI is often missed during diagnosis, in the case of soldiers they may be cleared to return to duty and are at risk of repeated exposures.
We have previously reported changes following exposure to a single blast in the noradrenaline, serotonin, and the neuropeptide galanin systems. These systems have been firmly linked to emotional regulation evident in the pharmaceutical interventions that exploit these pathways and the wealth of published literature.
However, the cumulative effect of multiple exposures has not been clearly ascertained hence we used a rodent model of blast-induced TBI to study the effects in these systems of interest.
Male rats were anaesthetized placed in a rigid metallic holder, which limited acceleration movements of the head and protected the animals' torso, and thereafter exposed to a single or double blast wave.
Samples have been evaluated for white matter injury and nerve cell death. Brain sections in the regions of interest have been used to investigate the transcript levels of the rate limiting enzymes tyrosine hydroxylase and tryptophan hydroxylase two (TPH2), and the neuropeptide galanin. Serum from these animals has also been processed to look at several biomarkers including, S100, GFAP, VEGF, phospho- and native tau levels.
We do not observe evidence of white matter injury or cell death in either the single or double exposed group, thus we can presume we have induced a mild TBI. We find elevated TH, TPH2, and galanin mRNA levels in the exposed groups relative to shams. This is to a similar level in both the single and double exposed groups, therefore we do not see evidence of a cumulative effect of repeated exposure in these stress systems studied. Thus suggesting one exposure alone elicits maximal response in these salient players in emotional regulation and further exposures may just sustain this response.

Title: Astrocyte reactivity following blast exposure involves aberrant histone acetylation

Authors: *Z. S. BAILEY[1], M. B. GRINTER[1], P. J. VANDEVORD[1,2];
[1]Biomed. Engin. and Mechanics, Virginia Tech., Blacksburg, VA; [2]Salem Veterans Affairs Med. Ctr., Salem, VA

Abstract: Traumatic brain injury has been deemed the signature injury of current wartime efforts and blast exposure is the most common cause. Clinical manifestations of blast induced neurotrauma (BINT) include a diverse array of cognitive and behavioral symptoms driven by persistent inflammation at the cellular level. Epigenetic regulation serves as an important mediator of gene expression and cellular function which may underlie the chronic inflammation likely resulting in neurodegeneration. We hypothesize that altered histone acetylation patterns may be involved in blast induced inflammation and the chronic activation of glial cells. This study aimed to elucidate changes to histone acetylation occurring following injury and the roles these changes may have within the pathology. Sprague Dawley rats were subjected to blast overpressure exposure (10 or 17 psi) within an Advanced Blast Simulator. Sham animals underwent the same procedure without blast exposure. Memory impairments were measured using the Novel Object Recognition (NOR) test at two and seven days post-injury. Tissues were collected at seven days for Western blot and immunohistochemistry analysis. Sham animals showed in-tact memory at each time point. The novel object discrimination decreased significantly between two and seven days for each injury group ($p<0.05$). This is indicative the onset of memory impairment. Western blot analysis showed glial fibrillary acidic protein (GFAP), a known marker of activated astrocytes, was elevated in the prefrontal cortex (PFC) following blast exposure at 10 and 17 psi. No changes were observed for Ionized Calcium-Binding Adapter molecule 1 (IBA-1), a marker for microglia. Analysis of histone protein extract showed no changes in the level of any total histone proteins within the PFC. However, acetylation levels of histone H2b, H3, and H4 were decreased in both groups ($p<0.05$). Colocalization immunofluorescence was used to further investigate any potential correlation between decreased histone acetylation and astrocyte activation. These experiments focused on the anterior cingulate cortex (ACC) and showed a similar decrease in H3 acetylation in astrocytes exposed to a 17 psi blast but not the 10 psi blast. Such changes may alter transcription and play a role in the chronic astrocyte activation associated with BINT. As such, revealing epigenetic alterations following BINT may lead to novel therapeutic targets.

Title: Network Trauma: Electrophysiological and subcellular damage after tangential 300-600g impacts *In vitro*.

Authors: E. A. ROGERS, *G. W. GROSS;
Dept Biolog Sci., Univ. North Texas, Denton, TX

Abstract: A ballistic pendulum impulse generator was used to apply different levels of g-forces to neuronal networks growing on microelectrode arrays (MEAs, 64 electrodes). This approach allowed simultaneous monitoring of neuronal morphology, action potential (AP) production, network activity patterns, and cell electrode coupling of individual units using AP waveshape templates. Quantitative comparisons of activity and morphology were possible before and within 8 min after impact, with continual post-impact monitoring for 48 hrs. The following results can be reported from 31 experiments to date: (1) Network adhesion was maintained after tangential impacts up to 600g. Pre-selected active units were lost in a range from 0 to only 5% (mean 1.5%). Increases and decreases of AP amplitudes (range: 10-40%) were seen indicating effects on cell-electrode coupling or membrane potentials. (2) Time lapse phase contrast microscopy showed nuclear displacement, including nuclear rotation after impact. Pre-impact observations (2-5 hrs) and non-impacted control networks (12-24 hrs) showed stable nuclei. (3) All 31 experiments showed a two-phase response: recovery and subsequent slow activity decay to a stable level plateau approximately 45% below reference. Phase 1 had three recovery modes: full temporary recovery (n=2), partial recovery (n=4), and a more complex two-plateau response (n=25). Pre-impact reference activity (total network spike production) was recorded for an average 4 hours (range 2 to 14 hrs). All changes were quantified relative to this reference. (4) The dominant Phase 1 response (n=25) featured a stepwise recovery over a period of 1 to 2 hours: A rapid activity increase to within 30 to 60% of reference forming a level plateau lasting from 5 to 20 min, followed by a climb to within 10 to 20% of reference where a second plateau was established for 1 to 2 hrs. A full recovery was never attained. (5) Sequential multiple impacts separated by 60-90 min showed compounding increasing damage (n=4).
We hypothesize that the injury profiles reflect two different mechanisms: Direct somal or synaptic damage that is partially repaired within 60min, followed by a long-term deficit in cell-cell communication reflected in altered spike cross correlations. Here, the cytoskeletal damage and nuclear dislocation manifests itself in disrupted protein transport into axons affecting

synaptic functions in a delayed manner. The heavy nucleus plays a major role in the cytoskeletal damage and concomitant transport disruption.

Title: Conjugated linoleic acid administration in male rats induces amnesia and exacerbates recovery from functional deficits induced by a penetrating controlled cortical contusion injury

Authors: *C. S. ATWOOD[1], I. M. ANDERSON[1], Q. BONGERS[1], A. JANSEN[1], C. NIER[1], M. WEHBER[1], A. KAPOOR[2], T. E. ZIEGLER[2], K. HAYASHI[1], S. VADAKKADATH MEETHAL[1], R. I. GEDDES[1];
[1]Med., [2]Natl. Primate Res. Ctr., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Conjugated linoleic acids (CLA) possess anti-cancer, anti-atherogenic, anti-adipogenic, anti-diabetogenic, and anti-inflammatory properties. Recently, oral CLA was shown to increase testosterone biosynthesis in exercising, but not sedentary, adult male humans and mice. While similar affects in rats remain controversial, testosterone treatment and/or exercise have been shown to diminish traumatic brain injury (TBI)-induced neuropathology, and reduce deficits induced by stroke in adult rats as well as offset hypogonadism and improve cardiorespiratory fitness in adult men with TBI. To test the impact of CLA on cognitive recovery following a TBI, 5-6 month old male Sprague Dawley rats received a penetrating controlled cortical impact (CCI; n=18) or Sham (n=12) injury and were injected with 50 mg/kg body weight of Clarinol® G-80 (80% CLA in safflower oil; n=16) or saline (n=14) every 48 h for 4 weeks. Plasma testosterone concentrations were significantly reduced post-trauma (from 5.9 ± 1.3 ng/mL to 1.5 ± 0.9 ng/mL; $p < 0.05$). CLA treatment did not restore plasma testosterone (1.7 ± 0.3 ng/mL, $p > 0.05$) to pre-injury concentrations or alter circulating concentrations in Sham animals. In Sham animals, CLA did not alter body weight but did markedly increase the latency to find the hidden MWM platform (40.3 ± 13.0 s) compared to saline treated Sham animals (8.8 ± 1.7 s). CCI injury in saline-treated rats produced a sizable cystic infarct (10.3 ± 1.7% of

cortical surface, $p < 0.05$), reduced mean body weight by ~10.8% ($p < 0.05$) and decreased rotarod performance by 30.2 ± 1.6% of baseline ($p < 0.05$). CLA injections did not alter CCI-induced neuropathology (cortical lesion size was 12.1 ± 1.6% of cortical surface, $p > 0.05$), body weight (~11.4% below baseline weight, $p > 0.05$) or deficits in rotarod performance (latency to fall of rotating rod was 35.7 ± 1.3% of baseline, $p > 0.05$). Like the Sham animals, CLA injections exacerbated the latency of CCI-injured rats to find the hidden MWM platform (66.8 ± 10.6 s) compared to CCI-injured rats treated with saline (30.7 ± 5.5 s, $p < 0.05$). These results indicate that chronic CLA treatment in adult male rats 1) does not alter circulating testosterone concentrations in either uninjured or CCI-injured animals, 2) is detrimental to medium-long-term spatial learning and memory in uninjured animals, and 3) limits cognitive recovery following a moderate-severe penetrating CCI.

Title: Repetitive blast exposure in mice and combat Veterans promotes a persistent profile of behavioral and dopaminergic dysfunction

Authors: *A. G. SCHINDLER[1], J. S. MEABON[2], K. D. MEEKER[3], G. LI[2], C. W. WILKINSON[3], E. PESKIND[2], D. G. COOK[3], J. J. CLARK[1];

Abstract: Mild traumatic brain injury (mTBI) has been called a "signature injury" of the Operation Iraqi Freedom/Operation Enduring Freedom/Operation New Dawn (OIF/OEF/OND) armed conflicts. Exposure to the primary blast overpressure generated by blast explosions is capable of causing injury; however the underlying pathophysiology is not well understood. Of significant concern is the potential for post-concussive symptoms and psychological dysfunction (e.g. irritability, impulsiveness, risk taking, aggression, substance use/abuse, PTSD, depression, and anxiety), but diagnoses and treatment options are limited. The mesolimbic dopamine system consists of dopamine-containing neurons in the midbrain that project and release dopamine onto their postsynaptic targets, including the nucleus accumbens (NAc). In healthy subjects this system plays a role in reward processing and decision making, but perturbations are implicated in a variety of psychological dysfunctions similar in nature to those seen following blast-related mTBI, raising the possibility that damage to this system might contribute to the underlying neural mechanisms of dysfunction following blast exposure. Indeed, blast-induced damage to the midbrain and NAc has been previously suggested, but a direct investigation of dopamine release post-blast has not been conducted. Likewise, while rodent models of blast-related mTBI have largely focused on subsequent memory-related cognitive effects, no study to date has utilized rodent models to examine the effects of blast exposure on behaviors related to psychological dysfunction and addiction liability such as novelty seeking and irritability. Therefore, in order to study the neurochemical and behavioral consequences of blast-related mTBI in rodents, the present study utilized an established mouse model that effectively recapitulates the blast forces experienced by active military personnel in the open field. Using this model we demonstrate that mild blast exposure(s) resulted in prolonged novelty seeking and irritability. Likewise, blast exposure(s) caused a prolonged potentiation of phasic NAc dopamine release in response to electrical stimulation of the PPT (measured via fast scan cyclic voltammetry; FSCV). Finally, we found an increase in irritability and PTSD symptoms among OIF/OEF combat Veterans with a history of blast-related mTBI that positively correlated with their CSF dopamine levels. Together these data support the hypothesis that dysfunctions following blast-related mTBI may result, at least in part, through perturbation of the mesolimbic dopamine system, highlighting potential new treatment targets and strategies.

Title: Defective methionine metabolism in the brain after repeated blast exposures might contribute to increased oxidative stress

Authors: *P. ARUN, W. B. RITTASE, D. M. WILDER, Y. WANG, I. D. GIST, J. B. LONG; Ctr. for Military Psychiatry and Neurosci., Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: Blast-induced traumatic brain injury (bTBI) is one of the major disabilities in Service Members returning from recent military operations. The neurobiological underpinnings of bTBI, which are associated with acute and chronic neuropathological and neurobehavioral deficits, are uncertain. Increased oxidative stress in the brain is reported to play a significant role promoting neuronal damage associated with both brain injury and neurodegenerative disorders. In this study, brain regions of rats exposed to repeated blasts in a shock tube underwent untargeted profiling of primary metabolism by automatic linear exchange/cold injection GC-TOF mass spectrometry and revealed acute and chronic disruptions in the metabolism of amino acids and antioxidants. Closely coupled repeated blast exposures (19 psi peak total pressure, 8 msec duration) affected the metabolism of the essential amino acids tryptophan, phenylalanine and methionine. Tryptophan levels decreased on day 1 whereas phenylalanine showed a significant increase in the brain at 28 days after blast exposure. Methionine sulfoxide, the oxidized metabolite of methionine, showed a sustained increase in the brain after blast exposure which was associated with a significant decrease in cysteine, the amino acid derived from methionine. Glutathione, the antioxidant synthesized from cysteine, similarly decreased as also did the antioxidant ascorbic acid. Reductions in ascorbic acid were accompanied by increased levels of its oxidized metabolite, dehydroascorbic acid and other metabolites such as threonic acid, isothreonic acid, glycolic acid and oxalic acid. In view of the fundamental importance of glutathione in the brain as an antioxidant, including its role in the reduction of dehydroascorbic acid to ascorbic acid, the disruptions in methionine metabolism elicited by blast might prominently contribute to neuronal injury by promoting increased and sustained oxidative stress. Increasing the levels of cysteine in the brain by dietary supplementation of cysteine or administration of N-acetyl cysteine could be a potential therapeutic strategy against bTBI.

Title: A proteomics study of the temporal and spatial changes following blast induced traumatic brain injury

Authors: A. KAMNAKSH[1], R. BEKDASH[1], I.-H. LIN[1], G. MUELLER[1], G. LING[1], A. SCRIMGEOUR[2], L. TONG[3], J. LONG[3], T. WESTMORLAND[4], W. TAYLOR[4], S. PARKS[5], *D. V. AGOSTON[6];
[1]USUHS, Bethesda, MD; [2]USAMRA, Nantucket, MA; [3]WRAIR, Silver Spring, MD; [4]ACI-AMT, Taylors, TX; [5]ORA, Frederiksburg, VA; [6]USU, Bethesda, MD

Abstract: The complexity of traumatic brain injury (TBI) as a disease entity is evident in the clinical spectrum of pathological changes and their neurobehavioral correlates. The affected cognitive and behavioral functions have precise neuroanatomical substrates (e.g., learning and memory are mediated by the hippocampal formation (HPF), anxiety by the amygdala). Apart from individual variability and preexisting conditions, it has been hypothesized that the deficits following TBI are a manifestation of the selective vulnerability of brain regions to blast. In an effort to better understand the pathomechanisms underlying the functional deficits and to identify putative biomarkers for blast-induced TBI (bTBI), we analyzed injury-induced changes in the tissue levels of protein biomarkers associated with inflammatory response, metabolic and vascular changes in functionally relevant brain regions as well as in serum and cerebrospinal fluid (CSF). Using the rodent and porcine models of mild bTBI, we found brain region-specific differences in biomarker levels at various post-injury time points. The inflammatory proteins interleukin 6 (IL-6) and interferon gamma (IFNγ) were significantly higher in the cerebellum (CB) than in the frontal pole (FRP) and HPF. Hydroxynonenal (HNE)-Michael adducts, proteins modified by HNE following lipid peroxidation, were also higher in the CB. Conversely, vascular

endothelial growth factor (VEGF) and hypoxia-inducible factor 1-alpha (HIF1α) were higher in the HPF. In the case of aquaporin-4 (AQP4), a high abundance water channel with distinct localization in the CNS, we detected temporal (as opposed to spatial) differences consistent with the fluid imbalances that are observed clinically (i.e., cerebral edema in the acute phase of TBI and gliosis in the chronic phase). The temporal and spatial differences in protein levels observed here demonstrate the selective vulnerability of brain regions to secondary injury mechanisms (e.g., hypoxia, inflammation, metabolic dysfunction) triggered by the exposure to blast. Therefore, determining injury-induced changes in biomarkers related to different functional classes, in select brain regions as well as in serum and CSF, can provide important and currently missing spatial information about the extent and nature of molecular pathology after TBI.

Abstract: Severe penetrating traumatic brain injury (TBI) is associated with the worst outcomes. No treatments are available, neural stem cell transplantation has emerged as putative therapeutic approach. We hypothesized that transplantation of FDA approved human fetal neural stem cells (hNSC) in a rat model of severe TBI i.e., penetrating ballistic-like brain injury (PBBI) would

uncover their efficacy. Adult Sprague-Dawley rats were subjected to unilateral PBBI and randomized to experimental groups, a week later immunosuppressed and microinjected with vehicle or green fluorescent protein (GFP) expressing hNSCs. Group sample sizes were based on previous literature and pilot data. Animals were tested for spatial learning and memory at eight weeks after transplantation using Morris water maze (MWM) and sacrificed at defined time points. Within the GFP cells expression of nestin was strong at week 1 and diminished by weeks 5 and 8. Immature neuronal marker doublecortin (DCX) was present at weeks 5 and 8. Mature neuronal marker NeuN and synaptophysin could be seen at week8. None of the transplanted expressed glial markers even at week 16. Some cells and processes followed white matter tracts but only GFP processes crossed internal capsule ipsilaterally or wrapped the thalamus bilaterally with processes reaching into the brainstem. MWM testing revealed amelioration of injury induced deficits in animals with transplants. Overall, these results indicate that PBBI is conducive to human fetal neural stem cells engraftment and that hNSC transplants show beneficial effects on cognitive outcome in this model of severe penetrating TBI. Importantly, the transplanted hNSCs appeared to develop normally: downregulating stem cells markers and acquiring neuronal markers. While hNSC cellular migration was more limited, the processes spanned long distances extending primarily through white matter tracts suggesting re-innervation of axonal processes may play a key role in providing therapeutic benefit

Title: Inhibition of caspase-3 protects a broad range of developing neurons andneural stem cells from chemotherapeutic-induced cell damage

Authors: *A. J. ELIA[1], J. HENDERSON[2];
[1]Campbell Family Inst. Breast Cancer Res., Univ. Hlth. Network, Toronto, ON, Canada; [2]Fac. of Pharmacy, Univ. of Toronto, Toronto, ON, Canada

Abstract: Cisplatin represents a widely utilized chemotherapeutic drug which exhibitscommon features in terms of mechanism of action with a variety of otherchemotherapeutic agents. Apoptosis, autophagy and necroptosis have all beenimplicated as mechanisms regulating cisplatin induced cellular injury. Inorder to determine the mechanism whereby agents such as cisplatin act toinduce cellular injury in vivo, CNS injury mapping was performed usinggenetically modified mice in embryos as a model of developing neuroepitheliaand stem cell populations. Cisplatin treatment in wildtype controls resultedin activation of executioner caspase-3 and caspase-7 activity, PARP cleavageand the induction of DNA repair with minimal stabilization of p53 despiteelevation in the expression of cell cycle regulator p21. Analysis ofcellular ultrastructure demonstrated features consistent with apoptosis. Bycontrast caspase-3 null embryos exhibited widespread protection from celldeath resulted in the virtual elimination of cell death for >24 hoursfollowing cisplatin treatment by all measures examined despite demonstrationof caspase-7 activity in these animals. The observed effects are widespreadwithin developing CNS neuroepithelia and extend to non-neural tissues suchas gut, lung, and kidney. Examination of tissues at longer periods followingcisplatin treatment revealed a delayed activation of an necroptotic form ofprogrammed cell death in the absence of caspase-3. This normally quiescentsecondary form of programmed cell death exhibits suggests that coordinatedsuppression of these pathways is critical for long-term inhibition ofp53-mediated cell death in a diverse array of tissues in vivo.

Title: Effects on the alpha 2 adrenoreceptor antagonist efaroxan on sensorimotor responses and the norepinephrine levels in the dentate gyrus after cortical damage

Authors: *L. RAMOS-LANGUREN[1], S. MONTES[2], G. GARCÍA-DÍAZ[3], N. CHÁVEZ-GARCÍA[2], C. RÍOS[1], R. GONZÁLEZ-PIÑA[3];

Abstract: Norepinephrine (NE) have shown to play an important role in motor recovery after brain injury. The effects elicited by this monoamine have been reported as distal from the area

directly affected. Remote changes may take place from minutes to weeks and will play an important role in post-stroke recovery. However, the mechanisms involved in spontaneous recovery have not been thoroughly delineated. Previously we reported that 10 and 20 days after cortical iron injection the NE levels in the dentate gyrus (DG, an important structure to plastic processes) increased, which was accompanied by sensorimotor recovery. Here, we analyzed the role of the alpha 2-adrenoreceptor antagonist efaroxan (Efx) as a possible neuroprotector. Therefore, we divided our test subjects (male Wistar rats) in three conditions, a) chronic administration of Efx before cortical injury (n=8), acute administration of Efx immediately (n=7) (b), and 20 days after injury (n=7) (c). Importantly chronic administration of Efx prevents the sensorimotor impair induced by cortical iron injection. Acute administration of Efx after injury did not improve sensorimotor performance. Finally, acute administration of Efx 20 days after injury increased the levels of NE. These results suggest that sensorimotor recovery after brain damage involved changes in NE levels on DG and these changes are modulated by alpha 2-adrenoreceptor. Furthermore, the blocking of these receptors prevents the induction of cortical injury, suggesting that Efx could have a neuroprotector effect enhancing NE release. In brief, these results support evidence to propose NE as a key molecule in the functional recovery of the central nervous system.

Abstract: Epilepsy is a neurological disorder of the central nervous system characterized by increased and abnormal synchronization of neuronal activity, which is clinically manifested among others by recurrent unpredictable and uncontrollable spontaneous seizures; the temporal lobe epilepsy (TLE) is the most common type of acquired and frequent epilepsy in adults. Epilepsy has been associated with oxidative and nitrosative stress due to prolonged neuronal hyperexcitation and loss neurons during seizures that may result in the mitochondrial dysfunction, increased production of both reactive oxygen species (ROS) and reactive nitrogen species (RNS). It has been clearly demonstrated that oxidative stress interferes with the expression of genes as well as transcriptional factors such asNrf2-dependent Antioxidant Response Element (Nrf2-ARE). In this study we evaluated the morphological changes and the immunohistochemical expression pattern of Nrf2 in the rat brain treated with KA and PTZ considered animal models of epileptic seizures. Nrf2-ARE immunoreactivity was observed mainly in astrocytes of hippocampal brain region in rats exposed at KA; whereas that slight immunoreactivity was observed on rats treated with PTZ. These preliminary results support that fully developed that Nrf2 increased expression is a part of protective mechanism against KA and PTZ toxicity.

Title: Evaluation of acute cell death in rat organotypic hippocampal slice cultures exposed to mechanical or blast injury

Authors: *A. GLAVASKI-JOKSIMOVIC[1,2,3], A. S. SHAH[1,3], B. V. APERI[1,3], S. N. KURPAD[1,2,3], B. D. STEMPER[1,3];
[1]Neurosurg., [2]Dept. of Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, Milwaukee, WI; [3]Clement J. Zablocki Veterans Affairs Med. Ctr., Milwaukee, WI

Abstract: Traumatic brain injury (TBI) is a major health problem and its underlying mechanisms remain elusive. In addition, preclinical and clinical studies suggest distinct mechanisms of blunt and blast injuries, although molecular and cellular effects of each are not well characterized. The aim of this study was to elucidate an acute cellular response to the weight-drop and blast overpressure injury in rat organotypic hippocampal slice cultures (OHCs). Hippocampi were dissected from neonatal Sprague Dawley rats (P7-10), cut into 400 μm thick slices, and grown using the membrane interface method. Following recovery period of 7-8 days, OHCs were injured using either blast or blunt mechanisms. For the blunt injury a custom made rod of the NYU weight-drop impactor was placed above the cornu Ammonis 1 (CA1) hippocampal region and dropped from a 6.25 mm height (impact velocity: 0.35 m/s). Alternatively, OHCs were exposed to either 138 ± 22 kPa (low) or 273 ± 23 kPa (high) overpressures using an open-ended helium-driven shock tube. Sham control sections were identically treated, but they were not injured. At 2 h post-injury, cell death in injured and control OHCs was assessed by a propidium iodide (PI) uptake assay. Microglial cells in OHCs were labeled with the isolecitin B4 (IB4) conjugated to FITC for live imaging in the acute phase post injury. Additionally, OHCs were fixed at 2 h post-injury and immunostained against neuronal nuclear antigen (NeuN) and glial fibrillary acidic protein (GFAP) to assess acute effects of injury on neurons and astrocytes, respectively. PI-stained dead cells were observed in traumatized OHCs already at 2 h following mechanical and blast injury. Dead cells were mainly positioned around the site of impact for the blunt injury, although a smaller number of dead cells were observed further away from the site of injury. In the blast-exposed OHCs, dead cells were present throughout the section. However, cells that were co-labeled with PI and IB4, GFAP, or NeuN were detected in both weight-drop- and blast-injured OHCs. Moreover, both injury paradigms evoked the morphological changes of astrocytes, including clasmatodendrosis characterized by cytoplasmic swelling, beading and dissolution of distal processes. Our preliminary data imply that glial cells and neurons in OHCs die in the early phase of mechanical and blast injury, but glial cells appear to be more affected. Future studies will elucidate whether early demise of glial cells is involved in the spread of neurodegeneration following blunt and blast TBI.

Title: Is docosahexaenoic acid neuroprotective after traumatic brain injury in rats?

Authors: ***L. S. BELAYEV**[1], L. KHOUTOROVA[1], A. OBENAUS[2], N. G. BAZAN[1]; [1]Neurosci. Ctr., LSUHSC, New Orleans, LA; [2]Loma Linda Univ., Loma Linda, CA

Abstract: Traumatic brain injury (TBI) remains the most common cause of death in persons under age 45 in the Western world. It is characterized by cerebral damage leading to impairment of neurobehavioral function. Docosahexaenoic acid (DHA) has been shown to possess neuroprotective properties in both *in vitro* and *in vivo* studies. We have previously demonstrated the beneficial effect of DHA in focal cerebral ischemia in rats. The purpose of this study was to determine whether treatment with DHA would be beneficial in a rat model of TBI. Male Sprague Dawley rats were anesthetized with 3% isoflurane, mechanically ventilated, physiologically regulated, and subjected to moderate right parieto-occipital parasagittal fluid-percussion injury. DHA (5 mg/kg) or saline treatment was administered i.v. at 1 h after TBI (n=8-10 per group). Behavior was evaluated on days 1, 2, 3 and 7 after TBI; a grading scale of 0-12 was employed (normal score=0, maximal deficit=12). *Ex vivo* imaging of the brains was conducted on 11.7T MRI on day 7. T2WI and apparent diffusion coefficient (ADC) maps were generated. After completion of MRI study on day 7, histopathology was conducted and the contusion areas and number of normal pyramidal neurons in the CA1 and CA3 regions were quantitated. The physiological variables were entirely comparable among the six groups. Treatment with DHA significantly improved the neurological score compared to saline on day 1 (5.8 ± 0.5 vs. 8.6 ± 0.3), day 2 (5.2 ± 0.6 vs. 9.1 ± 0.3), day 3 (4.6 ± 0.5 vs. 7.5 ± 0.5) and day 7 (3.7 ± 0.5 vs. 7.0 ± 0.6). Lesion areas were significantly smaller in DHA-treated rats compared to the saline group. These results suggest that DHA therapy is neuroprotective in rats following TBI and might provide the basis for future therapeutics in patients suffering from TBI.

Abstract: Introduction
Modern military conflicts have led to an increasing incidence of mild traumatic brain injury (mTBI) from exposure to explosive blast overpressure (BOP). Recent evidence has identified a novel pathway for clearing extracellular proteins and other substances from brain interstitial fluid via the glymphatic system, which plays an important role in the neuroprotective responses of the brain to TBI. The water channel aquaporin-4 (AQP4) is localized primarily in perivascular astrocytic endfeet and is critical in regulating glymphatic clearance. AQP4 mislocalization is associated with impaired glymphatic function and has been implicated in several neurological disorders. The goal of these experiments was to address in mice the effect of mild blast exposure on AQP4 protein expression levels and localization.
Methods
Using well established procedures, 3-4 month-old male C57BL/6J mice were exposed to primary BOP (19 psi peak intensity) using a helium-driven pneumatic shock tube. All experiments were done following procedures approved by the VA IACUC. Twenty-four hours after a single BOP, brains were analyzed using confocal microscopy. Changes in perivascular AQP4 localization were evaluated as previously described using threshold-based analysis of AQP4 immunoreactivity in different cerebellar cell layers.
Results
We focused on the cerebellum because our recent findings indicate this brain region is especially vulnerable to blast-induced mTBI. Immunofluorescence analysis of the entire molecular layer for all cerebellar lobules revealed no significant changes in perivascular AQP4 localization in blast-exposed versus sham-treated mice (n.s., mean=0.19 and 0.26; n=9 and 14, sham and blast, respectively). However, more fine-grained analysis measuring AQP4 localization in the superficial molecular layer revealed a significant loss of perivascular AQP4 localization in blast compared to shams ($p \leq 0.04$, mean=0.27 and 0.39, n=9 and 14, sham and blast, respectively).
Conclusions
These results indicate that a single blast exposure is sufficient to disturb the normal polarized pattern of AQP4 expression that favors perivascular localization. This suggests that, like other forms of TBI, mild blast exposure may disturb glymphatic function(s) that are subserved by astrocytic AQP4, thereby potentially impairing clearance of metabolic and injury-producing toxic substances from the brain.

Title: Mitigation of neuropathology and behavioral deficits in a rat model of brain injury to occupants of vehicles targeted by land mines by an advanced shock absorbing hull design

Authors: *F. TCHANTCHOU[1], W. FOURNEY[3], U. LEISTE[3], A. PUCHE[2], G. FISKUM[1];
[1]Anesthesiol., [2]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD;
[3]Aerospace Engin., Univ. of Maryland Col. Park, College Park, MD

Abstract: Exposure to blasts has resulted in more than 200,000 U.S military victims of TBI in the recent wars in Iraq and Afghanistan. Many were occupants of vehicles targeted by land mines. Using our novel rat model of under vehicle blast induced TBI, we found that underbody blast induced accelerations up to 2400G impaired hippocampus-dependent working memory and long term anxiety-like behavior, but no mortality. Exposure to 2600G resulted in high mortality (67%). These behavioral deficits were associated with several neuropathological markers, suggesting that military vehicle design needs to incorporate acceleration mitigation to reduce brain injury. We hypothesize that blast induced mortality and TBI can be mitigated by two hulls separated by crushable polyurea coated cylinders. Conscious male Sprague Dawley rats were placed in restraints secured on the top of two hulls. An explosive detonated beneath the bottom hull generated an accelerative force of 2600G on the top hull. In some experiments, the two hulls were separated by either uncoated or polyurea-coated aluminum cylinders. Blast survivors and sham rats were tested to assess working memory and anxiety-like behavior over one month. Other animals were euthanized and brain tissue collected for histological or biochemical analyses at 24hr post-blast. Statistical analyses was performed by one way ANOVA with Tukey-Kramer post-test analyses. The presence of polyurea-coated cylinders between the top and bottom hulls reduced blast induced acceleration from 2600G to 550G and completely prevented mortality. The presence of uncoated cylinders only reduced the acceleration to 2300G, with 29% mortality, emphasizing the importance of polyurea coating. The polyurea-cylinder hull design restored working memory to sham levels, while the presence of uncoated cylinders failed to provide protection. Similarly, polyurea coating significantly decreased anxiety-like behavior compared to uncoated cylinders. Histological analysis revealed a >3-fold increase in glial scar/astrocytic gliosis immunoreactivity in the brains of rats after blasts with uncoated cylinders, compared to shams ($p < 0.01$), whereas this form of inflammation was significantly reduced by polyurea-coated cylinders. In conclusion, exposure of rats to underbody blast-induced acceleration results

in brain inflammation within one day and behavioral deficits for at least one month. Mitigation of acceleration by hull designs that absorb the blast force protects against both mortality and neurologic impairment. Grant support: US Army W81XWH-13-1-0016

Title: Assessing glycomics and neuroproteomic changes in experimental tbi: comparative analysis of aspirin and clopidogrel

Authors: *F. H. KOBEISSY[1], H. BAHMAD[2], N. RAMADAN[2], R. ZHU[3], Y. MECHREF[3]; [1]Dept of Psychiatry, Univ. of Florida, Gainesville, FL; [2]American Univ. of Beirut, Beirut, Lebanon; [3]Texas Tech. University,, Lubbock, Texas, TX

Abstract: As populations age, the number of patients sustaining traumatic brain injury (TBI) and concomitantly receiving pre-injury antiplatelet therapy such as Aspirin (ASA) and Clopidogrel (CLOP) is rising. These drugs have been linked with unfavorable clinical outcomes following TBI, where the exact mechanism(s) involved are still unknown. In this novel work, we aimed to identify and compare the altered proteome profile imposed by ASA and CLOP when administered alone or in combination, prior to experimental TBI. Furthermore, we assessed differential glycosylation post-translational modification (PTM) patterns following experimental controlled cortical impact (CCI) model of TBI, ASA, CLOP and ASA+CLOP. Ipsilateral cortical brain tissues were harvested 48 hours post injury and were analyzed using an advanced neuroproteomics Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS) platform to assess proteomic and glycoproteins alterations. Of interest, differential proteins pertaining to each group (22 in TBI, 41 in TBI+ASA, 44 in TBI+CLOP, and 34 in TBI+ASA+CLOP) were revealed. Advanced bioinformatics/ systems biology and clustering analyses were performed to evaluate biological networks and protein interaction maps illustrating molecular pathways involved in the experimental conditions. Results have indicated that proteins involved in neuroprotective cellular pathways were upregulated in the ASA and CLOP groups when given separately. However, ASA+CLOP administration revealed enrichment in biological pathways relevant to inflammation and pro-injury mechanisms. Moreover, results showed differential upregulation of glycoproteins levels in the sialylated N-glycans PTMs which can be implicated

in pathological changes. Omics data obtained have provided molecular insights of the underlying mechanisms that can be translated into clinical bedside settings.

Abstract: Gulf War Illness (GWI) is a chronic multi-symptom disorder affecting returning military veterans and civilian workers of the 1990-91 Gulf War, where they were exposed to various chemical agents that disrupt cholinergic signaling. White matter integrity is compromised in these veterans, which led us to hypothesize that cholinergic signaling plays an important role in oligodendrocyte development and myelin physiology. Acetylcholine (Ach) receptors are widely expressed in oligodendrocyte lineage cells, both in-vitro and in-vivo. These receptors are functional and respond to Ach and other cholinergic agonists with increase in intracellular Calcium. Both expression and activity of these receptors, vary spatially and temporally, with development of the oligodendrocyte lineage. Stimulation of these receptors on oligodendrocyte lineage cells, both in isolated cultures and in co-cultures with neurons, have distinct effects on the size of the oligodendrocyte population and the extent of myelination. To assess the role of cholinergic signaling in-vivo and mimic the theater of war, we developed an animal model of GWI. These GWI mice were administered Corticosterone (Cort), a stress hormone, and Diisopropyl Fluorophosphate (DFP), an analogue of Sarin gas and an irreversible inhibitor of Acetylcholinesterase. Consistent with our in-vitro observations, white matter of these

GWI mice, changed in response to the strength and duration of these modulators of cholinergic signaling. Moreover, white matter integrity in these mice, as assessed by Diffusion Tensor Imaging, correlated with such changes.

Title: Phenelzine induces restoration of function following a medial frontal cortex contusion in adult male rats housed in standard environments, but not in adult male rats reared in enriched environments

Authors: *M. A. SEARLES;
Saginaw Valley State Univ., Wheeler, MI

Abstract: Every year approximately 1.7 million individuals suffer the consequences of traumatic brain injury (TBI), which is a leading cause of death and disability in the United States. Due to a lack of effective clinical treatment, many of the functional and cognitive deficits sustained from TBI are left untreated. Currently, Phenelzine (PZ) is used clinically for the treatment of anxiety and atypical depression. Furthermore, PZ has been shown to express neuroprotective effects in several models of ischemia- reperfusion and contusion brain injury. Additionally, research from our lab has shown that rats raised in enriched environment (EE) housing perform better during behavioral tasks than rats raised in traditional or standard laboratory environments (SE). The purpose of the current study was to examine the effect PZ administered post-injury may have on recovery of function following a medial frontal cortex (MFC) contusion in rats reared in EE housing. Twenty-seven, twenty-five day old male Long-Evans rat pups were reared in enriched environments (EE) for ninety days. Twenty-seven adult male rats were purchased from the same vendor and placed into SE upon arrival. After fourteen days in SE, eighteen SE-housed rats received MFC contusion injuries. After Ninety days in the EE, MFC contusion injuries were administered to eighteen EE-housed rats. After each injury, at ten minutes post-injury, half of the animals received a subcutaneous (10mg/kg) injection of phenelzine, and the other half received an injection of saline solution. Behavioral analysis was conducted one week post-injury and included the open field task (OFT), Barnes maze (BM), Morris water maze (MWM), rotor-rod (RR), elevated-plus maze (EPM), and forced-swim task (FST). Upon completion of behavioral

testing, the animals were euthanized and perfused, and their brains extracted. Tissue from the left hemisphere was embedded in paraffin, sectioned, and underwent hematoxylin and eosin staining. The right hemispheres were reserved for thick-sectioning analysis. Stereological analysis was performed to quantify total cortical volume as well as number of surviving cells in the hippocampus.

Title: The role of pontine alpha-2 receptors in the reinstatement of the motor deficit after cortical damage

Authors: G. GARCÍA-DÍAZ[1], L. E. RAMOS-LANGUREN[2], J. LOMELÍ-GONZÁLEZ[1], F. AYALA-GUERRERO[3], N. CHÁVEZ-GARCÍA[2], R. GONZÁLEZ-PIÑA[4], *S. MONTES[2]; [1]Escuela Superior de Medicina. Inst. Inst. Nacional de Rehabilitación, México, Mexico

Abstract: Norepinephrine (NE) plays an important role in the motor functional recovery after cortical damage. In addition, it has been suggested that there does exist distal effects from the area directly affected. The remote effects may take place in a period of time from minutes to weeks. However, these functional recovery mechanisms are not entirely clear. Recently, it has been found that NE inhibition in the pons is correlated with motor deficit after injury in the motor cortex. Within the pons, the locus coeruleus (LC) is the major noradrenergic nucleus in the brain and is the sole source of NE in many parts of the central nervous system. The LC area is rich in α2 adrenoceptors. Therefore, the modulation of this kind of receptors could delay or accelerate the time of functional recovery. The aim of this study was to analyze the role of α2 adrenoreceptor agonist clonidine (CL) in the NE content in the pons, in the motor deficit, and in the spontaneous activity after 20 days of cortical damage when the animals show signs of recovery. We divided the subjects into four following conditions: a) administration of clonidine 12μg/kg (n=6), b) administration of clonidine 25μg/kg (n=6), c) administration of clonidine 50μg/kg (n=6) and d) a sham group (n=6). Twenty days after the injury, NE levels in both hemispheres on the pons were similar to the Sham group. However, NE decreased significantly

in the clonidine-treated groups, suggesting that clonidine-treated recovered animals presented a reinstatement of the motor and sensorial deficit such as those which had occurred immediately after cortical damage. These results support the idea that NE is a key neurotransmitter for the recovery as well as the reinstatement of motor deficit.

Title: Effects of P2 receptor blocker MRS2179 against experimental cerebral contusion injury in rat

Authors: *T. KUMAGAWA, K. SHIJO, N. MORO, M. FUKUSHIMA, T. MAEDA, A. YOSHINO;
Neurolog. Surgery, Nihon Univ. Sch. of Med., Tokyo, Japan

Abstract: Previously we have reported the massive efflux of gliotransmitter ATP into the extracellular space immediately after experimental cerebral contusion injury. Released ATP from the injury stimulated astrocyte will generate calcium wave and activate neighbor microglia via P2 receptor. Subsequently activated microglia will initiate immune response including release of several cytokines, chemotaxis and phagocytosis to remove debris from the brain. Here we assessed the effect of MRS2179, a selective P2Y1 receptor blocker, if it will restrict inflammatory response and can be beneficial in a rat cerebral contusion model. Cerebral contusion injury model was made in SD rat. MRS2179 was in situ administrated into the contused brain by osmotic pump. Artificial cerebral spinal fluid was used as a control. Galectin-3, a marker of activated microglia was measured by western blotting and cytokines such as IL-1 beta, IL-4, IL-6, TNF alpha and NF-kB were measured by reverse transcription PCR, 1, 3 and 7 days following injury. Another group of rats were assessed for behavioral performance up to 28 days, including beam walk test, neurological response and plus maze test. Histological analysis revealed that Galectinn-3 was expressed only on the activated microglial cell. Expression of Galectin-3 and some cytokines were significantly suppressed by MRS2179 administration.

Although, MRS2179 did not improve the behavioral outcome. MRS2179 admitted to the contused brain might have some therapeutic effect, however further study is required to make a conclusion.

Title: Traumatic brain injury during adolescence enhances rewarding effects of a subthreshold dose of cocaine in mice

Authors: *L. CANNELLA[1], S. F. MERKEL[1], R. RAZMPOUR[1], M. SEASOCK[1], S. M. RAWLS[2], S. H. RAMIREZ[1];
[1]Pathology and Lab. Med., [2]Ctr. for Substance Abuse Res., Temple Univ. Lewis Katz Sch. of Med., Philadelphia, PA

Abstract: Traumatic brain injury (TBI) is an important public health problem as 1.7 million occur annually in the United States. One of the most common, chronic comorbidities seen in TBI patients is the development of a substance use disorder (SUD). Clinical reports suggest that age of injury can affect later drug use. Specifically, among a population of cocaine-dependent patients, 84% reported experiencing their first TBI before the onset of cocaine use. Yet, to date there is limited preclinical data related to the effect of TBI on drug abuse behavior and thus the mechanisms for this phenomenon remain unclear. Previously we investigated the effects of TBI on susceptibility to the rewarding effects of cocaine. Using conditioned place preference (CPP) as a measure of cocaine reward in male mice, we found that moderate TBI inflicted by Controlled Cortical Impact (CCI) during adolescence increased susceptibility to the rewarding effects of 10 mg/kg cocaine during adulthood. These results support clinical evidence that experiencing neurotrauma early in life can facilitate later susceptibility to psychostimulant addiction. The aim of the current study is to further investigate whether TBI during adolescence enhances the effects of a subthreshold dose of cocaine that typically does not produce a CPP

shift. A single CCI impact with a speed of 4.5 m/s, dwell time of 0.5 sec, and compression depth of 2 mm produced a moderate TBI in 6 week old, adolescent or 8 week old, young adult male C57BL/6 mice. Drug seeking behavior was assessed using the CPP assay two weeks after injury. Expression of immune response-associated genes was measured using qRT-PCR. We found that moderate TBI during adolescence, but not during young adulthood, augmented preference to the environment paired with 2.5 mg/kg cocaine, indicative of enhanced sensitivity. Additionally we detected increased expression of immune response-associated genes in the prefrontal cortex. These results further indicate that exposure to TBI during adolescence may enhance the abuse liability of cocaine in adulthood, suggesting that the threshold for the rewarding effects of cocaine could be lower in TBI patients. Moreover, future studies will focus on testing whether dampening of key neuroinflammatory responses post-trauma leads to the restoration of homeostasis in the reward circuitry.

Abstract: In this study we used the ferret to study TBI and correlate MRI markers with brain histology and behavioral assessment. The ferret is the smallest mammal with a gyrencephalic brain. We studied 15 adult male ferrets, 3 naïve and 12 receiving a mild controlled cortical impact on the somatosensory cortex (velocity = 5 m/s, depth of impact = 2 mm, dwell time = 100 ms, impactor tip diameter =3 mm). Brains were collected for ex vivo scanning and histology at 1 day post injury (1DPI), 4 weeks post injury (WPI) and 16WPI. The location of MRI abnormalities guided our choice of slices for immunohistochemical analysis. We used antibodies directed against astrocytes (glial fibrillary acid protein), microglia (Iba1), dendrites (microtubule

associated protein; MAP2), myelin (myelin oligodendrocyte glycoprotein), microtubules (Tuj1), phosphorylated tau, and inhibitory interneurons (parvalbumin). At 1DPI, we saw substantial changes in immunoreactivity for microglia that extended away from the injury, but very few changes in astrogliosis. At this time point, most of the histological as well as imaging abnormalities were contained within the gray matter. We also observed more subtle changes in myelin and neuronal markers including beta tubulin (Tuj1) and MAP2 that occurred mostly in the upper layers of the cerebral cortex. At 4WPI chronic reactive gliosis extended up to 2mm anterior and posterior to the injury epicenter. The density and hypertrophy of the activated microglia were most abundant in the subcortical white matter at 4WPI, reactive astrocytes occurred deep in the underlying white matter and extended into the internal capsule. The density of neuronal markers (MAP2, Tuj1) decreased in the cortical region of injury at 4WPI but returned to near normal values by 16WPI. At 16WPI micro- and astroglial immunoreactivity remained elevated and continued substantially into the white matter. Our behavioral analysis found that the ferrets initially showed impairments in mobility, but that these mostly recovered by 16WPI. At this time point, they demonstrated aspects of anxiety, however, by avoiding traveling in the center zone of an open field test. The animals had cognitive difficulties that continued up to 16WPI as seen in a T maze task and novel object recognition. Correlating the persistent behavioral alterations with histologic changes at the same time point suggests that markers representing inflammation may be more relevant to function than neuronal changes. These findings show that the gyrencephalic ferret is an important translatable model for TBI research; our ability to correlate histology with MRI also provides an important noninvasive tool to guide analysis.

Title: A new model for un-anaesthetised repeat closed head injury produces acute neurological deficits in the juvenile rat

Authors: *A. L. MECONI, R. C. WORTMAN, B. R. CHRISTIE;
Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: Pediatric concussion accounts for 144,000 emergency room visits annually in the United States. The prognosis for this type of injury varies greatly. Most subjects recover within a week, but some suffer motor and cognitive symptoms that can persist for months. The reason for these individual differences in recovery remains under investigation, but epidemiological evidence suggests that metrics like age and sex strongly influence outcomes. Children are more likely to sustain a concussion than adults, males experience a higher incidence than females, and females are more likely to have persistent symptoms. Experimental animal models of concussion have been crucial in identifying the physiological basis of variability in concussion symptoms, but they have disproportionately focused on adult male subjects. We have developed a new model to reliably induce concussion in young rats. This model is unique from previous juvenile concussion models because it does not require anaesthesia - which has neuroprotective properties that may confound experimental outcomes. Omitting anesthesia allows for more rapid and reliable symptom assessment immediately after a concussion. We have used a modified neurological severity score (NSS) to rapidly assess motor and cognitive deficits that occur during this previously inaccessible acute time window. Preliminary characterization in juvenile male and female rats suggests that single and repeat awake closed head injury (ACHI) produced by this new model acutely impairs NSS performance, with recovery after 7 days. Interestingly, similar to clinical evidence, there appears to be a subset of the population that is more severely affected by mild closed head injury despite having similar genetic and environmental histories. Continued efforts to characterize this model will allow us to investigate the physiological basis of concussion symptoms in these special populations.

Title: The effects of mild traumatic brain injury on hippocampal neuroinflammation in female juvenile rats

Authors: *M. A. CLARKSON[1], B. R. CHRISTIE[2], P. C. NAHIRNEY[2], A. L. MECONI[2], A. COLLINS[2], E. TRUESDELL[2];
[1]Neurosci., [2]Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: Mild Traumatic Brain Injury (mTBI) is being increasingly recognized as a serious health issue. Also commonly known as concussion, mTBI accounts for more than 80% of brain injuries. The prevalence of mTBI in athletes, particularly young athletes is of great concern as injury to the young brain can lead to long-term detrimental effects. This injury is known to have two phases; the primary phase, being the initial impact, followed by a secondary phase which constitutes a series of pathophysiological changes within the brain. To examine the role of inflammation in the secondary phase of injury, we performed immunostaining for immune cells, microglia and astrocytes in the hippocampus and cortex 7 days after mTBI. To replicate this common human injury, we used an awake closed head injury (ACHI) model to induce mTBI in non-anaesthetized juvenile female rats. The model allows us to produce acute neurological deficits similar to those produced by a concussion. In this study , we used confocal microscopy to quantify glial fibrillary acidic protein (GFAP) expression by astrocytes and ionized calcium binding adaptor molecule 1 (IBA1) expression by microglia. In both the CA1 region and dentate gyrus, no significant changes were found in astrocyte or microglial density following mTBI, suggesting that in this model there was not a significant chronic neuroinflammatory response following either single or repeated mTBI.

Title: Repetitive Closed-Head Impact Model of Engineered Rotational Acceleration (rCHIMERA) induced long-term cognitive impairment and persistent astrogliosis and microgliosis in mouse

Authors: *H. CHEN;
NIAAA/NIH, Rockville, MD

Abstract: Epidemiological and retrospective autopsy data suggested that repeated mild traumatic brain injury (rmTBI) or single severe brain injury is a high risk factor to develop of chronic traumatic encephalopathy (CTE), posttraumatic stress disorder (PTSD), Parkinson's and Alzheimer's diseases many years after the injury. Lack of proper animal models reflecting complex features of human TBI with long-term complications has been the major obstacle for translation from preclinical promises to therapeutic success. Recently developed Closed-Head Impact Model of Engineered Rotational Acceleration (CHIMERA) recapitulated in animals many of the functional and pathological features of human TBI. Using this model, we investigate the long-term neuropathological and cognitive functional consequences of rmTBI. C57BL/6 male mice at 12 weeks old were subjected to CHIMERA for three consecutive days (rCHIMERA) at 1day interval. Motor deficit was evaluated by beam walk and rotarod tests within 1 week post injury, and learning and memory was evaluated using Morris water maze test at 1 and 2 month. Microglia and astrocyte activation and axonal injury were detected by immunohistochemistry (IHC), GFAP and Iba-1 protein levels and GFAP, iba-1, APP and TNF-alpha gene expressions were analyzed by Western blotting and qRT-PCR at different time points. We found that learning and memory function was significantly impaired at 1 and 2 months after rCHIMERA. The injured mice also displayed prolonged loss of righting reflex and increased motor deficits. Extensive induction of GFAP and Iba-1 signals in white matter areas was indicated at the acute phase (1 and 7 days) and long-term phase (1, 2 and 3.5 months). GFAP and Iba-1 protein levels were also elevated at 1 month while GFAP gene level was increased at 1-7 days. APP deposition and TNF-alpha gene expression was upregulated only at 1 day post injury. In conclusion, rCHIMERA leads to a long-term cognitive impairment with persistent activation of astrocytes and microglia in the white matter. rCHIMERA may present a useful animal model to study long-term functional and neuropathological outcomes as well as cellular and molecular mechanisms of human rTBI to develop effective treatments for rTBI-induced long-lasting complications in humans. This research program is supported by Intramural program of NIAAA, NIH.

Title: Acute pathophysiologies associated with mild, “head on” concussion injury in the Sprague-Dawley

Authors: *S. M. VITA, K. R. CLARK, R. J. GRILL;
Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Approximately 2.5 million people per year are reported to have sustained a traumatic brain injury (TBI). However, as many cases of TBI are mild and are thus not reported, this number likely does not accurately represent the problem. Currently there are no effective treatment options available that will preserve or restore function lost to a mild-to-moderate TBI. While there are multiple reasons to explain this dearth of treatment options, one issue may be due a lack of animal models that adequately reproduce the pathophysiological events associated with mild, concussive TBI. We have chosen to employ the Maryland Model of “head on” concussion injury in the adult, male, rat (Kilbourne et al, Novel model of frontal impact closed injury in the rat, J. Neurotrauma, 26:2233-43, 2009) developed in the laboratory of Dr. Simard at the University of Maryland. This device produces a mild, head-on concussion-type injury, replicating both the impact and torque commonly experienced in human concussion events. In this study, we provide an initial characterization of the effects of mild concussion on acute tissue pathologies, such as deficits effecting the Blood Brain Barrier (BBB), activation of microglia (early indicators of immune and inflammatory activation) as well as neuronal pathology. Design: Adult, Sprague-Dawley rats were first anesthetized and then received bilateral surgical exposure of the malar processes of the skull. One cohort received a single, mild TBI insult while the sham group received only placement of the impounder tips against the malar processes, but no lesion. After lesion, subjects were returned to their home cages for recovery. Subjects were euthanized 24 hours post-injury with the brains removed for histopathological assessment. mTBI subjects showed elevated leakage to both endogenous IgG and albumin; serum proteins normally excluded from the brain by the BBB. While overt neuronal damage was not observed, we detected a breakdown in the cortical perineuronal network as evidenced by tissue labeling with the plant lectin, Wistereria floribunda. Preliminary data suggests that the Maryland Model produces subtle alterations in brain structure/integrity in both forebrain (coup) and cerebellar tissues (counter-coup). Subsequent studies will explore the evolution of these pathological events over time and whether they coincide with mTBI associated functional deficits. Our goal is to determine whether the Maryland Model of mTBI-induced concussive injury can serve as an effective means of both studying the long-term consequences of mTBI as well as developing novel, effective therapeutic interventions.

Title: Increased ethanol intake and progressive reductions in striatal cannabinoid receptor 1 protein levels following mild traumatic brain injury

Authors: B. L. SCHNEIDER[1,2], L. L. SUSICK[1,2], *A. C. CONTI[1,2];
[1]John D. Dingell VA Med. Ctr., Detroit, MI; [2]Neurosurg., Wayne State Univ., Detroit, MI

Abstract: Traumatic brain injury (TBI), of which mild TBI (mTBI) accounts for more than 80%, significantly increases the risk of developing alcohol use disorders (AUDs) over a patient's lifetime. With its known relationship to ethanol consumption and the physiological effects of ethanol, the endocannabinoid system has become of interest in AUDs secondary to TBI. Specifically, ethanol vapor and self-administration decreased striatal expression of cannabinoid receptor 1 (CB1) and altered ethanol preference has been observed following CB1 antagonism in rodent models. In this study, we investigated changes in ethanol consumption and cannabinoid receptor (CB1 and CB2) protein expression in the anterior striatum (ASTR) and nucleus accumbens (NAC) at 8-25 d post-mTBI. Anesthetized male C57BL/6 mice (8-10 wks) were given a mild, midline impact over the intact skull or sham surgery. At 14 d post-TBI, mice were evaluated for binge and chronic ethanol consumption. Injured mice demonstrated a delayed increase in chronic consumption, a consistent increase in ethanol preference, and an increase in binge pattern drinking compared to sham controls. At 8 and 25 d post-injury, brains from separate groups of mice were harvested and frozen. Protein lysates were made from 1.5 mm diameter tissue punches of striatal subregions taken from 2 mm thick coronal slices for immunoblot analysis. At 8 d post-injury, there was a trending decrease in CB1 in ASTR, which became significantly reduced at 25 d post-injury compared to respective sham controls. The NAC showed an initial increase in CB1 at 8 d following mTBI, but was decreased at 25 d compared to respective sham controls. The observed time- and region-dependent alterations in CB1 expression in the ASTR and NAC may underlie the progression of alcohol misuse that develops in the post-TBI period. This work was supported by resources from the John D. Dingell VA Medical Center, Detroit, MI.

Title: Pyridoxamine deficiency induces carbonyl stress and schizophrenia-like phenotypes in *Drosophila*

Authors: *K. KORI;
Tokyo Metorolitan Inst. of Med. Sci., Setagaya, Japan

Abstract: Advanced glycation end products (AGEs) are formed through non-enzymatic reaction, maillard reaction and oxidation stress, between sugars and proteins, lipids or nucleic acids. Pyridoxamine, one of vitamin B_6 is known to scavenge the intermediates of AGEs and also inhibit maillard reaction. The accumulation of AGEs is termed "carbonyl stress" and is kwon to involve in many diseases such as diabetes, kidney disease and aging. Recent studies reported 20 % of schizophrenia patients have mutation in GLO1 gene, which encodes enzyme detoxifies intermediates of AGEs. These patients exhibit high increase in AGEs and decrease in vitamin B_6.To address whether lack of vitamin B_6 causes carbonyl stress underlying schizophrenia, we tried to develop carbonyl stress model using *Drosophila*. To this end, we reared *Drosophila* on the sterilized defined medium lacking vitamin B_6 and found that deprivation of pyridoxamine increases pentosidine level about 5-fold, indicating that vitamin B_6 deficiency causes carbonyl stress. Moreover, this carbonyl stress model *Drosophila* show shorten life span, increased anxiety, fragmentation of nighttime sleep, reducing sugar preference, decreased courtship activity and memory impairment. Since these behavioral phenotypes are related to the symptom of schizophrenia, we suggest the carbonyl stress also impairs brain functions in flies.

Title: Regrowth of serotonin axons in the neocortex following a stab injury

Authors: *S. E. DOUGHERTY, Y. JIN, D. J. LINDEN;
Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Axon degeneration is a common occurrence in neurological disorders such as toxic chemical insults, stroke, concussion and traumatic brain injury. While most of this axonal loss is as yet irreversible, some neuron populations have shown a propensity to recover their axonal arbors through regeneration (of injured axons) or compensatory sprouting (of spared axons). Serotonergic neurons display an enhanced capacity for axonal regeneration after acute injury. One potential explanation is the ability of serotonergic axons to survive and grow within hostile extracellular conditions. Previous studies have shown that serotonin axons can extend through otherwise nonpermissive environments including glial scars and within the subventricular zone. To assess serotonin axon degeneration, regeneration, and sprouting following acute brain injury, we used a neocortical stab model in a Slc6A4 (serotonin transporter) - soluble EGFP BAC transgenic mouse. Immunohistochemistry on fixed tissue and chronic in vivo two-photon imaging through a cranial window overlying the neocortex have revealed new growth from the severed ends of axons, which extends across and beyond the stab rift. These studies reveal the dynamic nature of serotonin axonal regeneration and sprouting following a glial scar-forming injury. Can other neuromodulatory axons in the neocortex regrow following stab injury? Further investigations will assess dopamine and noradrenaline axons in this model.

Title: Diffusion Tensor Imaging detects alterations in the corpus callosum after mild TBI in the mouse

Authors: *P. N. VENKATASUBRAMANIAN[1], M. SMITH[1], D. R. SCHUBERT[2], J. C. PINA-CRESPO[3], K. MATHEWS[4], P. RIGBY[4], A. MANN[3], E. RUOSLAHTI[3], A. M. WYRWICZ[1], J. SPIESS[3,5];

Abstract: Purpose
Mild TBI is thought to induce axonal injury which might progress to chronic traumatic encephalopathy, post-traumatic stress syndrome, major depression and other pathological states. Using high resolution diffusion tensor imaging (DTI), we have investigated changes in brain microstructure in a mouse model of mild TBI and found changes in the corpus callosum (CC) that suggest chronic axonal injury.
Experimental
Male 7-8 week-old C57BL/6 mice were fixed in vertical position, heads down, in an aluminum shock tube with their back oriented towards the exit plane of the tube and hit with a supersonic helium wave at a peak reflective pressure of 70psi. On Days 2, 5 and 12 after the blast, the mice were cardiac-perfused and their brains removed for DTI at 14.1T. Multi-slice DTI of fixed brain was acquired using a spin-echo diffusion weighted pulse sequence: 59 μm x 59 μm in-plane, 0.5mm slice thickness, TR/TE 2500ms/16.5ms, duration of diffusion gradients 3ms, delay between diffusion gradients 7ms, 30 gradient directions and one b value = 1000 s/mm^2. Resulting images were processed to generate maps of fractional anisotropy (FA). Diffusion parameters measured from medial and lateral CC in slices containing the genu (CCg), body (CCb) and splenium (CCsp) of CC were compared between controls and mTBI mice on Day 2 (n=3), Day 5 (n=4) and Day 12 (n=3).
Results
High resolution DTI revealed subtle, region-specific changes in the CC at different time points after injury. On Day 2, FA was lower in both medial and lateral CCb (0.41±0.01 and 0.40±0.02, respectively) relative to controls (0.46±0.02 and 0.44±0.01) indicating axonal injury in CC after blast injury. CCg and CCsp showed no changes in FA on Day 2. Reduced FA values indicated axonal injury on Day 2, whereas in preliminary experiments enhanced tau phosphorylation was found only on Day 5. DTI showed that on Day 5, FA was higher in medial and lateral CCg (0.60±0.02 and 0.56±0.01 in mTBI vs 0.55±0.01 and 0.49±0.02 in controls), as well as in medial CCb (0.50±0.02). Increased FA was associated with increase in diffusivity along the fiber direction (axial diffusivity) and no change in radial diffusivity. The observed increase in FA might represent axonal compression. On Day 12, FA in CCg and CCb returned to normal values, whereas it decreased in medial CCsp (0.48±0.03 vs 0.55±0.02 in control) indicating that mTBI likely results in chronic structural changes in the CC.
Conclusion
Our blast injury model appears to be a useful paradigm to investigate mTBI in mice. High

resolution DTI reveals region-specific, chronic mictrostructural changes following mTBI in mice. (Supported by DARPA Cooperative Agreement HR0011-13-2-0017; Cortrop Inc.)

Title: Impact of chronic traumatic brain injury on noradrenergic innervation to the major anxiety-related neural pathways in rats

Authors: ***S. TSUDA**[1,2], J. HOU[1,2], R. NELSON[1], G. MUSTAFA[1,2], J. WATTS[1], F. J. THOMPSON[1,2,3], P. BOSE[1,2,4];
[1]Malcom Randal VA Med. Ctr., Gainesville, FL; [2]Physiological Sci., [3]Neurosci., [4]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Every year, approximately 1.7 million new cases of traumatic brain injuries (TBIs) occur in the United States, which often lead to long-term anxiety disorders. However, there has been no uniform consensus for an effective treatment for this disorder, partly due to the lack of comprehensive knowledge in the related neuropathology. Recently, TBI-induced significant injury of norepinephrine production site (i.e., locus coeruleus) has been shown and dysregulation of noradrenergic (NA) system has been implicated in TBI-induced anxiety related pathophysiology. Although the critical roles of the NA system in regulating anxiety have well been known, few studies have reported the impact of TBI on the NA innervation to anxiety-related brain regions following TBI. The purpose of this study was to characterize the changes in NAI to the major anxiety-related neural pathways following chronic closed-head TBI (cTBI; modified Marmarou TBI model, 450g / 1.25 m) in rats. In the current study, coronal brain sections of intact and injured animals which exhibited chronic anxiety-like behaviors in an elevated plus maze were used. Brain sections of the bed nucleus of the stria terminalis (BNST),

central nucleus of amygdala (CeA), dorsomedial hypothalamic nucleus (DMH), ventral subiculum (vSub), periaqueductal gray (PAG), and locus coeruleus (LC) were immnofluorescently labelled after being incubated with antibodies against dopamine beta-hydroxylase, neuronal nuclei, and NA receptors. Stereological analysis of the NA fiber density in these brain regions was performed and the number of NA cells in the LC was counted. The results showed that the number of NA cells in the LC and the NA fiber densities in the LC, PAG, and medial division of CeA were significantly reduced following chronic cTBI. In contrast, the NAI to the BNST, DMH, and vSub was significantly elevated following TBI. These results suggest that prolonged anxiety-like behaviors observed in these animals may partly be related to the dysregulated NA system in the AMG-BNST and the vSub-paraventricular nucleus of hypothalamus anxiety pathways. Current study would provide new information for understanding the anxiety-related cTBI neuropathology, which in turn may provide insights into a novel therapy for cTBI-induced anxiety disorders.

Title: Graded Mild traumatic brain injury (mTBI)-induces different trajectories reaching enduring multiple comorbidities

Authors: *F. J. THOMPSON[1,2,3], J. HOU[2], R. NELSON[1], G. MUSTAFA[2], J. JOSEPH[1], Z. WILKIE[1], P. BOSE[1,2,4];
[1]Brain Rehabil. Res. Ctr., North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Physiological Sci., [3]Neurosci., [4]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Traumatic brain injury (TBI) can produce life-long disabilities including cognitive, anxiety, balance, and motor deficits. Although newer imaging technologies and protein biomarkers are promising, these often do not provide accurate diagnosis of mTBI, and clinical consequences can be problematic due to inconsistent symptom clusters. Although acute symptoms typically resolve in days to weeks, a prolonged worsening of an array of somatic, emotional and cognitive symptoms may appear months to years following mTBI (Katz et al.,

2015). A recent report emphasized the chronic nature of disability in Veterans with mTBI who had significantly more cognitive, affective, vestibular and somatic symptoms persisting more than 4 years after the mTBI event(s) (Baldassarre et al., 2015). Most closed head TBIs (cTBI) are produced by head impact and may also include acceleration/deceleration with shearing of brain and white matter. The experimental model of cTBI induced by weight drop is known to produce hallmark TBI injuries (concussion, diffuse axonal injury, micro hemorrhages) (Bose et al., 2013; Foda and Marmarou, 1994; Marmarou et al., 1994; Hou et al., 2015; Mustafa et al, 2016). In addition, this injury is not further complicated by the surgery required for cortical exposure (Buki and Povlishock, 2006). However, graded mild intensities using this experimental cTBI model have not been comprehensively characterized for co-morbidities. The present study, used two intensities of weight drop (1.0 m and 1.25 m/450g) to produce closed head mild TBI (mTBI) to investigate the trajectory and magnitude of four comorbidities (cognitive, anxiety, vestibulomotor, and spinal reflex disabilities). Injuries were produced during general anesthesia (isoflurane), and time for righting recoveries were within 2 to 3 minutes longer than observed for non-injured sham animals. MRI images revealed no anatomical changes or hemorrhagic volumes. Collectively, these observations reflected characteristics of mild TBI. Cognitive tests were performed using spatial serial learning in a Morris water maze. Anxiety-like behavior was tested using measures of behavior in an elevated plus maze. Balance was tested using a rotorod. Spinal reflexes were evaluated for rate-dependent depression. For both TBI intensities, significant cognitive, anxiety, balance, and motor reflex changes were observed over the course of 18 weeks post injury. However, the milder TBI revealed considerably slower trajectories for the development of these changes. These studies emphasize the value for multiple time point neurologic assessments following mTBI.

Abstract: Repetitive mild traumatic brain injury (r-mTBI) is a risk factor for development of Chronic Traumatic Encephalopathy (CTE), a disease characterized by Tau pathology throughout the cortices, and often co-presenting with conditions such as Alzheimer Disease (AD). It has been well documented that mild to severe TBI can result in transient reductions in Cerebral Blood Flow (CBF), with severe injuries often accompanied by presence of varying degrees of vascular pathology post-mortem. Aberrant CBF readings precede gross Amyloid pathology in AD patients, suggesting that hypo-perfusion is key in the pathogenesis of conditions such as CTE and AD, for which r-mTBI is a pre-disposing factor. We have herein expanded on our previous animal model of r-mTBI, showing robust neuroinflammation and pronounced spatial memory deficit in wild type mice as late as 18 months post-injury. We now show this pathology and concomitant behavioral phenotype to be emulated in a separate animal model of r-mTBI, described herein, and accompanied by chronic impairment of global CBF, and altered expression of cerebrovascular markers. These results are the first to demonstrate chronic cerebrovascular dysfunction in the pathogenesis and evolution of r-mTBI-induced illness, and validate this model for investigation of CTE.

Abstract: We have developed an adult zebrafish model of mTBI using a non-puncturing weight drop method. Whole brain mRNA sequencing and CLARITY were performed at 3 and 21 days post injury and compared to sham controls. Our data suggest that 3 days immediately following mTBI a number of genes undergo expression changes, including several involved in circadian rhythms and cell proliferation. CLARITY protein changes include cell proliferation. At 21 days post mTBI induction, more genes show differential gene expression, including several involved in intermediate filament organization and inflammation. CLARITY protein changes include gliogenesis. Further work will focus on examining genetic and protein regulation at further time points to determine possible neural recovery pathways.

Title: Transcranial direct current stimulation (tDCS) improves neurological outcomes in a mice model of traumatic brain injury

Authors: *O. BRAGINA[1], E. NEMOTO[1], C. SHUTTLEWORTH[2], D. BRAGIN[1];
[1]Neurosurg., [2]Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM

Abstract: Objectives: Traumatic brain injury (TBI) causes long-term neurological disabilities in 7% of survivors for which there are no clinically proven neuroprotective therapies. Transcranial direct current stimulation (tDCS) is an electrotherapy currently being clinically tested for TBI. However, due to a lack of animal studies, optimal parameters for application are unknown. Our objective is to examine the most effective therapeutic parameters for tDCS in a mouse TBI model. We hypothesized that repetitive anodal tDCS, applied after TBI during recovery improves cognitive and motor neurologic outcome. Methods: Moderate TBI was induced by controlled cortical impact (CCI) with a Benchmark Controlled Cortical Stereotaxic Impactor using a 3 mm flat-tip impounder deployed at a velocity of 5m/sec and depth of 2.0 mm from the cortical surface. Repetitive anodal tDCS (0.1 mA/15min) or sham stimulation were applied under anesthesia during 2 weeks for 4 consecutive days with 3 days tDCS-free interval starting at 1 week after TBI. The anodal electrode coated with EEG cream was placed over the craniotomy;

the counter electrode on the thorax. Mice were tested for neurological deficits at 3 weeks after trauma using Rotarod testing for coordination and motor deficits, passive avoidance testing for learning and memory and novel object recognition memory testing. Results: CCI-induced moderate TBI caused tissue damage in the cortex and subcortical zones including hippocampus in the ipsilateral hemisphere as shown by T2 MRI and H&E staining. Nissl staining revealed a shrunken hippocampus and obvious shrinkage of parietal somatosensory cortex with 18% counted neuronal loss compared to contralateral hemisphere. TBI impaired motor function as it was shown at one week after injury by three-fold decrease of latency period on Rotarod comparing to uninjured animals. tDCS attenuated TBI-induced neurological impairments. Motor function assessed by Rotarod was better in tDCS mice compared to Sham, with latency to fall of 114.7 ± 17.6 and 79.3 ± 9.9 sec., respectively, $p<0.05$, n=10/group. The step-through retention latency of tDCS mice in Passive Avoidance was significantly longer ($P<0.5$) than that of Sham mice (324.5 ± 68.1 vs. 129.4 ± 59.9 sec., respectively). In the Novel Object Recognition, tDCS mice explored the new object more than the familiar one (58±28% vs. 42±27%) compared to Sham (51±25% vs. 49±26%), however difference was insignificant ($P=0.39$). Conclusions: Our studies show that two weeks of repetitive tDCS improves motor and cognitive deficits in mice with moderate TBI. Support: NIH-NIGMS P20GM109089-01A1

Title: Systemic administration of cell-free exosomes generated by human marrow mesenchymal stem cells cultured under 2D and 3D conditions improves functional recovery in rats after traumatic brain injury

Authors: Y. ZHANG[1], M. CHOPP[2,3], Z. G. ZHANG[2], M. KATAKOWSKI[2], H. XIN[2], C. QU[1], E. PIKULA[2], M. ALI[2], A. MAHMOOD[1], *Y. XIONG[1];

[1]Neurosurg., [2]Neurol., Henry Ford Hlth. Syst., Detroit, MI; [3]Dept. of Physics, Oakland Univ., Rochester, MI

Abstract: Multipotent human mesenchymal stem cells (hMSCs) improve functional outcome after experimental traumatic brain injury (TBI). The present study was designed to investigate whether systemic administration of cell-free exosomes generated from hMSCs cultured in 2-dimensional (2D) conventional conditions or in 3-dimensional (3D) collagen scaffolds promotes functional recovery and neurovascular remodeling in rats after TBI. Wistar rats were subjected to TBI induced by controlled cortical impact; 24 hours later tail vein injection of exosomes derived from hMSCs cultured under 2D or 3D conditions or an equal number of liposomes as a treatment control were performed. The modified Morris water maze, neurological severity score and footfault tests were employed to evaluate cognitive and sensorimotor functional recovery. Animals were sacrificed at 35 days after TBI. Histological and immunohistochemical analyses were performed for measurements of lesion volume, neurovascular remodeling (angiogenesis and neurogenesis), and neuroinflammation. Compared with liposome-treated control, exosome-treatments did not reduce lesion size but significantly improved spatial learning at 33-35 days measured by the Morris water maze test, and sensorimotor functional recovery, i.e., reduced neurological deficits and footfault frequency, observed at 14-35 days post injury ($p < 0.05$). Exosome treatments significantly increased the number of newborn endothelial cells in the lesion boundary zone and dentate gyrus, and significantly increased the number of newborn mature neurons in the dentate gyrus as well as reduced neuroinflammation. Exosomes derived from hMSCs cultured in 3D scaffolds provided better outcome in spatial learning than exosomes from hMSCs cultured in the 2D condition. In conclusion, hMSC-generated exosomes significantly improve functional recovery in rats after TBI, at least in part, by promoting endogenous angiogenesis and neurogenesis and reducing neuroinflammation. Thus, exosomes derived from hMSCs may be a novel cell-free therapy for TBI, and hMSC-scaffold generated exosomes may selectively enhance spatial learning.

Title: Enduring effects of environmental enrichment on functional network reorganization after experimental TBI in rats

Authors: *A. PAYDAR[1], D. ROBIO[1], S. SRINIVAS[1], Y. CAI[1], A. E. KLINE[2], N. G. HARRIS[1];
[1]UCLA, Dept. of Neurosurgery, BIRC, Los Angeles, CA; [2]Departments of Physical Med. & Rehabilitation, Critical Care Medicine, and Psychology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Current clinical rehabilitation strategies used after brain injury promote beneficial behavioral outcomes. However, therapies might be further optimized by using more detailed feedback from comparison of brain functional connectivity (fc) before and after intervention. We hypothesized that resting state fMRI (rsfMRI) should be an ideal technique to monitor whole brain function in response to rehabilitation. Our recent studies showed that fc is significantly impacted by experimental brain trauma in the rat, and that increased pericontusional and contralateral brain regions fc offsets the loss in connectivity from the injury core. However, it is unknown whether the beneficial effects of rehabilitation can be followed by monitoring brain circuity through changes in fc. We therefore determined fc following controlled-cortical-impact-injured over the forelimb sensorimotor cortex and in sham-injured adult rats that were then housed immediately after injury in either standard (STD) or environmentally enriched (EE) conditions for 4 weeks, and then for an additional 4 wks in STD conditions for all rats (n=5-6/group). We obtained behavioral grid-walk and rsfMRI data at 1, 4 & 8wks post-injury and analyzed data for network-based connectivity over 96 brain regions. The rsfMRI data confirmed our prior published work showing significant injury effects in STD conditions compared to sham-STD at all time-points ($P < 0.05$). There was no global effect of EE vs STD on any network parameter at 1wk post-injury, although there was a trend of reduced modularity (lowered arrangement of circuits into network components), and the number of grid-walk foot-faults was reduced following injury+EE compared to injury+STD. However, 4wks of EE normalized many of the persistent injury+STD effects of reduced shortest path and increased mean local connectivity to sham-STD / sham-EE levels. Low global modularity persisted at 4wks after injury+EE ($P < 0.05$) compared to injury-STD, sham-EE and sham-STD, all of which were not different, indicating a potential biomarker of reorganization due to EE. Importantly, these effects endured when measured 4wks after removal of EE conditions (8wks post-injury). These global effects were underpinned by significant regional effects of normalized connection strength in injured-EE vs injured-STD, bilaterally in S1 cortex, thalamus and caudate, and in contralateral hippocampus and M1 cortex ($P < 0.05$).

Title: The impact of MIF binding and CD74 on the activation and expansion of pro inflammatory B cells and gamma delta T cells in a fluid percussion model of traumatic brain injury

Abstract: The immune system responds to infection or injury, including TBI, via a well-orchestrated series of events that include an innate immune response in which cytokines and chemokines are released that recruit immune cells to the injury. An important pro-inflammatory cytokine released during the early response to injury is macrophage migration inhibitory factor (MIF). This fundamental component of the immune response may be involved in tissue repair, or tissue damage, and is part of the non-specific, innate immune response. If antigen is present following an injury, the innate immune response precedes antigen processing and presentation, and subsequent T cell recognition, the hallmarks of a transition from an innate to a specific, adaptive immune response. Our previous work demonstrated an early expansion and activation of splenocytes within 24 hrs of a traumatic brain injury (TBI), that was highly suggestive of an adaptive immune response. We subsequently demonstrated that the splenocyte expansion is dependent on invariant chain (CD74). The full-length CD74 molecule can exist as a cell surface receptor for macrophage inhibitory factor (MIF). MIF binding to full-length cell surface CD74 results in a signaling cascade that modulates cytokine and chemokine production. However, the proteolytic cleavage product of CD74, CLIP, has an additional function in antigen processing, the first step in the transition from an innate to an adaptive immune response. Depleting CD74 in our experiments resulted in a reduction in lesion size and neuroinflammation following fluid percussion injury (FPI). Several fundamental questions that remain to be answered are whether CD74 contributes to the neurodegenration of TBI via an innate response involving MIF or from its contribution to the transition between innate and adaptive immunity, or both and, importantly, how do these functions influence TBI-induced pathology? To address these questions, we administered ISO1, a MIF antagonist, at 30 minutes after an FPI. We then assessed splenocyte expansion and gamma delta T cell activation at 24 hrs after FPI. The 24 hour time point is when we have previously seen robust expansion of splenocytes, including gamma delta T cells. The

results show that treatment with ISO1 after FPI reduces the expansion of CLIP-bearing B cells, but had little to no effect on the expansion of gamma delta T cells. These results suggest that MIF might have a role in mediating specific, adaptive immune responses, in addition to its well-defined role in contributing to an innate immune response. Follow-up studies are currently underway to determine if ISO1 treatment will also be neuroprotective.

Title: Alteration of cardiac performance after traumatic brain injury through acute signaling mechanisms

Authors: *D. NIZAMUTDINOV[1], J. KAIN[2], L. A. SHAPIRO[3];
[1]Surgery, Texas A&M Univ., Temple, TX; [2]Surgery, [3]Surgery and Neurosurg., Texas A&M HSC, Temple, TX

Abstract: Autonomic nervous system innervation of the heart, and neuroimmune responses are possible mechanisms through which the brain can alter myocardial function. Traumatic brain injuries (TBI), are associated with various cardiovascular abnormalities including hyper- and hypotension, electrocardiographic (ECG) abnormalities, release of troponin C, cardiac dysfunction resembling myocardial infarction and significantly increase mortality and morbidity from cardiac pathologies. In animal models, stimulation of the hypothalamus induces cardiac hypertension and/or ECG abnormalities (myocardial necrosis, dysfunction of rhythmic activity-arrhythmias, bradycardia, tachycardia). These symptoms occur with acute stimulation of the hypothalamus, whereas chronic stimulation causes persistent irreversible ECG changes. The focal myo-cytolysis was reported in some patients who suffered from fatal intracranial hemorrhages, known as myofibrillar degeneration. It is now known that any neurological insults, including TBI, stroke, ischemia, and subarachnoid hemorrhage, can lead to adverse cardiovascular events, demonstrating a clear link between the brain and cardiac function. Therefore, the current study sought to examine activation of key cardiac cell signaling molecules responsible for regulation of contractile performance. We examined phosphorylation of protein kinase B (P-AKT) and phosphorylation of c-Jun N-terminal kinase (P- JNK) relative to total forms of both proteins, at 2 and 6 hrs after a fluid percussion injury (FPI), compared to sham FPI

animals. JNK and AKT are known to be involved in the regulation of cardiac calcium mobilization and direct orchestration of contractile elements of the heart.
The results demonstrate a 30% increase of P-JNK at the 2 hrs post-FPI time point and a 21% decrease at 6 hrs after FPI, relative to sham mice. Conversely, the P-AKT exhibited a 7% decrease at 2 hrs after FPI, and a 12% decrease at 6 hrs after FPI, compared to shams. It is possible that the observed 30% increase in phosphorylation of JNK at 2 hrs post-FPI is involved in an acute signaling response to compensate for the decrease of P-AKT at this time point. At 6 hrs post-FPI, the 51% decrease in P-JNK, compared to 2 hrs post-FPI, might be explained as a temporary/partial contractile decompensation. This hypothesis is supported by the observation of greater dephosphorylation of AKT at 6 hrs after FPI.
In conclusion, the presented data are consistent with previously reported clinical findings associated with acute ECG abnormalities in patients with TBI. Follow-up studies are planned to unveil fundamental mechanisms behind cardiac damage / recovery after TBI.

Title: Role of oxidation of kcnb1 potassium channels in mouse model of traumatic brain injury

Authors: W. YU[1], R. PARAKRAMA[2], S. TENG[2], M. GOWDA[2], Y. SHARAD[2], S. THAKKER-VARIA[2], J. ALDER[2], *F. SESTI[3];

Abstract: Keywords: oxidative stress, ROS, potassium channel, K+ channel, Kv2.1, KCNB1, dasatinib, Src kinase, primary neurons, morris water maze, rotating device, transgenic mouse.
Delayed rectifier potassium (K^+) channel KCNB1 (Kv2.1), which conducts a major somatodendritic current in cortex and hippocampus, is known to undergo oxidation in the brain but whether this can cause neurodegeneration and cognitive impairment was not known. Here, we used transgenic mice harboring human KCNB1 wild type (Tg-WT) or non-oxidable C73A mutant (Tg-C73A) in cortex and hippocampus, to determine whether oxidized KCNB1 channels

affect brain's function. Animals were subjected to traumatic brain injury (TBI), a condition characterized by extensive oxidative stress. Dasatinib, a FDA-approved inhibitor of Src tyrosine kinases was used to impinge on the pro-apoptotic signaling pathway activated by oxidized KCNB1 channels. Thus, typical lesions of TBI, namely inflammation (astrocytosis), neurodegeneration and cell death were markedly reduced in Tg-C73A and Dasatinib-treated non-Tg animals. Accordingly, Tg-C73A mice and non-Tg mice treated with Dasatinib exhibited improved behavioral outcome in the rotating test device (rotarod) and in the Morris Water Maze (MWM) compared to control. Moreover, the activity of Src kinases, along with oxidative stress, were significantly diminished in Tg-C73A brains. Together, these data demonstrate that oxidation of KCNB1 channels is a contributing mechanism to cellular and cognitive deficit in TBI and indicate a new therapeutic approach to this devastating condition.

Title: Sensor-based quantitation of a closed-skull weight drop model for traumatic brain injury

Authors: *J. ALLENDE LABASTIDA[1], S. ALI[2], J. GAO[1], T. J. DUNN[1], Y. YU[3], D. S. DEWITT[4], D. S. PROUGH[4], P. WU[1];

Abstract: Traumatic brain injury (TBI) represents a major public health burden, with an estimated 150-300 per 100,000 people suffering from TBI worldwide. The increased awareness of mild TBI such as concussion lead to more research and a growing body of literature being generated in the pre-clinical setting. However, there is a concern in animal models for mTBI and the reproducibility among studies and laboratories. Standardized experimentation will allow for high quality meta-analysis of data and more meaningful translation of preclinical research to the clinical setting. Recently, a closed-skull weight-drop injury model has been developed, including two of the mechanisms (impact and acceleration/deceleration) observed in most cases of TBI, making this model clinically relevant. However, uncertainty of the injury severity and variability are major concerns of this model. To address these problems, we added a set of sensors to the model that allowed us to measure the velocity of the falling weight and calculate its kinetic energy immediately before impact. Male C57BL/6 mice were allocated into 3 groups: sham injury as control and two TBI injury groups (each group injured with either a 95 g or 150 g weight dropped from a height of one meter). Locomotor activity was recorded 30 minutes after injury. We observed a dose-dependent decrease in the exploration activity after injury, and a partial recovery of locomotion at 4 days post-injury. Brains were collected 5 days post-injury for immunohistochemistry and Western blot analysis. Further characterization and optimization will yield a model that generates information of the forces responsible for injury, and ultimately reduces variability of the closed-skull weight drop model to promote translational TBI research.

Title: Administration of miR-155 antagomir following experimental traumatic brain injury (TBI) attenuates post-traumatic neuroinflammatory responses and improves neurological recovery

Authors: *R. J. HENRY[1], D. J. LOANE[2], B. E. SABIRZHANOV[2], B. A. STOICA[2], A. I. FADEN[2];
[2]Shock, Trauma & Anesthesiol. Reseach, [1]Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Traumatic brain injury (TBI) is a leading cause of mortality and disability worldwide, and is associated with chronic microglial activation that contributes to long-term neurodegeneration and neurological impairments. MicroRNAs (miRs) are small noncoding RNAs that regulate gene expression at a post-translational level. Recent data suggest that miR-155 and miR-124 control microglial activation phenotype balance following CNS injury. This study examined the expression profile of miR-155/miR-124 in mouse brain following TBI. In addition, this study examined the effect of acute intracerebroventricular (i.c.v.) administration of an miR-155 antagomir on post-traumatic neuroinflammation and neurological recovery after TBI.

Adult male C57Bl/6 mice (n = 6/group) underwent moderate controlled cortical impact (CCI) and cortical tissue was isolated from sham, 1h, 6h, 24h, 72h and 7d post-injury for miR-155/miR-124 expression analysis. In a follow up study C57Bl/6 mice (n=8/group) received a single i.c.v. injection of miR-155 or scramble antagomir (0.5nmol) immediately after CCI, and cognitive function was assessed in CCI mice at 7d post-injury using a Y-maze test. At 7d post-injury, mice from the second experiment were anesthetized and trancardially perfused with ice-cold 0.9% saline. Ipsilateral hippocampus was rapidly dissected, snap-frozen and stored at -80°C until assayed for miRs and inflammatory mediator gene expression. Data were analysed using one-way ANOVA followed by Student's Neuman-Keuls *post-hoc* test.

Following CCI, miR-155 expression was significantly increased at 24h post-injury and miR-124 expression significantly decreased at 1h post-injury, when compared to sham-injured controls. This increase and decrease in miR-155 and miR-124 expression, respectively, persisted through 7d post-injury. Administration of a miR-155 antagomir attenuated CCI-induced increases in mRNAs for pro-inflammatory mediator's iNOS and NOX2 at 7 days post-injury. Furthermore, miR-155 antagomir treatment reversed CCI-induced decreases in spontaneous alterations in the Y maze task at 7 days following injury.

In summary, these data demonstrate that experimental TBI is associated with an altered miR-155/miR-124 expression profile up to 7 days post-injury, and pharmacological inhibition of miR-155 following TBI is associated with both anti-inflammatory effects and improvements in functional recovery. Overall, these findings indicate that pharmacological regulation of inflammatory miRs, may offer a novel therapeutic approach for targeting neuroinflammatory responses in experimental TBI.

Title: Corticospinal tract pathology with impact acceleration: modeling diffuse axonal injury in the mouse

Authors: N. ZIOGAS[1], J. RYU[1], L. XU[1], P. TSOULFAS[3], *V. E. KOLIATSOS[2]; [1]Neuropathology, [2]Neuropathology, Neurology, Psychiatry, Johns Hopkins Univ., Baltimore, MD; [3]The Miami Project to Cure Paralysis, Maiami, FL

Abstract: Diffuse Axonal Injury (DAI) is a common lesion associated with Traumatic Brain Injury (TBI), from concussion to severe injury. Sequelae of DAI are diverse and include motor impairments, memory loss, loss of coordination and disorders of sleep and mood, suggesting that more than one brain network is affected. The cellular and molecular mechanisms of DAI are probably similar regardless of the network involved, and may be studied using axon bundles accessible to experimental manipulations. Such models can address axonal versus retrograde perikaryal changes, time course of events, and molecular targets for repair. Here, we exposed Thy1-eYFP-H transgenic mice with green labeling of layer V pyramidal neurons and their axons in the corticospinal tract (CST) to impact acceleration TBI of mild severity. Using CLARITY and two-photon microscopy coupled with high-working-distance objective with submicron resolution, we visualized in 3D the CST from cerebral peduncles to pyramidal decussation. Individual axons and classical axonal abnormalities were identified in exceptionally high detail. CLARITY-based immunohistochemistry (IHC) was performed to characterize cellular and molecular pathology including: the precise location of axonal abnormalities, for example nodes of Ranvier identified with Nav1.6 and Caspr IHC; microglial activation and axonal-microglial interactions using IHC for IBA1, CD206 and CD16/32. Using conventional histological methods, we explored molecular hypotheses of axonal demise, including JNK cascade activation ending in phosphorylation of c-Jun or SCG10. Using retrograde tracing, we identified the cell bodies of neurons projecting in the CST. We found that CLARITY is a very sensitive method for axonal lesions that often cluster in sites of crossing of CST with other axon tracts. We also found that pyramidal neurons projecting in the CST lose perikaryal volume by 23% 14 days after injury; perikaryal volume loss is significantly associated with p-c-Jun immunoreactivity. These

findings suggest that impact acceleration reliably causes axonal pathology in the CST that can be characterized with high-resolution neuroanatomy and can divulge important cellular and molecular changes of great significance to DAI and TBI.

Abstract: Traumatic brain injury (TBI) due to blast exposure is currently the most prevalent of war injuries. While secondary ocular blast injuries due to flying debris are more common, primary ocular blast exposure has been reported among survivors of explosions, but with limited understanding of the resulting retinal pathologies. Blast wave pressure of 120 ± 7 kPa causes damage to the brain in a rat model, however, the effects of blast wave pressure on the retina have not been well characterized. Using a compressed air-driven shock tube system, adult male and female C57BL/6 mice were exposed to blast wave pressure of 300 kPa (43.5 psi) per day for three successive days, and euthanized 30 days post injury. We assessed retinal tissues using immunofluorescence for glial fibrillary acidic protein (GFAP), microglia/macrophage specific protein Iba1, and phospho-PHF-tau (AT-270). Primary blast wave pressure resulted in activation of Müller glia, loss of photoreceptor cells, and expression of phospho-tau in retinal neurons and glia. Additionally, we observed activation of microglia based on an increase in Iba1, and CD68 immunoreactivity. These changes were detected 30 days after blast exposure, suggesting the possibility of chronic retinal injury and neuronal inflammation after primary blast exposure.

Title: Experimental traumatic brain injury induces changes resembling motor neuron disease that are exacerbated by pathological TDP-43

Authors: *S. R. SHULTZ[1], D. WRIGHT[2], X. TAN[2], T. O'BRIEN[1];
[1]Univ. of Melbourne, Parkville, Australia; [2]The Univ. of Melbourne, Melbourne, Australia

Abstract: Motor neuron disease (MND) is characterized by the progressive death of motor neurons, degeneration of the corticospinal tract, and the presence of transactive response DNA binding protein 43 (TDP-43) pathologies. To date the aetiology of MND remains largely unknown. Traumatic brain injury (TBI) has been linked to the later onset of MND, however a causal relationship between these conditions remains controversial. As such, here we administered experimental TBI via the fluid percussion model to rats and assessed for progressive MND-like abnormalities. Volumetric MRI found that TBI resulted in progressive atrophy of the motor cortices, and tensor-based morphometry and diffusion-weighted imaging revealed progressive degeneration within the corticospinal tracts. Rats given a TBI also had a reduction in neurons and an increase in phosphorylated and cytoplasmic TDP-43 in the motor cortex, fewer motor neurons in the spinal cord, muscle atrophy, and motor impairments. To further examine the potential role of pathological TDP-43 in this process we next administered TBI to transgenic mice that overexpress TDP-43 or wild-type mice. All TBI mice had pathological TDP-43 relative to their sham-controls, with TDP-43 + TBI mice having more than all other groups. While all mice given a TBI had significant neuronal death, it was worse in TDP-43 + TBI mice. TDP-43 + TBI mice also had worse cognitive and motor deficits compared to their wild-type counterparts. These findings suggest that TBI can induce a progressive disease process resembling MND and that TDP-43 pathologies may contribute to these effects.

Title: Pomegranate treatment for repetitive mild brain insults

Authors: *A. M. BRISENO[1], N. M. BAJWA[1], A. OBENAUS[2,3,4], R. E. HARTMAN[1];
[1]Dept. of Psychology, [2]Dept. of Pediatrics, [3]Div. of Interdisciplinary Studies, Loma Linda Univ., Loma Linda, CA; [4]Cell, Molecular, and Developmental Biol. Program, Univ. of California Riverside, Riverside, CA

Abstract: Humans may be subjected to a number of mild brain insults (e.g., general anesthesia, concussions) over their lifetime. The neuropathological effects of mild brain insults can accumulate, leading to the development of motor and cognitive deficits. Although there are currently no treatments that can restore lost function after repetitive brain injury, our laboratory has shown that dietary supplementation with pomegranate polyphenols can improve Alzheimer's-like neuropathology in transgenic mice, protect mice from the effects of irradiation with protons, and protect humans from post-operative cognitive deficits. Therefore, this study focused on the behavioral and neuropathological effects of repetitive brain insults (concussion/general anesthesia) in mice, and the use of dietary supplementation with pomegranate to ameliorate these effects.
Adult mice were given dilute pomegranate juice or control water for 1 week, followed by anesthesia, repeated anesthesia (3 days apart), or repeated concussive injury (a single closed-head concussion to each hemisphere 3 days apart). They were then maintained on the pomegranate juice or control diet for 2 additional weeks. Behavioral testing was administered 1, 3, 5, and 7-11 days after injury to assess cognitive, motor, and affective function. Repeated concussive injury, but not repeated anesthesia, induced motor and learning deficits, some of which were significantly reduced by pomegranate juice. These data suggest that the model of repeated closed-head concussive injury in mice may be used to test neuroprotective treatments in future translational studies. Furthermore, this study provides further evidence that a phytochemical-rich diet may provide significant neuroprotection from brain injury.

Hospital, Div. of Critical Care Med., Dept. of Anesthesiology, UBC, Vancouver, BC, Canada; [3]Vancouver Gen. Hospital, Div. of Critical Care Med., Dept. of Medicine, UBC, Vancouver, BC, Canada; [4]Vancouver Spine Surgery Inst., Dept. of Orthopaedics, UBC, Vancouver, BC, Canada

Abstract: Traumatic spinal cord injury (SCI) results in local and systemic vascular changes which make the spinal cord extremely vulnerable to ischemia, hypoxia, and energy dysfunction. Current guidelines recommend maintaining a mean arterial pressure (MAP) of 85-90 mmHg using volume expansion agents and vasopressors in an attempt to support the injured spinal cord with adequate perfusion. While the desire to prevent ischemia is understandable, indiscriminate augmentation of MAP in a traumatically injured cord with impaired vascular autoregulation may have deleterious effects. In this study we sought to determine the impact of MAP augmentation on vascular and metabolic responses as well as long-term behavioural outcomes following a contusion-compression injury of the spinal cord.
Using our porcine model of SCI, female Yucatan miniature pigs received a T10 contusion injury followed by 3-hours of sustained compression. 1-hour post-compression and decompression, norepinephrine (NE) was used to elevate MAP by 20 mmHg for a 1.0-hr period. Laser Doppler/oxygenation and pressure probes were inserted into the spinal cord 0.2 and 2.2 cm from the injury site to monitor the effects of MAP support on spinal cord blood flow (SCBF), $PaPO_2$, pressure over a 7-day period. Microdialysis samples were also collected and subsequently analyzed for lactate, pyruvate, glucose, glutamate and glycerol. Behavioural recovery was scored weekly according to the Porcine Thoracic Injury Behavioural Scale (PTIBS).
Data from the first 6 hours after SCI showed that proximal to the impact (0.2-cm location), NE infusion during the compressed and decompressed state of the spinal cord resulted in only a slight restoration of SCBF and PaO_2, though both still remained well below pre-injury levels. In the decompressed state, a decrease in L/P ratio was observed in the NE group to ~250% of pre-injury levels, while levels remained unaltered in the control group (~800% of pre-injury). Distal to the impact (2.2-cm location), NE infusion increased SCBF and $PaPO_2$ above pre-injury levels

both during the compressed and decompressed state of the spinal cord. Currently we are analyzing the intraparenchymal responses during the subsequent 7 days as well as the long-term behavioural consequences of MAP support.
Combined, our preliminary results suggest that MAP augmentation during compression and following decompression could partially restore post-traumatic ischemia/hypoxia at the injury site, but could potentially lead to hyperemia distal to the injury site. Identifying the functional consequences is currently being carried out.

Abstract: Recent work has shown that deafferentation caused by traumatic spinal cord injury (SCI) can trigger a change in brain state and induce cortical reorganization (Moxon et al. 2014). It is believed that these adaptive changes in response to injury within the motor and sensory systems play an important role in functional recovery after SCI. In an effort to assess time-dependent changes occurring in the forelimb and hind limb sensory-motor cortex, in this study somatosensory (SSEP) and motor evoked potentials (MEP) were used to evaluate immediate (i.e. within 1-3 hours) and long-term changes (12 weeks) using a porcine model of SCI.
Twelve female Yucatan pigs weighing 20-25kg were anesthetised using intravenous Propofol and Fentanyl. All animals received a midline contusion injury at the T10 level using a 50g impactor dropped from a height of 20 cm; this was followed by 5 minutes of sustained compression. Cortical SSEPs were measured using stimulation of the median nerve of the forelimb, and the medial plantar nerve (a branch of the posterior tibial nerve), of the hind limbs.

MEPs were recorded from the extensor carpi radialis muscle in the right forelimb of the animals. SSEPs and MEPs were recorded pre-surgery, post-laminectomy, and 5 minutes, 3 hours and 12 weeks after injury.
Immediately after SCI, upon stimulation of the injured hind limb, cortical SSEPs were completely abolished and did not recover even by week 12. SSEPs recorded upon forelimb stimulation remained unchanged directly after injury, however, a significant amplitude increase was observed at week 12 in comparison to pre-SCI. Moreover, MEPs recorded from the intact forelimb exhibited noticeably greater amplitude at 3 hours and 12 weeks post-SCI.
Taken together, our data demonstrate that besides an obvious loss of cortical responses to hindlimb stimuli, forelimb evoked responses markedly increased following contusion-compression SCI at T10. The increase in forelimb MEP amplitude immediately after SCI may indicate a change in the cerebral state of excitability, while the increase in SSEPs occurring over time (i.e., recovery) may be indicative of cortical reorganization.

Title: Duraplasty in acute traumatic SCI: the impact on metabolism, blood flow, oxygenation and pressure using a porcine model of SCI.

Authors: *N. MANOUCHEHRI[1], F. STREIJGER[1], K. SHORTT[1], K. SO[1], E. B. OKON[1], B. K. KWON[1,2];

Abstract: After traumatic spinal cord injury (SCI), secondary pathophysiologic processes and damage result in worsening the extent of the primary injury and ultimately functional outcome. One commonly observed secondary injury phenomenon in the acute injury period is progressive edema and swelling of the spinal cord. This may increase intraparenchymal spinal cord pressure as the cord swells and is compressed against the dura, resulting in a compromise in perfusion.

One way to potentially alleviate these effects is to expand the subarachnoid space by performing a duraplasty, which could potentially reduce intraparenchymal pressure and improve perfusion. Therefore, in this study, we determine the effect of expansive duraplasty on intraparenchymal pressure, cerebrospinal fluid pressure, blood flow, oxygenation, and metabolic responses in a porcine model of SCI.
Female Yucatan miniature pigs received a T10 contusion-compression SCI either with or without expansion duraplasty using an artificial dural graft. For the SCI-only animals the dura was left intact. Prior to injury, probes for microdialysis, blood flow (SCBF), oxygenation ($PaPo_2$), and hydrostatic pressure measurements were inserted into the spinal cord 0.2 and 2.2 cm from the injury site. Measurements occurred for 4 hours post-injury, after which the animals were recovered for continued monitoring over 7 days.
Contusion-compression SCI resulted in decreased SCBF levels close to the injury site (0.2-cm location) followed by a subsequent increase during the following days. Similarly, $PaPO_2$ plummeted immediately after injury and these levels remained low for the entire 7 day period post-injury. The L/P ratio increased within minutes, with a second continual increase at day 3. A gradual increase in L/P ratio was also observed at 2.2cm. Hydrostatic pressure remained consistently elevated for days and negatively correlated with changes in SCBF. An imbalance between SCBF and tissue metabolism was also observed, resulting in metabolic stress and insufficient oxygen levels.
The next step is to determine if expansion duraplasty can alleviate the observed increase in pressure and ischemia/hypoxia following SCI, a study that is currently being performed. Our preliminary data on 4 pigs shows promise, demonstrating the feasibility of the duraplasty technique and an enlargement of the dorsal subarachnoid space under the duraplasty. Microdialysis, blood flow, oxygenation, and hydrostatic pressure measurements are presently being analyzed.

Title: New neurotrauma marker panel of astroglial heterogeneity predicts severity and outcome after recoverable swine spinal cord injury

Authors: *I. B. WANNER[1], J. HALFORD[1], S. SHEN[2], J. A. LOO[2], R. KINSLER[3], P. CRIPTON[4], B. KWON[5], A. MAYER[6];

Network, Lovelace Resp. Res. Inst., Albuquerque, NM

Abstract: The broad heterogeneity of spinal cord injury (SCI) complicates patient assessment when determining urgent care, transportation needs and outcome prediction, requiring objective and sensitive techniques for rapid diagnosis. Biofluids offer a protein signature for tracking cellular pathophysiology after neurotrauma. We identified a novel neurotrauma marker panel and associated marker release to cell wounding and cell death in mechanically traumatized astrocytes (Levine et al., 2016). This new panel, measured in cerebrospinal fluid (CSF) and blood by immunoblot densitometry and mass spectrometry, was used to assess severity after contusion SCI in the Yucatan swine, along with quantitative histopathology and magnetic resonance imaging (MRI). In CSF, GFAP, S100β and new astroglial markers aldolase C (ALDOC), brain lipid binding protein (BLBP), and glutamine synthetase (GS) were robustly elevated 15-30 min post-SCI relative to baseline levels. GFAP and S100β decreased over time while ALDOC and GS remained elevated in the CSF 2-7 days post-injury. ALDOC was found in serum by 15-30min and peaked by 2 days post-SCI. Interestingly, acute ALDOC, BLBP, GS and GFAP CSF levels correlated well with cavity size and immunoglobulin extravasation to predict severity of tissue loss and hemorrhage at 7 days postinjury. Acute CSF levels of ALDOC and GFAP associated strongly with recovery of ambulation at 7 days postinjury using the porcine thoracic injury behavioral scale (PTIBS, Lee et al., 2013). Acute astroglial wounding shown by glial fiber fragmentation (clasmatodendrosis) was most abundant 1-2 hours after injury, while tissue loss evolved over 7 days postinjury. Severe, early clasmatodendrosis may contribute to increasing cavitation and acute astroglial biomarker release. At 7 days postinjury, elongated astrocytes formed perilesional bundles located separately from damaged neural tissue with wounded and territorial reactive astrocytes, documenting glial scar formation. Astroglial diversity was further defined by different astroglial marker expression providing molecular and structural heterogeneity in astroglial injury response. In summary, histopathology and cell fate-defined markers with fast release kinetic and prolonged elevation provide new tools for acute diagnosis and prognosis that help elucidate the acute pathophysiology of trauma and support patient risk stratification. Our data indicate that early trauma events predispose the unfolding severity range and recovery potential after contusive SCI. Ongoing investigations will examine acute care conditions like rough ground transportation as well as correlation with quantitative MRI.

Abstract: With no real treatment options currently available to clinicians, there is an urgent need for non-invasive biomarkers to aid in the scientific development and clinical validation of novel therapies for acute spinal cord injury (SCI). Micro RNAs (miRNAs) are small regulatory noncoding RNA molecules around 22 nucleotides in length that mediate post-transcriptional silencing of gene expression via the identification of specific sequences in target messenger RNA. Besides their specific spatial, temporal and cellular-level expression, our interest in miRNAs stems from their stability within blood, making it possible for blood samples to be used to measure markers specific to the injured central nervous system. In this study, we compared the miRNA expression profiles of serum and cerebrospinal fluid (CSF) collected from human patients with SCI. Patients classified as AIS A, B, or C were recruited as part of an ongoing, multi-center study (CAMPER; clinicaltrials.gov NCT01279811). In order to collect CSF samples, a lumbar indwelling intrathecal catheter was inserted prior to surgery (within 48 h of injury) and CSF samples were collected every 6-8 h for 5 days. Blood samples were collected simultaneously in order to compare CSF and serum miRNA profiles. Additionally, control ‘‘non-injury’’ CSF samples were collected via a single lumbar puncture from patients undergoing hip or knee surgery during their spinal anesthetics, or intra-operatively from patients undergoing lumbar spine fusions. Next-generation sequencing technology was used to compare effects of injury severity on miRNA levels obtained daily over a period of 5 days post-injury. Extracellular

miRNAs were isolated and sequenced using the Illumina HiSeq 2500 system. Generated data was processed using the Mayo Clinic's Comprehensive Analysis Pipeline for miRNA Sequencing Data (CAP-miRSeq), and aligned miRNA reads were used to compare differential expression. Here, we present miRNA profiles in CSF and serum clinical samples during acute and sub-acute stages after SCI. Our results reveal pronounced trends in miRNA expression and their potential target interactions provide valuable insight into the molecular mechanisms of SCI. This analysis was done in parallel to the investigation of miRNA in the serum of pigs following SCI. This characterization is important to establish whether biomarkers of SCI found in pigs can be transferred to humans and vice-versa.

Title: Overexpression of KLF6 in corticospinal tract neurons promotes axon growth after spinal injury

Authors: ***Z. WANG**, I. VENKATESH, N. KRUEGER, D. NOWAK, B. CALLIF, B. MAUNZE, M. G. BLACKMORE;

Abstract: Axonal regeneration in the central nervous system is limited in part by a developmental decline in the intrinsic regenerative capacity of central nervous system (CNS) neurons. Changes in gene expression are likely involved, and thus transcription factors that orchestrate gene expression are attractive targets to understand and overcome intrinsic limits to axon growth in adult neurons. We have shown previously that forced expression of pro-regenerative transcription factors, including Sox11 and a transcriptionally activated form of

Krüppel-like factor 7 (VP16-KLF7), can enhance the regenerative ability of injured corticospinal tract (CST) neurons. Here we assessed the ability of KLF6, a transcription factor closely related to KLF7, to promote CST regeneration. KLF6 was delivered to cortical neurons by injection of AAV-KLF6 along with AAV-EGFP tracer, and animals were subjected to pyramidotomy or unilateral cervical hemisection. KLF6 expression promoted a robust increase in midline crossing by transduced (EGFP+) CST axons in the pyramidotomy model, and extensive CST growth in the spinal injury model that extended up to 3mm from the injury site. Immunohistochemistry confirmed viral-mediated upregulation of KLF6 protein, but also revealed endogenous expression of KLF6 in cortical neurons that appeared largely unaffected by spinal axotomy. Intriguingly, forced expression of KLF6 had more modest effects in sensory neurons confronted with spinal injury, causing a decrease in net retraction but not sprouting or regeneration beyond the injury site. To identify potential functional interactions with other pro-regenerative transcription factors, either Sox11 or Myc were co-expressed with KLF6 in cortical neurons challenged with spinal injury. Neither combinatorial treatment resulted in significant increases in CST axon growth above the level of KLF6 alone. Ongoing experiments are testing co-expression of KLF6 with additional pro-regenerative factors including Jun and DCLK. In addition, using CRISPR-mediated knockdown in a Cas9-expressing transgenic mouse, we are currently testing combined KLF6 overexpression and knockdown of PTEN. Finally, RNAseq experiments are underway to identify KLF6 target genes. Overall, these data identify KLF6 as a potent transcriptional promoter of axon regeneration in the injured CST.

Title: Combined rehabilitation and genetic enhancement of intrinsic regenerative growth ability to improve behavioral outcomes after spinal injury.

Authors: ***A. A. KRAMER**, Z. WANG, E. BALLE, L. K. HOLAN, N. KRUEGER, J. A. EVANS, M. G. BLACKMORE;
Marquette Univ., Milwaukee, WI

Abstract: Spinal cord injury (SCI) is a debilitating condition as adult CNS neurons are not able to regenerate lost axons, resulting in a loss of function below the injured region. To restore function, axons must be stimulated to regenerate and reconnect with appropriate postsynaptic targets. Recent work from our lab shows that in corticospinal tract neurons, overexpression of pro-regenerative transcription factors; including KLF7, Sox11 and more recently KLF6, leads to a significant increase in axon growth after spinal injury. Moreover, these stimulated CST sprouts show co-localization with the presynaptic marker VGLUT1 and the excitatory postsynaptic marker PSD-95, suggesting synaptic competence. Yet tests of forelimb function including a horizontal ladder task and staircase pellet retrieval showed no improvement in KLF6 or Sox11-treated animals. One possibility is that inappropriate synaptic targeting by newly grown CST axons may limit behavioral recovery. We are therefore exploring wheel running as a form of self-motivated rehabilitation to improve behavioral outcomes. Preliminary data indicate that access to running wheels after SCI improved performance on a horizontal ladder test. In current experiments we are testing the hypothesis that rehabilitation therapy in conjunction with genetic treatment may provide a means to guide newly sprouted axons to appropriate postsynaptic partners. The current study combines wheel running with KLF6 overexpression in the motor cortex, which we have recently shown to produce robust CST axon growth. Pellet retrieval and ladder crossing tasks will assess fine motor skills, and immunohistochemistry will determine the frequency and distribution of synaptic markers associated with sprouting CST axons in injured tissue. This combined genetic and rehabilitation approach may lead to better targeting of the newly sprouted axons to the appropriate postsynaptic targets and ultimately functional synapses and improved behavior.

Title: Combined expression of pro-regenerative transcription factors and transplanted stem cells to promote corticospinal tract regeneration.

Authors: *N. JAYAPRAKASH, Z. WANG, N. KRUEGER, A. KRAMER, M. BLACKMORE; Marquette Univ., Milwaukee, WI

Abstract: The failure of axon regeneration in the injured spinal cord results in partial or complete loss of function distal to the injury. To restore the function, severed axons must regrow and functionally reconnect to appropriate targets below the injury site. We have shown previously that forced overexpression of pro-regenerative transcription factors including Sox11 and KLF7 promotes axon growth in corticospinal tracts (CST) neurons. Moreover, using optogenetic stimulation to specifically stimulate CST axon terminals, we have shown that newly sprouted, genetically stimulated axons are able to form functional synaptic connections with spinal neurons. However, these experiments were performed in models of partial spinal injury, and growing CST axons were observed mainly in trajectories that circumvented injuries, taking advantage of spared tissue. Here we tested the ability of Sox11 or KLF7-stimulated axons to regenerate through more complete spinal injuries. Adult mice were subjected to complete thoracic crush injuries or severe cervical injuries in which 1mm of tissue was unilaterally removed. Cortical neurons were treated with AAV-Sox11 or AAV-VP16-KLF7 along with AAV-EGFP tracer. CST axons were not observed to traverse these sites of injury. Combined, these data suggest that KLF7- and Sox11-based interventions enhance innate growth ability while maintaining the capacity for synaptic integration, but do not confer the ability to extend into sites of spinal injury. Recent reports indicate that transplanted stem cells can serve as a substrate for CST growth in the injured spinal cord. Accordingly, in current experiments we are combining transcriptional manipulation of injured cortical neurons with transplantation of embryonic and induced pluripotent stem cells into C5 unilateral injury sites. Preliminary data confirm integration of the transplanted cells and fiber outgrowth into host tissue. Ongoing assessment of CST growth into and beyond the grafts will assess the utility of combined stem cells treatment and gene therapy to re-establish lost synaptic connection following spinal cord injury.

Abstract: Gene therapy is a powerful strategy to deliver a therapeutic protein to the injured spinal cord. Persistent, uncontrolled expression of a therapeutic gene, however, may have unacceptable side effects. Restricting transgene expression to the appropriate therapeutic time window is therefore essential. The doxycycline (dox)-inducible system is the most commonly used inducible gene expression system, but this system depends on a foreign transactivator (TA) which is immunogenic. This currently limits the in vivo use of this system. The glycine-alanine repeat (GAr) of the Epstein-Barr virus nuclear antigen-1 (EBNA-1) inhibits presentation of EBNA-1 to cytotoxic T cells, allowing virus-infected cells to evade the host immune system. Recently we showed that TA fused to GAr generates a chimeric transactivator (GArTA) which retains its function and has an immune-evading advantage over TA in a bioassay for human antigen presentation (Hoyng 2014).
In this study we compared the performance of the original TA and the new GArTA in the spinal cord. Lentiviral vectors carrying TA or GArTA under a CMV promoter (LV-CMV-TA and LV-CMV-GArTA) were each injected in the spinal cord of adult rats in a 1:1 mixture with LV carrying luciferase (luc) under the control of a doxycycline responsive promoter (LV-TRE-luc). LV-CMV-luc was used as control. The luc reporter allowed longitudinal in vivo monitoring of transgene expression. Control rats injected with LV-CMV-luc show initial high luc expression which significantly declined over a 12 week period. LV-CMV-TA/TRE-luc and LV-CMV-GArTA/TRE-luc injected rats show clear dox-inducible luc expression during the 1st cycle of dox administration, however, a 2nd exposure to dox fails to re-induce expression with both systems.
Methylation is known to silence the CMV promoter. We therefore repeated the experiment with LV vectors in which CMV was replaced by the PGK promoter. Indeed, with 10-fold less viral vector injected, LV-PGK-luc activity was 10-fold higher in the first 3 weeks after injection compared to LV-CMV-luc. After 3 weeks LV-PGK-luc mediated expression also started to decline but stabilizes over time. Both LV-PGK-TA/TRE-luc and LV-GArTA/TRE-luc are inducible 3 times. However, LV-GArTA/TRE-luc continued to be inducible, while the inducibility of PGK-TA/TRE-luc significantly declined during the 4th and 5th dox-cycle, suggesting that the use of GArTA provides an immune-advantage over TA. In future experiments the novel transactivator will be tested in the context of vectors that are gaining

increasing acceptance as clinical gene expression platforms, i.e. integration deficient lentiviral and adeno-associated viral vectors.

Title: Gene therapy using a stealth gene switch for GDNF expression promotes long distance regeneration of motor axons following a spinal ventral root avulsion

Authors: *R. EGGERS[1], F. DE WINTER[1], S. A. HOYNG[1,2], R. C. HOEBEN[3], M. J. A. MALESSY[2,1], M. R. TANNEMAAT[4,1], J. VERHAAGEN[1];
[1]Neth Inst. Neurosci, Amsterdam, Netherlands; [2]Neurosurg., [3]Mol. Cell Biol., [4]Neurol., Leiden Univ. Med. Ctr., Leiden, Netherlands

Abstract: In patients longitudinal spinal cord lesions of the brachial plexus often cause permanent loss of motor and sensory function. Until recent, such lesions were considered impossible to repair. After experimental lumbar ventral root avulsion, reimplantation promotes motoneuron survival and a limited degree of axon regeneration. Prolonged, uncontrolled viral vector-mediated expression of glial cell-line derived neurotrophic factor (GDNF) in reimplanted ventral roots enhanced motoneuron survival and axonal outgrowth into the root, however, persistent GDNF expression also leads to trapping of regenerating axons and a failure to reinnervate the hind paw (Eggers, MCN 2008). The goal of the current study was to overcome these adverse effects by exerting temporal control over the expression of GDNF using a novel stealth gene switch (Hoyng, Gene Therapy 2014). GDNF expression was regulated in the transduced reimplanted ventral roots (L3-6) of adult Wistar rats using doxycycline-supplemented food for 4 or 12 weeks (wk) post-surgery. This resulted in a 5 fold increased expression of GDNF for either 4 wk followed by a decline to baseline expression levels, or in persistent expression of GDNF for 12 wk. Significantly increased motoneuron survival was observed in all GDNF treated groups irrespective of the doxycycline treatment period. At the reimplantation site, robust regrowth of regenerating motor fibers into the root occurs in both GDNF groups compared to GFP control. However, persistent GDNF expression resulted in coiled fiber growth and disrupted myelination. The diameter of the ventral roots exposed to persistent GDNF

expression is significantly increased in comparison to GFP controls. In contrast, in the 4 wk GDNF treatment group, the large numbers of axons in the ventral root display a longitudinally organized growth pattern and the roots are less enlarged. Biweekly compound muscle action potentials (CMAP) measurements revealed that 4 wk GDNF expression led to an earlier recovery of a CMAP and a significant increase in amplitude compared to animals with persistent GDNF expression and GFP controls. Further histological analysis of axon regeneration and muscle reinnervation is currently ongoing. Taken together, these results show that timed GDNF expression using our novel stealth gene switch in a long distance regeneration model results in enhanced motoneuron survival and prevents local trapping of regenerating motor axons at sites of high GDNF expression. The observed improved CMAP values indicate that timed GDNF expression results in a potentiation of long distance regeneration and muscle innervation.

Title: Regulateable Chondroitinase ABC gene therapy as a treatment for spinal cord injury

Authors: ***E. R. BURNSIDE**[1], F. DE WINTER[2], A. DIDANGELOS[1], N. D. JAMES[1], K. BARTUS[1], E. M. MUIR[3], J. VERHAAGEN[2], E. J. BRADBURY[1];
[1]King's Col. London, London, United Kingdom; [2]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Following spinal cord injury the extracellular matrix undergoes significant remodeling. Scar formation is associated with upregulation of molecules known to be inhibitory to neural plasticity and recovery of function, including chondroitin sulphate proteoglycans (CSPGs). Enzymatic removal of CSPG glycosaminoglycan chains by the bacterial protein Chondroitinase ABC (ChABC) renders the matrix more permissive to recovery, however this is curtailed by rapidly diminishing enzyme activity. We have previously demonstrated that gene therapy using a modified ChABC gene compatible with expression and secretion by mammalian

host cells confers sustained and long-term delivery of ChABC to the injured spinal cord following a single administration. This treatment resulted in dramatic reduction in pathology and significant improvements in functional recovery following clinically relevant spinal contusion injury at both thoracic and cervical levels in adult rats. We now use novel immune-evasive vectors to enable regulatable gene therapy to exert greater control over ChABC expression, where ability to switch off delivery of ChABC greatly improves safety of the treatment. Using this system, doxycycline administration results in high expression of the ChABC gene and extensive functional enzymatic removal of inhibitory components present in the extracellular matrix. We also show this is accompanied by pro-reparative changes in inflammatory markers. We aim to utilise this system to manipulate timing and duration of ChABC delivery to adult rats which have received a clinically-relevant contusion injury to the cervical spinal cord and investigate its efficacy in promoting functional recovery. This represents both an experimental tool to optimise and control ChABC delivery to understand the role of timing in ChABC treatment, and a step towards clinical feasibility of ChABC gene therapy.

Title: Rhoa knockdown by pgp/rhoa sirna nanoparticle increases axon growth after spinal cord injury

Authors: S.-J. GWAK[1], C. MACKS[1], K. WEBB[1], M. LYNN[2], *J. LEE[1];
[1]Bioengineering, Clemson Univ., Clemson, SC; [2]Neurosurg., Greenville Hlth. Syst., Greenville, SC

Abstract: Spinal cord injury results in permanent disruption of axonal pathways that leads to loss of motor and sensory function. The long-term goal of our work is to develop neuron-specific polymeric micelle nanoparticles for combinatorial delivery of bioactive molecules targeting different barriers to neuroplasticity and axonal regeneration. RhoA is a shared target of signaling

pathways activated by diverse extracellular molecules present in the injured spinal cord. In this study, we investigated the ability of amphiphilic copolymers (poly (lactide-co-glycolide)-g-polyethylenimine : PgP) carrying Rho A siRNA to improve axonal regeneration. Compression injuries were created by application of a vascular clip for 10 minutes at the T9 level of the spinal cord in adult male rats and then PgP/RhoA siRNA polyplexes (20 µg siRNA) were injected at the injury site. At 1, 2, and 4 weeks, rats were sacrificed and total RNA isolated for qRT-PCR analysis. For histological evaluation, rats were sacrificed via cardiac perfusion with 4% paraformaldehyde at 4 weeks and the spinal cords retrieved, sectioned longitudinally, stained for neurofilament and GFAP, and digitally imaged. RhoA mRNA expression was significantly reduced in animals receiving PgP/RhoA siRNA nanoparticles compared to the untreated SCI group and were not significantly different from the sham group at all time points. Significant knockdown of RhoA expression in the nanoparticle-treated group was maintained up to 4 weeks. We also observed an extensive necrotic lesion cavity and significant reactive astrogliosis in the untreated SCI animal group, while reduced cavitation/astrogliosis and axonal regeneration into the lesion site in the nanoparticle-treated group was observed at 4 weeks post-injection. These studies demonstrate that PgP is a promising therapeutic siRNA delivery carrier in rat compression spinal cord injury model *in vivo*. Currently, we are evaluating the effect of PgP/RhoA siRNA on functional recovery by Basso-Beattie-Bresnahan (BBB) locomotor rating scale and contact placing test in rat compression SCI model.

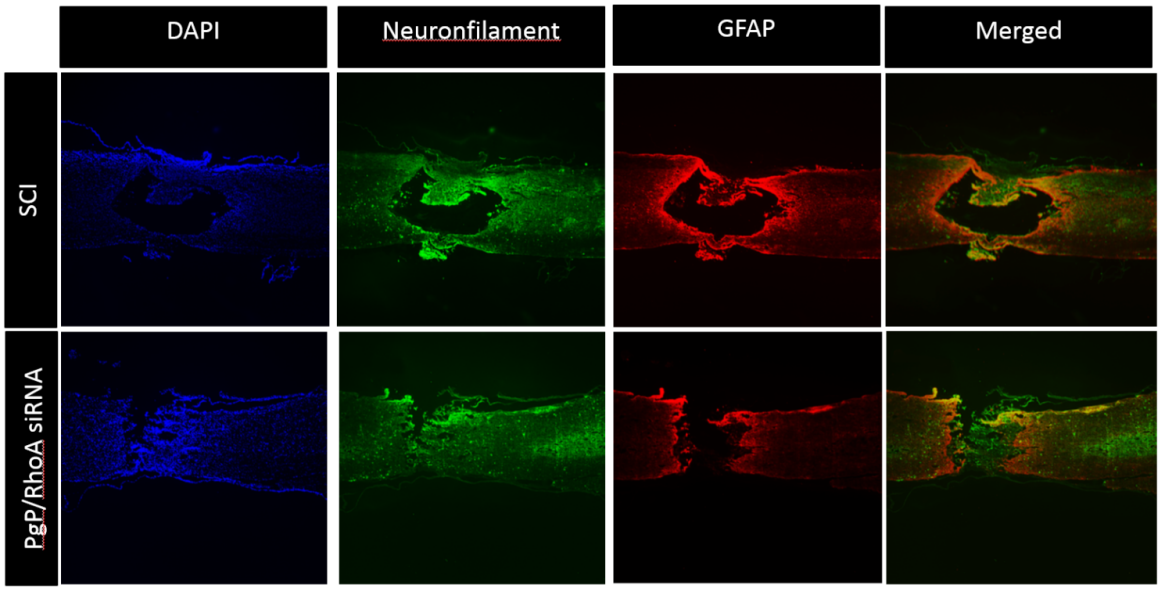

Figure 1.Immunohistochemical staining of neurofilament and GFAP in spinal cord at 4weeks post-injury. Top: Untreated spinal cord, showing an extensive necrotic lesion cavity and significant reactive astrogliosis, Bottom: PgP/RhoA siRNA polyplex-treated spinal cord, showing reduced cavitation/astrogliosis and axonal regeneration into the lesion site. Title: Stretching distrupts locomotor function in rats with spinal cord injury: static stretch and hold vs dynamic range of motion patterns

Authors: *A. KELLER[1,2], K. NORD[3], C. HAINLINE[3], D. PRINCE[4], A. SHUM-SIU[4], D. S. K. MAGNUSON[4];
[2]Physiol., [3]Bioengineering, [4]Neurolog. Surgery, [1]Univ. of Louisville, Louisville, KY

Abstract: Stretching therapy remains a leading technique utilized by physical therapists to manage spasticity and contractures in patients with spinal cord injuries (SCI). Preclinical studies in support of current clinical practices are lacking and systematic clinical studies are inconclusive. Using a rat model of incomplete SCI, we showed previously that a daily protocol of hindlimb static stretching (1 min each) had a negative impact on locomotor function of animals with acute or chronic, mild or moderately severe SCI. We found that stretching induced EMG responses in both the stretched and unstretched limbs that were qualitatively similar to clonus and spasms observed in patients in response to stretch. The objective of the current study was to determine if stretching delivered dynamically would also result in locomotor deficits in rats with SCI. Eight female Sprague Dawley (SD) rats were given moderate SCI contusions at T10 and were allowed to recover for 6 weeks to achieve a plateau in locomotor function before the initiation of the stretching protocol. The stretching protocol consisted of our standard 6 stretch positions performed bilaterally in a dynamic (rhythmic) fashion: 2 seconds on, 1 second off for 1 minute, 5 days a week for 4 weeks. Locomotor function was assessed using the BBB Open Field Locomotor Scale, 3D kinematics and gait. Dynamic stretching resulted in significant but temporary disruption to the locomotor function of the animals similar to that observed following static stretching. These results further extend our observation of the stretching phenomenon into a different modality of stretching that can be perceived as less intense yet equally detrimental to the locomotor function. Clinical relevance of the stretching phenomenon is still to be determined. However, based on our previous findings suggesting that rats and humans have similar EMG responses to muscle stretch we hypothesize that stretching may also have a negative impact on the locomotor function of patients with SCI. We believe future clinical studies are warranted in order to determine if stretching is detrimental to patients with SCI.

Title: Stretching disrupts locomotor function in rats with spinal cord injury: Role of nociceptive afferents.

Authors: *D. S. MAGNUSON[1], A. KELLER[2], S. KRUPP[3], K. NORD[4], C. HAINLINE[4], D. PRINCE[1], A. SHUM-SIU[1], J. C. PETRUSKA[3];

Abstract: Stretching remains a front-line approach to deal with the loss of joint range-of-motion and spasticity after spinal cord injuries (SCI). The scientific rationale and evidence-based support for employing a stretching approach is weak, and systematic clinical studies showing efficacy are lacking. Existing studies have focused on understanding the effects of stretch on joint range of motion and have not considered the potential impact on neurological function. We showed recently that a static stretch-and-hold protocol applied to rats with T10 contusive injuries (mild, moderate or moderately-severe) severely but temporarily disrupts locomotor function when applied acutely or chronically. The underlying mechanisms by which stretching is disruptive to locomotion are unknown. The objective of the current study was to determine the role of nociceptive afferents in the mediation of the stretch-induced locomotor deficits by assessing C-fiber depleted animals. Two-day-old female SD rats received intraperitoneal injections of capsaicin (CAP, n=8), vehicle (VEH, n=8) or no injection (CON, n=8). The effectiveness of the capsaicin induced C-fiber depletion was determined functionally when the animals were 3 months old using behavioral pain assessments and by confirming the absence of cutaneous trunci muscle reflexes in response to a noxious heat stimulus. Animals were then given moderately-severe contusive SCI at T9. Our standard static stretching protocol (1 minute stretch-and-hold of each major hindlimb group, repeated twice) was initiated 6 weeks post-SCI and was carried out 5 days a week for 5 weeks. Locomotor function was assessed weekly using BBBs and biweekly using kinematics. Stretching significantly disrupted locomotor function of the VEH animals. In contrast, CAP animals had only minor drops in hindlimb locomotor function which were significantly different from the VEH group at most time points during the stretching protocol. Similar to previous observations locomotor deficits were temporary. Our data suggests that stretch-induced locomotor deficits after incomplete SCI involve the activation

of nociceptive afferents. These findings have significant implications that extend beyond stretching as a therapy due to the multiple sources of nociceptive feedback to the spinal cord after SCI (pressure sores, muscle contractures, etc) that potentially hinder spinal cord motor and locomotor function.

Title: Grafts of multipotent neural progenitor cells in models of cervical contusive SCI: engraftment, axonal outgrowth and functional effects.

Authors: *J. H. BROCK[1,2], L. GRAHAM[3], S. IM[3], N. ARMSTRONG[3], M. TUSZYNSKI[3,2]; [1]Dept Neurosci, UCSD, La Jolla, CA; [2]VA, La Jolla, CA; [3]UC San Diego, San Diego, CA

Abstract: We examined whether grafts of rat multipotent neural progenitor cells (NPCs) would support axonal outgrowth and influence functional outcomes in models of cervical contusive injury. Adult Fisher 344 rats underwent unilateral C6 contusive injuries using an Infinite Horizons impactor equipped with a 2 mm impactor tip set at a force of 200 kilodynes and no dwell time. Two weeks later, syngeneic rat E14 spinal cord-derived multipotent NPCs were grafted into the lesion site, and forelimb funtional outcomes were examined using the Montoya staircase. Anatomical analyses demonstrate NPC survival and differentiation in the lesion site, and extensive axonal outgrowth into the host spinal cord. Grafts attenuated host glial responses, assessed by GFAP immunoreactivity, and reduced deposition of inhibitory CSPGs surrounding the lesion site. Grafted animals exhibited superior functional outcomes in forelimb function

compared to lesion-only or fibroblast controls ($P<0.05$). Thus, NPCs survive grafting to sites of contusive SCI, extend axons, alter host injury responses and support partial functional improvement. We are currently assessing NPC grafts in models of chronic contusive injury.

Med. and Biomed. Sciences, Colorado State Univ., Fort Collins, CO; [5]Neurol., David Geffen Sch. of Medicine, Univ. of California, Los Angeles, Los Angeles, CA; [6]Neurosurg., Univ. of California San Francisco, San Francisco, CA

Abstract: We previously demonstrated that human neural stem cells (hNSCs) and multipotent neural progenitor cells (hNPCs) grafted into sites of rodent spinal cord injury (SCI) survive, extend axons, form synapses, support host axon regeneration, and improve functional recovery (Lu et al., *Cell*, 2012; Lu et al., *Neuron*, 2014; Kadoya et al., *Nat Med*, 2016). We are translating

this approach to non-human primates (Rhesus macaques).
Using the H9 human embryonic stem cell line, we generated neural stem cells using published protocols (Li et al., *PNAS*, 2011). Adult rhesus macaques underwent C7 lateral hemicontusions (N=2; Salegio et al., *J Neurotrauma*, 2016) or lateral hemisection lesions (N= 5; Rosenzweig et al., *Nat Neuro* 2010). H9-derived human NSCs were grafted into the SCI sites between 2 and 12 weeks after injury (2, 4, 6, 6, 8, and 12 wks). Subjects received 20 million GFP-expressing NSCs, suspended in a two-part fibrin matrix and growth factor cocktail (Lu et al., *Cell*, 2012). Subjects were immunosuppressed with prednisone, mycophenolate, and tacrolimus, and were sacrificed 3 - 21 weeks after grafting (3, 8, 16, 16, 18, 18, and 21 wks).
Five of the seven subjects (including both subjects with hemicontusions) had surviving grafts. All surviving grafts differentiated into both neurons and glia, and extended up to hundreds of thousands of new axons; some of these reached very long distances, up to 50 mm, in the host spinal cord. Graft filling of the lesion site varied, indicating the need for further optimization of the grafting method, immunosuppression protocol, or both.
These findings indicate that human neural stem cells can be grafted to sites of subacute to chronic primate SCI, survive, and extend remarkable numbers of axons over long distances. Grafting can be successfully accomplished in sites of contusive SCI, the most common mechanism of human injury. Further optimization of grafting methods is needed prior to potential human translation, highlighting the importance of utilization of larger animal models for methods development and safety assessments.

Abstract: Grafting of cell-seeded alginate capillary hydorgels into a spinal cord lesion site allows for axonal bridging and physically directs regenerating axonal growth in a linear pattern. However, without an additional growth stimulus, bridging axons fail to extend into the distal host spinal cord. In the present study, we used a combinatorial strategy combining alginate hydrogels seeded with syngeneic Schwann cells (SCs) and a distal gradient of brain-derived neurotrophic factor (BDNF) to explore whether long-descending propriospinal axons can regenerate across an alginate hydrogel to re-enter the host spinal cord. Adult Fischer 344 rats underwent a **l**ateral C5 hemisection immediately followed by 1) implantation of an alginate scaffold pre-seeded with SCs into the lesion site, and 2) injection of adeno-associated virus expressing either tetracycline-regulated (tet-on) BDNF or green fluorescent protein (GFP) as control into the caudal spinal cord ipsilateral to the lesion. After four weeks, ELISAs from spinal cords demonstrated tight BDNF regulation and establishment of a gradient caudal to the lesion. Grafted SCs survived well in the scaffolds, improved the host/graft continuity, and sustained axonal growth along the capillaries. Descending supraspinal and propriospinal axons traced by biotinylated dextran amine (BDA) and immunolabeled for serotonin extended throughout the scaffolds. The number of regenerated axons significantly increased when caudal BDNF was turned on. Ongoing experiments examine longer time points in vivo and more distal virus injections to further extend the gradient of AAV-mediated BDNF expression.

Title: Surface modification and cell seeding into capillary alginate hydrogels promote axonal regrowth in the acutely injured spinal cord

Authors: *T. SCHACKEL[1], M. GÜNTHER[2], S. LIU[2], B. SANDNER[2], M. MOTSCH[2], R. MÜLLER[3], R. PUTTAGUNTA[2], N. WEIDNER[2], A. BLESCH[4];

Inst., Univ. of Indianapolis, Sch. of Med., Indianapolis, IN

Abstract: Axonal bridging across an extended lesion site remains a major challenge after spinal cord injury (SCI). We have previously shown that axons can be guided in rostrocaudal direction by the implantation of alginate-based hydrogels into a spinal lesion cavity allowing axons to bridge over 2 mm. To further enhance axonal growth into scaffolds, we examined the stability and biological effects of hydrogel surface modification with poly-L-ornithine (PLO) and laminin (Lam) or surface modification combined with cell seeding into hydrogel channels. PLO and Lam peptides electrostatically bound to the hydrogel surface remained stable and biologically active *in vitro* at 37°C for at a minimum of 2 weeks including repeated washes. Surface modification significantly increased cell attachment/survival of bone marrow stromal cells (BMSCs) and postnatal cortical astrocytes, and promoted DRG neurite outgrowth compared to controls. For *in vivo* studies, adult female *Fischer-344* rats underwent lateral C5 hemisection, followed by acute implantation of hydrogels (2 x 2 x 1.3 mm). Four weeks after SCI, uncoated control scaffolds were only partially filled with host cells. In contrast, surface-modified hydrogels showed a significantly higher number of infiltrating cells ($p<0.05$). Host cells colonized the hydrogel channels and covered large portions of capillary walls. Infiltrated host cells were identified primarily as Schwann cells and macrophages, whereas astrocytes were absent in the scaffolds and only found in the periphery of the lesion site. Anterograde tracing of propriospinal as well as other descending tracts with BDA revealed ingrowth of axon bundles into the microchannels. Immunolabeling with β-tubulin showed re-growing axons both at the peripheral and central regions of the scaffold. Surface modification resulted in a 1.5-fold increase of axons at the hydrogel entry sites ($p<0.05$). The effect of additional astrocyte seeding (2 µL; 100,000 cells/µL) into hydrogel microchannels prior to transplantation is subject of ongoing experiments.

Title: Vasopressin and polyuria after acute spinal cord injury

Authors: *L. R. MONTGOMERY, C. HUBSCHER;
Dept. of Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: Spinal cord injury (SCI) often leads to bladder dysfunction which severely impacts patient morbidity and quality of life. While improvements in bladder function is a top priority for SCI individuals, research in this important area is very limited. Polyuria (the increased production of and/or passage of urine) is often seen following SCI and leads to more frequent bladder catheterizations and disruptions in sleep and daily activities. The mechanisms that underlie the development and continuation of polyuria after SCI are unknown. One of the major hormones responsible for the regulation of water balance is vasopressin. When vasopressin levels are decreased there is a concomitant increase urine production in response. Although vasopressin is a major regulator of urine output and urine output increases after SCI, data is currently scarce with regard to the impact that SCI may have on vasopressin levels. A cohort of adult male Wistar rats was given a moderate-severe T8 spinal contusion (215 kdyn), and found to have a significantly increased urine output over 24 hours at two weeks post injury compared to preinjury baseline levels. Urinalysis revealed that the specific gravity and creatinine levels were significantly decreased at two weeks post-SCI, indicating that the urine was less concentrated. At this same time point, basal levels of plasma vasopressin also decreased significantly. Despite this decrease in vasopressin levels, blood osmolarity (the strongest stimulus that controls circulating vasopressin levels) did not change. To determine the mechanisms by which SCI could influence vasopressin levels, corticosterone levels were also measured at this time point. An increase in corticosterone is known to suppress vasopressin release from the hypothalamus. At two weeks following SCI, corticosterone levels increased significantly. Thus it appears that several factors contribute to the development of polyuria after SCI. Having identified that vasopressin levels decrease after SCI and a mechanism that can lead to this decrease, we can now use these targets to develop interventions that may decrease polyuria within the SCI community and thereby improve the quality of life for SCI individuals.

Title: Cardiovascular regulation post-epidural stimulation in cervical spinal cord injury

Authors: *B. DITTERLINE[1,2], S. WANG[1], S. ASLAN[1], S. HARKEMA[1];
[1]KY Spinal Cord Injury Res. Ctr., [2]Physiol. and Biophysics, Univ. of Louisville, Louisville, KY

Abstract: Background. Persons with SCI often have poor blood pressure (BP) regulation, which decreases quality of life and increases morbidity and mortality when compared to non-injured persons. Increased morbidity results, in part, from impairment to the sympathetic nervous system, resulting in poor reflex response, persistent hypotension and bradycardia, and bouts of orthostatic hypotension. We observed previously that spinal-cord epidural stimulation (SC-ES) for motor rehabilitation resulted in improvements to BP and heart rate (HR). The goal of this study is thus to determine if SC-ES, alone and with activity-based interventions, can re-engage spinal reflexes that would potentially regulate blood pressure, leading to increased resting cardiovascular (CV) outcomes.
Methods. An orthostatic stress test was used to assess hemodynamics, autonomic activity, and baroreceptor sensitivity at rest and during orthostatic stress. Prior to implantation, a 24-year old male, C5 AIS-A, was assessed of CV outcomes and demonstrated an overall impairment to CV regulation, including decreased sympathetic nervous system activity, poor reflex regulation, and orthostatic hypotension. The first intervention, cardiovascular training with epidural stimulation (CV-ES), utilizes SC-ES to increase resting blood pressure to a "normal" range. The second intervention was voluntary-motor training with epidural stimulation (Vol-ES) concurrent with CV-ES. An orthostatic stress test was performed after 80 sessions of CV-ES, and after 80 sessions of combined Vol-ES and CV-ES.
Results. We found improvements to his cardiovascular regulation following CV-ES: orthostatic hypotension that occurred during the pre-intervention assessments (81 ± 6/48 ± 2 mmHg) was ameliorated (120 ± 2/72 ± 5 mmHg); there was increased sympathetic (123±93 ms^2 to 999±918 ms^2) and respiratory-mediated oscillations of HR (56±52 ms^2 to 778±755ms^2) while seated; and an increased baroreceptor effectiveness (up-up: 26 ± 19 % to 60 ± 18%) and sensitivity (up-up: 3±1 to 19±10 ms/mmHg; down-down: 3±1 to 20±12 ms/mmHg) while seated. Additionally, the increases to cardiovascular function were sustained with the addition of Vol-ES: no orthostatic hypotension occurred (120/74 ± 14/16 mmHg), cardiac autonomic activity remained high (LF

power: 1638 ± 2037 ms^2; HF 583 ± 782 ms^2), as did baroreceptor effectiveness (up-up: 42± 14%; down-down: 68±31%).
Conclusions. Epidural stimulation has the potential to improve blood pressure regulation in persons with SCI, which may improve their quality of life and lead to a decrease the morbidity and mortality risk.

Title: Activity-based training with spinal cord epidural stimulation promoted the recovery of lower limb motor function independent from spinal stimulation in a chronic motor complete paraplegic

Authors: *E. REJC[1], C. ANGELI[2], D. ATKINSON[1], S. HARKEMA[1];
[1]Neurolog. surgery, Univ. of Louisville, Louisville, KY; [2]Frazier Rehab Institute, Kentucky One Hlth., Louisville, KY

Abstract: In the last lustrum, studies have shown that the combination of spinal cord epidural stimulation (scES) and activity-based training progressively re-enabled standing with balance assistance and volitional control of lower limbs in individuals with chronic motor complete spinal cord injury. However, the presence of scES was always required to perform these motor tasks. In the present study, we show that a chronic (6.8 years post injury) motor complete

individual regained significant lower limb motor function without scES after completing 31 months of activity-based training with epidural stimulation, which included standing, stepping and volitional lower limb movements from supine position. In particular, the participant regained the ability to stand on both legs as well as on one leg without scES, bearing full body weight, while using upper limbs to assist balance. Electromyographic (EMG) activity was properly modulated in a task specific manner. The transition from sitting to standing was accompanied by increased EMG activity of knee extensors and plantar-flexors. Also, during one-leg standing, EMG activity of the unloaded leg muscles was negligible, while the knee extensors of the loaded leg were more active than during bilateral standing. In addition, the research participant recovered the ability to volitionally perform isolated hip flexion and knee extension movements from a supine position without scES. Interestingly, this individual was able to volitionally induce a general co-activation of the lower limb muscles from a supine position without scES as early as 5 months after the beginning of training with scES. However, this achievement did not coincide with any improvement in the generation of motor patterns effective for over-ground standing without scES. In conclusion, we demonstrated that an individual with chronic motor complete spinal cord injury recovered the capability to modulate the excitability of spinal networks to physiological states sufficient for generating: *i)* lower limb antigravity extension patterns allowing independent standing and *ii)* volitional movements performed by proximal lower limb muscles. It can be surmised that prolonged activity-based training with scES promoted the strengthening of supraspinal connectivity to the spinal motor circuitry below the level of injury resulting in descending motor inputs sufficient for enabling lower limb motor control in the absence of scES.

Title: Targeting improvements in bladder function with epidural stimulation after human spinal cord injury

Authors: *C. HUBSCHER[1], A. HERRITY[2], L. MONTGOMERY[1], A. WILLHITE[2], C. ANGELI[2], S. HARKEMA[2];
[1]Dept Anatom. Sci. & Neuro, Univ. Louisville Sch. Med., Louisville, KY; [2]KSCIRC, Frazier Rehab Inst., Louisville, KY

Abstract: Deficits in urological function after spinal cord injury (SCI) include neurogenic detrusor overactivity and uncoordinated bladder and external urethral sphincter contractions, resulting in inefficient emptying and high intravesical pressure. Urinary retention and an inability of the bladder to store urine under appropriately low pressures can lead to infection and ultimately impact renal health. Current therapeutic approaches aim to manage both the storage and voiding phases of bladder function and include intermittent catheterization, pharmacologic and surgical interventions, as well as urethral stents. While most of these strategies are necessary for urological maintenance post-injury they oftentimes are associated with dose-limiting side effects and therefore remain inadequate. Neuromodulation has also been implemented in various formats as a promising alternative treatment for neurogenic bladder in an effort to regain control of function after SCI. Thus, this study investigated bladder outcomes in AIS grade A and B subjects receiving spinal cord epidural stimulation (scES) at L1-S1 spinal levels in combination with locomotor and/or stand training by our research team at the University of Louisville Human Locomotion Research Center. Urodynamic assessments were performed at pre- and post-training time-points and cystometrograms were captured with and without the use of scES. In addition, specific configurations and parameters optimal for continence and micturition were identified in several subjects during filling cystometry. We found that while locomotor training resulted in improvements in bladder capacity and voiding efficiency, the use of scES further enhanced these parameters and in a frequency-dependent manner. Importantly, as capacity increased, bladder pressures continued to remain low, indicating better compliance. Overall, scES may help contribute to an improvement in quality of life by providing a means of extending the time to catheterization under safe pressures and restoring efficient bladder emptying, ultimately preserving lower and upper urinary tract health.

Title: Lumbosacral spinal cord epidural stimulation enables step like patterns during BWST stepping in motor complete paraplegics

Authors: *C. A. ANGELI[1,2], S. HARKEMA[2,1];
[1]Frazier Rehab Inst., Louisville, KY; [2]Univ. of Louisville, Louisville, KY

Abstract: Epidural stimulation of lumbosacral spinal cord, combined with activity based training, enabled four motor complete paraplegics to progressively regain full weight bearing standing and achieve voluntary movement of their lower extremities. The aim of this study was to investigate the effects of different stimulation parameters on EMG patterns during stepping. Four participants with a motor complete injury implanted with an epidural electrode array over the L1-S1 segments of the spinal cord participated in this study. EMG, kinematics and ground reaction forces were recorded during stepping on a treadmill with body weight support. In this study we showed that three out of four individuals with a clinically motor complete spinal cord injury had the capacity to voluntarily modulate the motor output during stepping when the lumbosacral spinal cord was stimulated with individual-specific parameters optimal for stepping. Modulation of EMG activity was also shown during the stand to step transition highlighting the role of sensory information and the capacity of the spinal cord to interpret this information. We assessed the individual specificity of stimulation parameters by testing the stimulation configurations optimal for stepping across participants. In all cases, EMG was modulated differently when an individual was stimulated using parameters specific for other participants. Stimulation parameters selectively modulated the lumbosacral neural networks during stepping. EMG patterns observed during stepping are dependent on stimulation strength, frequency and electrode selection. These results have important implications with respect to: 1) how lumbosacral neural networks can be selectively modulated by varying the epidural stimulation parameters, and 2) identifying strategies that are likely to be most efficacious in enabling improved motor function for stepping after motor complete paralysis.

Title: Acute pain after SCI exacerbates progressive hemorrhagic necrosis

Authors: *M. K. BRUMLEY, J. D. TURTLE, J. M. FORSBERG, J. W. GRAU;
Texas A&M Univ., College Station, TX

Abstract: Noxious input after SCI exacerbates progressive hemorrhagic necrosis
Vascular damage is a major factor in the pathogenesis of traumatic spinal cord injury (SCI). Progressive hemorrhagic necrosis (PHN), a devastating phenomenon that occurs soon after SCI, is mediated through the activation of sulfonylurea receptor 1-transient receptor potential melastatin 4 (Sur1-Trpm4) channel. PHN is characterized by capillary fragmentation and petechial hemorrhaging at the lesion site, and contributes to tissue loss and glial scarring after SCI. We have previously shown that peripheral noxious stimulation administered soon after SCI induces a recovery deficit. Further, noxious input increases the amount of red blood cells at the lesion site, which may indicate significant vascular damage. The present study assessed the impact of nociceptive stimulation on the development of PHN following SCI. Hemorrhage, capillary segmentation, and SUR1-Trpm4 upregulation were all assessed as markers for the development of PHN. To assess hemorrhage, adult rats received a laminectomy and a moderate contusion injury at the T12 vertebra. After a 24-hour recovery period, half of the subjects received noxious input in the form of six minutes of electrical stimulation applied to the tail. At 3 hours post-treatment, subjects were sacrificed and a 1-cm section of lesion tissue was collected, sectioned, and stained with hematoxylin and eosin. The amount of hemorrhage was determined by a blinded observer as a percentage of the total section area. Subjects that received shock had over twice as much hemorrhage at around the lesion site compared to subjects that received SCI alone. To determine the effect of noxious input on the expression of the SUR1-Trpm4 channel, we used co-immunoprecipitation to pull down SUR1 and western blotting to identify Trpm4. Noxious input resulted in the upregulation of SUR1-Trpm4 channel. Additionally, in a subset of subjects, tissue was stained with FITC-tomato lectin to visualize lesion-site vasculature. Ongoing studies are examining the degree of capillary fragmentation at the lesion site. Based on these findings, acute pain appears to induce PHN after contusive SCI.

Title: Spared fibers promote the development of secondary spinal injury in response to acute pain

Authors: ***J. A. REYNOLDS**, J. D. TURTLE, Y.-J. HUANG, M. M. STRAIN, J. W. GRAU; Texas A&M Inst. for Neurosci., Texas A&M Univ., Bryan, TX

Abstract: Events soon after spinal cord trauma alter spinal cord function and drastically impact functional outcomes. Guided by our work in a transection model of spinal learning, we hypothesized that uncontrollable noxious input (C fiber activation) undermines spinal function by engaging a pro-inflammatory state (central sensitization). In a clinically relevant model of spinal cord injury (SCI), C fiber input exacerbates inflammatory processes within the lesion, increases cell death, fosters the development of progressive hemorrhagic necrosis (M. Brumley, SfN, 2016), and impairs locomotor recovery (Grau, 2004, *J Neurotrauma* 21: 1795). The present study examined how spared fibers impact the development of hemorrhage and cell death at the lesion site, and the degree to which noxious stimulation affects tissue outside of the injured region. Adult male Sprague-Dawley rats received a spinal contusion injury at the T12 level. 18 hours following injury, locomotor function was assessed using the BBB scoring method. Half the subjects received a spinal transection at T2. Six hours following secondary surgery, half the subjects in each condition received electrical stimulation of the tail at an intensity that engages C fibers. Protein extracts of the spinal cord segments were analyzed with immunoblotting, targeting the pro-inflammatory cytokines IL-18 and IL-1β. Replicating ongoing studies, noxious stimulation increased cytokine expression and hemorrhage in rats that received a contusion injury alone. Spinal transection prior to stimulation blocked the detrimental effects of C fiber input. Ongoing studies are exploring the regional distribution of these effects. Our results show that spared descending fibers enhance the adverse effect that noxious stimulation has on spinal injury.

Title: Spinal block with lidocaine: An effective treatment for reducing secondary injury after SCI and noxious stimulation

Authors: *J. TURTLE, M. M. STRAIN, Y.-J. HUANG, J. A. REYNOLDS, M. K. BRUMLEY, J. W. GRAU;
Texas A&M Univ., Bryan, TX

Abstract: Over 90% of spinal cord injuries (SCI) are caused by trauma and are often associated with peripheral tissue damage and pain. Our lab has shown that nociceptive stimulation increases lesion volume, induces neuropathic pain, and undermines functional outcomes in a rat model of SCI (Grau, 2004, *J Neurotrauma 21*: 1795). The current standard of care for the treatment of acute pain after trauma is poorly defined and opiates are commonly prescribed due to their ease of use and commonality. Unfortunately, treatment of nociceptive stimulation after SCI with morphine does not prevent the detrimental effects of stimulation (Hook, 2007, *Beh Brain Res, 2*: 281) and morphine treatment per se impairs outcomes after SCI (Hook, 2009, *J Neurotrauma 26*: 741). Here, we examined a new therapeutic strategy for the treatment of acute pain after SCI. In the first experiment, we examined the impact of epidural lidocaine on molecular indices of inflammation, cell death, and hemorrhage. Subjects received a moderate contusion injury to the lower thoracic cord. Twenty-four hours later, locomotor function was assessed and subjects were randomly assigned to one of four groups (lidocaine or vehicle crossed with shocked or unshocked). Subjects received a lidocaine or vehicle injection under isoflurane anesthesia. Thirty minutes later, shocked subjects were restrained in Plexiglas tubes and received six minutes of intermittent uncontrollable electrical stimulation to the tail. Controls were restrained, but did not receive stimulation. Three hours later, one centimeter of tissue from the lesion was collected and analyzed. Lidocaine treatment blocked stimulation-induced increases in TNF, IL-1β, IL-18, caspase 3, and hemorrhage. We then examined whether epidural lidocaine would also block the

effects of stimulation on behavioral recovery. Subjects were treated identically, but locomotor function and weight were assessed for a six-week recovery period. At the completion of the experiment, locomotor function (beam and ladder) and pain (mechanical reactivity, tail flick, girdle) were further examined. As was seen in the prior experiment, epidural lidocaine blocked all deficits induced by nociceptive stimulation. These results demonstrate that noxious stimulation adversely affects recovery after SCI and show that this effect is blocked by epidural lidocaine. This treatment could be readily translated to clinical use.

Title: CX3CR1-deficient microglia and macrophages enhance endogenous repair, axon sprouting and synaptogenesis after spinal cord injury in mice.

Authors: *C. M. FRERIA, J. C. HALL, P. WEI, D. M. MCTIGUE, P. G. POPOVICH; Dept. of Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Impaired signaling via CX3CR1, the fractalkine receptor, promotes recovery after traumatic spinal contusion injury in mice, a benefit achieved by reducing macrophage-mediated injury at the lesion epicenter. Here, we tested the hypothesis that CX3CR1-dependent changes in microglia and macrophage function will enhance neuroplasticity. Eighty-five male and female $CX3CR1^{+/+}$, $CX3CR1^{-/-}$, $CX3CR1^{+/-}$ mice were anesthetized and subjected to moderate SCI (75kdyn, IH device). After 4, 14, 28 or 56days, mice were euthanized and their spinal cords processed for immunohistochemistry, Golgi-Cox staining and transmission electron microscopy. *In vitro* assays were used to evaluate microglia/macrophage-mediated neuron pathology. RT-PCR was used for analysis of macrophage phenotype. New data indicate that in the presence of inflammatory stimuli, CX3CR1-deficient microglia and macrophages adopt a reparative phenotype and increase expression of genes that encode neurotrophic and gliogenic proteins. At the lesion epicenter (T8 spinal level), the microenvironment created by $CX3CR1^{-/-}$ microglia augments NG2 cell responses and increases axon sparing and sprouting of serotonergic axons. Several segments below the lesion, in lumbar spinal cord, reduced inflammatory signaling in

$CX3CR1^{-/-}$ microglia is associated with reduced dendritic pathology as well as improved axonal and synaptic plasticity on ventral horn motor neurons. Together, these data indicate that CX3CR1, a microglia-specific chemokine receptor, is a novel therapeutic target for enhancing neuroplasticity and recovery after SCI. Genetic deletion of CX3CR1 allows microglia and macrophages to remain responsive to inflammatory signaling but with a reduced capacity for neuronal killing. Moreover, loss of CX3CR1 signaling improves the ability of microglia to repair or remodel the spinal cord. Whether these microglia effects on axons and synapses are direct or indirect is unknown; however, these data have significant implications for recovery after SCI. Indeed, genetic polymorphisms of CX3CR1 or immune modulatory interventions that specifically target microglia could enhance endogenous repair and spontaneous recovery and also could provide a neural substrate that is more responsive to rehabilitation.

Title: Proliferating $NG2^{+}$ cells are required for glial and fibrotic scar formation and maintenance of tissue integrity after spinal cord injury in mice

Authors: *Z. C. HESP[1], R. SUZUKI[2], A. NISHIYAMA[2], D. M. MCTIGUE[1];
[1]The Ohio State Univ., Columbus, OH; [2]Univ. of Connecticut, Storrs, CT

Abstract: Spinal cord injury (SCI) is characterized by an initial wave of cell death, followed by significant cell proliferation, gliosis, and the formation of astrocytic and fibrotic scars, the latter of which are critical in limiting lesion expansion. Our prior work and that of others reported dense NG2 accumulation around and within the lesion acutely after SCI, as well as chronically increased NG2 in the surrounding spared tissue. The significant increase in NG2 after SCI can

stem from two endogenous cell populations: $NG2^+$ glia and $NG2^+$ immature pericytes, both of which proliferate in response to injury. Considering the widespread increase in NG2 after SCI, particularly around/within the glial scar, we asked the question: What is the contribution of proliferating $NG2^+$ cells to scar formation and tissue repair after traumatic CNS injury? Several studies have used NG2-null mice or NG2-neutralizing antibodies in SCI paradigms, but these models only impair the expression of the NG2 molecule without killing cells. To answer this question, we used a thymidine kinase/ganciclovir (Tk/GCV) paradigm in a novel mouse line (*NG2-Tk* mice) to selectively ablate proliferating $NG2^+$ cells in the first 1-2wpi after SCI. In this model $NG2^+$ cells express HSV1 Tk which converts GCV into a cytotoxic triphosphate that is incorporated into the DNA of dividing cells, causing cell cycle arrest and apoptosis. *NG2-Tk* and wildtype mice received a moderate C5 hemicontusion injury followed by subcutaneous implantation of a minipump filled with GCV or saline whose guide cannula was inserted into the right lateral ventricle for continuous infusion directly into the CSF. Two cohorts of mice received GCV for 7 and 11 days post-SCI before sacrifice, and a third cohort received GCV or saline until 14dpi, at which point pumps were removed and mice survived until 21dpi. Tissue was processed for IHC, and spinal cords were labeled for neurofilament, NG2, GFAP, Mac1, PDGFRβ, and laminin. Overall, the data show that loss of proliferating $NG2^+$ cells over the first 7-11dpi caused significant edema, prolonged hemorrhage, and lesion expansion. It also caused pronounced disruption of glial scar formation and near complete abolishment of the fibrotic scar and intra-lesion ECM deposition, which began to show signs of recovery only after a week of GCV removal. An apparent benefit of breakdown of the glial and/or fibrotic scar was enhanced neurite growth into the lesion core by 21d in *NG2-Tk* mice. These data reveal novel ways in which proliferating $NG2^+$ cells play a fundamental role in tissue protection and repair following SCI through promotion of vascular integrity, glial scar compaction, and ECM deposition.

Title: Gut dysbiosis impairs recovery after spinal cord injury

Authors: *K. A. KIGERL[1], L. WANG[2], J. C. E. HALL[1], X. MO[3], Z. YU[2], P. G. POPOVICH[1]; [1]Dept. of Neurosci., [2]Dept. of Animal Sci., [3]Ctr. for Biostatistics, The Ohio State Univ., Columbus, OH

Abstract: The trillions of microbes that exist in the gastrointestinal tract (microbiome) have emerged as pivotal regulators of normal mammalian development and physiology. Disrupting the microbiome, i.e. dysbiosis, can cause or contribute to neurologic disease, but whether dysbiosis affects recovery or lesion pathology after spinal cord injury (SCI) is unknown. New data in this report show that traumatic SCI increases intestinal permeability and bacterial translocation from the gut. These changes are associated with activation of immune cells in gut-associated lymph tissues (GALT). Bacterial 16S ribosomal RNA (rRNA) gene sequencing data reveal SCI-dependent changes in the composition of gut microbiota. These changes are initiated during the first week post-injury and continue throughout the first month. To test the whether this post-injury dysbiosis affects recovery and pathology after SCI, we completed a "gain-of-function" study in which intestinal dysbiosis was induced prior to SCI. This was accomplished using a cocktail of broad-spectrum antibiotics. Experimental induction of dysbiosis before SCI impaired functional recovery and exacerbateed spinal cord pathology. Conversely, when the microbiota was protected from the effects of SCI using a commercial probiotic (VSL#3), we noted significant neuroprotection and improved functional recovery with evidence of a protective immune response in GALT. VSL#3-mediated protection was associated with significant changes in the composition of the gut microbiota (as shown by 16 rRNA gene sequencing). These novel data indicate that the gut microbiome play a pivotal but previously unappreciated role in regulating recovery of neurologic function and neuropathology after SCI.

Title: Spinal cord injury-induced pain and motor deficits in rats

Authors: *T. NDAM[1,2], J. CUI[1,2], Z. QU[1,2], M. BEKEMEIER[4,2], D. K. MILLER[4,2], A. SIMONYI[3,2], W. R. FOLK[3], G. Y. SUN[3,2], Z. GU[1,2];
[1]Pathology & Anatom. Sci., [2]Ctr. for Translational Neurosci., [3]Biochem., Univ. of Missouri Sch. of Med., Columbia, MO; [4]Psychological Sci., Univ. of Missouri, Columbia, MO

Abstract: Spinal cord injury (SCI) affects more than one million people in the United States and leads to varying degrees of sensory abnormality including both musculoskeletal and neuropathic chronic pain as well as motor deficits. SCI-induced chronic pain is the most common symptom in up to 70 % of SCI patients and has a major impact on their quality of life. SCI leads to marked changes in the synaptic circuits in the dorsal horn cells and inflammation of the spinal cord caused by activation of microglial cells through the release of inflammatory factors. Most rodent models of SCI are limited to reduced motor functions and sensory deficits, and because of variations in impact of the unilateral contusion/paralysis often occurs, and thus at-level or below-level neuropathic pain can be poorly controlled. To be able to control the severity of injury and pain after SCI, we have developed a contusion SCI model in rats where the lamina and spinous process at T10 were removed and replaced with a plastic chip. Graded injuries were induced through an electromagnetic impactor with various velocities at a depth of 2 or 3 mm. Assessments of both motor and sensory behaviors were conducted before and after SCI and in sham control rats via measures of locomotor function, mechanical allodynia, thermal hyperalgesia and anxiety-like behaviors. Rats were sacrificed 22 days after SCI and spinal cords were evaluated for tissue damage using H&E staining. SCI rats exhibited impaired motor function on hind limbs, although some recovery was observed across 22-day period. These rats showed an increased hyper-sensitivity to thermal and mechanical stimuli, relative to sham control rats. H&E staining showed mild damage of the spinal cord with gliosis infiltration. These findings demonstrate graded contusion SCI induces hyper-sensitivity to thermal and mechanical stimuli as a reproducible chronic pain model in rats. Our study with this model may lead to a better understanding of the underlying mechanisms of inflammation in musculoskeletal and/or neuropathic pain after SCI, as well as development of biomarkers and treatment for patients with SCI.

Title: Anti allodynic effects of medicinal herbs in a rat model of oxaliplatin induced neuropathic pain through the suppression of spinal glial activation

Authors: *J. LEE[1,3], W. KIM[1], H. YOON[3], H. BAE[2], S. KIM[2];
[1]Dept. of physiology, [2]BK 21 Plus Korean Med. Sci. Ctr., Kyung Hee Univ., Seoul, Korea, Republic of; [3]BK 21 Plus Korean Med. Sci. Ctr., Grad. School, Kyung Hee Univ., Seoul, Korea, Republic of

Abstract: Activation of spinal glial cells, such as microglia and astrocytes, and increase of pro-inflammatory cytokines levels in the spinal cord play a crucial role in the pathogenesis of neuropathic pain. A single injection of oxaliplatin (6 mg/kg, i.p.), a widely used anticancer drug against metastatic colorectal cancer, can induce acute peripheral neuropathy. Gyejigachulbu-tang (GBT), herbal formula consisting of *Cinnamomi Cortex, Aconiti Tuber* and other medicinal herbs, has been used in East Asia to treat various pain symptoms. This study investigated whether and how GBT, *Cinnamomi Cortex*, or *Aconiti Tuber* alleviates oxaliplatin-induced cold and mechanical allodynia in Sprague Dawley rats. The behavioral signs of cold and mechanical allodynia were evaluated by a tail immersion test in cold water (4 ℃) and a von Frey hair test, respectively. Significant pain behaviors were observed three days after an oxaliplatin injection. GBT (400 mg/kg), *Cinnamomi Cortex* (200 mg/kg) or *Aconiti Tuber* (200 mg/kg) was orally administrated for five consecutive days after oxaliplatin injection. Behavioral studies reveal that GBT, *Cinnamomi Cortex* and *Aconiti Tuber* have potent relieving effects against oxaliplatin-induced cold and mechanical allodynia by increasing the tail withdrawal latency to cold stimuli and mechanical threshold. Immunohistochemistry studies show that both GBT and *Cinnamomi Cortex* suppress activation of spinal microglia and astrocytes, whereas *Aconiti Tuber* suppresses only activation of spinal astrocytes. Increased pro-inflammatory cytokines, interleukin-1 β and tumor necrosis factor, after oxaliplatin injection were decreased by GBT, *Cinnamomi Cortex* and *Aconiti Tuber*. In summary, GBT, *Cinnamomi Cortex* and *Aconiti Tuber* have potent anti-allodynic effect on oxaliplatin-induced neuropathic pain via attenuating activation of spinal glia and release of pro-inflammatory cytokines. This study suggests that GBT could be an alternative therapeutic agent on oxaliplatin-induced neuropathy, and that *Cinnamomi Cortex* and *Aconiti Tuber* may play a major role in this efficacy of GBT.

Title: Vagus nerve stimulation paired with rehabilitation improves functional recovery following peripheral nerve injury.

Authors: *E. MEYERS, R. GRANJA, R. SOLORZANO, G. BENDALE, P. GANZER, N. ROBERTSON, K. ADCOCK, M. ROMERO-ORTEGA, M. KILGARD, R. RENNAKER, S. HAYS;
Univ. of Texas At Dallas, Richardson, TX

Abstract: Peripheral nerve injuries affect an estimated 20 million Americans and frequently result in long-term loss of motor control in the upper extremities. Patients often undergo extensive physical rehabilitation but most fail to achieve substantial recovery of function, highlighting the need for improved rehabilitative interventions. Reorganization of neural circuitry, or neuroplasticity, throughout the central nervous system is believed to be largely responsible for recovery. Previous work from our lab has shown that pairing vagus nerve stimulation (VNS) with a motor movement drives substantial neuroplasticity observed by an increase in the cortical representation of the paired movement. Additionally, we have shown that pairing VNS with rehabilitation improves motor function in rat models of ischemic stroke, hemorrhagic stroke, traumatic brain injury and spinal cord injury. We hypothesized that pairing VNS with rehabilitation would improve functional recovery following peripheral nerve injury. Adult female Sprague-Dawley rats were trained on the isometric pull task, an automated, quantitative measure of forelimb strength. Upon reaching task proficiency, peripheral nerve injuries of the median and ulnar nerves in the right forelimb were performed. Following 6 weeks of homecage recovery, animals were randomly assigned to either the rehabilitation only group (Rehab), or the group receiving vagus nerve stimulation paired with rehabilitation (VNS+Rehab). Animals underwent rehabilitative training for an additional 7 weeks and the VNS+Rehab group received VNS paired with successful pull attempts. At the conclusion of behavioral testing, intracortical microstimulation (ICMS) of the motor cortex was performed in all animals, and Von Frey sensory testing of the forepaws.
VNS paired with rehabilitative training significantly improved recovery of forelimb function after PNI compared to rehabilitative training without VNS. ICMS motor maps revealed a significantly greater cortical area that evoked forelimb grasp responses in the VNS+Rehab group

compared to the Rehab group. Von Frey testing revealed decreased withdrawal response thresholds to a mechanical stimulation in the VNS+Rehab group, suggesting partial recovery of mechanical sensation.
Peripheral nerve injuries remain a serious condition, and injuries to the forearm and hand often lead to severe and life-long disabilities. Current treatment options in the chronic phase of injury are limited. Here we show that vagus nerve stimulation delivered as an adjunct to rehabilitative training has the capacity to promote functional recovery in a rat model of peripheral nerve injury.

Title: The removal of proprioceptive IA afferent synapses from motoneurons after nerve injury occurs through a mechanism dependent on chemokine receptor CCR2

Authors: *T. M. ROTTERMAN, F. J. ALVAREZ;
Physiol., Emory Univ., Atlanta, GA

Abstract: Peripheral nerve injury results in axotomy of motor and sensory axons as well as a central immune response in which microglial cells become activated in the spinal cord ventral horn, migrate towards axotomized motoneurons and release a host of pro-inflammatory mediators. This inflammatory reaction results in a leaky blood-spinal cord barrier, allowing blood-born monocytes to infiltrate in a CCR2-dependent manner. These cells can then differentiate into phagocytic macrophages inside the spinal cord. In parallel, the central axons and synapses of axotomized proprioceptive IA afferents are permanently removed from the ventral horn causing the withdrawal of their monosynaptic connections with motoneurons (MNs) and ultimately the loss of the stretch reflex. To test the hypothesis that CCR2+ macrophages could be related to the degradation of central IA afferent collaterals and synapses we used

heterozygous “knock-in” CCR2 (RFP/+) and “knockout” (KO) homozygous CCR2 (RFP/RFP) transgenic C57Blk/6 mice to label infiltrating peripheral monocytes (RFP) and delete the receptor necessary for their recruitment. In these mice we retrogradely labeled lateral gastrocnemius MNs with Fast Blue, followed by a second surgery in which the sciatic nerve was transected and immediately repaired with fibrin glue. Mice survived 2 months following the injury, to allow peripheral axon regeneration and muscle reinnervation, at which point they were perfusion-fixed and the lumbar spinal cord sectioned and immuno-labeled for the vesicular glutamate 1 transporter (VGLUT1), a marker of IA afferent synapses. Fast Blue labeled MNs were confocal imaged and reconstructed in 3D using Neurolucida software to map their VGLUT1+ synapses on MN somas and proximal dendrites in heterozygous and KO mice. We found that sham control CCR2 het mice had a VGLUT1 somatic density of 0.74±0.11 (standard deviation) per 100 μm^2 and a linear dendritic density of 17.96±1.51 per 100 μm. Two months after injury CCR2 hets showed a 64% decrease in synaptic contact density around the soma (0.27±0.11) and a 40% decrease on the proximal dendrites (10.75±1.72). In contrast, in CCR2 KO mice, VGLUT1 contact density on the soma was partially preserved (0.43±0.06) and completely preserved on the dendritic arbor (16.41±0.92). Since the majority of IA afferent synapses are located on MN dendrites, these data suggests that deleting CCR2 preserves the majority of the IA afferent input that would be lost on MNs after nerve injuries.

Title: Enhancing peripheral nerve regeneration through combined tissue engineering and gene therapy

Authors: *F. BUSUTTIL[1], M. P. HUGHES[1], K. S. BHANGRA[2], P. J. KINGHAM[3], J. B. PHILLIPS[2], A. A. RAHIM[1];

Abstract: Peripheral nerve injury (PNI) affects up to 5% of trauma patients and is associated with motor, sensory and autonomic impairment in the affected area. Following PNI, axonal regeneration is dependent on Schwann cells, which express regeneration-assisting genes. However, this pro-regenerative phenotype is not always maintained long enough to ensure functional recovery. Tissue engineered three dimensional (3D) constructs containing therapeutic cells that maintain the appropriate phenotype may help enhance nerve regeneration. An *in vitro* proof-of-concept study was carried out to deliver luciferase and green fluorescent protein (GFP) genes to rat Schwann cells (SCL4.1/F7) and to assess whether the transduced cells were still viable for the construction of 3D collagen constructs that can be used to enhance nerve repair. The Schwann cells were successfully transduced using the bicistronic lentiviral vector produced and the highest transduction efficiency was obtained at a multiplicity of infection of 100. This was confirmed by fluorescence microscopy, bioluminescence imaging and flow cytometry. Following incorporation into the collagen constructs, stereoscopic fluorescence microscopy and confocal microscopy showed that the transduced cells had distributed evenly throughout the constructs. Bioluminescence imaging confirmed that the Schwann cells were still viable after seeding into the constructs. No fluorescence or bioluminescence was observed in the untransduced cells or in the control constructs seeded with the untransduced cells. The results from this study suggest that Schwann cells can be transduced effectively using lentiviral vectors and then used to engineer tissue engineered nerve repair constructs. The approach has also been applied successfully to clinically relevant sources of therapeutic cells. This study provides the basis for potentially delivering genes that either maintain the Schwann cells in their pro-regenerative phenotype or which increase vascularisation following implantation. Additionally, the luciferase gene in the lentiviral vectors provides a powerful means to track cell fate *in vivo* during preclinical testing.

Title: Analgesic effects of bee venom and bee venom derived phospholipase A_2 in a mouse model of oxaliplatin-induced neuropathic pain

Authors: *W. KIM[1], D. LI[1], J. LEE[2], H. BAE[2], S. KIM[2];
[1]Dept. of Physiology, Kyung Hee Univ., Seoul, Korea, Republic of; [2]BK21 plus Korean Med. Sci. Ctr., Kyung Hee Univ., Seoul, Korea, Republic of

Abstract: Oxaliplatin, a chemotherapeutic drug for colorectal cancer, induces peripheral neuropathy characterized by dysesthesias of the hands and feet, which is a major dose-limiting side effect. Even a single administration of oxaliplatin can evoke this abnormal sensation, aggravated by cold and mechanical stimuli, to about 90% of treated patients. Bee venom (BV) has been traditionally used in Korea to alleviate pain and a recent clinical trial has suggested that BV may be effective for chemotherapy induced peripheral neuropathy. Here, we investigated the anti-allodynic effect of BV and further examined whether a co-administration of BV with morphine could have an additive on oxaliplatin-induced neuropathic pain in mice, as BV is known to be mediated by spinal noradrenergic and serotonergic receptors, whereas morphine by opioidergic receptors. The cold and mechanical allodynia signs were evaluated by acetone and von Frey hair test on the hind paw, respectively. The most significant allodynia signs were observed at three days after an injection of oxaliplatin (6 mg/kg, i.p.). BV (0.25, 1, and 2.5 mg/kg, s.c.) or morphine (0.5, 2, and 5 mg/kg, i.p.) alone showed dose-dependent anti-allodynic effects. The combination of BV and morphine at intermediate doses showed a greater and longer effect than either BV or morphine alone at the highest dose. Intrathecal pretreatment with the opioidergic (naloxone, 20 μg) or 5-HT_3 (MDL-72222, 15 μg) receptor antagonist, but not with α2-adrenergic (idazoxan, 10 μg) receptor antagonist, blocked this additive effect. Furthermore, we assessed the preventive and curative effects of BV derived phospholipase A_2 ($bvPLA_2$) on oxaliplatin-induced neuropathic pain in mice. Daily treatment with $bvPLA_2$ (0.2 mg/kg, i.p.) for five consecutive days prior to the oxaliplatin injection markedly inhibited the development of cold and mechanical allodynia, and suppressed infiltration of macrophages and the increase of IL-1β level in the DRG. Such preventive effects of $bvPLA_2$ were completely blocked by depleting regulatory T cells with CD25 antibody pre-treatments. Moreover, daily administration of $bvPLA_2$ (0.2 mg/kg, i.p.), after an oxaliplatin injection, for five consecutive days markedly attenuated cold and mechanical allodynia, which was more potent than the effect of BV (1 mg/kg, i.p.). In sum, these results suggest that BV can effectively attenuate cold and mechanical allodynia induced by an oxaliplatin injection, and that morphine can reinforce this effect. Also, $bvPLA_2$ may play an important role in this analgesic effect of BV, as it has shown a preventive and curative effect on oxaliplatin-induced neuropathic pain.

Title: MCT1 in Schwann cells expedites regeneration of injured peripheral nerves and is necessary for maintenance of aging sensory axons

Authors: *M. K. JHA, K. RUSSELL, A. SINGH, Y. LEE, J. D. ROTHSTEIN, B. M. MORRISON;
Johns Hopkins Univ., Baltimore, MD

Abstract: The proper functioning and maintenance of peripheral nerves, especially regenerating nerves, requires high metabolic provisions and heavily depends on monocarboxylates, principally lactate, as an energy source. Monocarboxylate transporters (MCTs), as downstream mediators, govern cellular levels and functional consequences of monocarboxylates. MCT1 is the predominant lactate transporter in the peripheral nervous system and is expressed mostly in Schwann cells, nerve perineurium, and DRG neurons. By employing MCT1 heterozygote null mice, we previously reported that nerve regeneration, in both sensory and motor axons, depends on MCT1 function. These findings led us to investigate the potential contribution of Schwann cell-specific MCT1 in nerve regeneration and axonal physiology. We confirmed that our laboratory-generated P0Cre::MCT1LoxP mice, which have selective knockdown of MCT1 in Schwann cells, were normal in development; unimpaired in anatomical and electrophysiological features; and devoid of any evidence of degeneration. The Schwann cell-specific ablation of MCT1 was sufficient to delay the sciatic nerve regeneration following crush. Furthermore, these mutant mice developed reduced distal amplitude of tail sensory nerves, but not sciatic motor nerves, with age compared to wild-type mice, indicating that Schwann cell-specific MCT1 is pivotal to maintain the functioning of sensory, but not motor, nerves during aging. Taken together, our results not only illuminate the role of lactate and its transporter MCT1 in regeneration and age-associated deterioration of peripheral nerve, but also advocate their implications as potential targets for the development of pharmacotherapies for peripheral neurodegeneration and axonal neuropathies.

Title: Excitability changes in aged regenerating axons

Authors: M. MOLDOVAN[1,2], S. ALVAREZ[1], D. CINTEZA[3], *C. KRARUP[2,1];
[1]Neurosci. and Pharmacol., Univ. of Copenhagen, Copenhagen, Denmark; [2]Rigshospitalet, Copenhagen, Denmark; [3]"Carol Davila" Univ. of Med. and Pharm., Bucharest, Romania

Abstract: Following an interruption of continuity, peripheral axons have the ability to regenerate and reestablish functional connections with their targets. The internodal length remains short. Our previous experimental work in various species and clinical studies in humans indicated that distal to a nerve lesion, this increase in number of nodes leads to a persistent impairment of excitability where the increased voltage-gated Na^+ channel (VGSC) influx could reach neurotoxic levels during strenuous activity. Recently, we found that in aged mice there is an ectopic expression of the “sensory neuron specific” $Na_V1.8$ VGSC on motor axons leading to depolarizing shift in membrane potential which could aggravate these changes. The aim of this study was to chart the changes in regenerating motor axon excitability of aged C57BL/6 mice (more than 20 months old) after a unilateral sciatic nerve lesion. Regeneration at 5 months after section and reconstruction was markedly impaired in aged mice. Nevertheless, after a crush lesion, the recovery of plantar compound muscle action potentials evoked after tibial nerve stimulation at ankle was similar to mature mice. We therefore chose the ideal regeneration environment following the crush lesion to investigate the recovery of multiple measures of tibial motor axon excitability by “threshold-tracking” at ankle and at the sciatic notch. At ankle, regenerating motor axons showed persistent impairment in both voltage-dependent and passive membrane properties, consistent with previous reports on younger mice. The extent of these changes in the aged mice was additionally altered by a depolarizing shift in membrane potential. This was similar to the excitability differences with mature mice on the unlesioned side. Nevertheless, in contrast to mature mice, in aged mice, regeneration also aggravated the depolarizing excitability features at the sciatic level (proximal to the lesion). This changes could be attenuated acutely by the $Na_V1.8$ blocker Compound 31 (Bioorg. Med. Chem. Lett. 2010, 20,

6812; AbbVie Inc.). Taken together our data suggest that process of regeneration aggravates the VGSC expression changes in aged motor axons.

Title: Multifunctional nerve conduit for peripheral nerve regeneration.

Authors: *H. AHN[1,2], M.-S. KIM[1,2], J.-W. KIM[1,2], J. HYUN[1,3,2];
[1]Dept. of Nanobiomedical Sci., [2]Inst. of Tissue Regeneration Engin., Dankook Univ., Cheonan-si, Korea, Republic of; [3]Dept. of Rehabil. Med., Dankook Univ. Col. of Med., Cheonan-si, Korea, Republic of

Abstract: Peripheral nerve injury is common and damaged peripheral nerves usually regenerate spontaneously, however the capacity for regeneration is not complete and remain motor and sensory dysfunctions and neuropathic pain in the clinical setting. Commercially available nerve conduits still cannot show better regeneration effects than autologous nerve graft. The aim of our study is to develop an ideal nerve conduits which act physical and biochemical cues for outgrowing axons after peripheral nerve injury and which function for axonal regeneration is comparable to autologous nerve graft.We developed a nerve conduit which contains numerous aligned microchannels and a selective permeable outer tube structure for physical cue, and sustained release of nerve growth factor within microchannels for biochemical cue. We performed *in vitro* study using a three dimensional culture system to detect neurite outgrowth within microchannels in the nerve conduit at first, and found that poly(lactic-co-glycolic acid)

(PLGA)-based microchannels were more effective for neurite outgrowth of neurons in dorsal root ganglion than polycaprolactone (PCL)-based microchannels, and tetraglycol was used as a solvent to make PLGA or PCL solution. Microchannels were developed using phosphate glass microfibers which were dissolved in distilled water, and heparin was used for the controlled release of nerve growth factor (NGF) within microchannels. *In vivo* studies were performed to the transected sciatic nerve of rats, and a 16mm-long NGF-containing PLGA nerve conduit was implanted. Autologous sciatic nerve and the PLGA or PCL nerve conduit without NGF were used as controls. We found that the length of axons from proximal stump was superior in PLGA nerve conduit-implanted group than PCL nerve conduit-implanted control at 2 weeks after implantation, and notably functional assessments including von Frey hair test and sciatic functional index, muscle fiber size, compound muscle action potential indicated that the NGF-containing PLGA nerve conduit is comparable to autologous nerve graft at 16 weeks. We concluded that our new nerve conduit is effective for axonal regeneration after peripheral nerve injury, and might substitute for autologous peripheral nerve.

Title: Benefits of combinatorial therapies for improving functional recovery in a rat model of facial nerve injury

Authors: ***E. M. RUNGE**[1,3], T. J. ASANTE[1], H. R. WELCH[1], C. L. WALKER[1,3], A. R. BEST[2], J. L. MULDOON[1], K. J. JONES[1,3];

Abstract: Injury to the facial nerve due to trauma or surgical intervention for head and neck pathologies is common; however, few effective treatments eliciting full functional recovery following facial nerve injuries exist. Previous studies in our laboratory have found that single-agent therapies, while effective in improving functional recovery, are insufficient in promoting complete functional recovery after nerve injury. Consequently, combination therapies are an area of emphasis in our research. We have found that treating the repaired injured nerve with polyethylene glycol (PEG), a sealant that acts to fuse damaged cell membranes, and methylene blue (MB), an antioxidant, improves functional recovery in a rat model of facial nerve transection and suture. In particular, we observed significant recovery of vibrissae movement beginning at two weeks post-injury and suture that continued until the end of the study sixteen weeks later. We are also investigating the use of systemic testosterone propionate (TP) and direct electrical stimulation (ES) of the facial nerve in combination with PEG/MB in anticipation of improving the rate and extent of recovery beyond those observed for individual treatments. Given the ease in application of these various therapies, either singularly or in combination, we anticipate that these studies will aid translation of such methods for application in human facial nerve injury patients. Supported by a Roudebush VA IIMR Young Investigator Award (CLW) and IUCRG grant from IUSM (KJJ).

Title: Distinct expression profiles of LncRNAs between ipsilateral and contralateral in adult rats following unilateral brachial plexus root avulsion

Authors: *Y. GUANGYIN[1], X.-Y. XU[2], Y. TANG[2], L.-L. LIU[2], X. CHEN[3], Z. QIU[4], Q. YAN[4], Q. ZHU[4], Z. WU[4], L. ZHOU[2,5];
[1]Zhongshan Sch. of Medicine, Sun Yat-Sen Universi, Guangdong, China; [2]Dept. of Anat., Zhongshan Sch. of Medicine, Sun Yat-Sen Universi, Guangzhou, China; [3]Dept. of Anesthesiology, The First Affiliated Hosp. of Sun Yat-Sen Univ., Guangzhou, China; [4]Zhongshan Sch. of Medicine, Sun Yat-sen Univ., Guangzhou, China; [5]Guangdong Province Key Lab. of Brain Function and Dis., Guangzhou, China

Abstract: Long noncoding RNAs (lncRNAs) are pervasively transcribed and have a critical role in genome regulation. Brachial plexus root avulsion (BPRA) induces multiple pathophysiological events consisting of altered levels of specific proteins, which collectively leads to dramatic motoneuron death. To identify the spinal cord lncRNAs involved in the BPRA, we describe the expression profile of lncRNAs in ipsilateral half compared to the contralateral half of the spinal cord using Arraystar Rat LncRNA/mRNA analysis. Unilateral BPRA resulted in significant alterations in lncRNAs expression. In the ipsilateral half of the spinal cord, on the 3rd day after the injury, 41 lncRNAs were upregulated, and 11 were downregulated (≥2.0-fold, $p<0.05$); 349 mRNAs were upregulated and 51 were downregulated (≥2.0-fold, $p<0.05$). And on the 14th day after the injury, 48 lncRNAs were upregulated, and 27 were downregulated (≥2.0-fold, $p<0.05$); 378 mRNAs were upregulated and 67 were downregulated (≥2.0-fold, $p<0.05$). Our previous studies have demonstrated that the spatial and temporal characteristic of Nos1 and Capn2 induced by avulsion injury is the crucial factor cause motoneurons death. Co-expression analysis shows that AF128540 and S69236 may target Nos1 and Capn2 mRNAs. In the present study, the upregulation of AF128540 and the downregulation of S69236 were highly in accordance with the Nos1(upregulation) and capn2(downregulation) mRNAs expressions. Thus, avulsion-induced activation of AF128540/Nos1 and S69236/Capn2 mechanisms may contribute to injured motoneuron degeneration. Pathway analysis indicated that 55 pathways corresponded to upregulated transcripts and that 10 pathways corresponded to down regulated transcripts (P-value≤0.05) on the 3rd day after the injury. And 52 pathways corresponded to upregulated transcripts and that 12 pathways corresponded to downregulated transcripts (P-value≤0.05) on the 14rd day after the injury. The expression of MRAK034299(downregulation, 4.1-fold, $p<0.05$) was highly in accordance with Adra1d (downregulation, 3.4-fold, $p<0.05$) gene expression. Pathway analysis the MRAK034299 target gene-Adra1d may be involved in calcium signaling pathway, cGMP-PKG signaling pathway, neuroactive ligand-receptor interaction, ect. Thus, the MRAK034299 may contribute to avulsion-induced motoneuron apoptosis or survival via Adra1d mechanism. Our present study show distinct expression profiles of LncRNAs in injured spinal cord following brachial roots avulsion. The data of the alternative lncRNAs and mRNAs in the spinal cords of the adult rats provide information and target genes for further research on the motoneuron diseases.

Title: Detection of pup odors by non-canonical adult vomeronasal neurons expressing an odorant receptor gene is influenced by sex and parenting status.

Authors: *T. S. NAKAHARA[1], P. G. RIBEIRO[1], P. H. M. MAGALHAES[1], P. H. M. NETTO[1], X. IBARRA-SORIA[2], D. W. LOGAN[2], F. PAPES[1];
[1]Dept. Genet. and Evolution, Univ. of Campinas (UNICAMP), Campinas, Brazil; [2]Wellcome Genome Campus, Hinxton, Wellcome Trust Sanger Inst., Cambridge, United Kingdom

Abstract: Background: Olfaction is a fundamental sense through which most animals perceive the external world. The olfactory system detects odors via specialized sensory organs such as the main olfactory epithelium and the vomeronasal organ. Sensory neurons in these organs use G-protein coupled receptors (GPCR) to detect chemosensory stimuli. The odorant receptor (OR) family is expressed in sensory neurons of the main olfactory epithelium, while the adult vomeronasal organ is thought to express other types of receptors. Results: Here we describe *Olfr692*, a member of the *OR* gene family identified by next-generation RNA sequencing, which is highly upregulated and non-canonically expressed in the vomeronasal organ. We show that neurons expressing this gene are activated by odors emanating from pups. Surprisingly, activity in *Olfr692*-positive cells is sexually dimorphic, being very low in females. Our results also show that juvenile odors activate a large number of *Olfr692* vomeronasal neurons in virgin males, a situation in which infanticide is displayed. In contrast, activity substantially decreases in parenting males (fathers), where infanticidal aggressive behavior is not frequently observed. Conclusions: Our results describe for the first time a sensory neural population with a specific molecular identity that is involved in the detection of pup odors. Moreover, it is one of the first reports of a group of sensory neurons the activity of which is sexually dimorphic and depends on social status. Our data suggest that the *Olfr692* population is involved in mediating pup-oriented behaviors in mice

Title: Native olfactory sensory neuron imaging with swept confocally-aligned planar excitation (scape) microscopy

Authors: *L. XU[1], W. LI[2], V. VOLETI[2], E. M. C. HILLMAN[2], S. J. FIRESTEIN[1];
[1]Biol. Sci., [2]Biomed. Engin., Columbia Univ., New York, NY

Abstract: Recording activity in olfactory sensory neurons (OSNs) has traditionally been done by using calcium imaging of individual dissociated cells or through electroolfactogram (EOG) field potential recordings of large numbers of cells. Both methods have considerable disadvantages. Many cells are damaged during the dissociation process and they are effectively axotomized. EOG uses an intact preparation but provides no cellular resolution and there is significant variability from preparation to preparation. It is also difficult to control stimulation in the EOG preparation.

We have developed a novel OSN imaging method that takes advantage of genetic tools and a recently developed microscopy technique, called Swept Confocally-Aligned Planar Excitation (SCAPE) microscopy. SCAPE-based OSN imaging enables widespread recording of cells in the olfactory epithelium of OMP-CRE$^{+/-}$GCaMP6f$^{-/-}$ mice, without damaging the nasal turbinate and preserving neuron innervations to the olfactory bulb by using a perfused half-head preparation. This method allows us to directly image large areas of the intact olfactory epithelium at over 10 volumes per second at cellular resolution. Compared with dissociated cell imaging, SCAPE provides increased sensitivity for detecting OSN responses, yielding more than two orders of magnitude more active neurons for similar olfactory stimuli. Cells remain healthy for longer, allowing more experimental conditions to be tested. The native tissue condition also enables us to draw a 3D response map for each odorant along the nasal turbinate for cross-comparison. Thus this method allows us to monitor odor-induced activity in large numbers of cells (as with the EOG) but with single cell resolution (as with dissociated cells) under precise delivery of controlled odor stimuli.

Title: A mathematical model for the response of olfactory sensory neurons to odor mixtures

Authors: ***A. MARASCO**[1], A. DE PARIS[1], M. MIGLIORE[2,3];
[1]Mathematics and Applications, Univ. of Naples Federico II, Napoli, Italy; [2]Natl. Res. Council, Palermo, Italy; [3]Yale Univ., New Haven, CT

Abstract: Most real world odors are complex mixtures consisting of dozens, often hundreds of components, and olfactory systems have evolved to recognize and discriminate them. The sensory process starts with the interaction of odorant molecules with the dendritic membrane of olfactory sensory neurons (OSNs). It has been widely demonstrated that, in most cases, the response of OSNs to (single) odor stimuli can be conveniently reproduced by a sigmoidal shape with concentration, usually implemented as a Hill function. However, the response to a mixture of odorants is not a simple function of the response to the individual components, and its properties are empirically classified as suppression, hypoadditivity, synergy, inhibition, and overshadowing. The models proposed in the literature to describe the responses of OSNs to single odors and binary mixtures cannot reproduce all of them. Here, we present a mathematical model able to predict all types of mixture interactions among N odorants ($N \geq 2$). The model has been validated against a number of different experimental findings. All the typical, experimentally measurable, characteristics of the response curves (i.e. steepness, midpoint, and asymptotic value) can be mathematically expressed by a non-linear combination of the parameters for the individual components. Furthermore, we show that it is possible to find suitable mathematical conditions for all parameters and concentrations, in such a way to make it possible to design mixtures with specific properties. The results suggest a way to predict the overall behavior of a receptor type in response to a mixture composed of any number of components, provided that the individual response curves and their relative concentration ratios are known. A rigorous analysis of the mathematical structure of the 3-dimensional *odor response*

space (*ORS*), suggests that any dose-response curve of an odor receptor can be obtained as a combination of three (out of four) "*primary odor responses*" with specific properties, opening the way to an objective procedure to obtain specific olfactory receptor responses by manipulating mixtures in a mathematically predictable manner.

Title: Effects of glycosylation in activity dependent cAMP mediated olfactory signaling

Authors: *S. RYU[1], T. SHIM[1], S. Y. KIM[1], J. GOLEBIOWSKI[2], C. MOON[1];
[1]department of Cognitive & Brain sciences, DGIST, Daegu, Korea, Republic of; [2]Inst. of Chem. CNRS, Univ. of Nice Sophia Antipolis, Nice, France

Abstract: Protein functions are often regulated by reversible post-translational modifications (PTMs) including phosphorylation, glycosylation, and ubiquitination. Odorant stimulation to odorant receptors (ORs) undergoes phosphorylation as a regulatory mechanism which is essential in the olfactory signal transduction including such as desensitization. Different from phosphorylation, little is studied about glycosylation of ORs in the olfactory signaling. Here, we demonstrated that glycosylation may have functional roles in cAMP mediated olfactory signaling in an activity dependent manner. We found increases in expression of glycosylation enzymes upon odorant stimulation in primary cultured olfactory sensory neurons (OSNs) of rat pups. In contrast, the overall glycosylated protein levels of OSNs were simultaneously decreased after odor stimulation. As the ORs are the key proteins in odorant stimulated olfactory signaling, we targeted ORs and performed site-directed mutagenesis of glycosylation sites within the OR sequence in order to examine the roles of glycosylation using HEK293T cells derived *in vitro* system. Glycosylation of ORs has an effect on cAMP mediated signaling, and also cAMP responsive binding protein (CREB) activity upon odorant stimulation. Our results suggest a novel regulatory mechanism in ligand-odorant receptor signaling. Moreover, we again underline the importance of odorant stimulation dependent regulatory mechanism in the olfactory sensory system.

Title: What makes pineapple smell like a pineapple? Here's how medicinal chemistry would slice it.

Authors: *N. TAHIROVA[1], E. POIVET[2], L. XU[1], S. FIRESTEIN[1];
[1]Columbia Univ., New York, NY; [2]New York Univ., New York, NY

Abstract: Several hundreds of olfactory receptors (ORs) are expressed in the mammalian olfactory system. Receptor-ligand interactions are the first step in sensing the complex mixtures that initiate smell perception. Although it is clear that different ORs are selective toward different odorant ligands, there is a disparity in how odorants are classified. While some use traditional organic chemistry methods to group these molecules (a physics or molecular approach), others look entirely at the perceptual output of the subjects in response to the odors (a psychological approach). Both of these methods pay insufficient attention to the reaction of the olfactory sensory neurons (OSNs) – a *biological* level.
Medicinal chemistry, a pharmacological technique used widely in the pharmaceutical industry, emphasizes biological function over chemical form. Since each mature OSN expresses one type of OR, we can test the parameters of odorant recognition for odors related by medicinal chemistry principles using calcium imaging on dissociated OSNs and mouse behavioral assays. For example, flipping an ester group within a ligand while maintaining its position will not change the OR binding ability of the ligand. To this end, we have tested a panel of 6-carbon long esters and reverse esters with pineapple-like scents. By varying the position or direction of the ester group along the carbon chain of these molecules, we are modifying their hydrophobic chain length, a property that might change their interaction with the ORs. Testing this mechanism allows us to make certain predictions about the nature of odorant selection by the OR family. In our study, we find that while reversing the ester group has almost no effect on odorant binding, shifting its location along the carbon chain significantly reduces the OR activation overlap. Our results show that medicinal chemistry may be an efficient tool to slice through some of the mysteries of olfaction.

Title: Motile cilia in sensory organs: more than just generating flow?

Authors: *N. JURISCH-YAKSI, I. REITEN, S. FORE, R. PELGRIMS, M. HOFFMANN, E. YAKSI;
Kavli Inst. For Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: The cilium is a small cellular appendage projecting from the surface of most cells, like a tiny antenna. It can generate flow or play a structural, sensory or signaling role in many tissues. Hence, defects in cilia observed in ciliopathy patients affect multiple organs, including the brain, and result in hydrocephalus, anosmia and neurological disorders.
Motile cilia, which cover most epithelia and the brain ventricles, generate flow to move fluids, particles and molecules at even macroscopic scales. Interestingly, they can also sense and respond to their environment by changing their beating frequency. Even though their beating is extremely important for proper organ function, very little is known about intrinsic mechanisms regulating their beating frequency.
Using the olfactory epithelium of the zebrafish as model system, we are studying the cellular and physiological mechanisms regulating ciliary function and motility in vivo in a living animal. Our results suggest that ciliary beating is regulated by several environmental factors and genetic ablation of ciliary beating has important functional consequences for the ciliated cells as well as neighbouring cells in the epithelium, i.e. olfactory receptor neurons. Altogether we expect our work to set a framework for studying and characterizing human ciliopathies using zebrafish as a model organism. With its low cost, established genetic tools, small size and transparency, zebrafish is an excellent animal model that is amenable for high throughput genetic and in vivo drug screens.

Title: Hormonal modulation of pheromone detection enhances male courtship sucess

Authors: *H. LIN, J. W. WANG;
Section of Neurobio. Div. of Biol. Sci., UCSD, LA Jolla, CA

Abstract: During the lifespans of most animals, reproductive maturity and mating activity are highly coordinated. In *Drosophila melanogaster*, for instance, male fertility increases with age and older males are known to have a copulation advantage over young ones. The molecular and neural basis of this age-related disparity in mating behavior is unknown. Here we show that the Or47b odorant receptor is required for the copulation advantage of older males. Notably, the sensitivity of Or47b neurons to a stimulatory pheromone, palmitoleic acid, is low in young males but high in older ones, which accounts for older males' higher courtship intensity. Mechanistically, this age-related sensitization of Or47b neurons requires a reproductive hormone, juvenile hormone, as well as its binding protein Methoprene-tolerant in Or47b neurons. Together, our study identifies a direct neural substrate for juvenile hormone that permits coordination of courtship activity with reproductive maturity to maximize male reproductive fitness.

Title: Inhibition of olfactory behavior in *Drosophila melanogaster* larvae through antagonism of the odorant receptor co-receptor (Orco) subunit

Authors: D. KEPCHIA, S. MOLIVER, K. CHOHAN, C. PHILLIPS, *C. W. LUETJE;
Mol. and Cell. Pharmacol. (R-189), Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Many insect behaviors are driven by olfaction, making odorant receptors (ORs) appealing targets for control strategies. Insect ORs, a family of odorant-gated ion channels, are heteromeric complexes of unknown stoichiometry that are composed of a representative from a large, variable family of odorant binding subunits and a highly conserved co-receptor subunit (Orco). Orco directed agonists and antagonists have recently been identified and we have shown that phenylthiophenecarboxamide structures competitively antagonize the Orco subunit. Importantly, Orco antagonists also act allosterically to inhibit OR activation by odorants.
To assess the utility of Orco antagonists as inhibitors of insect olfactory behavior, we focused on a series of phenylthiophenecarboxamides with halogen substitutions that increased volatility. In an electrophysiology assay, these compounds functioned as Orco antagonists when tested against ORs from *D. melanogaster*, *Anopheles gambiae* (malaria vector mosquito) and *Culex quinquefasciatus* (West Nile Virus vector mosquito). We then assayed *D. melanogaster* larvae in an olfactory chemotaxis behavioral assay to determine whether an airborne Orco antagonist could alter olfactory behavior. Larvae were placed in the center of a 10 cm Petri dish, flanked on either side by small filter paper disks at the dish perimeter. Highly diluted ethyl acetate (EA, a potent attractant) was placed on one filter and mineral oil (vehicle) was placed on the other. After a 5 min migratory period, the location of larvae was documented and attraction to EA was measured as a response index (RI). The RI towards EA was consistently robust. Genetically modified larvae lacking the EA responsive odorant binding subunit Or42b, or lacking Orco, were not attracted to EA. Larvae showed no preference when vehicle was placed on both filter disks, or when EA was placed on both filter disks. Attraction to EA was masked when EA was also added to a large filter disk attached to the inside of the dish lid, while vehicle in the lid filter disk had no effect. When a volatile Orco antagonist (halogen-substituted phenylthiophenecarboxamide) was placed in the dish lid filter, attraction to EA was abolished. In contrast, larval aversion to light was unaffected by the presence of the Orco antagonist. The ability of an airborne Orco antagonist to alter olfactory behavior in *D. melanogaster* larvae suggests that olfaction mediated behaviors of disease vector mosquitoes might also be manipulated through Orco antagonism.

Title: The locally distinctive cGMP response in an olfactory sensory neuron of *Caenorhabditis elegans*.

Authors: *H. SHIDARA, K. ASHIDA, K. HOTTA, K. OKA;
Lab. of Biophysics and Neuroinformatics, Keio Univ., Yokohama-Shi, Japan

Abstract: Cyclic guanosine monophosphate (cGMP) has important roles in signal transductions of many animals as a second messenger. In *Caenorhabditis elegans*, the second messenger is required for sensing of odor, temperature and gas. Especially, for olfactory sensing, the cGMP in AWC sensory neuron plays two distinctive functions: odor sensation and adaptation. For odor sensation, odorants may bind to G protein-coupled receptors (GPCRs), which activate Gi-like proteins at cilia of AWC. Then, the activated Gi-like protein increases cGMP production to regulate cGMP-dependent channels (Bargmann, 2006). For odor adaptation, cGMP binds to cGMP-dependent protein kinase G (PKG), induces translocation of PKG into the nuclear, and changes cellular physiological functions (O'Halloran et al., 2009). Although many functions relating to cGMP in AWC have been supported by genetic and molecular studies, region-specific cGMP dynamics in AWC have not been mentioned yet. Because the cilia are far from the soma in AWC, the cGMP dynamics at each region may be different. In our study, we visualized local cGMP dynamics and showed the distinct cGMP response to odorants at each region in AWC. To elucidate the temporal and spatial cGMP activities, we used the genetic cGMP indicator, cGi500 (Russwurm et al., 2007), with str-2 promoter for expression in AWC. Transgenic worms were fixed in microfluidic devices and exposed to isoamyl alcohol (odor). In the soma, the odor exposure increased the cGMP level. After the odor was removed, the cGMP level returned to the basal level. On the other hand, in the cilia, the cGMP level decreased immediately after exposure to odor and returned to the basal level in about 10 sec. Interestingly, the cGMP response in the dendrite, which neighbors the cilia, was not similar to one in the cilia but in the soma. These results showed the local specific cGMP response in the cilia, the dendrite and the soma of AWC.

Abstract: The nematode *Caenorhabditis elegans* uses a small number of sensory neurons to respond to a wide variety of odors. The identities of the odor receptors and an understanding of what they respond to and how they are organized is largely unknown. We are pursuing analysis of putative odor receptors. We are using translational GFP fusions to localize candidate proteins, generating knockout mutants using the CRISPR technique, and knocking down gene expression of candidates using RNA interference. Knockouts and RNA interference-induced worms will be tested in chemotaxis assays for odor responses.

Title: Biological sex modulates chemosensory function to bring about sex differences in *C. elegans* behavioral prioritization

Authors: *D. S. PORTMAN, K. A. FAGAN, E. WEXLER;
Ctr. for Neural Develop. and Dis., Univ. of Rochester, Rochester, NY

Abstract: Internally represented 'states' allow animals to dynamically and adaptively modulate their behavioral priorities. How and where these states are encoded within the nervous system, and how they reconfigure the properties of neural circuits, are central issues in behavioral neurobiology. Sex differences provide a unique example of natural variation in behavioral states and an ideal opportunity to understand their mechanistic underpinnings. Though the nematode C. elegans has a simple, compact nervous system, it exhibits robust behavioral states that are deeply influenced by biological sex. Our recent work has focused on understanding how biological sex modulates chemosensory circuits and behavior. Surprisingly, our results indicate that the modulation of sensory function itself is a key point of regulatory control. In adults, the two sexes of C. elegans (males and hermaphrodites, essentially self-fertile females) differ in several behaviors mediated by shared chemosensory circuits. For example, while hermaphrodites prioritize food detection, well-fed males tend to leave food in search of mates. In contrast, hermaphrodite-derived pheromones elicit weak repulsion in other hermaphrodites but strong attraction in males. We have found that the genetically determined sexual state of two pairs of sensory neurons in the worm's head are critical for implementing both of these differences. In the AWA neuron pair, genetic sex regulates expression of a key food chemoreceptor, odr-10, such that it is highly expressed in hermaphrodites but weakly expressed in males. Genetic 'sex-reversal' of this neuron is sufficient to reverse this expression pattern and alter behavioral prioritization. We have found that Insulin-like (daf-2) and TGFbeta (daf-7) signals are important contributors to this sex difference; moreover, these signals also regulate food detection as a function of nutritional state. Similarly, the ADF neurons are specialized by genetic sex to efficiently detect hermaphrodite pheromones only in males. Genetic masculinization of this neuron pair in hermaphrodites confers pheromone-sensitivity to them and generates pheromone attraction. Together, these studies identify sensory neurons as a key focus of sexual modulation, reinforcing the emerging idea that dynamic sensory function is an important contributor to state-dependent behavior. Understanding these regulatory interactions should shed light more generally on the mechanisms by which genetic sex modulates neural development and function.

Title: Characterization of odorant receptor expression and its glycosylated form in the olfactory and non-olfactory system

Authors: *T. SHIM, S. RYU, S. KIM, G. V. RONNETT, C. MOON;
Brain&Cognitive Sci., DGIST, Daegu, Korea, Republic of

Abstract: The initial step in odor detection occurs by the interaction of odorous molecules with odorant receptors (ORs) in the olfactory cilia of olfactory sensory neurons (OSNs). OR protein is a member of large G protein coupled receptor (GPCR) family, and the amino acid sequence of each OR proteins are variable. Numerous studies have been done by targeting specific regions within the OR sequence to elucidate particular roles or regulatory mechanisms of ORs. In contrast, studies to examine the expression of broad range of ORs and general distribution of OR proteins in the olfactory system have not been thoroughly performed. Thus we here have employed sequence-specific rabbit polyclonal antibodies against ORs from BLAST analysis, and the amino acid sequences we chose appear to be highly specific to ORs from various species. The sequence-specific peptide antibodies have recognized ORs localized in the rat olfactory cilia, and pre-absorbed antibodies with the sequence specific peptide showed significantly decreased immunoreactivity in both immunohistochemistry and immunoblot, indicating that this antibody detects ORs specifically. Interestingly, the antibodies appeared to detect glycosylated form of ORs as well as ORs in non-olfactory tissues, indicating novel regulatory mechanisms of ORs during olfactory signal transduction and ectopic expression of ORs. Our studies demonstrate that employment of sequence specific OR antibodies in cellular biological studies is feasible, and open intriguing possibilities for roles of ORs besides olfaction.

Title: Cyclophosphamide induced loss in olfactory cell populations.

Authors: ***N. AWADALLAH**[1], K. B. JOSEPH[1], K. PROCTOR[2], R. DELAY[1], E. DELAY[1]; [1]Biology/Neuroscience, [2]Med. Lab. & Radiation Sci., Univ. of Vermont, Burlington, VT

Abstract: Chemotherapy patients often experience chemosensory changes during and after drug therapy. Cyclophosphamide (CYP) is one of the first chemotherapy drugs with known cytotoxic and destructive effects, specifically on the taste cell cycle. **Similar to the taste system, the sense of smell is dependent on olfactory neurons that undergo rapid replacement. Therefore, we asked if a single injection of CYP would affect olfactory neurons in a similar form?** Due to a lack of knowledge on how CYP affects olfactory neurons, we examined the effects of CYP on olfactory neurons located in the main olfactory epithelium (MOE) and the vomeronasal organ (VNO). We used an antibody to Ki6, a protein expressed solely in cells undergoing division. ~100 male mice were given a single, IP injection of CYP (75 mg/kg) and sacrificed from 1 day to 125 days' post-injection. Mice were perfused with 4% paraformaldehyde, decalcified with EDTA, cryo-protected, sectioned and incubated with a Ki67 antibody (Thermo scientific). There were clear differences between the MOE and the VNO across all the time points. At 1-day post injection, the MOE looked damaged, especially in the dendritic region while the VNO was structurally unaffected. Both tissues showed a decrease in Ki67 protein label compared to controls. During the peak days' post injection, Ki67 labeling either surpassed or were equal to levels of labeling of control animals. By day two, neither tissue showed any Ki67 labeling. Between days four and six post injection there was a surge in Ki67 labeling, but this dramatically decreased by day 14. Recovery was noticeable complete by 30 in the MOE and 45 days in the VNO. However, labeling levels were almost absent by day 60. Interestingly, we see an increase in Ki67 labeling starting at 75 days' post injection and a recovery of proliferation by day 125. We are continuing on to observe the effects of CYP on the horizontal and globose basal cells using Keratin 5. So far, our data suggest that the olfactory tissue in the main olfactory epithelium was more affected by CYP than the VNO.

Title: Neural coding and discrimination of high-order sound statistics in the inferior colliculus

Authors: *F. KHATAMI, M. SADEGHI, H. L. READ, I. H. STEVENSON, M. A. ESCABI; Univ. of Connecticut, Storrs, CT

Abstract: Natural sounds exhibit high-order statistical regularities that are critical for neural coding and perception. Recently, it has been demonstrated that high-order statistical regularities in the spectrograms of sound textures, such as water, fire, and other environmental sounds, are critical for discrimination and identification (McDermott and Simoncelli, 2011). Furthermore, it is well known that neural responses in the central auditory system can be modulated by a variety of high-order sound statistics, including modulation and correlation statistics. Here we test the hypothesis that neural responses in the inferior colliculus are modulated by high-order statistical regularities in sounds and that statistical features of the neural response can ultimately be used to discriminate and categorize sounds. We performed recordings in inferior colliculus of unanesthetized rabbits in response to an ensemble of texture sounds (water, fire, speech babble etc.). We synthetically manipulated each sound by selectively adding or removing high-order statistics using the synthesis algorithm developed by McDermott and Simoncelli (2011). We show that neural response statistics, including spike timing precision and firing reliability, were modulated with manipulations of the sound statistics. Using neurometric and ideal observer analysis we demonstrate that neural response statistics can be used to discriminate sounds and that removing the high-order sound statistics decreases neural classification performance. These findings suggest that neural response statistics in the inferior colliculus have the capacity to convey information about statistical regularities in sounds that are critical for sound categorization.

Title: Chronic Ca^{2+} imaging reveals strong suppressive effects of anaesthesia on spontaneous and sound-evoked responses in dorsal inferior colliculus

Authors: *A. B. WONG, J. G. G. BORST;
Dept. of Neurosci., Erasmus MC, Rotterdam, Netherlands

Abstract: The inferior colliculus (IC) is a major auditory processing center, which receives input from major brainstem auditory nuclei. The non-lemniscal regions of the IC, dorsal cortex (DCIC) and lateral cortex (LCIC), are major targets for feedback projections from the cerebral cortex, making them likely susceptible to anaesthetic effects. Moreover, a large part of the DCIC lies superficially, making it a favorable structure for chronic *in vivo* two-photon imaging. Using Ca^{2+} imaging, we measured spontaneous and sound-evoked activities of the same IC neuronal population in mice when the animals were awake and during anaesthesia with ketamine/xylazine. GCaMP6s was expressed in IC neurons through the injection of AAV-vector. Pure-tone stimuli of various frequencies and intensities were presented while fluorescence of GCaMP6s was recorded by two-photon imaging. In an awake animal, a substantial portion of cells showed inhibitory response to pure tone stimuli, as indicated by a decrease in GCaMP6s fluorescence. We also observed excitatory responses to tone offset in some cells. Upon ketamine/xylazine anaesthesia, we noticed a decrease in baseline GCaMP6s fluorescence, which we interpret as a decrease in spontaneous activity. Inhibitory and offset responses were greatly diminished. Onset excitatory responses often showed an increase in threshold or a decreased amplitude. Some cells showed a shift in their characteristic frequency during anaesthesia. The same neurons were imaged after the animals recovered from anaesthesia to confirm that the changes were temporary and due to anaesthesia. Pupil size, whisker movement and body movement of the animals were recorded to further probe the effect of alertness. Post-hoc histology was performed on imaged cells to relate their neurochemical properties to their response characteristics. Our findings suggest the presence of tonic excitation on IC neurons in awake animals, which is suppressed during anaesthesia.

Title: Cell type specific connectivity and function in auditory midbrain

Authors: ***C. CHEN**[1], M. CHENG[1], T. ITO[2], M. ONO[3], S. SONG[1];
[1]Tsinghua Univ., Beijing City, China; [2]Univ. of Fukui, Fukui, Japan; [3]Kanazawa Med. Univ., Ishikawa, Japan

Abstract: The auditory midbrain or inferior colliculus (IC) is believed to be the first integration center in the auditory pathway, with information from lower brainstem nuclei, contralateral IC and auditory cortex. Different sources of input create functional domains in the IC in which excitatory and inhibitory neurons receive specific combination of inputs. However, the connectivity and function of different excitatory and inhibitory cell types is still unknown. Here, we combined the monosynaptic rabies virus tracing, Cre transgenic mice and *in vivo* two photon calcium imaging methods to address those questions. To exam the inputs to specific cell type, rabies virus were injected in the IC of 5 Cre transgenic mouse lines, labeling excitatory VGlut2, inhibitory VGAT, parvalbumin (PV), somatostatin (SOM) and vasoactive intestinal peptide (VIP) positive neurons. Four IC subregions were labeled by rabies virus, include the dorsal, central and external part of IC (ICD, ICC, and ICX). In all IC subregions, inhibitory neurons received significant lower portion of excitatory inputs than excitatory neurons, and no significant difference was found in the inhibitory inputs to both cell type. For both cell types, the fraction of subcollicular inputs was nearly equal with that of commissural IC inputs, but significant less than that of local inputs. All cell types examined, i.e. VGlut2, VGAT, PV, SOM and VIP had commissural, ascending or descending projections, suggesting that these molecules are not the marker of interneuron in the IC. To exam the functional differences between excitatory and inhibitory neurons, we injected AAV-flex-GCaMP6 to the IC of VGlut2-Cre or VGAT-Cre mice, and performed in vivo two photon calcium imaging to monitor the auditory feature that encoded by excitatory and inhibitory neurons. Spectral and temporal coding properties were resolved by pure tones and sinusoidal amplitude modulation (SAM) stimulus, respectively. In contrast to the broad tuning width of inhibitory neurons which had been widely observed in the cortex, the results show that inhibitory neurons in the IC had sharper spectral tuning width than excitatory neurons. For temporal coding properties, the inhibitory neurons usually preferred the low modulation SAM stimulus, while the excitatory neurons had preference for modulation frequency as high as 500Hz. For both cell types, the response profiles of neighboring neurons

were similar in general, but neuron pairs with quite heterogeneous response were always found. The physiological differences of excitatory and inhibitory cell types could be partially explained by their biased excitatory bottom-up and feedback inputs based on anatomy.

Title: Nonstationary correlation statistics allow robust sound category identification

Authors: M. SADEGHI, I. H. STEVENSON, *M. A. ESCABI;
Univ. of Connecticut, Storrs, CT

Abstract: Natural and man-made sounds, including both background and vocalized sounds, can vary on multiple time and frequency scales and exhibit unique statistical regularities in the sound spectrogram. Recently, it has been demonstrated that humans perceive and utilize high-order statistical regularities to categorize and discriminate sounds. Furthermore, neurons in the central auditory system can respond selectively to various high-order sound statistics, including the modulation spectrum and correlation structure of the sound. Here we test the hypothesis that nonstationary high-order statistics derived from computational auditory cochlear model enable discrimination and identification of sound categories from a computational standpoint. We used a catalogue of natural and man-made sounds to test the information carrying content of various high-order sounds statistics. Time-varying statistics related to the sound correlation structure and modulation spectrum where extracted for each sound at time-scales comparable to perceptual and neural (auditory cortex) integration times. For each sound category we construct a high-dimensional prior over sound statistics. Then using naïve Bayes classification, we show that the these high-order statistics allow categorizing sounds at time-scales comparable to neural and perceptual integration.

Title: Learning and performance variability in a rodent model of multi-channel cochlear implant use

Authors: *J. KING[1], I. SHEHU[2], M. A. SVIRSKY[1], R. C. FROEMKE[1];
[1]New York Univ. Sch. of Med., New York, NY; [2]Hunter Col., New York, NY

Abstract: Cochlear implants (CIs) are neuroprosthetic devices that can restore meaningful hearing to the profoundly deaf. However, asymptotic speech recognition and time to reach asymptotic levels are variable, ranging from 0 to 100% speech recognition and from <6 months to >2 years, respectively (Tyler et al., 2000; Chang et al., 2010). To determine neural mechanisms that underlie individual differences in the time course of adaptation to CI stimulation as well as in steady state outcomes, we developed a rat model of CI use. Female Sprague-Dawley rats are first trained on a self-initiated broadband (half-octave pure tone spacing) and narrowband (quarter-octave pure tone spacing) frequency detection task. Once animals have learned both tasks (d'>1.7), they are bilaterally deafened with a combination of ototoxic drugs and intracochlear trauma (>50 dB hearing loss), and unilaterally implanted with an 8-channel array in the scala tympani. Following surgical recovery and objective sound processor programming, the animals are initially tested on the broadband frequency detection task using CI stimulation as their exclusive input; this is their first day of stimulation. They then receive further targeted training to improve their behavioral performance. Day 1 initial performance is highly variable (n=3; d': -0.18, 0.21, and 0.86) but overall relatively poor; over a period of weeks, while learning trajectory and peak performance differ across animals (n=3; d':

0.94, 1.15, and 2.38), all animals improve significantly compared to their initial performance ($p<0.01$). This model of initial and learning variability captures some key features of clinical outcome variability with regards to vowel and word recognition with a CI in post-lingually deaf users.
In order to explore the neural correlates of these phenomena, we are using chronic micro-electrocorticography (μECoG) in CI animals throughout the behavioral testing and learning period with the CI. In collaboration with the Viventi lab, the Froemke lab has developed a μECoG system for recording from auditory cortex in awake, freely moving animals (Insanally et al., 2016). The 60-contact arrays can record stable tonotopic maps over a period of weeks to months. We are expanding this setup to include chronic cortical recordings within the behavior boxes during CI learning and performance. We expect that cortical representations of CI channels will be overlapping or indistinguishable in the initial phase, correlating with relatively poor initial performance, and that the CI channel representations will become more defined with training and experience, correlating to improved behavioral performance with the CI.

Title: The intrinsic physiology of inhibitory brainstem neurons changes during auditory development

Authors: ***B. J. CARROLL**[1], R. BERTRAM[2], R. L. HYSON, 32301[3];
[1]Florida State Univ., Tallahassee, FL; [2]Mathematics, [3]Psychology, The Florida State Univ., Tallahassee, FL

Abstract: Developmental changes in membrane properties promote the ability of excitatory neurons in the brainstem to code aspects of sound, including the timing and amplitude of a stimulus. Some of these changes coincide with the onset of hearing, suggesting that sound-driven activity in the nervous system produces developmental plasticity of ion channel expression. While it is known that the coding properties of excitatory neurons are modulated by inhibition in the mature system, it is unknown whether there are also developmental changes in the membrane properties of brainstem inhibitory neurons. We investigated the primary source of inhibition in the avian auditory brainstem, the superior olivary nucleus (SON), which displays sound-driven activity in mature animals. The present studies test the hypothesis that, as in excitatory neurons,

the membrane properties of these inhibitory neurons also change during the time of hearing onset. We examined SON neurons at different stages of auditory development: embryonic days 14-15 (E14-15), a timepoint at which cochlear ganglion neurons are just beginning to respond to sound, later stages of embryonic development (E18-19), and after hatching (P0-P1). We used *in vitro* whole-cell patch electrophysiology to explore neuronal excitability, measured as a neuron's ability to sustain tonic firing over a range of current steps. The results showed that SON neurons in young embryos were less likely to display tonic firing compared to those of older embryos and hatchlings, particularly at higher current injections. Biophysical models and voltage-clamp recordings were employed to examine how passive and active membrane properties contribute to the observed age-related differences.

Title: Resistance to spike depression of a rat central axon terminal during *In vivo* high-frequency firing

Authors: ***M. C. SIERKSMA**, J. G. G. BORST;
Dept. of Neurosci., Erasmus MC, Rotterdam, Netherlands

Abstract: By controlling calcium influx, the shape of the presynaptic action potential (AP) has a large impact on neurotransmitter release. Because of the small size of most terminals in the CNS, little is known about the regulation of their shape during natural firing patterns *in vivo*. The calyx of Held is a giant axosomatic terminal in the auditory brainstem, whose accessibility to patch-clamp recordings in slices has led to a detailed knowledge of its biophysical properties. Here, we report on whole-cell and juxtacellular recordings from calyceal terminals in newborn rat pups. Upon hyperpolarizing current injections the terminal revealed a depolarizing sag. Depolarizing current injections showed substantial outward-rectification and triggered a single, overshooting AP. Already at postnatal day (P)2, the calyx showed a characteristic burst firing pattern during spontaneous activity, which has previously been shown to originate from the cochlea.

Remarkably, despite the young age of the animals (P2-6), even at frequencies over 100 Hz the AP showed little or no depression nor broadening. In contrast, APs that were evoked by constant-current injections did depress and broaden. The rate of rise of the AP depended strongly on the preceding membrane potential, and the membrane potential in between the APs of a high-frequency train predicted whether the APs would depress or even potentiate. Instead of a slow depolarizing after-potential, as previously observed in slices, *in vivo* an AP was often followed by a hyperpolarization, which effectively prevented spike depression. Our findings imply that the *in vivo* shape of the calyceal AP minimizes activity-dependent changes, and show that the calyx of Held is reliably showing high-frequency activity already soon after its formation.

Title: The role of nitric oxide in modulating neuronal activity in the ventral cochlear nucleus

Authors: *A. HOCKLEY[1,2], J. I. BERGER[1], P. A. SMITH[2], M. N. WALLACE[1], A. R. PALMER[1];
[1]MRC IHR, Nottingham, United Kingdom; [2]Univ. of Nottingham, Nottingham, United Kingdom

Abstract: Tinnitus chronically affects an estimated 10-15% of adults and is characterised by the perception of sound independent of external stimuli. Nitric oxide synthase (NOS) expression has been studied in guinea pig ventral cochlear nucleus (VCN) where it is located in a sub-population of each cell type. Following unilateral acoustic over-exposure, a within-animal asymmetry of NOS expression was found exclusively in the 75% of animals that developed tinnitus (Coomber et al., 2015). The decrease in NOS expression in the contralateral VCN was observed as soon as 1 day after acoustic-over exposure, and the asymmetry in NOS expression was strongest at eight weeks after noise exposure. This provided evidence for a role of nitric oxide (NO) in tinnitus, and not simply as a biomarker for hearing loss.
Here, we describe the use of iontophoresis to apply the NOS inhibitor L-N^G-Nitroarginine methyl ester (L-NAME) to units within the VCN of the anaesthetised guinea pig. Upon identification and characterisation of a single unit, hour-long, pure tone pulse-trains were presented at the characteristic frequency (200 ms tone pip, 800 ms silence, 3600 repeats). The number of spikes per one second sweep were counted, allowing analysis of the changes in auditory-driven or spontaneous activity. An 80nA ejection current was applied through an

iontophoresis barrel containing 50mM L-NAME during a 20 min. period starting 15 min. after the start of the pulse-train; allowing assessment of the impact of blocking NO production on identified neuronal types.
Reducing NO production through NOS inhibition caused a significant increase in spontaneous and auditory-driven firing rate in 20% (2/10) of our VCN unit sample. This effect was found in both chopper and primary-like units. These results indicate that NO has a role within the VCN of reducing neuronal excitability. This effect of NO on excitability may be altered in tinnitus animals, producing a change in transmission with potential to contribute to the 'increased central gain' thought to be present in tinnitus animals.
The next stage will involve application of L-NAME to VCN neurons in guinea pigs following noise exposure and behavioural confirmation of tinnitus, therefore allowing us to determine the functional role of NO in tinnitus.

Title: Nitrergic Signalling in the bullfrog IC

Authors: *A. W. STAFFORD;
Biochem. and cellular and molecular biology, Univ. of Tennessee, Knoxville, TN

Abstract: Nitric Oxide (NO) is a gaseous molecule that functions as a retrograde messenger subserving long-term potentiation in the hippocampus where it plays a significant role in learning and memory. Activation of glutamate N-methyl-D-aspartate (NMDA) receptors stimulates NO production via the activity of nitric oxide synthase (NOS). NO is released and subsequently enhances the presynaptic release of glutamate. Staining for β nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) as well as immunohistochemical studies have revealed the presence of NOS-labeled neurons in a number of vertebrate brain structures including the inferior colliculus (IC), an important auditory processing center. These neurons presumably produce and release NO. However, the function of NO in auditory processing at the level of the IC is not known. Here we address this issue using single-unit recording combined with microiontophoresis to investigate the role of NO in the analysis of acoustic signals by neurons in the IC of the American bullfrog *Lithobates catesbeiana*. Of particular interest was

how NO modulates the responses of IC neurons to natural conspecific and heterospecific calls. *In vivo* iontophoretic application of L-NAME (a NOS inhibitor) was used to evaluate the effect of NO on the sound-evoked responses of neurons (n=8) in the IC. No change in best frequency, threshold, or tuning curve of units was seen during L-NAME application. In contrast, unit responses increased to conspecific bullfrog calls while remaining relatively unchanged in their responses to heterospecific calls during L-NAME application. Our data suggest a role for NO in gain control in the IC that may influence the output of neural circuits engaged in the analysis of behaviorally relevant acoustic signals, such as speech.

Title: Sensory and motor activity in the superior colliculus of the actively orienting bat

Authors: *M. J. WOHLGEMUTH, III[1], C. F. MOSS[2];
[2]Psychological and Brain Sci., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: The superior colliculus (SC) is a multimodal structure involved in integrating sensory signals into motor commands for species- specific orienting behaviors. The SC is laminated, with superficial sensory layers sending excitatory projections ventrally into sensorimotor and motor layers. Prior work has investigated the SC in visuomotor orientation in primates, but it is still an open question how sensory signals guide motor commands for species- specific orienting. To bridge this gap, we collected multichannel recordings from the SC of the echolocating bat as it performed natural orienting tasks. The echolocating bat serves as an excellent model for investigating sensorimotor processes in the SC because of the temporally discrete active sensing system it uses to probe the environment. The bat's spatial orientation behaviors involve the production of sonar vocalizations that return sonar echoes, and these echoes then influence motor planning for the next vocalization. Whereas primate studies often use "delay- period" activity before the initiation of a saccade to study how sensory activity affects motor planning, the orienting behaviors of echolocating bat naturally include delay-

periods between the reception of the echo and production of the next sonar vocalization. Furthermore, the timing of echo arrival and sonar vocal onset provide millisecond resolution for analyzing behaviorally relevant neural signals in the SC. We hypothesize that the orienting behaviors of the bat are tied to coordinated activity patterns across pools of SC neurons, such that superficial layer neurons are active during echo arrival, intermediate layer neurons are active for echo arrival and sonar vocal production, and deep layer neurons are active for sonar vocal production. To test this hypothesis, we designed a behavioral paradigm where the bat tracked and intercepted prey from a stationary position while SC recordings were collected simultaneously across laminae. We find that superficial neurons are indeed active during echo arrival, intermediate neurons are active before vocal onset and again at echo arrival time, and the deep layer neurons are active before vocal onset. This sensorimotor- timed activity suggests that a cascade of activity travels through the dorsal/ventral axis of the SC. In addition, the timing of individual neuronal activity indicates functionally relevant connections for sensorimotor integration in the SC. Our data present a novel data on population level activity related to sensation and motor action for spatial orienting behaviors in the SC; and also pose new questions on the nature of sensorimotor signals propagating throughout the SC laminae.

Title: Neuronal activity packets as basic units of neuronal code

Authors: *A. LUCZAK[1], B. L. MCNAUGHTON[1], K. D. HARRIS[2];
[1]Neurosci, Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Univ. Col. London, London, United Kingdom

Abstract: Neurons are active in a coordinated fashion, for example, an onset response to sensory stimuli usually evokes a 50-100ms long burst of population activity. Recently it has been shown that such 'packets' of neuronal activity are not randomly organized, but rather composed of stereotypical sequential spiking patterns. It has been shown that such packets are ubiquitous feature of stimulus evoked as well as of spontaneous network activity, and are present across different brain states. Although these packets have a generally conserved sequential spiking structure, the exact timing and number of spikes fired by each neuron within a packet can be modified depending on the stimuli. Here we present evidence that packets can be a good candidate for basic building blocks or 'the words' of neuronal coding, and can explain the mechanisms underlying multiple recent observations about neuronal coding, such as: multiplexing, LFP phase coding, and provide a possible connection between memory preplay and replay.

Title: Multi-channel open-loop thalamo-reticular architectures support thalamocortical wave propagation

Authors: *J. W. BROWN[1], D. A. LLANO[2];
[1]Col. of Med., [2]Neurosci. Program, Dept. of Mol. and Integrative Physiology, Beckman Inst., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Although the function of the thalamic reticular nucleus (TRN) remains poorly understood, both experimental studies and computational models have potentially implicated this elusive structure in phenomena ranging from attention and multi-sensory integration to epileptiform activity. It was recently demonstrated that a single-channel “open-loop” thalamo-reticular model, in which the TRN neuron is not reciprocally excited by thalamocortical (TC) neuron it inhibits, can paradoxically enhance TC output and consequently cortical activity across a broad parameter space defined by the input frequencies to the TC and TRN neurons. Here, we extend this open-loop architecture to include five thalamo-reticulo-cortical columns, representing distal, sequentially interconnected loci within a thalamocortical network. The most basic version

of this circuit, based on elaborating the single-column model developed by Willis et al. (2015), is able to sustain the propagation of spindle-like waves across the length of the network at a constant velocity. We demonstrate that the spatiotemporal profile of this wave propagation, including its periodicity and decay parameters, can vary robustly as a function of TC/TRN input profiles (e.g., Poisson-based, periodic) and adding and tuning intra- and inter-columnar synapses, including both GABAergic and electrical connections between TRN neurons. These findings are related to the physiology underlying both normal and pathological processes and compared to closed-loop models capable of approximating the same phenomena.

Title: Nominally non-responisve sensory and frontal cortical cells encode task-relevant variables

Authors: *M. INSANALLY[1], I. CARCEA[1], B. ALBANNA[2], R. FROEMKE[1];
[1]New York Univ., NY, NY; [2]Fordham Univ., NY, NY

Abstract: Single-unit activity recorded from behaving animals can often have heterogeneous response profiles. A fraction of recorded cells typically exhibit trial-averaged responses with obvious task-related features, such as pure tone frequency tuning in the auditory cortex, or ramping activity in secondary motor areas. However, a substantial number of cells do not appear to fire in a task-related manner and require different analytical methods. We analyzed single-units recorded from rats during a frequency recognition task in order to identify to what extent task variables are reflected in individual spike trains of every recorded neuron - independently or as part of small ensembles of cells. Adult rats were trained on a go/no frequency recognition task that required them to nosepoke to a single target tone for food reward and withhold from responding to multiple nontarget tones. Using multielectrode arrays we recorded from 66 single-units in the auditory cortex and 57 single-units in the frontal cortex (FR2). While the trial-averaged responses of some cells exhibited obvious and statistically significant task-related features, many cells were nominally non-responsive (31/66 AC cells and 35/57 FR2 cells from

six animals had neither significant tone-modulated activity or ramping activity; $p < 0.05$, 5,000 bootstraps). This variable activity is the only information available to downstream cells and circuits and must be decoded by other brain regions in real time on single trials. Accordingly, we devised a novel spike-timing based algorithm for trial-by-trial decoding. We found that: 1) Nominally non-responsive neurons represent behavioral variables. Our analysis shows that, in fact, the activity of cells that seem unresponsive when trial-averaged can and often do reflect basic differences in sensory stimulus encoding and decision-making. 2) We identified many 'multiplexed' neurons that simultaneously represented both the sensory input and the upcoming behavioral decision (43% of cells were multiplexed, with accuracy index ≥ 0.05 for both stimulus category and choice). 3) Frontal cortex has a better representation of task-relevant auditory stimuli than auditory cortex. Auditory cortex reliably responds to pure tones in untrained animals. However, when tones take on behavioral significance, this information is encoded more accurately in frontal cortex, suggesting that this region is critical for identifying the appropriate sensory-motor association.

Title: Top-down and bottom-up control through distinct phase-amplitude couplings in macaque auditory cortex

Authors: ***C. D. MÁRTON**[1,2], M. FUKUSHIMA[3,2], S. SCHULTZ[1], B. B. AVERBECK[2]; [1]Neural Coding Lab, Imperial Col. London, London, United Kingdom; [2]Lab. of Neuropsychology, Unit on Learning and Decision Making, NIH/NIMH, Bethesda, MD; [3]Lab. for Marmoset Neural Architecture, RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: Cross-frequency coupling of neuronal oscillations is well-documented as a phenomenon across different tasks and regions. However, it remains poorly understood with regards to its function in information processing (Aru et. al., Curr Opin Neurobiol, 31:51-61, 2015). Here we analyzed local field potential signals from simultaneous multi-site recordings in the macaque auditory cortex to systematically investigate the prevalence of cross-frequency couplings (CFC) across the auditory hierarchy. Three monkeys were implanted with micro-

ECoG arrays, and electrodes were partitioned into four sectors along a caudorostral axis in the supratemporal plane (STP). Recordings were made while awake monkeys listened to 20 different types of conspecific vocalizations (Fukushima et. al., J Neurosci, 34(13): 4665-4676, 2014). Quantifying phase-amplitude CFC using multivariate regression techniques, we find Theta to Alpha & Low Gamma and Alpha to Low & High Gamma couplings significantly more pronounced ($p<0.01$) in the top-down direction, and Alpha to Theta & Beta ($p<0.01$) in the bottom-up direction (*Figure 1).* The results depicted here are from one monkey. The pattern of higher Alpha to Gamma remains consistent ($p<0.01$), albeit less widespread among Gamma bands, and mostly restricted to specific sector pairs in the remaining two animals. The findings raise the need to incorporate top-down effects into current models of Theta to Gamma CFC (Hyafil et. al., eLife, 4: 3958, 2015). Moreover, selected CFCs (black box, *Figure 1*) were found to allow classification of coo- vs. non-coo type calls with an average loss rate of ~7% (SVM classifier, leave-one-out validation), suggesting CFCs play a role in stimulus processing. Top-down phase-amplitude CFCs (from regions higher in the auditory hierarchy to lower ones) may allow for enhanced stimulus processing in early areas (Luczak et. al., Nature, 16(12):745-755, 2015; Giraud & Poeppel, Nature Neurosci., 15(4): 511-517, 2012).

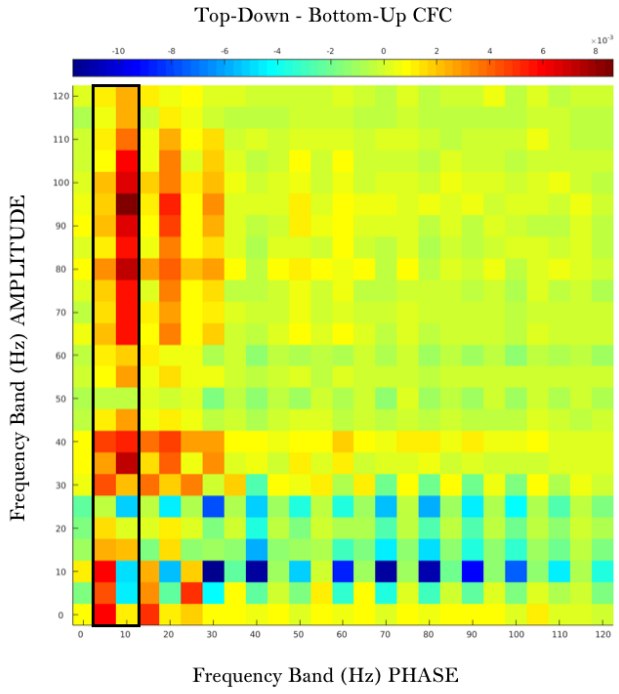

Figure 1: Difference between top-down and bottom-up cross-regional phase-amplitude coupling (i.e. Theta (Sector 4, located at rostral end of STP) to Gamma (Sector 1, located at the caudal end of the STP), depicted as a mean across all possible cross-regional combinations between the four sectors in the STP. The repetitive bands reflect harmonic effects of low-frequency phenomena.

Title: Coding sound loudness by pulse amplitude or pulse duration in cochlear implants: does it matter for cortical neurons?

Authors: *V. ADENIS[1], P. STAHL[2], D. GNASIA[2], B. GOURÉVITCH[1], J.-M. EDELINE[1]; [1]Neuro-Psi, Orsay, France; [2]Neurelec / Oticon Med., Vallauris, France

Abstract: Improving the coding strategies in cochlear implants (CI) is still the subject of intense investigations: the stimulation mode, the pulse shape and grounding schemes can lead moderate to important effects on the spread of excitation, electrode discriminability and nerve excitability. For example, several strategies are currently used to code loudness such as increasing the pulse amplitude, the pulse duration or the pulse rate. This study aims at comparing the responses obtained from the eighth nerve and the auditory cortex to stimulations delivered through a cochlear implant and for which increases in sound loudness were coded either by pulse amplitude or by pulse duration. Experiments were performed in urethane anesthetized guinea pigs (6-18months old). A map of the primary auditory cortex (AI) was first established by inserting an array of 16 electrodes (2 rows of 8 electrodes separated by 1mm and 350µm within a row) and quantifying the tonotopic gradient in AI based on multiunit recordings. A dedicated electrode-arrays (400µm) was then inserted in the cochlea (4 electrodes inserted in the 1st basal turn) and its connector was secured on the skull. The electrode array was placed back in the auditory cortex at the exact same location. A dedicated stimulation platform developed by Neurelec/Oticon was used to generate electrical current delivered by the implanted electrode. The eight nerve fibers were then stimulated with 20 levels of pulse amplitude or 20 levels of pulse duration generating similar charges. The patterns of cortical sites activated corresponded to the CI stimulating electrode. Furthermore, little differences in the cortical responses were found when the pulse duration was used rather than the pulse amplitude. The cortical responses evoked by electrical stimulations were often of shorter duration than the acoustic responses; the firing rate evoked by both the pulse duration and pulse amplitude strategies was usually higher than the one evoked by pure tones. These data suggest that, at the level of the primary auditory cortex, equivalent cortical activation can be achieved by coding sound loudness with pulse amplitude or with pulse duration.

Title: Distinct timescales for neural discrimination of sound envelope shape in three auditory cortical fields.

Authors: *A. OSMAN[1], C. LEE[2], M. ESCABI[3], H. READ[4];
[1]Biomed. Engin., [2]Behavioral Neurosci., [3]Biomed Engin., Electrical Engin., [4]Behavioral Neuroscience, Biomed. Engin., Univ. of Connecticut, Storrs, CT

Abstract: Mammals discriminate sounds based on perception of timbre and loudness due to temporal shape cues including duration and rate of change in sound envelope amplitude (Iverson and Krumhansl 1993; Irino and Patterson 1996, Drullman, Festen et al., 1994; Geffen et al., 2011). Mammals need cortex to detect temporal sound cues but the underlying cortical circuits and coding mechanisms for this ability remain unknown. Here we propose that cortical neuron spike timing patterns can be used to discriminate differences in sound envelope shape cues in three auditory cortical fields of the rat.
Single neuron response spike trains were recorded from layer 4 neurons in surgically exposed primary (A1), ventral (VAF) and caudal suprarhinal (cSRAF) auditory cortical fields of the rat as the physiology and corresponding thalamocortical pathways have been well described (Polley et al., 2007, Storace et al., 2010, 2011, 2012, Higgins et al., 2010). Spiking responses were probed with fifty-five unique noise burst sequences that varied in noise burst duration but had fixed noise burst repetition rate. To evaluate temporal patterns, spike trains were convolved with an exponential kernel having an evaluation window or time constant, Tc (van Rossum, 2001). A sound sequence discrimination index (d-prime) was computed from the evaluated spike train responses (Zheng and Escabi, 2012, Gai and Carney, 2008). Next, for each pair of spike trains, the Tc was varied between 1 and 256 ms to determine time window yielding optimal (aka maximal) sound sequence discrimination.
In all fields, we find a rank order increase in the synchronized response duration with A1 < VAF < cSRAF to any given sound shape (Lee et al., 2016). Similarly, here we find a rank order increase in Tc yielding best discrimination with: A1 < VAF < cSRAF (logarithmic means: A1:

33 ms (1.03), VAF: 39 ms (1.02), cSRAF: 44 ms (1.03), $p < 0.001$). A1 neurons discriminate small differences in sound envelope shape (e.g. 2Hz vs 4Hz). Whereas, VAF and SRAF are better than A1 at discriminating large differences in sound envelope shape (e.g. 2Hz vs 64Hz). These results indicate that cortical neuron spike-timing patterns can be used to discrimination of sound envelope temporal shape cues. Furthermore, distinct response timescales allow for complementary sound shape discrimination in primary versus non-primary auditory cortices. The multi-scaled organization could in theory provide a behavioral advantage to mammals for discriminating temporal shape cues in the sound envelope.

Title: Interactions of simultaneous sound representations in the primate inferior colliculus

Authors: ***S. M. WILLETT**, V. C. CARUSO, S. T. TOKDAR, J. M. GROH;
Duke Univ., Durham, NC

Abstract: When multiple stimuli activate overlapping populations of neurons, it is unclear how the brain preserves information about each stimulus. Two possible mechanisms that might support the accurate perception of multiple stimuli involve sorting neurons into subpopulations either across time or based on their tuning properties. Such mechanisms limit the number of stimuli encoded by any given neuron at any given time, thereby, enhancing the degree to which different stimuli are encoded by different neurons. We have previously found evidence of the sorting-across-time mechanism in the inferior colliculus (IC) by using multiple simultaneous sounds of similar frequencies, so that each individual sound activated similar populations of neurons (Caruso et. al, 2015, Soc. Neuro Abstr DP07.04/DP04). Here, we tested whether this sorting-across-time mechanism (time-division multiplexing) also occurs for more dissimilar sound frequencies eliciting a lower degree of overlap in neural representations. In this case an alternative coding mechanism could involve the refinement of the tuning of individual cells, leading to separate populations of neurons representing each sound. Thus, we investigated the responses of individual neurons in the IC in the presence of multiple sounds drawn from a larger range of frequencies. Single neurons were recorded in an awake, behaving rhesus macaque

during a dual sound localization task. The monkey was required to make either a single saccade to the location of one sound or a sequence of saccades to the locations of two simultaneously presented sounds. Frequency tuning was measured by presenting a fixed set of eight bandpass filtered noise frequencies alone or in combination with either a lower or higher frequency noise. As in our previous study, spike counts on single sound trials were modeled by Poisson distributions. The spike counts on dual sound trials were tested to see if they were best described by a mixture of the Poisson distributions observed on single sound trials, consistent with a sorting-across-time coding mechanism vs. other possibilities consistent with averaging, winner-take-all, or summation. We found that sorting-across-time was evident in some neurons even for sounds that were quite different from each other in frequency. Additionally, we found sharpening in neural tuning supporting an increased separation between representations of simultaneous sounds. Overall, these data suggest the IC could be using multiple mechanisms to increase encoding efficiency.

Title: Persistent activity in auditory cortex during passive listening

Authors: J. LEE[1], *J. E. COOKE[1], X. WANG[2], D. BENDOR[1];
[1]UCL, London, United Kingdom; [2]Johns Hopkins Univ., Balitmore, MD

Abstract: Persistent activity, the elevated firing of a neuron after the termination of a stimulus, is hypothesized to play a critical role in working memory. This form of activity is therefore typically studied within the context of a behavioural task, which includes a working memory component. Here we investigated whether persistent activity is observed in primary sensory cortex in the absence of any explicit behavioural task. We recorded spiking activity from single units in the auditory cortex (A1, R and RT) of awake, passively-listening marmosets. We observed persistent activity that lasted from a few hundred milliseconds to many seconds following the termination of the acoustic stimulus, in the absence of a task. Phasic persistent activity primarily occurred in units that showed strong phasic onset responses while sustained offset responses primarily occurred in units that showed sustained responses during the stimulus.

Long duration persistent activity, on the order of seconds, was observed primarily in units that showed dramatic suppression in during the stimulus. Given that these responses were observed in passively listening animals, persistent activity in sensory cortex may have functional importance beyond storing behaviourally relevant information in working memory. These findings also indicate that, despite the prevalence of balanced excitation and inhibition observed in A1 neurons, a range of unbalanced excitation-inhibition dynamics may exist in marmoset auditory cortex.

Title: Predominance of dormant sensory neurons and learning-induced recruitment in auditory cortex

Authors: *X. CHOU[1,2], F. LIANG[1,3,5], H. LI[1,3,5], M. ZHOU[1,3], Q. FANG[1,2], H. W. TAO[1,4], L. I. ZHANG[1,3];

Abstract: The general principle for how the external world is represented by neuronal populations in sensory cortex remains being actively investigated. In awake mouse primary auditory cortex, we surprisingly discovered that predominant neurons in layer 2/3 were dormant, showing no spike responses to sound stimuli of any fundamental category, while the remaining neurons responded to a broad variety of sound categories. Interestingly, dormant neurons all received sound-evoked synaptic inputs, but spiking failed due to a weak excitatory drive and low excitation/inhibition (E/I) ratio. The cortical sparseness developmentally emerged in an acoustic-experience dependent manner, along with differentiation of E/I ratio from a unimodal to bimodal

distribution. Furthermore, the sparseness can be down-regulated by associative learning in a stimulus-specific manner, through modulating layer 1 inhibitory circuits. Thus, the majority of supragranular neurons are on reserve for sensory representation, and recruitments of these under-committed cells can contribute importantly to functional evolution and plasticity of the brain.

Title: Neurofilament heavy chain expression and neuroplasticity in rat auditory cortex after unilateral and bilateral deafness

Authors: ***M.-H. PARK**[1], H. LEE[1], S. OH[2];
[1]SMG-SNU Boramae Med. Ctr., Seoul, Korea, Republic of; [2]Seoul Natl. University, Col. of Med., Seoul, Korea, Republic of

Abstract: Deafness induces many plastic changes in the auditory neural system. For instance, dendritic changes cause synaptic changes in neural cells. SMI-32, a monoclonal antibody to neurofilament protein, reveals auditory areas and recognizes non-phosphorylated epitopes on medium- and high-molecular-weight subunits of neurofilament proteins in cortical pyramidal neuron dendrites. We investigated SMI-32-immunoreactive (-ir) protein levels in the auditory cortices of rats with induced unilateral and bilateral deafness. Adult male Sprague-Dawley rats were divided into unilateral deafness (UD), bilateral deafness (BD) and control groups. Deafness was induced by cochlear ablation. All rats were euthanized, and the auditory cortices were harvested for real-time quantitative polymerase chain reaction (RT-qPCR) and Western blot analyses at 2, 4, 6, and 12 weeks after deafness was induced. Immunohistochemical staining was performed to evaluate the location of SMI-32-ir neurons. SMI-32 mRNA expression and SMI-32-ir protein levels were increased in the BD group. In particular, SMI-32-ir protein levels increased significantly 6 and 12 weeks after deafness was induced. In contrast, no significant changes were detected in the right or left auditory cortices at any time point in the UD group. Taken together, BD induced plastic changes in the auditory cortex, whereas UD did not affect

the auditory neural system sufficiently to show plastic changes, as measured by neurofilament protein level.

Title: Neuronal adaptation to background sound level statistics in the inferior colliculus of macaques.

Authors: F. ROCCHI, *R. RAMACHANDRAN;
Dept. of Hearing & Speech Sci., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: The detectability of a target sound embedded in background noise is affected by the properties of the acoustic scene. The responses of auditory neurons change systematically depending on the spatiotemporal relationship between foreground and background sound levels. Recent physiological studies conducted on anesthetized animals suggested that responses of auditory neurons adapt to the statistics of the environment. It is generally accepted that changes of the mean sound pressure level lead to significant variations in the neuronal activity. However, it is still unclear how such adaptation to environmental statistics may influence signal detection and the underlying neuronal responses in awake behaving subjects. To answer that question, we measured the responses of well isolated single units in the inferior colliculus (IC) of nonhuman primates (*Macaca mulatta* and *Macaca radiata*) while these subjects performed a reaction time Go/No-Go detection task. Monkeys were trained to detect a 50 ms tone that was either simultaneously gated with a burst of noise or embedded within a continuous noise background, whose amplitudes were randomly sampled (every 50 ms) from a distribution with high and low probability regions. The mean of the distribution (centroid of the high probability region) matched the sound pressure level used in the gated noise condition, and was played simultaneously with the tone. Similar to anesthetized animals, awake macaque IC neuronal responses adapted to the mean noise amplitude by shifting their dynamic range to higher sound levels. However, neuronal adaptation was significantly modified by the addition of a foreground stimulus. Although behavioral and IC neurometric threshold shifts to tones were not affected by backgrounds statistics, the rate responses of IC neurons reflected the statistical noise properties.

Simultaneously gated noise caused higher baseline responses and higher rate compression compared to the noise distribution. Behavioral and IC neurometric thresholds did not vary with the width of the high probability region (variance). However, the slope of IC neurometric functions was observed to be significantly shallower when the variance was increased, suggesting that neuronal sensitivity might change as a function of the variability within the acoustic scene. Additionally, neuronal response to each 50 ms of noise amplitude was affected by the sound pressure level of the prior noise, implying that variables other than statistics may cause adaptation. Our results indicate that the mean of the sound pressure levels might not be the primary factor in the neuronal adaptation process.

Title: A novel method for analyzing cortical steady state responses

Authors: *P. KRAUSS, A. SCHILLING, C. METZNER, K. TZIRIDIS, H. SCHULZE; Univ. of Erlangen-Nurnberg, Erlangen, Germany

Abstract: We present a novel method for analyzing and modeling high-dimensional data such as multichannel cortical recordings. Our method is derived from multidimensional scaling (MDS), a datamining method which aims to project N points from high-dimensional space onto a lower dimensional target space such that all mutual Euclidean distances are preserved. However, a fundamental shortcoming of classical MDS is the impossibility of assigning coordinates in target space to points that have not been taken into account for the previous scaling procedure. To do so requires performing a new run of the scaling procedure with all previous points plus the additional new point, thus making it impractical for applications where the coordinates of new points have to be estimated, since the computational complexity of MDS is of order $O(N) \sim N^2$. Overcoming this problem we project a grid from k-dimensional space to 2-dimensional target space while preserving all mutual distances. Thus new data points can directly be projected without performing new computations by simply mapping them to the nearest grid point. Furthermore, we generalize classical MDS to non-Euclidean distances such as the Mahalanobis distance. We investigate spontaneous and stimulus (pure tones lasting 120 seconds) driven steady state activity of auditory cortex using 16-electrode arrays. The temporal development of the spatial activity pattern across the channels corresponds to a trajectory in an abstract 16-

dimensional state space. Projecting trajectories corresponding to different conditions reveals attractor-like dynamics. In addition, we use our animal model to induce auditory phantom percepts (tinnitus). The development of tinnitus corresponds to an increasing resemblance of spontaneous activity to stimulus driven activity. Our method enables inferring the pitch of the tinnitus precept from recorded data, which we validate using a behavioral tinnitus assessment paradigm.

Title: The impact of hearing loss on the neural representation of speech in noise in the gerbil auditory midbrain

Authors: *J. A. GARCIA-LAZARO[1], D. MCALPINE[2], R. SCHAETTE[1];
[1]Ear Inst., London, United Kingdom; [2]The Australian Hearing Hub, Macquarie Univ., Sydney, Australia

Abstract: The healthy human auditory system is capable of understanding speech in complex 'cocktail party' environments, even when the target speech may be quieter than the surrounding babble. However, understanding speech in the presence of noise is considerably degraded for those with hearing impairment, who struggle not only with a loss of audibility, but also with a loss of intelligibility. Even with hearing aids, they are often able to 'hear' speech in background noise, but they are unable to understand it. To determine which factors contribute to the loss of speech intelligibility, we used an animal model to investigate how a controlled acoustic noise insult impacts on the neural representation of speech-in-noise in the auditory midbrain. Hearing loss was induced in adult gerbils through exposure to octave band noise (2-4 kHz) at 105 dB SPL for 2 hours under anaesthesia. Control animals received a sham exposure. Auditory brainstem response (ABR) thresholds were measured before and after noise insult, and after a recovery period of 4 weeks. We performed *in vivo* electrophysiological recordings in the inferior colliculus (IC) under ketamine/xylazine anesthesia using 32-channel tetrode arrays. To investigate the neural representation of speech in noise, we presented 16 different vowel-

consonant-vowel (VCV) tokens from an adult female talker in speech-shaped noise (at either 60 or 75 dB SPL), with signal-to-noise ratios (SNRs) varying from -12 to +12 dB.
In noise-exposed animals, we observed a marked increase in neuronal response strength for the 60, but not the 75 dB SPL condition. To determine the effects on the neural representation of speech in noise, we used a neurogram-based distance metric and a PSTH-based classifier to assess how well the individual VCV stimuli could be discriminated based on the neural responses. In noise-exposed animals, there was a decrease in discrimination performance when background noise intensity was increased from 60 to 75 dB SPL. In contrast, performance increased slightly in the control group. These findings are consistent with noise-induced damage to low spontaneous rate fibers in the auditory nerve, and increased neuronal response gain in the central auditory system. Taken together, our results show how peripheral and central processes can impact on functional hearing.

Title: Simultaneous estimation of receptive fields and intrinsic dynamics of auditory neurons using affine-invarient MCMC

Authors: T. D. ROBBINS[1], *C. MELIZA[2,3];
[1]Cognitive Sci. Program, [3]Dept. of Psychology, [2]Univ. of Virginia, Charlottesville, VA

Abstract: Quantitative models of neural responses to sensory input can yield insights into information flow and processing in the brain. For example, spectrotemporal receptive fields (STRFs) of neurons at successive stages of the auditory pathway are increasingly matched with species-specific vocal elements and learned acoustic features. STRF models typically represent spiking with a static non-linearity and a rate-based, inhomogeneous Poisson process, which may fail to represent many features of intrinsic neural dynamics and their contribution to information processing. Recently, statistical methods have been developed to infer parameters and

unmeasured states of dynamical neuron models by statistically assimilating responses to intracellular current injection. Here, we combine dynamical neuron models with linear STRFs to analyze extracellular recordings of auditory responses in the zebra finch pallium. This method takes a Bayesian approach to parameter optimization by using an affine-invariant Markov Chain Monte Carlo algorithm to estimate posterior distributions for each parameter, including the coefficients of the STRF. We validate the technique against simulated data from a range of neuron models and compare to rate-based estimation methods.

Title: Combining multi-unit recording and flavoprotein fluorescence imaging reveals field- and layer-specific sound-evoked neural responses in the rodent auditory cortex

Authors: *J. NISHIKAWA, T. HAGA, Y. TACHIBANA, Y. OHTAKA, Y. YANAGAWA, H. OSANAI, T. TATENO;
Hokkaido Univ., Sapporo, Japan

Abstract: The auditory cortex (AC) processes complex sounds through its field and laminar structure, however, little is known about the relationship between the structure and functions. In this study, we combined multi-unit recording and flavoprotein fluorescence imaging to reveal field- and layer-specific sound-evoked neural responses in the rodent AC. First, we examined information flow of the AC in sound processing. To identify the primary auditory field (A1) and anterior auditory field (AAF), we conducted flavoprotein fluorescence imaging in urethane-anesthetized rats in response to several tone bursts. Next, we inserted a 16-ch silicon probe to the fields, and recorded single-units and local field potentials (LFPs) to various tone bursts. After cortical layers' identification using LFP recording, we calculated frequency response areas and spectro-temporal receptive fields (STRFs) of each single-units. As a result, the AAF had

significantly higher auditory threshold, longer latency and narrower band properties than the A1. In addition, layer 2/3 (L2/3) had significantly longer latency and narrower frequency-band properties than layer 4 (L4). Layer 5/6 (L5/6) had significantly longer latency and shorter duration than L4. These results indicate that the processed information of sound mainly flows from the A1 to the AAF and, in each field, from L4 to L2/3, and then to L5/6. These results will help us to understand the auditory processing on the hierarchical field and laminar structure in AC. Second, we investigated social-context dependency of the receptive fields. In our previous chronic recording in freely moving mice, success rate for observing auditory response was not high because of individual differences in the location of AC. To improve the success rate, we executed transcranial flavoprotein fluorescence imaging in anesthetized mice before the implantation, and identified the exact location of AC in each animal. Next, we surgically implanted a microdrive with a tungsten electrode exactly into the AC location. These procedures improved the success rate in the chronic neural recording from 26.3% to 100.0%. We recorded neural responses to various tone bursts in social context (with a stranger) and alone context (without a stranger) in their recording cage, and calculated STRFs in both contexts. Consequently, response areas of each STRF shrank both in frequency and time axes. These results suggest that such social context sharpens the tuning of AC neurons.

Title: how grit can overcome oculomotor insufficiencies and change gpa

Authors: *T. GORJI[1,2], D. LARRANAGA[3], A. S. HOCHMAN[2], J. R. MIER[4], S. A. DREW[5]; [1]Psychology, California State University, Northridge, Tarzana, CA; [2]Psychology, California State University, Northridge, Northridge, CA; [3]Psychology, California State University, Northridge, Nothridge, CA; [4]California State University, Northridge, Northridge, CA; [5]California State Univ. Northridge, Northridge, CA

Abstract: Introduction: In performing near work tasks individuals may experience symptoms of visual discomfort. Symptoms may include headaches, eyestrain, double vision, blurred vision, and sensitivity to light. Two systems contributing to near work performance are the: (1) Accommodative, in which the lenses thickens or thins while focusing on the target and (2)

Vergence, focusing on the rotation of the eyes inwardly while focusing on the target. Insufficiencies in both these ocular systems can occur and several surveys have been developed to measure visual discomfort associated with these conditions. **Methods**: We administered the Visual Discomfort Survey (VDS) and the Convergence Insufficiency Symptom Survey (CISS), which are closely associated with accommodative insufficiency and convergence insufficiency, respectively. We also administered the Academic Problems Survey (APS) to assess students' academic difficulties as well as a survey to assess grit, the perseverance and passion for long-term goals (Duckwoth et al., 2007). **Results**: We used a Sobel test and multiple linear regressions to evaluate the relationship between oculomotor symptoms (VDS & CISS), APS, and Grit. Our results indicate that Grit acts as a mediator between symptoms and GPA. Grit is also a predictor of APS. **Discussion**: This suggests that Grit will help students to overcome their oculomotor insufficiency symptoms and achieve higher GPA. A Sobel Test revealed that Grit significantly accounts for a portion of the variance in oculomotor symptoms and GPA.

Title: Apparent motion extrapolates size, shape and brightness.

Authors: *C. CHUNHARAS[1,2], V. RAMACHANDRAN[1];
[1]UCSD, La Jolla, CA; [2]Med., Chulalongkorn University, KCMH, Bangkok, Thailand

Abstract: A large, 2.5 degree, shaded disc A was flashed on the screen followed by a small, 1 degree, disc B shifted horizontally. Disc A was seen to simultaneously move and shrink as expected. Intriguingly, the disc was seen to become 10% smaller at its destination in frame 2 than its true size; a new illusion we call "size extrapolation". We found the effect to be almost as compelling with homogeneous discs which we used in a more formal experiment. To demonstrate that size expansion was correlated with the strength of perceived motion, we varied the SOA between the flashing discs resulting in different magnitude of apparent motion ("Korte's law"). Control experiments showed that the effect was not due to either size contrast, size adaptation or figural after effect. This effect is reminiscent of "visual inertia" in apparent motion, in which a spot in apparent motion has a tendency to continue its trajectory when confronted with a choice. A similar but less compelling effect was observed when the disc

changed shape or brightness rather than size. The extrapolation was then along the corresponding dimension. Curiously, the effect was compelling only for the direction of shrinkage compared to expansion. Our results are a striking example of the principle that perception involves making "educated guesses" or predictions based on the immediate past; and using them to resolve ambiguity in interpreting both the currently ongoing onslaught of sense impressions as well as the immediate future.

Title: Neural representation of multiple moving stimuli with competing features in cortical area MT is drastically altered by spatial arrangement of visual stimuli

Authors: *S. WIESNER, X. HUANG;
Neurosci., Univ. of Wisconsin Madison, Madison, WI

Abstract: Objects in the natural world usually have multiple visual features that each can vary in signal strength and the spatial layout of the objects may also vary, making it important to study how the visual system encodes multiple visual stimuli and whether spatial arrangement affects the neural representation. We have shown that neuronal responses in extrastriate area MT elicited by two overlapping, moving stimuli can be described as a weighted sum of the neuronal responses elicited by the individual stimulus components plus a nonlinear interaction term, and the response weight is stronger for the component that has a higher signal strength (Xiao et al., 2014, J Neurophysiol). These results are consistent with the idea of normalization. Here we investigate how MT neurons respond to multiple moving stimuli that have competing visual features and the effect of spatial arrangement of visual stimuli.
We recorded from neurons in area MT of fixating monkeys and used motion coherence and luminance contrast as two competing features. Visual stimuli were two random-dot patches moving simultaneously in different directions separated by 90°. The diameter of each patch was

3°. One patch moved at a high coherence (100%) with a low contrast (36%) (HCoh/LLum), whereas the other moved at a low coherence (60%) with a high contrast (77%) (LCoh/HLum). The two patches were placed within the receptive fields (RFs) of MT neurons, and either overlapped, or were separated with at least 1° gap in-between. We varied the vector-averaged direction of the two patches to characterize direction tuning curves.
We found that although MT response elicited by HCoh/LLum patch alone was significantly stronger than that elicited by LCoh/HLum patch, MT response elicited by both patches was strongly biased to the component response elicited by LCoh/HLum patch when the two patches overlapped. The average response weight for LCoh/HLum patch was 0.9, significantly larger than the weight of 0.2 for HCoh/LLum patch. As the spatial arrangement changed from overlapping to non-overlapping, the mean weight for LCoh/HLum patch reduced to 0.6 and the weight for HCoh/LLum patch increased to 0.8. MT response was now biased to the response elicited by HCoh/LLum patch. The effect of spatial arrangement on response weights was highly significant. When overlapping, the two stimulus patches compete within the RFs of both V1 and MT neurons, whereas when not overlapping, the two patches can only fit and thus compete within the RFs of MT neurons, but not V1 neurons. The effect of spatial arrangement on MT responses may reflect response normalization occurring at different stages of visual processing that favors different stimulus features.

Title: The Spatial temporal filter for motion integration for smooth pursuit eye movements

Authors: *T. MUKHERJEE, C. SIMONCINI, L. C. OSBORNE;
Univ. of Chicago, Chicago, IL

Abstract: Motion processing is integral to how our brain perceives and responds to the natural visual world. Motion is used to identify objects, to track and intercept moving targets, to determine the body's movement through space, to perceive depth, and other behaviors. Despite the enduring interest in motion integration, a direct measure of the space-time filter that the brain imposes on a visual scene has been elusive. This is perhaps because of the challenge posed by measuring a three dimensional function from perceptual reports in psychophysical tasks. We take a different approach. We exploit the close connection between visual motion estimates and smooth eye movements to measure stimulus-response correlations across space and time, computing the space-time filter directly. In pursuit, the eyes rotate smoothly to stabilize the retinal image of a moving target, thereby improving visual acuity. Pursuit can be driven by the motion of small objects against a background and by spatially distributed motion such as random dot kinetograms. In this sense, pursuit bridges two different scales of spatial motion processing, one operating on local motion contrast and another that sums motion over larger visual regions. Motion integration need not be accomplished by a fixed function, so we explore both the commonalities and differences across stimulus forms in both humans and monkeys. These results allow us to evaluate theories of motion integration that have arisen from psychophysical studies and analyses of cortical physiology. We find that motion is not weighted equally within the visual field. The most weight is given to motion a few degrees from the fovea depending on the aperture size, and in front of and slightly above the direction of eye movement. Convolving the filter with an optic-flow based representation of the stimulus allows us to predict eye acceleration for novel stimulus forms. Our data are not consistent with perceptual surround suppression observed in prior studies, hypothesized to arise from the preferential activation of neurons with center-surround receptive fields. Rather we find that uniform textures are processed distinctly from non-uniform textures, in agreement from recent physiological analysis of V1 neuron behavior.

Abstract: Most human fMRI studies have used the contrast moving vs static flow fields to map the motion response regions in the human brain (Tootell et al 1997, Sunaert et al 1999). We investigated the motion responsive regions in the human brain by means of intracerebral recordings made for diagnostic purposes in 55 hemispheres (L=30, R=25) of 51 patients with drug resistant epilepsy. We calculated the optic flow from video clips (240 videos each 2.5 s) depicting various tool and hand actions (Peeters et al., 2009) presented to the participants. We cross-correlated the speed extracted from the optic flow with the intra-cerebrally recorded high gamma power (50-150Hz), and generated correlation maps using the mapping procedure by Avanzini et al 2016. Only regions sufficiently explored (2 leads per disc) and consistently responding (at least 20% significant correlation) were visualized. The motion responsive regions were more extended in the left than the right hemisphere, consistent with a stronger flow in the right than left hemifield. Motion responsive regions in the left hemisphere included regions expected from earlier imaging studies, notably the MT cluster, extending into the LO complex and into the posterior middle temporal gyrus (pMTG), V3C/D and neighboring ventral intraparietal sulcus (VIPS), dorsal intraparietal sulcus anterior/medial (DIPSA/DIPSM) and a retro-insular region (Sunaert et al 1999). Additionally, motion responses were observed in hV4/VO1 and collateral sulcus, in SPL dorsal from DIPSA, in an occipito-parietal cluster extending from PGp, and in a precentral
gyrus site. For each correlating lead, two indices were computed comparing the correlation with hand vs tool flow, and correlation with contralateral vs bilateral optic flow. Most of the extra-occipital regions were more correlated with the bilateral than the contralateral flow, indicating that most RFs in these regions were bilateral. Very intriguingly, several motion regions in left hemisphere fell apart into dorsal sectors dominated by hand videos and ventral ones dominated by tool videos: in pMTG, in the hV4/fusiform region, and most notably, in the PPC, SPL and VIPS being dominated by hand videos and DIPSA/DIPSM and the occipito-parietal cluster by tool videos. These results underscore the importance of the time resolution of intracerebral recordings, reveal motion responsiveness over a wider extent than previously known, and suggest a sorting of tool and natural effector dynamic signals.

Title: A 9.4T human fMRI study reveals differential laminar responses for visual motion in eye- and world-centered reference frames in area V3A

Authors: *F. MOLAEI-VANEGHI[1,2,3], K. SCHEFFLER[1], A. BARTELS[1,2,3];
[1]Max-Planck Inst. for Biol. Cybernetics, Tübingen, Germany; [2]Vision and Cognition Lab, Ctr. for Integrative Neuroscience, Univ. of Tübingen, Tübingen 72076, Germany; [3]Dept. of Psychology, Univ. of Tübingen, Tübingen 72076, Germany

Abstract: Neural mechanisms underlying a stable perception of the world during pursuit eye movements are not fully understood. Both, perceptual stability as well as perception of real-world motion are the product of multi-modal integration between retinal motion (visual motion signals) and efference copies of eye movements (non-visual motion signals). The comparison between these two signals allows differentiating between self-induced motion and external, real-world motion. Recently, pursuit-paradigms revealed that human area V3A responds to motion predominantly in a world-centered rather than in a retina-centered reference frame (Fischer et al., 2012). This indicates that V3A integrates retinal motion with non-retinal eye-movement signals. In this study we combined ultra-high-field (9.4T) human fMRI, state of the art pulse sequences, and laminar analysis to find out if there is a differential involvement of cortical layers in the processing of real world motion compared to retinal motion in area V3A. We used a 2D GE EPI sequence with 0.8 mm isotropic resolution to measure BOLD signal at different cortical depths while subjects performed a visual pursuit task. The paradigm involved a 2x2 design containing real motion and visual pursuit, which allowed separating responses to retinal and real motion while fully controlling for pursuit-related effects. A laminar surface-based analysis method was used to study the relationship between spatial localization and activation strength as a function of cortical depth by sampling the BOLD signal from the superficial, middle, or deep cortical lamina in area V3A.
The results show that signals related to retinal motion were evenly spread across layers with a bias towards deep layers of V3A while real-motion responses had a gradient with a peak in superficial layers. The differential laminar response profile is compatible with differential local processing for the two motion types. The stronger involvement of superficial layers during real motion processing may be indicative of feedback related processing, possibly through mediation

of efference-copy related signals from higher-level regions such as parietal cortex or smooth pursuit fields of the frontal eye fields with which V3A has direct connections. Future studies are needed to clarify the reasons for differential laminar responses and to identify communication pathways leading to V3A.

Title: Resolving the apparent motion paradox by rTMS

Authors: *J. CSATLOS[1,2], S. SHIMOJO[3], R. J. BUCHANAN[4,5], Z. NADASDY[6]; [1]Eötvös Lóránd Univ., Budapest, Hungary; [2]Dept. of Theory, Complex Systems and Computat. Neurosci. Group, Wigner Res. Sch., Austin, TX; [6]St. David's Neurosci. and Spine Inst., Austin, TX

Abstract: Apparent motion (AM), more specifically beta motion as defined by Wertheimer in 1912, is a percept of continuous motion induced by the quick succession of static images. Although the effect is the key principle behind motion pictures and animation, the experience demonstrates a still unresolved paradox. Namely, the observer perceives the motion before the second image is exposed, while the direction of motion, in theory, cannot be resolved until the second image is exposed. This paradox can be approached by two types of models: one type posits that apparent motion is postdictive, i.e. motion percept is generated retrospectively, after the second image is flashed, and the experience is subjectively backdated to an earlier time. We considered an alternative model and hypothesized that AM may rely on a spreading activation to neurons between the cortical representations of the motion inducers. When spreading ring-waves emanating from two cortical sources meet, they generate an interference pattern, which activates neurons along the likely motion trajectory, even though no stimuli were presented between the AM inducers. We tested this latter hypothesis with an experiment done on normal human subjects (n=21), which determined the psychometric function for near-threshold stimuli flashed between two AM inducers. The subjects' task was to discriminate between a low luminance

triangle and a square flashed briefly during the AM sequence between the AM inducers. We showed that the detection threshold between the AM inducers is (i) an exponential function of the distance between the two AM inducers (ANOVA $F=399.75$, $P<0.001$) and (ii) it is periodic. The spatially periodic modulation of threshold is consistent with the proposed interference model. Next, we demonstrated by using rTMS, that this interference in V1-V2 is susceptible to a 100 ms excitatory train of 40 Hz pulses (signed rank test: 17.500, $p = 0.0292$, $df=20,1$). In summary, our results confirm that the spreading activation model can explain the AM paradox. Second, we were able to unravel the causal role of cortical excitatory waves in the modulation of detection threshold along the path of motion perception. Third, our rTMS protocol proved that the spreading activation underlying apparent motion is localized to the V1-V2 areas. Because the cortical interference model necessitates the exposure of second stimulus before the interference is induced, this model is partly consistent with the postdictive model. However, in contrast with the postdictive model, the cortical motion interpolation and concomitant motion readout may start before the presentation of the second phase of the AM inducer.

Title: Selective computation of path-dependent and -independent rotations in macaque parietal cortex

Authors: ***Z. CHENG**, B. LIU, Y. GU;
Inst. of Neuroscience, CAS, Shanghai City, China

Abstract: We experience complex visual stimulation patterns due to our different kinds of self-motion through the environment. Whether the brain can use the visual information to compute both the heading directions and trajectories of body during natural navigation remains debating and unclear. In the current study, we use optic flow stimuli containing motion parallax information to simulate three self-motion conditions: (1) Path-dependent-rotation condition, where subjects were moving along a curved path without any rotations around the body axis; (2) Path-independent-rotation condition, where subjects were moving along a straight path while rotating one's body either clockwise or counter-clockwise; and (3) Curvilinear motion condition

resulted from matched path-dependent and -independent rotations, where subjects were moving along a curved path while rotating one's body such that the gaze was always kept aligned with the path. We then collected extracellular activities from three cortical areas in which multisensory translation and rotation signals have been reported previously: the dorsal portion of the medial superior temporal area (MSTd), ventral intraparietal area (VIP), and visual posterior sylvian fissure (VPS). We found that the path-dependent rotation signals did not significantly alter the tuning properties of parietal neurons in response to translation stimuli, while the path-independent rotation signals led to significant gain modulation, bandwidth change and preference shift. In the curvilinear motion condition, the responses followed more closely with those in the path-independent rotation. Our data indicates that path-dependent and –independent rotations are selectively represented in the parietal cortex. Therefore, parietal neurons cannot distinguish path-independent rotations versus curvilinear motion based on the visual inputs alone.

Title: Hierarchical effects of contrast and motion coherence in human visual cortex

Authors: *D. BIRMAN, J. GARDNER;
Psychology, Stanford Univ., Stanford, CA

Abstract: Contrast and motion coherence are fundamental visual attributes that control the perceptual strength of random dot displays. Past studies of the representation of these attributes in humans have examined only a few specific cortical regions and have used manipulations in which both contrast and motion coherence changed simultaneously. As human visual cortex is highly sensitive to changes in contrast, isolating responses to motion coherence may have been confounded by contrast changes. Here we independently varied the contrast and coherence of random-dot displays while participants performed an unrelated task and asked how topographically mapped cortical areas throughout the visual hierarchy represent these visual attributes. Methods. We measured BOLD responses in human participants to random dot displays with contrasts of 25-100% and motion coherences of 0-100%. Retinotopic mapping was first performed with drifting bars to identify visual areas. In subsequent sessions participants

were shown two 11.5x14 deg patches of dots, centered 7.75 deg to the left and right of fixation, while performing a fixation task. The patches consisted of equal proportions of black and white dots (21 dots/deg, linearized gamma) which increased in contrast, coherence, or both for 2.5 s before returning to a constant incoherent background of 25% contrast for 2.65 - 11.5 s. BOLD response to each contrast and coherence condition were estimated using a finite impulse response model averaged across voxels in each cortical area. Contrast and coherence sensitivity was determined by finding the Naka-Rushton or linear function, respectively, that best fit the measured BOLD responses. Results. Later cortical areas were less sensitive to changes in stimulus contrast compared to earlier areas (V1-V3), as expected from previous findings. In contrast, a subset of later areas (V3A, MT) showed consistent sensitivity to motion coherence, but earlier areas (V1-V3) did not. The neural response to motion coherence in our data appeared as an increasing function of stimulus coherence, consistent with previous models of MT neural responses (Rees et al., 2000; Simoncelli and Heeger, 1998). Our data confirm that even when attention is directed away from stimuli, MT and V3A parametrically increase response as a function of motion strength. Independently manipulating contrast and motion coherence allows for experimental designs to study how these two ways of changing the strength in visual stimuli determine motion perception.

Title: Synergistic encoding of multiple visual features in MT neurons and implications for natural vision

Authors: *M. V. MACELLAIO, B. LIU, L. C. OSBORNE;
Neurobio. Dept., Univ. of Chicago, Chicago, IL

Abstract: Most sensory neurons encode information about more than one stimulus parameter, complicating the brain's decoding task. For example, neurons in cortical area MT encode both object motion direction and speed, and the brain must seemingly obtain independent estimates of both in order to guide behavior. Here we examine the computational consequences and benefits of multiplexed sensory information in the context of direction and speed representation in MT. We performed extracellular single-unit recordings in area MT of monkeys performing a fixation task. Random dot patterns moved coherently within apertures scaled to the classical receptive field size. We generated 2D direction-speed, direction-time, and speed-time tuning curves for each neuron from motion steps with pseudorandom direction-speed pairings. We also computed the information about direction, speed, and time encoded by each unit collectively and individually. We find that the encoding is synergistic, meaning that more information is encoded about combinations of variables, e.g. direction+speed, than the sum of the information about each individually. Synergy is often thought to arise based on anisotropies in feature selectivity, such that the tuning for one parameter is influenced by the value of the other. However, we find that the direction-speed tuning for most MT units is separable over the first 200ms of their response to a motion step (index values > 0.95). In comparison, 2D direction-time and speed-time tuning is much less separable (index values > 0.6). Contrary to intuition, separability and synergy are anticorrelated, as we demonstrate analytically with Poisson models. Temporal patterning within spike trains also cannot account for our result: although two-spike synergy is present, it is a small contribution. We find evidence that the brain uses synergy to its advantage by decoding direction and speed jointly to drive smooth pursuit eye movements, causing local fluctuations in eye direction and speed to be correlated. Joint encoding of direction, speed, and time may also benefit motion perception in natural vision: we discover that MT cells preferentially code for qualities of natural motion, especially changes in direction and speed.

Title: Neural response to object motion-in-depth independent of vergence eye movements

Authors: *A. WADA[1,2], Y. SAKANO[1,2], H. MIZUSHINA[3], H. ANDO[1,2];
[1]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Info. and Communications Technol., Suita, Japan; [2]Grad. Sch. of Frontier Biosci., Osaka Univ., Suita, Japan; [3]Grad. Sch. of Sci. and Technol., Tokushima Univ., Tokushima, Japan

Abstract: Perceiving an object moving toward or away from self has ecological importance including avoidance of approaching objects. The retinal image contains motion components derived by both the object's actual motion and self-originated movements (e.g., eye movements). Therefore, a computation to dissociate these different sources of retinal motion is necessary to accurately perceive object motion in the external world. The current study investigated the still unexplored neural mechanism underlying the detection of object motion in the depth dimension. We conducted a preliminary fMRI experiment, aimed at identifying neural responses to object motion-in-depth defined by binocular disparity that are invariant to the presence of vergence eye movement. Object motion stimuli were random dots that sinusoidally oscillated in depth provided by changes in binocular disparity. We also controlled vergence eye movement, of which target trajectory in depth was set identical to that of random dots to cancel the retinal motion induced by object motion. The experimental paradigm of Fischer et al. (2012) was adapted, in which the presence of each of the object motion and eye movement were combined to yield four experimental conditions: (A) object motion with vergence, (B) no object motion with vergence, (C) object motion without vergence, and (D) no object motion without vergence conditions. Here, retinal motion induced by either vergence or object motion was present in conditions B or C, respectively. On the other hand, retinal motion was either canceled by vergence or absent in conditions A or D, respectively. The design enabled us to separately identify the effect of object (A and C vs. B and D) and retinal (B and C vs. A and D) motion-in-depth. Six normal subjects (four males) participated in the fMRI experiment. We also ran two functional (motion and retinotopic) localizer experiments to identify visual areas V1, V3A, V3B, and hMT+. A region-of-interest analysis identified significant effect of both object and retinal motion-in-depth in V3A, V3B, and hMT+, whereas only V3A among the assessed regions exhibited a significantly larger effect of object compared to retinal motion-in-depth. In contrast to previous studies that reported the involvement of hMT+ in estimating visual motion-in-depth from binocular information, our present results may further suggest a distinct role of V3A in computing object motion-in-depth by discounting the retinal motion component originating in vergence eye movements.

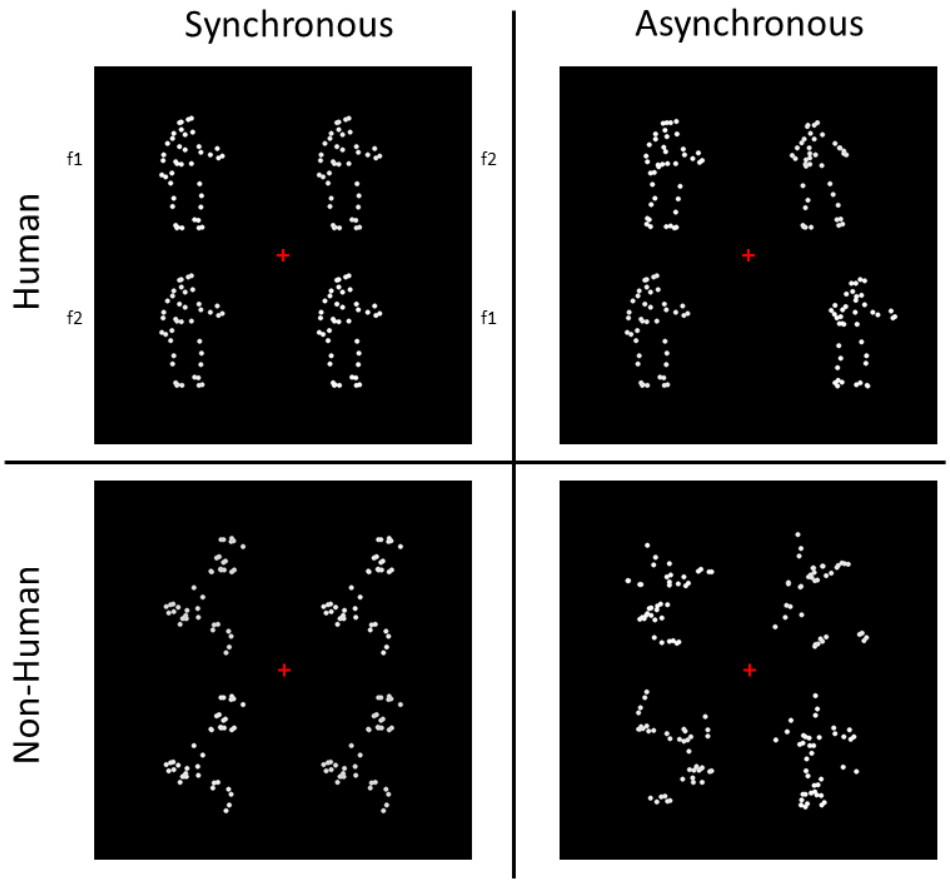
Title: Synchronous human motion is processed by two distinct mechanisms in the brain

Authors: *N. ALP[1], A. NIKOLAEV[2], N. KOGO[2], J. WAGEMANS[2];
[1]Lab. of Exptl. Psychology, [2]KU Leuven, Leuven, Belgium

Abstract: The brain has dedicated networks for perception of motion synchrony and perception of interacting human bodies. However, it is not clear to what extent the corresponding perceptual processes in the visual system are similar or distinct. Here, we manipulated the temporal coherence of the motion patterns (synchronous vs asynchronous) and the biological agency (human vs non-human) of the multiple point-light displays (PLDs) in a 2X2 experiment.



For this purpose, the frequency-tagging technique was applied in combination with EEG recording. In the synchronous human motion condition, the motions of the PLDs were synchronous as in a group of dancers. In the asynchronous human motion condition, this synchronous motion was destroyed by starting each PLD with a different frame. In the synchronous non-human motion condition, we used identical cluster-shuffled PLDs, which started their motion from the same frame and followed the same motion sequence. In the asynchronous non-human motion condition, we used different cluster-shuffled PLDs and each cluster started their motion from different frame and followed a different motion sequence. The luminance intensity of the point lights was modulated with different frequencies for the different PLDs (PLD1=f_1 and PLD2=f_2 and vice versa). In the frequency spectrum of the steady-state visual evoked potentials, we found two emergent frequency components, which suggested distinct mechanisms for different levels of interactions between PLDs. The integration of motion synchrony is reflected in the second-order component (f_1+f_2) while the integration of multiple human configurations was found in the third-order component ($2f_1+f_2$). These findings suggest that the process of integrating the visual information of motion synchrony is distinct from the integration process of multiple human bodies. We speculate that the differentiation on frequency order may reflect that integration based on synchronous
motion happens at a lower level, while integration based on human configuration happens at a higher level.

Title: GABA and visual context processing in autism spectrum disorders

Authors: ***M.-P. SCHALLMO**, A. V. FLEVARIS, A. M. KALE, R. A. BERNIER, S. O. MURRAY;
Univ. of Washington, Seattle, WA

Abstract: Previous work has demonstrated altered visual processing in autism spectrum disorders (ASD). Notably, individuals with ASD have shown substantially reduced motion duration thresholds (measured psychophysically) compared to neuro-typical (NT) observers. We replicated this finding using an unmedicated sample of young adult ASD and NT participants. Further, we show how the standard normalization model of early visual processing can account for these psychophysical results. Specifically, the model suggests reduced normalization strength in ASD, a proposal that is consistent with prominent excitation/inhibition hypotheses of ASD. We further investigated the possible role of the neurotransmitter γ-aminobutyric acid (GABA) by using magnetic resonance spectroscopy to measure GABA concentrations in medial occipital lobe (early visual cortex), lateral occipital lobe (including area MT), and dorsal parietal lobe (sensorimotor cortex). While our preliminary results showed that overall GABA concentrations did not differ between ASD and NT in any region, we did find that across all subjects, the strength of spatial context effects in our motion discrimination task correlated with the concentration of GABA in lateral occipital cortex (but not in other regions).

Title: Effects of stimulus size and contrast on motion perception: Comparing psychophysics and fMRI

Authors: *A. V. FLEVARIS, M.-P. SCHALLMO, A. KALE, S. O. MURRAY;
Dept. of Psychology, Univ. of Washington Dept. of Psychology, Seattle, WA

Abstract: In a well-known effect of spatial context, more time is needed to discriminate the direction of motion for a high contrast pattern as its size increases. It has been proposed that this effect reflects surround suppression in area MT, whereby stimulation in the surround of the classical receptive field (CRF) suppresses the response to a stimulus in the CRF, making it more difficult to perceive. At low contrast, on the other hand, increasing stimulus size reduces the amount of time necessary to discriminate motion. This effect is assumed to reflect spatial summation in MT, wherein larger stimuli evoke an enhanced response. In order to link these psychophysical effects to the underlying neural mechanisms, we compared psychophysical motion duration thresholds to high (98%) and low (3%) contrast drifting gratings with fMRI responses to the same drifting gratings. Gratings were presented in three different sizes: 1°, 2°, and 12° in diameter. In the psychophysical task, participants reported the direction of motion of the grating and stimulus duration thresholds were measured for each contrast and stimulus size. In the fMRI experiment, participants ignored the stimuli and instead attended to a stream of shapes at fixation and pressed a button whenever a target shape appeared. Stimulus conditions were blocked and percent signal change was measured for each contrast and stimulus size in visual areas MT and V1. MT and V1 were each localized separately for each participant. Psychophysically, we replicated prior results showing suppression at high contrast and summation at low contrast. The fMRI results in areas MT and V1 were similar to psychophysical results overall but showed distinct patterns between areas. In V1, we found suppression at high contrast, but we did not see summation at lower contrast. In MT we found summation at low contrast but no evidence of suppression. These results suggest that the differences in motion perception across stimulus size may not be explained solely by activity in area MT. Instead, a combination of activity across areas including V1 and MT may underlie the psychophysical effects.

Title: Response properties of global motion sensitive neurons in the zebra finch vestibulocerebellum

Authors: ***A. H. GAEDE**, D. L. ALTSHULER;
Zoology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Visual guidance is a key component of avian flight that has been relatively unexplored. A flying bird perceives large-field visual motion, or global optic flow, as it moves through its environment, and this strong visual signal is processed in the accessory optic system. This signal is passed from the retina to two midbrain nuclei, one of which, the lentiformis mesencephali (LM) is hypertrophied in hummingbirds, suggesting an important role in stabilization. Information from the LM converges in the cerebellum; the LM projects both directly and indirectly (via a climbing fiber pathway through the medial column of the inferior olive) to the vestibulocerebellum, providing an expedited route from eye to premotor areas. Extensive research in the pigeon vestibulocerebellum has revealed parasagittal functional zones that can be identified with neurochemical staining and responses to global motion. Complex spike activity of Purkinje cells in the flocculus (lateral regions) of the vestibulocerebellum responds to optic flow resulting from self-rotation about the vertical or horizontal axes. Because zebra finch LM neurons prefer higher pattern velocities than pigeons and have a broader speed tuning width than hummingbirds, we hypothesized that further velocity tuning occurs in the zebra finch flocculus. Using standard electrophysiological techniques and computer-generated stimuli (a single plane of random dots), we characterized the response properties of these motion-sensitive cells in the flocculus of zebra finches (*Taeniopygia guttata*), which are small birds that do not hover and do not have a hypertrophied LM. As in pigeons, we found that zebra finch complex spike activity in the flocculus is directionally selective, as demonstrated by increased firing in response to motion in the preferred direction and suppression of spontaneous firing in the anti-preferred direction. Furthermore, we found that climbing fiber-mediated complex spike activity is tuned to visual stimulus velocity. In this study, we examine the distribution of preferred velocities in the flocculus, as well as the width of the velocity-tuning

response. In zebra finches, the speed tuning width of complex spike activity was narrower than the speed tuning width of LM cells. Furthermore, the preferred velocity of optic flow sensitive Purkinje cells recorded in the flocculus extended across a lower range than that of the LM. The level at which velocity tuning to a given visual stimulus occurs could differ across avian species that have different flight behaviors. How the climbing fiber-mediated response to visual stimuli in the flocculus compares to the response in the LM has yet to be investigated.

Title: Voluntarily tracking moving clouds Effects of spatial frequency bandwidth on human smooth pursuit

Authors: ***K. MANSOUR POUR**[1], L. PERRINET[2], G. MASSON[2], A. MONTAGNINI[2];
[1]Neurosciences, CNRS, Inst. De Neurosciences De La Timone, marseille, France;
[2]Neurosciences, Inst. de Neurosciences de la Timone, UMR7289, CNRS & Aix-Marseille Univ., marseille, France

Abstract: The properties of motion processing for driving smooth eye movements have been extensively investigated using simple, artificial stimuli such as gratings, small dots or random dot patterns. We know however very little about this processing in the context of complex, natural images. We have previously investigated the human ocular following responses to a novel class of random texture stimuli of parameterized naturalistic statistics: the *Motion Clouds*. In Fourier space, these dynamical textures are designed with a log normal distribution of spatial frequencies power multiplied by a pink noise power spectral density that reduces the high frequency contents of the stimulus (Sanz-Leon et al. 2011). We have previously shown that the precision of reflexive tracking increases with the spatial frequency bandwidth of large (>30° diameter) patterns (i.e. the width of the spatial frequency distribution around a given mean spatial frequency; Simoncini et al. 2012). Now, we extend this approach to voluntary tracking and focused on the effects of spatial frequency bandwidth upon the initial phase of smooth pursuit eye movements. Participants were instructed to pursue a large patch of moving clouds (mean speeds: 5, 10 or 20°/s) embedded within a smoothing Gaussian window of standard

deviation 5°. The motion stimuli were presented with four different spatial frequency bandwidths and two different mean spatial frequencies (0.3 and 1 cpd). We observed that smaller bandwidth textures exhibit a stronger spectral energy within the low spatial frequency range (below 1cpd), yielding to shorter latency of smooth pursuit eye movements. A weak and less consistent effect was found on initial eye acceleration, contrary what was previously observed with OFR. After 400ms, the steady-state tracking velocity matched the mean visual motion speed and pursuit performance was comparable with that observed with a control, small dot motion. Motion clouds offer an efficient tool to probe the optimal window of visibility for human smooth pursuit through the manipulation of both the mean and the variability of spatial frequency.

Title: High spatial frequency components of white noise stimuli suppress initial disparity-vergence responses in humans

Authors: ***B. M. SHELIGA**, C. QUAIA, E. J. FITZGIBBON, B. G. CUMMING;
Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: We recorded horizontal disparity-vergence responses (DVRs) to vertical 1D noise stimuli, and vertical DVRs to horizontal stimuli, in two human subjects. For a given disparity we compared DVRs to white noise with those to white noise after removing certain spatial frequency (SF) bands (central SF values varied from 0.0625 to 4 cpd; Gaussian envelope on log scale), and to stimuli containing only those SF bands. Removing low SF components *reduced* DVR magnitudes (measured as total displacement in the first 50ms of the response), and the SFs associated with the greatest reduction were close to those that produced the maximal response when presented alone. This suggests that low SF components contribute to the DVR drive. In contrast, removing higher-SF components *increased* DVR magnitudes. This suggests that high SF components suppress the DVR. These components presented alone produced small responses. As disparity increased, the optimal SF for both effects - reduction and increase - shifted towards lower SFs. We previously demonstrated a similar phenomenon in ocular following produced by

moving noise stimuli. There the effect of high SFs could be explained as an artifact of discrete temporal sampling by the display, since high SF components moved with high temporal frequencies. Such an explanation cannot be applied to disparity, and so these results suggest that the suppression produced by high SFs is not an artefact, but reflects a computation that is applied in natural viewing. After the initial 50ms the effect of high SF components reverses - removing them reduces the late response - indicating that the interaction between SF components changes over time. This may reflect "Coarse to Fine" processing of disparities.

Title: The neural mechanisms in MST underlying Pinna- Brelstaff rotational visual illusions

Authors: ***J. LUO**, X. LI, K. HE, J. YIN, I. ANDOLINA, Y. GU, W. WANG;
Inst. of Neurosci., Inst. of Neurosci., Shanghai, China

Abstract: The Pinna illusion is a striking example of the perception of rotation in the absence of real physical motion. Upon physically approaching or receding from the Pinna-Brelstaff figure, the observer experiences vivid illusory counter rotation of the figure. This visual phenomenon of illusory rotary motion is a well-known example of integration of local cues to form a global percept. Using psychophysical tests and functional magnetic resonance imaging (fMRI) of visual cortices V1-V4v, MT, and MST of the dorsal and ventral visual pathways, we recently found that the Pinna-Brelstaff figure (illusory rotation) and a real physical rotation control stimulus both predominantly activated subarea MST in hMT+, each with a similar response intensity. However, the detailed neural mechanisms underlying the Pinna illusory rotation remain unknown. By manipulation of the physical characteristics of the Pinna-Brelstaff figure, we could generate 3 types of illusory motion: rotation, expansion and contraction. We performed single-unit recordings of MST in awake macaques, and found that up to two-thirds of MST neurons encode these illusory motions, the majority of whose responses corresponded to illusory expansion and contraction. The tuning preferences of these MST neurons were similar between conditions of real and illusory motions. We have preliminary data in recording neural responses

to the same stimulus in area V5/MT, and found only weak responses which predominantly related to real motion components. These results confirm that neurons in area MST respond equivalently to illusory or real rotations, expansions and contractions. Together all these findings suggest that the representation of illusory and real complex motion fields in primate MST relies on a similar cascade of neural integrative mechanisms as physical motion from earlier visual areas.

Title: Optic flow parsing in macaque monkeys

Authors: ***N. E. PELTIER**[1], D. E. ANGELAKI[3], G. C. DEANGELIS[1,2];
[1]Brain and Cognitive Sci., [2]Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY; [3]Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: As we move through the world, our retinas are presented with a structured pattern of motion called optic flow. Typically, optic flow reflects some unknown combination of object motion and self-motion. It is essential to separate the sources of retinal motion in order to interact with objects and avoid obstacles as we navigate. A simple scheme that explains how we compensate for self-motion when estimating the motion of independently moving objects is called optic flow parsing (e.g., Warren and Rushton, 2009, Curr. Biology). According to the flow parsing hypothesis, we can detect the motion of an object relative to the world by identifying motion vectors that are inconsistent with the global pattern of optic flow due to self-motion. As a result, we can estimate object motion in the world by subtracting out the retinal motion that results from self-motion. The flow parsing hypothesis uniquely predicts perceptual biases that are not predicted by other models, and its mechanism is simple enough to be feasibly implemented by neurons. However, the neural mechanisms of flow parsing remain unknown. To explore neural correlates of flow parsing, we trained macaque monkeys to perform fine

discrimination of object motion (left or right relative to vertical), and we presented object motion together with optic flow fields that simulated forward self-motion, backward self-motion, or no self-motion (0% coherence). The monkey's perception of object motion was systematically biased by the presence of background optic flow, consistent with flow parsing. When we masked the optic flow surrounding the object, the bias in perceived object motion was slightly decreased but not extinguished. Even when optic flow was masked in the entire hemifield surrounding the object, we still observed systematic biases due to the direction of simulated self-motion. This suggests that the monkey may infer a global optic flow field and subtract the inferred optic flow vectors around the object to compute object motion.
Because flow parsing entails the subtraction of different motion vectors in each part of the visual field, we hypothesized that neural correlates of flow parsing may appear in retinotopic visual areas containing a motion map, such as the middle temporal (MT) area. We recorded neural activity from MT neurons, using 24-channel V-Probes, while the monkey discriminated object motion during simulated self-motion. Preliminary neural results show that the responses of some MT neurons to object motion are modified by the direction of self-motion simulated by optic flow. Our findings establish a robust animal model of flow parsing, and suggest that area MT may be part of the underlying neural mechanisms.

Title: Training alters the causal contribution of area MT to visual motion perception

Authors: ***L. D. LIU**[1], C. C. PACK[2];
[1]Neurol. and Neurosurg., [2]Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada

Abstract: Visual stimuli elicit neural activation in a large number of distinct cortical areas. In principle, visual perception could arise from a distributed process that combines information across these areas, or it could rely exclusively on the areas that are most specialized for each stimulus. We have examined these possibilities, using single-unit recording, reversible

inactivation, and microstimulation of the middle temporal (MT) area, while monkeys performed a motion discrimination task. Area MT of the visual cortex is highly specialized for processing visual motion.
Monkeys were trained to report the direction of motion of a moving grating, which has been shown to be represented in many different visual cortical areas. Following this training, fluctuations in single units MT activity showed little correlation with the animals' choices. Moreover, reversible inactivation of MT, using muscimol injections, had little effect on behavioral performance (22% increase in psychophysical thresholds). Microstimulation had a small, but significant bias on the monkeys' choices toward the preferred directions of the stimulation sites, and at the same time decreased the slope of the psychometric functions. These results suggest that the brain uses a distributed representation to make perceptual decisions, so that area MT is not necessary for motion perception of a moving grating.
The same monkeys were then trained over several weeks to report the motion direction of random dots embedded in noise. This stimulus elicits far stronger direction selectivity in MT than in most other areas, suggesting that it is a specialized probe of MT; as in previous studies, we found that MT inactivation devastated behavioral performance for this stimulus. Surprisingly, training on the dots task led to dramatic changes in the relationship between area MT and perceptual decisions. First, there was a significant increase in the correlation between MT neuronal selectivity and choice probability in single-unit responses to gratings. Second, following dots training muscimol injections led to a very large decrease in performance on the grating motion task (500% increase in psychophysical threshold). Finally, the bias induced by microstimulation was larger and the decrease in the slope was smaller than before training on the dots task.
Together, these results suggest that the readout of sensory information depends strongly on perceptual experience: Even for tasks that involve a common stimulus feature (e.g., motion), perceptual decisions can rely on different brain regions for different types of stimuli, consistent with the idea of a flexible, distributed process.

Title: Localization and functional characterization of human area prostriata using fMRI

Authors: *H. YAMAMOTO[1], Z. LIN[2], K. OKAMOTO[2], S. OHNO[4], S. KANAZAWA[3], J. WU[2];
[1]Kyoto Univ., Kyoto 606-8501, Japan; [2]Grad. Sch. of Natural Sci. and Technol., [3]Grad Sch. of Medicine, Dentistry, Pharmaceut. Sci., Okayama Univ., Okayama, Japan; [4]Dept. of Radiology, Okayama Univ. Hospital, Okayama Univ., Okayama, Japan

Abstract: In monkeys, the area prostriata is a small limbic region located between the anterior calcarine fissure and hippocampal formation. Although its function has been elusive since its description by Sanides (1969), a recent study on monkeys demonstrated its visual responsiveness, especially to high-speed visual motion stimuli appearing in the far periphery. The purpose of the present study was to find a human homolog of the area prostriata. To this end, we used functional magnetic resonance imaging (fMRI) in conjunction with a custom-made wide-field visual display system to investigate brain responses to visual motion in the far peripheral visual field.
Two types of experiments were conducted using 20 subjects. The first experiment was designed to locate the area prostriata. In a scanning run, moving bars (5-55°) were presented in the periphery with alternating static bars in a standard block-design paradigm. Throughout the scanning run, the subjects were required to perform a rapid serial visual presentation (RSVP) task at the fovea, in which a target letter had to be detected among distractor letters. In the second experiment, we employed a rapid event-related design to assess functional properties of the area prostriata with regard to its receptive field, speed tuning, and attentional processing. Visual stimuli were either high- (60°/sec) or low- (20°/sec) speed moving bars presented at eccentricities either 5-25° or 40-60°, leading to four trial conditions. One of the four stimuli was presented in each trial and the subjects were required to perform the central RSVP task during half of the scanning runs. In the other half of the scanning runs, the subjects were required to detect abrupt changes in motion.
The localizer experiment showed, as expected, that peripheral motion stimuli evoked responses in visual areas MT+ and V6, as well as in the periphery of V1. In addition to these areas, we found a robust activation in a small limbic region located at the isthmus of the cingulate gyrus. In view of its anatomical location, this region may be the human homolog of the area prostriata. According to the results of the second experiment, the human prostriata tended to show larger responses to far peripheral and high-speed motion stimuli, similar to what has been observed in monkeys. Interestingly, the human prostriata displayed a unique property regarding attention: its activity increased, not in the motion-detection task, but in the RSVP task, which is in clear contrast to attentional processing in MT+ and V6. These results help in understanding the visual cortical network necessary for peripheral vision and the functional roles of the human area prostriata.

Title: Pupillary response to objects and perceived motion.

Authors: *S. BEUKEMA[1], B. JENNINGS[2], J. OLSON[3], F. KINGDOM[2];
[1]Neurosci., [2]Ophthalmology, [3]Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: In two experiments investigating pupil-size changes to objects and textures, pupillary response differences were observed between various conditions. Experiment 1 had participants passively view static images that contained textures perceived as inherently static, or inducing a strong sensation of (illusory) motion. Despite literature reporting pupillary constrictions to the perception of coherent physical motion, our results indicate a pupillary dilation to the illusory motion textures as compared to the perceptually static textures - potentially implicating differences arising from tangible vs. intangible perceptual states. Experiment 2 had participants view images with elements forming objects, non-objects, and random patches. A greater pupillary dilation response was observed for the perception of objects relative to the other conditions, potentially outlining the recruitment of high-level cognition for top-down semantic processes inherent in object-recognition. Together, these experiments further highlight pupillometry as a useful means to explore high-level visual processes through the identification of physiological pupil-size differences to distinct perceptual states.

Title: A biologically-based computational model to deliver unambiguous motion information and overcome the X-junction illusion

Authors: P. ZAREI ESKIKAND[1], T. KAMENEVA[1], *M. R. IBBOTSON[2], A. BURKITT[1], D. GRAYDEN[1];
[1]Electrical and ELectronic Engin., Univ. of Melbourne, Melbounre, Australia; [2]Natl. Vision Res. Inst., Melbourne, Australia

Abstract: The end-points of an object, called intrinsic terminators, represent unambiguous motion information. They assist in overcoming the aperture problem and achieving an accurate estimation of motion in area MT of the visual cortex [1]. However, the extrinsic terminators formed at the intersection of two overlapping objects themselves result in ambiguous motion signals [1]. We investigate, using a computation model, how interactions between form and motion information may assist MT neurons to differentiate intrinsic from extrinsic terminators. The motion model has two stages: a model of V1 neurons, including standard complex neurons and end-stopped neurons, and MT, which has integration and segmentation neurons. Integration MT neurons propagate the motion information through excitatory interconnections from the terminators of the stimulus along the object. Segmentation neurons control the activity of the integration neurons by responding to the discontinuities in the stimulus and suppressing the activity of integration neurons via inhibitory connections. In the proposed model, MT neurons additionally receive form information from bipole neurons in V2. These neurons have two extensive receptive fields that result in the perception of coherency when both parts of the receptive fields are active simultaneously [2]. There are inhibitory interactions between bipole neurons that have receptive fields with opposite orientations, which suppress the activity of bipole neurons when an apparent terminator is formed by overlapping objects [1]. The excitatory connections between MT neurons are activated when the corresponding bipole neurons at the same locations are active. Therefore, motion signals are propagated along the orientation of an object when the corresponding bipole cells are active. In the case of an X-junction formed by two crossing bars moving in opposite directions, bipole cell activity is suppressed, which prevents the propagation of the ambiguous motion information from the extrinsic terminators. The results show that, despite the inability of end-stopped neurons to distinguish two different types of terminators, bipole neuron activity at the intrinsic terminators results in an accurate representation of motion by MT neurons. 1. Title: Retinal stabilization reveals limits of efference copy influence on heading tuning in the medial superior temporal area (MST)

Authors: ***T. MANNING**, K. BRITTEN;
Univ. of California, Davis, Davis, CA

Abstract: The use of optic flow information in the calculation of heading direction and guidance of self-motion has been well established over the past few decades by a number of neurophysiological, computational, and behavioral studies. Eye movements performed while the body is moving, however, substantially distort the optic flow patterns falling on the retina. Observers are able to compensate for these movements perceptually, but the mechanism by which this occurs is unknown. One hypothesis for which there is psychophysical support states that heading representations are stabilized by efference copy signals related to ongoing eye movements. To test this hypothesis at the physiological level, we performed single-unit recordings from neurons in MST while a monkey performed a smooth pursuit task. Neurons in this region are selective for both the direction of heading and eye rotation, and their activity has been causally linked to the perception of heading. In the task, the animal fixated or pursued a small target in a virtual reality environment that simulated different observer translations through a three-dimensional cloud of dots. To reveal the presence of efference copy signals, two manipulations were made to the visual stimulus. First, we simulated the optic flow distortions on the retina that result from pursuit while the monkey fixated a stationary target. This stimulus is retinally identical to what results from translation with pursuit, but eliminates efference copy signals. Second, we counteracted the retinal effects of pursuit by counter-rotating the virtual camera using feedback from a scleral search coil eye tracker. This feedback system performed at frame rate (120 Hz) with a fixed single-frame lag. This manipulation produces a retinal stimulus identical to the one resulting from translation with fixation, but efference copy signals related to

pursuit would remain active. Based on the analysis of a preliminary sample of neurons, we find that both manipulations substantially change their responses to heading tuning in MST. The simulated and stabilized pursuit conditions resulted in opposite shifts of the neurons' preferred heading directions from the normal pursuit case. As expected from previous work, simulated pursuit produced substantial shifts in tuning in the direction of pursuit. Tuning under stabilized pursuit, however, closely matched the cells' preference while the eyes were stationary. These results suggest there is only a modest direct modulatory role of efference copy signals in area MST.

Title: Functional analysis of visual responses with an ultra high filed MRI in awake marmorets

Authors: *T. KANEKO[1], J. HATA[1], N. KISHI[1], H. OKANO[2,1];
[1]RIKEN Brain Sci. Inst., Wako, Japan; [2]Dept. of Physiol., Keio Univ. Sch. of Med., Shinano-machi, Japan

Abstract: Growing interest in viral and genetic manipulations on non-human primates brings neuroscientists' attention to marmosets(*Callithrix jaccus*), as their high reproductive efficiency and easy husbandry cost comparing to other primates. However, question remains to what extent the brain of marmosets shares functional architecture with that of other primates, such as humans and macaques. This is not only important to utilize marmosets as a model to develop therapeutic strategies for human psychiatric/neurological disorders, but also to understand the evolution of primate brain. Functional MRI is most suitable to this question as it allows whole brain analysis and also can accommodate various kinds of cognitive tasks. The goal of the present study was to develop functional MRI setup for awake animals, and to demonstrate feasibility of our system. We developed 8-channel phased array coil which was compatible to head-post system to restrain head motion of animals. Visual stimulus was presented on a screen located inside the scanner by which relatively large visual field (about 42 degree) can be stimulated. With this setup, we observed robust blood oxygen level dependent signal by visual stimulation. Significant signal

change was observed throughout various parts of cortical and subcortical areas. Most of these areas correspond with predictions derived from putative anatomical homology to other primate species. We also mapped visual motion sensitive areas by computing the contrast between static and drift grating stimulus. Visual motion activated at MT complex, and the activity extended to rostral on ventral part of lateral surface of the temporal cortex. The observed functional segregation at the temporal lobe is similar to those of other primate species such as macaques and humans. We also observed that foveal V1 showed biased activation to static stimulus, while peripheral V1 was activated more by motion stimulus. These features correspond well with reported physiological property of this area in macaques. Furthermore, we have not observed motion selective response around putative V2 and V3 so far. This is distinctive from the results of macaques, and might suggest the functional difference of these early visual areas among species. In summary, these results demonstrated the potential of the developed system to create functional map of the marmosets' brain at macro-level perspective, and to elucidate similarity and dissimilarity of functional architecture among primate species.

Title: Neurons in macaque area MT signal depth from motion parallax by combining extra-retinal signals regarding both eye and body rotation

Authors: ***V. KOGAN**[1], D. E. ANGELAKI[2], G. C. DEANGELIS[1];
[1]Brain and Cognitive Sciences, Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY; [2]Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Motion Parallax (MP) refers to the relative image motion of objects located at different depths, caused by the translation of the observer. In the absence of pictorial depth cues, MP is ambiguous regarding depth sign (near vs. far). Theoretical work by Nawrot and Stroyan (2009) showed that the critical variable for disambiguating depth sign from MP is the rate of change of eye rotation relative to the scene (R_{es}), which is determined by the combination of eye rotation relative to the head (R_{eh}), head rotation relative to the body (R_{hb}), and body rotation relative to the world (R_{bw}): $R_{es} = R_{eh} + R_{hb} + R_{bw}$.

We showed previously (SfN, 2015) that macaques can discriminate depth sign from MP under some combinations of R_{eh} and R_{bw} that produce the same R_{es} ($R_{hb} = 0$ by design). Discrimination performance was robust when R_{eh} and R_{bw} had the same sign, mostly robust for when $R_{es} = R_{bw}$ ($R_{eh} = 0$), and quite erratic when R_{eh} and R_{bw} had opposite signs. This suggested that the brain relies on both R_{eh} and R_{bw} signals to disambiguate depth from MP, but that these signals are not ideally combined into an estimate of R_{es}.
Neurons in macaque area MT combine retinal image motion with extra-retinal signals regarding R_{eh} to signal depth sign from MP (Nadler et al., 2008, 2009). It remains unclear, however, whether MT neurons also incorporate vestibular rotation signals (R_{bw}) to compute depth sign. We recorded from single MT neurons while animals were translated back and forth by a motion platform. The animal's task was solely to maintain fixation on a world-fixed target, making smooth eye movements as needed. The motion platform could rotate the whole body around an axis through the eye, to generate various combinations of R_{bw} and R_{eh} that produce the same R_{es} ($R_{hb} = 0$ in all cases). In all conditions, image motion of a patch of random dots simulated a surface that appeared at one of several different depths, and we measured depth tuning curves of MT neurons under various combinations of R_{bw} and R_{eh}.
Preliminary results show that MT neurons use both vestibular rotation signals (R_{bw}) and eye rotation signals (R_{eh}) to compute depth sign from MP. Analogous to behavioral data measured separately, MT neurons have only slightly reduced depth-sign selectivity when $R_{es} = R_{bw}$ ($R_{eh} = 0$), indicating that vestibular rotation signals alone can generate selectivity. However, neural depth-sign preferences reverse (and weaken slightly) when eye and body rotations are in opposite directions (opposite signs of R_{bw} and R_{eh}), indicating that eye rotation signals dominate. Our findings show that neural computations of depth from MP incorporate both efference copy signals regarding eye rotation and vestibular signals regarding body rotation.

Title: Visual processing of motion-selective information in the larval zebrafish brain

Authors: *C. RIEGLER[1,2], D. GUGGIANA-NILO[1], F. ENGERT[1];
[1]Harvard Univ., Cambridge, MA; [2]Univ. of Vienna, Vienna, Austria

Abstract: The vertebrate retina extracts spatiotemporal features of the visual environment and diverse retinal ganglion cell (RGC) types carry extracted information into the brain. We studied how and where the direction of object motion, a behaviorally relevant feature, is represented, and further processed, in the retinorecipient arborization fields(AFs) of larval zebrafish. First, we created a functional map that describes the response properties of the RGCs that project to each AF. Of the 10 AFs, the largest is the optic tectum (homologous to the mammalian superior colliculus) and in addition there are 9 smaller AFs. Using 2-photon microscopy and GCaMP6 targeted to synaptic terminals, we recorded from all RGC terminals while showing behavior-relevant directional visual stimuli. One such visual stimulus was whole-field motion, which triggers the optomotor response. In this behavior fish turn their body and swim in the direction of perceived motion. Direction selective information is thus necessary for calculating the direction of perceived motion. Similarly, visually driven escape responses, triggered by an approaching black edge, lead to directed escape turns away from the edge. Therefore both behaviors require direction selective information. We found that the majority of OFF, ON and ON-OFF direction selective terminals are located in the optic tectum and one extratectal area termed arborization field 6 (AF6). Given this exclusivity, we asked if the same population of RGCs projects into both retinorecipient areas. Targeted laser ablation of individual AFs shows at least one subset of direction selective RGCs that both, projects to the posterior AF6, and is also responsible for conferring directional selectivity to the posterior optic tectum. Finally, the same ablation impairs all turning behaviors to whole-field visual motion but has a lesser effect on directed escape responses. These findings establish the entry into two different behavioral circuits that require similar but not identical directional information.

Abstract: Due to their immature stage at birth, ferrets have become an important animal model for the study of visual system development. So far, most studies have focused on lower visual processing stages such as primary visual cortex (V1), leaving the functional development of higher order areas unexplored. Here, we begin to address this issue by investigating higher order area PSS.
PSS is located in the posterior bank of the suprasylvian sulcus. Previous studies demonstrated a high degree of direction selectivity in PSS, and impaired motion detection after PSS lesions. However, without determining responses to more complex motion stimuli, it remains an open question whether PSS indeed is a higher order motion area. In a first set of experiments, we therefore tested PSS responses to stimuli designed to reveal signatures of higher order motion processing. We chose two stimulus sets commonly used to compare processing in macaque areas V1 and MT, coherent plaids and transparent motion stimuli. Both test the integration of local motion signals. Plaids are constructed by superimposing two component gratings drifting in different directions. Perceptually, they appear as a coherent plaid drifting in a third direction. Our data demonstrate that neurons in ferret V1 respond only to the motion of the component gratings. In contrast, PSS contains a population of neurons that respond to the motion of the plaid pattern. Transparent motion stimuli are generated by superimposing two fields of dots moving in opposite directions. Perceptually, they appear as two surfaces sliding across each other. V1 neurons were largely unaffected by the addition of a second field of dots, but responses in PSS neurons were suppressed under these stimulus conditions. Our data therefore reveal motion integration processes in PSS that exceed those found in V1, and suggest PSS as a higher order motion area.
As a first step towards studying PSS development, we determined the developmental time course of PSS direction selectivity. Our data show a rapid development of direction tuning after eye opening (P32-34), with mature selectivity levels reached by P36-38. This parallels the time course established for direction selectivity development in V1. Our data also suggest that direction selectivity is higher in PSS than V1 throughout development.
In conclusion, PSS provides an exciting opportunity to investigate the development of higher order visual functions. A better understanding of their development at the neural circuit level is critical, as these functions are often impaired in developmental disorders.

Title: Binocular contrast summation for visual motion processing in humans

Authors: *C. QUAIA, B. M. SHELIGA, L. M. OPTICAN, B. G. CUMMING;
LSR, Natl. Eye Inst., Bethesda, MD

Abstract: Binocular contrast summation, the advantage conferred by seeing a stimulus through two eyes instead of one, is usually quantified by the ratio (binocular gain) between the detection threshold for static stimuli viewed binocularly and monocularly. It typically ranges between 1.4 and 2. When matching higher contrasts, the binocular gain is usually close to 1.0 - one eye is as good as two. Here we quantify binocular summation for the motion signals that drive reflexive eye movements. We recorded, in three human subjects, the short-latency ocular following responses (OFRs) that are induced by the sudden motion of a large visual stimulus. First, we measured the contrast response functions (CRFs) for sinusoidal drifting gratings (0.25 cpd, 20Hz) presented monocularly or binocularly in a large (28 deg diameter) circular aperture. We found that the responses were always much stronger for binocular than monocular stimuli. Binocular gain was as high as 10 at low (2.5%) contrast, and asymptotically approached 2 at high (80%) contrast. Perceptual gains for contrast matching with the same stimuli were much lower, similar to values reported for static stimuli. Next, we measured the CRFs for 1D random line stimuli (RLS) drifting at high speed (40 deg/s). We used two binocular conditions, presenting either the same RLS to both eyes (correlated condition), or different RLS to the two eyes (uncorrelated condition). Again OFRs to the binocular stimuli were considerably stronger than those elicited by the monocular stimuli, and the binocular gain decreased as contrast increased. The responses to correlated stimuli were always strongest, with responses to uncorrelated stimuli falling between those to correlated and monocular stimuli. At the highest contrast, the binocular gain was 2 for correlated stimuli, and around 1.4 for uncorrelated stimuli. A very simple two-stage model fit the data well. The first, monocular, stage is characterized by a strong contrast gain control, similar to that of magnocellular neurons in LGN. The second (binocular) stage, sums the outputs of the monocular stages from each eye, and has an input-output relationship that is expansive at low inputs, and slightly compressive at high inputs (similar to that of cortical neurons). The responses to uncorrelated RLS at all contrast levels were well described by multiplying the monocular outputs by 0.65 before feeding them to the binocular stage. We conclude that, unlike for contrast perception, there is a strong binocular advantage for motion processing: two eyes are much better than one. This implies that different neural substrates subserve these two binocular summation processes.

Title: Human white-matter pathway communicating parietal and posterior-insular cortex

Authors: *H. TAKEMURA[1,2,3], M. UESAKI[2,4,5], H. ASHIDA[4];
[1]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communicatio, Suita-shi, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Grad. Abstract: Human brain comprises cortical regions selective for sensory information in parietal and posterior-insular cortex. Previous fMRI study has reported concurrent activations in parietal and posterior-insular cortex during visual optic-flow stimulation, suggesting that these areas may involve with the integration of visual and vestibular information for self-motion perception (Cardin & Smith, 2010; 2011). This study aimed to clarify how these areas communicate through white-matter pathways by combining functional and diffusion MRI. Using functional MRI, we identified the cortical regions activated by optic-flow stimulation in parietal and posterior-insular cortex (VIP, p2V, PcM, PIC) in six participants. We then analyzed diffusion MRI data collected from identical participants, by using Ensemble Tractography method (Takemura et al., 2016). We generated whole-brain connectome by combining the output of probabilistic tractography with four different parameter settings (MRtrix, Tournier et al., 2012), and optimized the connectome using Linear Fascicle Evaluation (Pestilli et al., 2014). We then identified the fascicles having one endpoint near parietal cortex and the other endpoint near posterior-insular cortex. As a result, we consistently identified the white-matter fascicle connecting parietal and posterior-insular cortex in all hemispheres we analyzed. The anatomical shape and location of this fascicles are consistent with the fascicle, named *Stratum Proprium of Interparietal Sulcus (SPIS)*, reported in classical and recent fiber dissection studies (Sachs, 1892; Vergani et al., 2014). Using Virtual Lesion method (Pestilli et al., 2014), we also identified significant statistical evidence in support of SPIS. Furthermore, we also found that SPIS endpoints are near to cortical regions activated by optic-flow stimulation in the parietal cortex (VIP, p2V, PcM) and posterior-insular cortex (PIC). Taken together, these findings suggest that the sensory regions in parietal and posterior-insular cortex communicate throughout the SPIS. The SPIS may support

sensory integration underlying self-motion perception, which requires visual and vestibular information represented in parietal and posterior-insular cortex.

Title: Integration of visual and extra-retinal self-motion during voluntary head movements in the human brain

Authors: *A. SCHINDLER[1,2,3], A. BARTELS[1,2,3];
[1]Ctr. for Integrative Neuroscience, Univ. of Tübingen, Vision and Cognition Lab., Tübingen, Germany; [2]Dept. of Psychology, Univ. of Tübingen, Tübingen, Germany; [3]Max Planck Inst. for Biol. Cybernetics, Tübingen, Germany

Abstract: Our phenomenological experience of the stable world is maintained due to continuous integration of visual self-motion with extra-retinal signals. This mechanism is not only essential for locomotion and navigation but also a crucial prerequisite for virtually any successful interaction with our environment. Constraints in fMRI acquisition methods previously prevented the study of neural processing associated to integration of visual signals with those related to head-movement. Here, we developed a novel and ecologically valid fMRI paradigm that enabled us to study integration of optic flow with extra-retinal heading signals while observers performed voluntary head movements. Our results provide first evidence for the multisensory integration of head-motion in human regions MST, VIP, the cingulate visual area (CSv) and a region in pecuneus (Pc) that are known to process visual self-motion signals. In addition, we found multisensory heading integration in posterior insular cortex (PIC) that we suggest to be homolog to monkey visual posterior sylvian (VPS). In contrast, no integration was found in parieto-insular-vestibular cortex (PIVC). These results identify for the first time head-movement related

integration of visual heading signals in the human brain, and identify a clear functional segregation of the human posterior insular cortex.

Title: Dopamine preserves visual motion perception despite noise interference of human V5/MT

Authors: ***B. M. SEEMUNGAL**[1], N. YOUSIF[2], R. Z. FU[2], B. ABOU-EL-ELA-BOURQUIN[2], V. BHRUGUBANDA[2], S. R. SCHULTZ[3];
[2]Brain Sci., [3]Bioengineering, [1]Imperial Col. London, London, United Kingdom

Abstract: When processing sensory signals, the brain must account for noise, both in the stimulus and that arising from within its own neuronal circuitry. Dopamine receptor activation is known to enhance both visual cortical signal-to-noise-ratio ('SNR') and visual perceptual performance, however it is unknown if these two Dopamine-mediated phenomena are linked. To assess this link we used single pulse transcranial magnetic stimulation (TMS) applied to visual cortical area V5/MT to focally reduce the SNR, and hence disrupt visual motion discrimination performance to visual targets located in the same retinotopic space. The hypothesis that Dopamine receptor activation enhances perceptual performance by improving cortical SNR predicts that Dopamine activation should antagonise TMS-disruption of visual perception. We assessed this hypothesis via a double-blinded, placebo controlled study with dopamine receptor agonists Cabergoline (D2 agonist) and Pergolide (D1/D2 agonist), administered in separate sessions (separated by 2 weeks) in 12 healthy volunteers in a William's balance-order design. TMS degraded visual motion perception when the evoked-phosphene and the visual stimulus overlapped in time and space, in the Placebo and Cabergoline conditions but not with Pergolide. This suggests that Dopamine D1 (but not D2) receptor activation, enhances cortical SNR to

boost perceptual performance. That local visual cortical excitability was unchanged across drug conditions suggests the involvement of long-range intra-cortical interactions in this D1 effect. Since increased internal noise (and hence lower SNR) can impair visual perceptual learning, then improving visual cortical SNR via D1 agonist therapy may be useful in boosting rehabilitation programmes involving visual perceptual training.

Title: Frequency of visual gamma oscillations in adults with ASD: a pilot study.

Authors: ***E. OREKHOVA**[1,3], J. SCHNEIDERMAN[4], S. LUNDSTRÖM[2], B. RIAZ[4], S. RAJAEI[2], N. HADJIKHANI[5,2], O. SYSOEVA[3], T. STROGANOVA[3], C. GILLBERG[2]; [1]Gillberg Neuropsychiatry Ctr., [2]Gillberg Neuropsychiatry Ctr. (GNC), Univ. of Gothenburg, Gothenburg, Sweden; [3]Autism Res. Laboratory, Ctr. for Neurocognitive Res. Neurosci & Physiol., MedTech West, Sahlgrenska Acad. and Univ. of Gothenburg, Gothenburg, Sweden; [5]Martinos Ctr. for Biomed. Imaging, Harvard Med. School, MGH/MIT/HST, Charlestown, MA

Abstract: An altered balance between excitation and inhibition (E/I) in neural networks is a likely underlying cause of neurobehavioral deficits in autism spectrum disorders (ASD). Frequency of gamma oscillations depends on the level of excitation of parvalbumin-containing inhibitory neurons and appears to be a useful index of inhibitory efficiency in ASD. Gamma oscillations in the visual cortex are reliably induced by high-contrast moving visual stimuli and their frequency is modulated by velocity of the motion. We have previously shown that modulation of gamma frequency by velocity is reduced in children with ASD and mild intellectual disability, putatively reflecting decreased inhibition in visual cortex (Stroganova et al. JND, 2015, 7:21). Here we investigated visual gamma frequency and its modulation by motion velocity in high-functional (HF) adults with ASD.

We recorded MEG in 11 ASD and 19 neurotypical (NT) subjects aged 19-50 years while they watched high-contrast circular gratings moving with velocities of 1.2 (Vel1), 3.6 (Vel2), or 6.0 (Vel3)°/s. The gamma frequency (e.g., fVel1) was defined as the maximal reliable stimulus-induced increase of sensor power between 40-100Hz in 0.4-1.2 sec post-stimulus.
The peak frequency of gamma oscillations increased with increasing velocity of visual motion in both NT and ASD subjects (p's<0.00001). Unlike our previous findings in children, modulation of gamma frequency by velocity was unremarkable in HF adults with ASD. In the NT group the fVel1, fVel2 and fVel3 decreased with age (p's<0.05), while no correlation with age was found in the ASD group (p's>0.7). The separate slope analysis revealed group differences in regression to age for fVel1 and fVel3 (p<0.05). When the age was accounted for separately in the ASD and NT groups, gamma frequency was higher (p<0.05) in the ASD participants in Vel1 and Vel3 conditions (NT: fVel1-3= 53.4, 64.4, 71.0; ASD: 54.7, 65.0, 71.9 Hz, at 30 years).
The absence of the normal age-related decrease of gamma frequency in adults with HF ASD on the group level points to the presence of pathological factors that affect visual gamma frequency to the greater extend than age. The atypically increased gamma frequency in participants with ASD suggests on average higher than normal excitability of the inhibitory interneurons in visual cortex, which may result in stronger inhibition. Most importantly, comparison of the present results in HF adults with those previously obtained in children with ASD and variable IQs using the same paradigm suggests that the extent and direction of the E/I abnormalities in individuals with ASD may depend on age and/or vary with severity of intellectual disability.

Title: Selective cortical responses to relative object/background motion

Authors: ***M. I. SERENO**[1], C. OZOLINS[2], M. SOOD[2], C. GALLETTI[3], P. FATTORI[4];
[1]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA;

[2]Psychological Sci., Birkbeck Univ. of London, London, United Kingdom; [3]Dept. di Farmacia e Biotecnologie, [4]Dept. of Pharm. and Biotech., Univ. di Bologna, Bologna, Italy

Abstract: During active vision, local motion signals capable of driving neurons in V1, layer 4B, are typically detected at many retinal locations. Sources include coordinated movements of scene contours due to self-motion as well as movement of objects -- such as other agents -- relative to the background. It has long been known that responses to preferred classical receptive field motion can be enhanced by presentation of non-preferred motion to the non-classical surround, even in V1 (review: Allman et al., 1985). In this study, we searched for human visual areas that selectively and retinotopically responded to local relative object/background motion. Color photographs of village street scenes (Eguisheim, Alsace) were continuously and smoothly moved around a central position by temporally smoothing sequences of small flat-random displacements (avoids long term drift). One or more rings of 10 superimposed colored objects (animal and tool images with transparent backgrounds) were similarly moved, with 9 objects moving along with the background and 1 object moving relative to it using a different random stream of similar-amplitude movements. Subjects fixated centrally during each run. The polar angle of the relatively moving object was varied in a periodic fashion (8 cycles in 512 sec). Since much of the retinotopy found in higher visual areas reflects sustained spatial attention (Saygin and Sereno, 2008), subjects had to perform a continuous attention-demanding task to report when any object slightly changed color. Color-change targets were randomly distributed in polar angle. Single objects were given a greenish (or reddish) cast for 130 msec by increasing green (or red) by 25% and by decreasing red (or green) by 25% in order to reduce spurious luminance-based apparent motion signals. Temporally jittered targets appeared once every 2 to 3 seconds. Wide-field direct-view experiments analyzed by phase-encoded methods and sulcus-based surface alignment (freesurfer, csurf) showed strong selective retinotopic responses in V3A, V6, and MSTd, with weaker responses in MT. The retinotopically balanced stimulus elicited no periodic response in early visual areas (V1-V3) and the attention-demanding task completely suppressed responses in occipital, parietal, and frontal visual attention areas. This suggests that relative motion is selectively computed by V3A, V6, and MSTd independent of endogenous attention.

Title: (Mis-)perception of motion in depth originates from underestimation of binocular extraretinal signals

Authors: *T. MURDISON[1,2,3], G. LECLERCQ[4,5], P. LEFÈVRE[4,5], G. BLOHM[1,2,3];

Neurosci. (CNCN), Kingston, ON, Canada; [4]ICTEAM Inst., [5]Inst. of Neurosci. (IoNS), Univ. catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract: Perception of motion in the depth dimension is essential to moving through the world. To estimate 3D motion, the brain uses extraretinal signals - including ocular vergence, horizontal and vertical version - to interpret binocular inputs. However, the extent to which these extraretinal signals contribute to perception of motion in depth is unclear. To answer this question, we asked 13 participants to estimate 3D motion without any visual references, forcing them to utilize extraretinal cues to reconstruct the spatial motion.
Participants sat in complete darkness while fixating one of 9 locations (horizontal version angles of -30°, 0° or 30° and vergence angles of 8.8°, 4.8° or 3°). We moved an LED around fixation along an arc in the horizontal depth plane with one of 36 possible trajectories. After target motion, participants were instructed to reproduce their perception of the motion in space using a touchscreen. After observing version-induced systematic errors in estimated trajectories relative to the spatial motion, we compared these perceptions to the output of a 3D kinematic eye-head-body (forward and inverse) model describing the predicted target motion either based solely on retinal motion or instead based on a transformation of retinal motion into spatial coordinates. For the transformation model, we varied the contributions of reference vergence, horizontal version and the gain of motion in depth to the inverse model and found the set of extraretinal parameters that resulted in a predicted trajectory best representing the reproduced motion.
Across participants, we found that perceived trajectories were best captured with a version estimate of 19.5° ± 6.0° (mean ± SD) for a true horizontal version of 30°, a gain term accounting for 65% ± 14% of the motion in depth, and a reference vergence angle of 6.7° ± 1.4°. These findings were consistent with previous studies reporting underestimates of horizontal version and depth changes, and point toward a partial transformation of retinal motion signals into spatial coordinates resulting in substantial errors in motion perception.

Title: Representation of egomotion in non-human primate

Authors: *B. R. COTTEREAU[1], S. RIMA[1], Y. TROTTER[1], A. T. SMITH[2], J.-B. DURAND[1]; [1]Ctr. de recherche Cerveau & Cognition, Toulouse, France; [2]Royal Holloway, London, United Kingdom

Abstract: During locomotion, the central nervous system has to monitor the optic flow that falls on the retina. Electrophysiological recordings have led to the belief that in primate, visual areas MST and VIP have a central role in this process. Recent neuroimaging studies in human have however suggested that the cortical network processing egomotion-compatible optic flow might be more extended and complex than originally believed. The aim of this study is to characterize this network in non-human primate. fMRI recordings were performed at 3T in 3 awake behaving macaques using a specialist 8-channel coil positioned above the animal's head. The experimental protocol was similar to that of a previous human study: we used a block design paradigm where the stimuli alternated between a baseline (i.e. fixation point only), a single patch of egomotion-compatible optic flow ('EC') and an array of nine similar optic flow patches that was inconsistent with egomotion ('EI'). Eye position was monitored while the monkeys performed a fixation task and only the runs where the percentage of correct fixation was above 85% were processed. Data were analyzed using SPM12 and the cortical areas responding specifically to egomotion-compatible optical flow were obtained from the general linear model. Consistent with human data and single-cell studies in macaque, significant activations were found in dorsal MST, in area VIP and in the visual posterior sylvian area (VPS). Responses in all these areas, and also in the frontal eye field (FEF) and area FST, were significantly stronger for the 'EC' condition. We also found a preference for the 'EC' condition in area V6 and in the cingulate sulcus but it was weak, whereas these two regions are particularly responsive in human using the same protocol. Altogether, our results suggest that if monkeys also have extended cortical networks to guide their navigation, there are important differences from those observed in human.

Title: Fewer neurons in MT are direction selective to random dot stimuli after chronic V1 lesions in adult marmoset monkeys

Authors: ***M. A. HAGAN**[1], T. CHAPLIN[1], K. R. HUXLIN[2], M. G. P. ROSA[1], L. L. LUI[1]; [1]Dept. of Physiol., Monash Univ., Clayton, Australia; [2]Flaum Eye Inst., Univ. of Rochester, Rochester, NY

Abstract: Damage to the primary visual cortex (V1) results in a scotoma in the corresponding parts of the visual field. However, both humans and monkeys retain some unconscious visual faculties, or "blindsight", within cortically blind (CB) fields, presumably via pathways that bypass V1.

The motion-sensitive, Middle Temporal Area (MT) is thought to mediate blindsight, as MT neurons respond to stimuli inside the scotoma following V1 lesions in both Old and New World monkeys (Rodman et al., 1989; Rosa et al., 2000). However, these prior studies quantified MT responses 1-3 months after damage; there is little data looking at long-term effects on MT responses following V1 lesions. This is important, as visual abilities in humans take ~6 months to stabilize post-lesion after an initial period of spontaneous plasticity (Zhang et al., 2006).

We recorded from 88 MT cells in 3 anesthetized, adult marmosets, 7-11 months after unilateral V1 lesions. The size and location of each scotoma was determined by recording from remaining V1 neurons around the lesion border. Using moving, random dot stimuli, we found that MT receptive fields in the scotoma differed in shape (quantified by comparing the Gaussian peak of each receptive field to its centre of mass) from those outside the scotoma ($p=2.15x10^{-4}$, Wilcoxon's rank sum). We then compared direction selectivity of cells in V1 lesioned animals to data from two control animals. The majority of MT neurons in controls were direction selective

(80%, 40 total cells); V1 lesioned animals had fewer direction selective cells with receptive fields located inside (22.5%; $p = 5.55x10^{-7}$, Binomial distribution) and outside the scotoma (36%; $p = 3.28x10^{-5}$, Binomial distribution). Receptive fields outside the scotoma included cells within the lesion project zone, which had remapped post-lesion.
Our data suggest that MT responses exhibit dramatic changes after long-standing V1 lesions. The persistence of MT responses within the scotoma may account for the simple, residual motion perception reported in blindsight patients. The decreased proportion of directionally selective cells could also explain the compromised global motion perception in these same patients (Weiskrantz et al., 1995; Azzopardi and Cowey, 2001; Huxlin et al., 2009). However, a small number of direction selective neurons was maintained long-term. We posit that these cells may be recruited through training to recover global motion discrimination in CB fields (Huxlin et al., 2009; Das et al., 2014).

Title: The effect of a transient congenital visual deprivation on the neural systems for visual and sound motion processing

Authors: *D. BOTTARI[1,2], R. KEKUNNAYA[3], M. HENSE[2], S. SOURAV[2], R. BALACHANDAR[3], N. F. TROJE[4], B. RÖDER[2];
[1]Univ. of Hamburg, Hamburg, Germany; [2]Biol. Psychology and Neuropsychology, Univ. of Hamburg, Hamburg, Germany; [3]LV Prasad Eye Inst., Hyderabad, India; [4]Dept. of Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Permanently blind individuals have been shown to possess a superior sound-motion processing capability. Brainimaging studies have reported an activation of visual-motion sensitive areas (e.g. MT+) during the processing of auditory motion stimuli. In contrast, typical sound-motion related areas (as the posterior planum temporale, PT) seem to be less activated in permanently blind as compared to sighted controls. If sight can be restored, we would predict incomplete recovery of visual-motion processing along with persisting enhanced auditory motion

processing skills. Alternatively, it could be speculated that visual-motion processing recovery results in the loss of the superior auditory motion processing abilities. Behavioral studies have shown impaired global motion processing after sight restoration following a compete blindness. We used a combined behavioural and electrophysiologcal assessment of visual and auditory motion processing in individuals who were born with bilateral congenital cataracts (cc) which were removed a few months up to several years later. Two additional control groups were tested: a group of visually impaired individuals without a history of congenital blindness (developmental cataract, dc) and a group of matched heathy controls (mc). In experiment 1 the electroencephalogram was recorded in response to moving dots (1 sec) with four levels of motion coherence (30%, 50%, 70% and 90%). In a separate behavioral assessment, discrimination thresholds for global motion were assessed. In experiment 2 sound-motion stimuli (700 ms) with four difficulty levels (by manipulating the SNR) were employed. In both EEG tasks participants were asked to discriminate the motion direction of infrequent target trials. In experiment 1 the cc group displayed higher threshold than the other two groups in discriminating global motion stimuli. The cc group showed an overall significantly reduced alpha activity. In the mc, alpha oscillatory activity was modulated by the global visual motion coherence level. In experiment 2 the cc group outperformed both control groups in sound-motion discriminations; they displayed an overall enhanced beta activity compared to the two control groups. In each group the level of beta activity varied with sound-motion SRN. These results suggest persisting crossmodal plasticity (oscillatory activity changes) and crossmodal compensation (enhances auditory motion processing skills) due to congenital blindness despite on average several years since sight restoration.

Title: Gain adaptation with and without rate adaptation in cortical area MT

Authors: *B. LIU, M. MACELLAIO, L. OSBORNE;
Neurobio. Dept., Univ. of Chicago, Chicago, IL

Abstract: Sensory neurons respond to changes in stimuli with a modulation of their firing rate, but that response is highly context-dependent. The mean, variance, higher order stimulus statistics drive changes in a neuron's state that impact how information about the stimulus is encoded. These adaptive changes can result in an efficient representation of the incoming signal within the neuron's limited response bandwidth. In previous studies of cortical adaptation, changes in sensitivity to stimulus fluctuations (gain adaptation) were coupled to changes in firing rate, typically a fast transient rate change that relaxes more slowly over time with dynamics on many time scales (rate adaptation). Here we show that gain adaptation and rate adaptation are independent processes in the intact brain. We recorded extracellular activity of single units in area MT in alert monkeys using stochastic motion stimuli that varied in direction or speed on short (20ms) timescales, and stepped between different mean and/or variance levels at longer (250ms-2s) intervals. We find that step changes in variance of time-varying motion stimuli centered on the flank of the tuning curve, where neurons are most sensitive to direction and speed fluctuations, can produce very rapid changes in response gain without changes in firing rate. However, the same neurons driven by fluctuations along the preferred–null axis produce both the rate-independent fast gain shift and the slower rate adaptation observed in previous studies. We find that the dominant rate-adaptation time constants in MT neurons, determined by exponential fits to the firing rate relaxation, have a mean of 87ms for upward shifts in velocity variance, and 96ms for downward variance shifts, similar to reported time constants for synaptic facilitation and depression. The rate adaptation time constants for upward and downward variance steps were correlated, but were independent of the timescale of the transient onset responses to motion steps. The rapid gain changes were almost too fast to resolve, suggesting that neither intrinsic, conductance-mediated adaptation nor synaptic adaptation mechanisms can account for the observed neural behavior. An information theoretic analysis of coding in both the preferred-null and flank-centered cases indicates that the rapid gain rescaling alone is responsible for information recovery after a step change in motion variance.

Title: Efficient coding of optic flow can account for MSTd visual response properties

Authors: *M. BEYELER[1], N. DUTT[2], J. L. KRICHMAR[3];
[1]Computer Sci., Univ. of California Irvine Dept. of Computer Sci., Irvine, CA; [2]Dept. of Computer Sci., [3]Dept. of Cognitive Sci., Univ. of California, Irvine, Irvine, CA

Abstract: Neurons in the dorsal subregion of the medial superior temporal (MSTd) area respond to large, complex patterns of retinal flow, implying a role in the analysis of self-motion. Some neurons are selective for the expanding radial motion that occurs as an observer moves through the environment ("heading"), and computational models can account for this finding. However, ample evidence suggests that MSTd neurons may exhibit a continuum of visual response selectivity to large-field motion stimuli. Furthermore, the underlying computational principles by which these response properties are derived remain poorly understood. Here we describe a computational model based on the hypothesis that neurons in MSTd efficiently encode the continuum of large-field retinal flow patterns on the basis of inputs received from neurons in MT with receptive fields that resemble basis vectors recovered with nonnegative matrix factorization (NMF). These assumptions are sufficient to quantitatively simulate several essential response properties of MSTd neurons, such as 3D translation and rotation selectivity, tuning to radial, circular, and spiral motion patterns, as well as heading selectivity. This finding suggests that these properties might emerge from MSTd neurons performing a biological equivalent of dimensionality reduction on their inputs. Furthermore, the model accurately captures prevalent statistical properties of visual responses in macaque MSTd, such as an overrepresentation of lateral headings that can predict behavioral threshold of heading discrimination and heading perception during eye movements. At the population level, model MSTd efficiently and accurately predicts a number of perceptual variables (such as heading and eye rotation velocity) using a sparse distributed code, consistent with ideas from the efficient-coding and free-energy principles. The present work offers a biologically plausible account of a wide range of visual response properties ranging from single-unit selectivity to population statistics, and thus provides

a further step towards a scientific understanding of the often noninuitive response properties of MSTd neurons.

Title: Task- and time-dependence of population codes for motion in marmoset MT

Authors: ***E. ZAVITZ**, H.-H. YU, M. G. P. ROSA, N. S. C. PRICE;
Monash Univ., Clayton, Australia

Abstract: Perception depends on decoding the activity of populations of sensory neurons. The firing rate of the down-stream neurons that contribute to this decoding is thought to be determined by a weighted sum of the inputs received from lower-order sensory neurons. Previous studies have suggested that the nature of the task may affect this weighting; yet work on adaptation-related perceptual aftereffects suggests that the flexibility of the read out is limited. To examine the necessity of a flexible readout, we compared the decoding performance and profiles of weights when linear decoders were specifically trained on identification and discrimination tasks, to performance and weights with a single, general model. We recorded spiking activity from 136 direction-selective single units in the middle temporal area (MT) of four sufentanil-anaesthetised marmoset monkeys (*Callithrix jacchus*). Visual stimuli comprised 500 ms of coherent dot motion, followed by 500 ms of blank screen, with 12 motion directions randomly interleaved. Using a generalized linear model, we learned each neuron’s optimal weights for solving 2- and 12-alternative forced choice direction identification tasks. A neuron's learned weight depends almost entirely on (1) the relationship between the neuron’s preferred

direction and the direction being decoded, and (2) the direction selectivity of the neuron. In a 12 AFC task, the optimal weights are highest when firing rates are highest, i.e. when the preferred direction is the same as the decoded direction. In a 2 AFC task, the weights are zero when the preferred direction of the neuron aligns with the discrimination boundary. Across neurons, the shapes of these functions are consistent, but the amplitudes vary widely. This variance is largely predicted by direction selectivity, as neurons that are more direction selective have higher weights. To assess how general these models are, we compared the decoding performance on the two types of task using the learned weights to performance using a reduced model that assigned weights based only on preferred direction and direction selectivity. Surprisingly, this reduced model completely accounted for decoding performance in 12 and 2 AFC tasks, but the template model learned in the 12 AFC task was equally effective in the 2 AFC task. These results demonstrate that a rigid, template-based population code produces sufficiently stable and high-quality decoding over time and across perceptual tasks, and can account for the existence of adaptation-induced perceptual aftereffects.

Title: Dynamics of population codes of stimulus features in primate area MT

Authors: *E. GODDARD[1,2,3], S. G. SOLOMON[4], T. A. CARLSON[1,2,3];
[1]Macquarie Univ., Sydney, Australia; [2]ARC Ctr. of Excellence in Cognition and its Disorders (CCD), Sydney, Australia; [3]Sch. of Psychology, Univ. of Sydney, Sydney, Australia; [4]Dept. of Exptl. Psychology, Univ. Col. London, London, United Kingdom

Abstract: The middle-temporal area (MT) of primate visual cortex plays a key role in the perception of motion. Neurons in area MT are generally thought to transform the signals of localised motion detectors into a representation of motion that is invariant to other image

attributes, including contrast and contour orientation. Electrophysiological studies have explored response properties of single neurons within area MT. This work suggests that the distinct motion sensitivity of area MT takes times to develop. Here, we explored how the encoding of direction by MT evolves over time in population responses. We performed extracellular recordings from populations of neurons in area MT of anaesthetised marmoset monkeys, during presentation of large moving gratings. Using multivariate classification analysis, we measured the stimulus-related information that was present in the spiking responses. Using Representational Similarity Analysis (RSA) we were then able to reveal the order in which different features of the moving gratings (spatial and temporal frequency, direction and orientation) are evident in the population response. We found a striking dependence of the population response on grating orientation at response onset, which shifted towards an orientation-invariant representation of direction over the first 100ms of response, consistent with single-unit work. In addition our analyses show that the contour-orientation dependent response and the shift toward invariance are most pronounced for stimuli of high spatial frequency and low temporal frequency. Our work demonstrates the dynamic encoding of motion primitives and emergent motion features (contour invariant responses) at the population level in MT neurons.

Title: A neural model of how direction and disparity signals interact in MT and MSTd to extract object motion during self-motion

Authors: *O. W. LAYTON[1], B. R. FAJEN[2];
[2]Cognitive Sci., [1]Rensselaer Polytechnic Inst., Troy, NY

Abstract: As humans move through the world, we must perceive the motion of objects that move independently from ourselves. Remarkably, our perception of an object's trajectory relative to the stationary environment is at best weakly affected by our self-motion. This suggests that the visual system recovers the world-relative motion of objects from the observer-relative pattern of motion that strikes the eye of the moving observer (i.e. sum of motion arising from the observer and objects). According to the flow parsing hypothesis, the visual system extracts

world-relative object motion by factoring out the component of the optic flow due to observer's self-motion (Rushton & Warren, 2005). While studies have established the essential role of the global pattern of motion, consistent with the flow parsing account, it remains unclear how the visual system robustly recovers world-relative object motion under a wide range of circumstances. In particular, humans are capable of perceiving the world-relative trajectory, whether the object is stereoscopically defined and spatially separated from the background environment (Warren & Rushton, 2007) or appears at the same depth as the background (Warren & Rushton, 2008). Previously, Layton & Fajen (2015, SfN) built a neural model of cortical areas MT and MSTd that demonstrates how the visual system may rely on a temporal solution to recover world-relative object motion. While MT responses may initially reflect the retinal motion of an object, the response shifts over time through feedback from MSTd cells that respond to the global pattern of motion and local interactions with MT cells tuned to opponent motion. We expanded the model to clarify how motion and disparity signals may interact to recover an object's world-relative trajectory as it moves through depth. Our results show that feedback from MSTd cells leads to stronger directional modulation in MT cells tuned to congruent disparities (Roy & Wurtz, 1990), which suggests a more complete recovery of world-relative object motion when the object is stereoscopically defined. We show how disparity and directionally tuned suppressive receptive field surrounds in MT- may provide a redundant local mechanism to complement the opponent motion antagonism included in the model of Layton & Fajen (2015, SfN).

Title: Causal evidence of directional signals in macaque middle temporal area pooled for heading computation based on optic flow

Authors: *Y. GU[1], X. YU[2];
[1]Syst. Neurosci., [2]Inst. of Neurosci., Shanghai, China

Abstract: Accurate heading perception relies on visual information integrated across a wide field, i.e. optic flow, but how this spatial pooling mechanism is implemented by underlying

neural circuitry remains unclear. In the current study, we trained macaques to judge heading directions based on global optic flow, with or without local perturbation cues, while we simultaneously recorded from the middle temporal area (MT). MT neurons typically contained much smaller receptive fields that occupied only a restricted visual field compared to those in the downstream areas, e.g. MSTd, yet they were highly responsive to the global heading stimuli. Electrical microstimulation in MT significantly biased the animals' heading judgments for nearly half of the cases, and for majority of them, the biased directions were predictable from the tuning curves of the stimulated neurons. Interestingly, the microstimulation effects on the behavior were significantly larger when neurons with excitatory receptive field surrounds were artificially activated compared to those neurons with inhibitory surrounds. Hence our data provide direct neurophysiological evidence demonstrating that the local visual motion signals represented in MT are weighted pooled by downstream areas such as MSTd for global heading computation. Such an integration mechanism also accounts for the biased heading estimation effect in the situation when part of the visual field is distorted, e.g. by moving objects independent on ego-motion, as observed in many psychophysical studies.

Title: Rats can process high level motion: a behavioral study using a discrimination task

Authors: ***R. BELLACOSA MAROTTI**, S. E. ROSSI, D. F. ZOCCOLAN;
Cognitive Neurosci., SISSA - Intl. Sch. For Advanced Studied, Trieste, Italy

Abstract: Rats are emerging as interesting models of high-level visual processing, as they can perform complex visual tasks, such as invariant visual object recognition. Still, very little is known about how these animals process high-level motion signals, i.e., whether they can discriminate global motion of a complex pattern. Previous findings on humans and primates suggest that an integrative stage is required for correct discrimination of these patterns.
This study investigates how rats perform high-level motion discrimination, to assess whether this species can be a useful model of late stages of motion processing.
We tested 12 long-evans rats in a global motion discrimination task using plaid patterns. Plaids

are formed by two superimposed gratings moving towards different directions. Perceived direction is obtained by combining the directions of the grating components. Rats had to discriminate vertical (either upward or downward) from horizontal (either leftward or rightward) motion. We first trained rats using 100% coherently moving random dots at different display contrasts (0.3 to 1 Michelson) and dot sizes (0.5 to 8 deg). Dots were drifting at 40 deg/s. We then tested task generalization to drifting gratings and plaids (0.7 contrast, 0.25 cycles/deg spatial frequency, 10 and 1 Hz temporal frequency). In generalization trials, no feedback was provided to the animals about the correctness of their responses. This ensured spontaneous response to novel stimuli.
We found that rats were able to discriminate dot directions at most size and contrast combinations, with higher discriminability at intermediate values. Generalization was successful with plaids, especially at high temporal frequency (~77% correct responses on average). Performance with gratings was instead below chance (~37% correct responses on average) for both drifting and static patterns.
Results show that rats can successfully perceive the global direction of plaids, spontaneously generalizing to these patterns after having been trained with dots. By contrast, they seem to adopt a strategy based on orientation rather than direction when dealing with gratings. This indicates that rats are capable of processing high-level motion, but they likely rely on different perceptual strategies depending on the pattern they have to process.

Title: MT neurons have different tuning properties at contrast threshold and above

Authors: *A. PAWAR, S. GEPSHTEIN, T. D. ALBRIGHT;
Salk Inst. VCL-A, La Jolla, CA

Abstract: Background: Behavioral studies of visual perception often employ stimuli near the threshold of visibility (for example by measuring contrast sensitivity of humans and animals) and also well above the threshold. But the neural mechanisms underlying visual perception are most commonly studied using suprathreshold stimuli, under the assumption that many characteristics

of neuronal responses at the threshold and above the threshold are similar to one another. Here we investigate neuronal behavior across the full range of luminance contrasts and ask whether cell tuning at the threshold can be accurately predicted from suprathreshold contrast measurements. **Methods:** We measured responses of 80 cells in the middle temporal (MT) area of the visual cortex of one alert macaque monkey engaged in a fixation task. The stimuli were sinusoidal gratings at multiple contrasts (0.5-100%) at 5 spatial frequencies (SF) and 1-3 temporal frequencies (TF). For each cell, we obtained response functions and contrast sensitivity functions (CSF). We defined the response function as the firing rate measured at a fixed contrast for multiple SFs. We defined CSF as the reciprocal of the contrast at which the firing rate was one standard deviation above the resting firing rate for multiple SFs. We compared the SF peaks of response functions for multiple contrasts with the SF peaks of contrast sensitivity within cells. **Results:** A previous study concluded that response functions at 25 and 50% contrasts in anesthetized cats were an accurate predictor of the sensitivity function in MT cells (Movshon et al., 1978). We found that peaks of CSF and response functions matched only in 25% of all cases and mostly at lower contrasts (below 15%). At high contrasts, the peak of the response function tended to drift toward low or high SF. We modeled frequency tuning of the network using a canonic inhibition-stabilized circuit (arXiv:1410.4237). At low stimulus contrasts, in the linear regime, such a circuit behaved as a linear filter intrinsically tuned to stimulus frequency. At high contrasts, in the nonlinear regime, the intrinsic tuning of the circuit changed and its frequency tuning shifted similar to that of MT neurons. Compared to the contrast normalization models, in which visual cortical computation are represented by banks of frequency-tuned linear filters with a separate stage of response nonlinearity (Carandini & Heeger, 2012), this model dynamically changes its tuning properties as a function of contrast. **Conclusions:** MT neurons have different tuning properties at the threshold of luminance contrast and above the threshold. This behavior is predicted by a model of canonic cortical computation.

Title: The appearance and disappearance of visual forms defined by differential motion evokes distinctive EEG responses in school-age children

Authors: *R. O. GILMORE, D. A. FOUAD, 16802, M. G. DEXHEIMER, 16802, A. R. SEISLER;
Penn State Univ., University Pk, PA

Abstract: Differential motion patterns aid in the segmentation of visual figures from the background. Adults show evoked brain responses to time-varying motion-defined forms over posterior scalp regions (Fesi et al., 2011; 2014); in these participants, EEG amplitudes scale with the magnitude of direction differences between the figure and background. However, little is known about the development of brain responses to motion-defined forms in childhood. In this study, we measured steady-state visual evoked potential (SSVEP) responses in n=37 children (mean age: 6.4 years; 16 female). Participants passively viewed random dot kinematogram displays that depicted visual forms which differed in direction from uniform background motion by 5, 45, or 180 deg. Four 9x9 deg square-shaped figure regions emerged from and disappeared into the background at a rate of 1.2 Hz (F1). Figure and background regions were populated with white (39 cd/m^2) dots on a black (.065 cd/m^2) background at a density of 10%; dot positions were updated at 36 Hz (F2). Each condition was presented at two speeds (1.2 and 6.0 deg/s). EEG was collected at 432.43 Hz using a 128 channel EGI system and PowerDiva Video 3.4 software and submitted to a discrete Fourier transform. The complex domain (real and imaginary) components of each channel were analyzed using mixed-effects MANOVA, with direction difference and speed as fixed factors and participant as a random factor. We chose $p<.0005$ as our alpha level to reduce the likelihood of reporting false positives. Statistically significant effects for direction were found at 1F1, 2F1, and 3F1, and these showed a broad distribution across the scalp. No channels met criterion for the effect of speed at any harmonic. Many, but not all channels showed the scaling of amplitude by figure/background direction difference found in adults, an effect particularly pronounced at 3F1. Complex domain plots of the most reponsive channels at 2F1 and 3F1 showed consistent phase and amplitude profiles. These results show that the appearance and disappearance of visual forms defined by local motion differences engages a widespread network of brain regions in school-age children that is similar but not identical to adults.

Title: Visual projection neurons link feature detection to distinct behavioral programs in *Drosophila*

Authors: *M. WU[1], A. NERN[2], W. WILLIAMSON[2], M. MORIMOTO[2], M. REISER[2], G. CARD[2], G. RUBIN[2];
[1]Dr. Gerald Rubin's lab, [2]HHMI/Janelia Res. Campus, Ashburn, VA

Abstract: How does a brain use visual information to guide behavior? To address this question, we study a class of *Drosophila* visual projection neurons called lobula columnar (LC) cells. LC neurons project from early visual processing areas to distinct central brain structures called optic glomeruli. We anatomically describe 22 different LC types and show that, for several types, optogenetic activation in freely moving flies evokes specific, highly penetrant behavioral phenotypes including jumping, backward walking and reaching. The takeoff jumping and backward walking phenotypes of two LC types closely resemble natural avoidance behaviors triggered by a visual loom. *In vivo* two-photon calcium imaging reveals that these LC types respond to looming stimuli, while another type does not, but instead responds to the motion of a small object. Furthermore, to emulate the naturalistic activation of these neurons, which would typically consist of asymmetrical visual stimulation - stronger on one eye than the other - we used a genetic approach to stochastically label and activate LC neurons on only one side of the brain. We found that such unilateral activation can result in either attractive or aversive turning behaviors depending on the cell type. Taken together, our results suggest that LC neurons convey information on the presence and location of behaviorally relevant visual features and that LC activation mimics the presence of such features in the environment, triggering specific behavioral responses. Our data provide a starting point to further study the processing of visual information in the brain for generating appropriate behavioral programs.

Title: Dynamic motion-tuning of macaque MST neurons before impending saccades

Authors: *J. DUIJNHOUWER, B. KREKELBERG;
Rutgers University-Newark, Newark, NJ

Abstract: Saccadic eye movements enhance vision by quickly directing the high acuity fovea at points of interest within the visual scene. However, they do this at the expense of adding spurious motion to the visual stream. We investigated how motion-tuning of neurons in the middle superior temporal (MST) cortex area of the macaque changes before an impending saccade. We performed single-unit recordings of the responses to random sequences of motion steps in eight different directions, while the macaque made cued saccades between two horizontally separated fixation points. We extracted motion tuning parameters using a generalized linear modeling approach and compared motion tuning parameters well before the saccade with those just prior to it. We found that the amplitude of motion tuning strongly reduced before a saccade, whereas the untuned component of the response increased. The preferred direction and tuning-width were not systematically affected. Both a decrease in amplitude and an increase in the untuned response are compatible with a reduced behavioral sensitivity to motion, hence we hypothesize that these tuning changes serve to reduce the disrupting effects of saccades.

Title: Freeze or flight: vision guides choice of defence strategies in mice

Authors: G. DE FRANCESCHI, T. VIVATTANASARN, A. B. SALEEM, *S. G. SOLOMON;
Univ. Col. London, London, United Kingdom

Abstract: In prey species like mice, avoidance of predators is key to survival and drives instinctual behaviours such as freeze and flight. Previous work has shown that mice generally flee to a refuge when presented with a dark looming visual stimulus (Yilmaz and Meister, 2013, Curr Biol 23, 2011-15). Freezing behaviour has instead mainly been investigated using real predators or their odours. Here we asked if variation in visual stimulus alone can determine if mice choose freeze or flight behaviour. We monitored acclimatised mice freely exploring an arena that was surmounted by a monitor. Visual stimuli were triggered when mice neared the centre of the arena, and we measured responses to one visual stimulus per day. The 'loom' stimulus was an expanding black disc (increasing to 50 degrees in 0.25s), simulating an approaching predator. The 'sweep' stimulus was a 5 degree black disc translating on the monitor at 21 degrees/s, simulating a gliding predator. We defined freezing as reduction of movement speed to less than 2 cm/s, for at least 0.5s. Confirming previous work, most mice showed rapid flight behaviour in response to a looming stimulus (88% of trials). By contrast, mice generally froze in response to the sweep stimulus (84% of trials), and showed flight behaviour in 22% of trials, usually after freezing. White sweep stimuli produced similar results. Further tests showed similar freeze responses to sweep stimuli at 5 and 42 degrees/s, with increased probability of subsequent flight at higher sweep speeds. At the highest speed tested (84 degrees/s), mice showed sub-second flight behaviour in response to sweep stimuli but this response was preceded by a brief freeze (ca. 0.2s). Flight responses to loom stimuli did not show this brief freeze. We have discovered that a sweeping visual stimulus elicits a strong defensive response: freezing. Using the same apparatus a different visual stimulus, loom, elicits an opposing defensive response: flight. Together these provide a simple, easily controlled behavioural paradigm, in which mice make behavioural choices based on vision alone.

Title: Sharper, stronger, faster upper visual field representation in primate superior colliculus: implications for afferent and efferent collicular topography

Authors: *Z. M. HAFED, C.-Y. CHEN;
Werner Reichardt Ctr. For Integrative Neurosci., Tuebingen, Germany

Abstract: The primate superior colliculus (SC) is critical for a variety of visual, cognitive, and motor functions. An overwhelming assumption about the SC's anatomical representation of space is that it magnifies foveal representations, but equally so for different elevations from horizontal. Here we demonstrate a dramatic and categorical difference in the SC's representation of upper (UVF) versus lower (LVF) visual fields. We recorded from 419 visual, visual-motor, and motor-related SC neurons in 2 monkeys. The monkeys performed a variety of standard behavioral tasks, including visually-guided, delayed-visually guided, and memory-guided saccades. Our neural database (covering fovea to ~20 deg eccentricities and -90 to 90 deg directions from horizontal), allowed us to functionally identify differences between UVF and LVF representations. We found that UVF response fields (RF's) are much smaller than LVF RF's. Moreover, this effect persisted for both visual as well as saccade-related RF's. UVF visual RF's additionally exhibited stronger and lower-latency visual responses, as well as higher spatial frequency preferences. Given the importance of SC visual responses in influencing saccadic reaction times (SRT's), these results provide a direct neural mechanism for behavioral observations of shorter UVF SRT's. Such shorter SRT's have eluded a clear neurobiological substrate for several decades. Moreover, motivated by UVF/LVF RF differences, we also searched for and found additional saccade effects. For example, UVF saccade endpoint accuracy was higher, even for memory-guided saccades in the absence of a visual stimulus. This may be a direct consequence of smaller UVF saccade-related RF's, independent of visual representations. Finally, we found that there are structural implications of smaller UVF RF's on SC topography. Specifically, ensuring coverage of the UVF by the SC would require an over-representation of this field in the SC's neural tissue. We confirmed this by analyzing preferred directions and eccentricities at SC surface for many electrode tracks, and we found a significant UVF over-representation. Because this observation is dramatically different from the universally accepted Ottes et al. (1986) model of SC retinotopic mapping, we developed a modified model of afferent/efferent topography, which is more accurate, and which motivates recasting of structure-

function relationships in the visual system in general. Despite its appearance as a continuous layered sheet of neural tissue, the SC contains a functional discontinuity between UVF and LVF representations, paralleling a physical discontinuity present in cortical visual areas.

Title: Visual receptive fields and cortical oscillations during saccadic suppression in area V4

Authors: *T. P. ZANOS[1,2], P. J. MINEAULT[2], D. GUITTON[2], C. C. PACK[2];

Abstract: We explore our visual surroundings by moving our eyes to point our retinas at behaviorally relevant areas of our visual fields. These rapid displacements of our retinal image might be expected to produce a perception of sudden jumps of the visual image, but nevertheless our visual perception remains stable. One of the best known mechanisms for maintaining perceptual stability is *saccadic suppression*, a decrease in visual sensitivity that occurs with each eye movement. While saccadic suppression has been well documented both psychophysically and neurophysiologically, its underlying mechanisms are not fully understood. One plausible candidate is a saccade-triggered reduction in the gain of visual responses to specific stimuli. Alternatively, saccadic suppression might involve *additive* influences on visual responses, independent of any specific stimulus. Moreover, these influences might be identical across the visual field, as suggested by some recent psychophysics, or they might be stronger in the peripheral visual field, as suggested by older psychophysical studies. We have examined these issues in visual cortex area V4, where neurons are known to be strongly modulated by both visual stimuli and saccades. In order to study the dynamics of neural signals across this map, we chronically implanted 10x10 microelectrode arrays into dorsal V4 of two macaque monkeys. We examined the activity of single neurons and local field potentials (LFPs) during experiments in which the monkeys made saccades into and out of the area of the visual field accessible to the

arrays, while we simultaneously presented a sparse noise visual stimulus to map single-neuron receptive fields. A model-based approach allowed us to separate and track the multiplicative and additive parts of the responses of V4 neurons in space and time. We show that a significant number of V4 neurons exhibit neural correlates of saccadic suppression. This suppression transitions between two phases that are characterized by differences in both their retinotopic organization and their mechanistic aspects. The first phase, occurring before and during the execution of a saccade, is driven by a multiplicative suppression that is roughly the same across all eccentricities. This is followed by a second phase that involves an additive component limited only to peripheral neurons. The transition between these two phases is accompanied by a strong increase in the power of alpha-band (7-13Hz) LFP activity at peripheral V4 sites. Together these results may account for various psychophysical results, and suggest a new mechanistic interpretation of saccadic suppression.

Title: Monitoring cortical state to explain variability in visual detection behavior and evoked responses in primary visual cortex

Authors: *G. T. NESKE, D. A. MCCORMICK;
Neurosci., Yale Univ., New Haven, CT

Abstract: Processing of sensory stimuli is strongly dependent on cortical state. While the most dramatic shift in state occurs during the transition from sleep to wakefulness, the waking period itself is associated with frequent state fluctuations. These waking state fluctuations significantly influence both sensory-evoked responses in primary sensory cortices and perceptual decision making.
The cortical state that promotes optimal sensory processing is unclear. Using pupillometry to track the full spectrum of waking states, our group recently showed that the highest gain and reliability of evoked responses in mouse primary auditory cortex and optimal performance on an

auditory detection task occur during a state characterized by intermediate arousal without locomotion (*Neuron*, 87: 179, 2015). Yet, many previous investigations of state-dependent sensory processing in mouse primary visual cortex (V1) have suggested that optimal sensory processing occurs during locomotion. Would an analysis of the full spectrum of waking states reveal that optimal visual detection and V1 gain modulation occur during intermediate arousal without locomotion, as in the auditory system, or would such an analysis confirm that optimal visual cortical processing in fact occurs during locomotion?
