Abstract: Chemotherapy-induced peripheral neurotoxicity is often a dose-limiting side effect which can persist following cessation of treatment. We are in the process of systematically evaluating the time course and extent of neuropathy recovery in mice up to six months post dosing for four chemotherapies: eribulin (ERIB), paclitaxel (PAC), ixabepilone (IXA) and vinorelbine (VINO). We are evaluating six independent end-points including nerve conduction/amplitude, sciatic nerve /dorsal root ganglia (DRG) morphology, foot pad intra-epidermal fiber density (IEFD), corneal fiber density, microtubule biochemistry and drug pharmacokinetics. The in-life portion of the study is complete and analyses are underway. Mice received MTD doses of ERIB (1.2 mg/kg), PAC (30 mg/kg), IXA (2 mg/kg), or VINO (11 mg/kg) IV 3 times a week for 2 wks. Nerve conduction deficits for all four chemotherapies were maximal between 1-2 wks after cessation of dosing. After 3-6 mo, deficits largely recovered for ERIB and IXA, but remained significant in PAC mice at 6 mos; 3-6 mo VINO studies are underway. Axonal levels of tubulin and acetylated tubulin in sciatic nerve increased at 24h but returned to normal at two wks after PAC or ERIB. Occasional myelin abnormalities persisted, though less than at 24h and axonal density deficits recovered in ERIB, but not in PAC treated mice. Similar studies with VINO and IXA are ongoing. Preliminary DRG morphological analysis indicated PAC induced neuronal damage out to 3 mo post dose; morphometric analysis confirmed reduction in sensory neuron size. Peripheral nerve fiber degeneration, supported by a decrease in g-ratio, was present in sciatic nerves of PAC and IXA-treated mice at 2 wks, but partially resolved at 3 mo. Despite no severe morphological changes in nerves of ERIB and VINO mice, g-ratios were slightly decreased at 2 wks. Corneal immunostaining with confocal microscopy found acute nerve fiber loss between 1 and 2 wks, with varying degrees of regeneration at 6 mo post dose. IENFD analysis of vehicle mice found a stable mean value of 81.4 fibers/mm. In contrast, PAC treatment caused a monotonic mean decrease to a mean nadir of 12.9 fibers/mm 2 wks post and recovered fully by 6 mo. IXA -treated mice also had a decrement to 28.4 fibers/mm by 2 wks and full recovery by 4 wks. These data indicate that unmyelinated sensory fibers are prominently affected and that PAC-induced axon loss is more

severe than IXA. Analyses of ERIB and VINO IENFD and all PK samples are pending. Overall, data suggest more severe deficits with PAC treatment and a longer recovery. Updated results will be presented for each endpoint analysis.

Title: PGN-503, a herpes simplex virus based vector expressing neurotrophin-3 for the prevention and treatment of chemotherapy induced peripheral neuropathy

Authors: ***J. R. GOSS**, D. KRISKY, K. BOUCH, M. O'MALLEY, S. COGHLAN, J. WECHUCK;
Periphagen Inc, Pittsburgh, PA

Abstract: Chemotherapy induced peripheral neuropathy (CIPN) is devastating constellation of symptoms that arise as a complication in patients receiving chemotherapy for cancer. It presents as a stocking and glove neuropathy characterized by numbness, paresthesia, and occasionally burning pain in the feet and hands. It can develop in up to 90% of all patients receiving chemotherapy, depending on the dose and type of drug. The development of CIPN may result in dose reduction of the chemotherapy agent, a switch to less efficacious agent, or even cessation of all chemotherapy treatment. Currently there are no approved therapies for the treatment of CIPN. PGN-503 is a new investigational drug designed to prevent and/or treat CIPN. It is a herpes simplex virus type 1 based vector expressing human neurotrophin-3 (NT-3). Following an intradermal injection, PGN-503 is taken up by sensory nerve terminals, transported back to the cell body, and directs the expression of NT-3. NT-3 is a well-studied neurotrophic factor

necessary for the growth and maintenance of sensory neurons. Neurotrophic factors, including NT-3, have been shown to be efficacious in the treatment of drug-induced neuropathies and the neuropathy associated with diabetes, however, attempts to use recombinant human trophic factor peptides in patients has proven difficult, likely due to the inability to deliver a sufficient amount at the site of the peripheral sensory nerves without adverse systemic side effects. In order to overcome this barrier, we have chosen to use a herpes simplex virus (HSV) vector to direct the expression of NT-3 directly in the peripheral sensory nerves at risk of developing neuropathy. In a series of preclinical studies, we examined the efficacy of PGN-503 in mouse models of CIPN induced by paclitaxel, oxaliplatin, and bortezomib. In all models a single injection of PGN-503 into the plantar surface of the hind paws 3 days prior to chemotherapy dosing, was sufficient to protect the mice from developing CIPN as assessed by electrophysiological analysis.

Title: Prevention of oxaliplatin-induced neurotoxicity involving decrease in peripheral blood flow by oral administration of goshajinkigan

Authors: T. KONO[1,2], *Y. OMIYA[3], H. SEKINE[3], M. YAMAMOTO[3], K. MIYANO[4], Y. KASE[3], Y. UEZONO[4];
[1]Fac. of Pharmaceut. Sci., Hokkaido Univ., Hokkaido, Japan; [2]Ctr. for Clin. and Biomed. Res., Sapporo Higashi Tokushukai Hosp., Hokkaido, Japan; [3]Tsumura Res. Labs., Tsumura & Co., Ibaraki, Japan; [4]Div. of Cancer Pathophysiology, Natl. Cancer Ctr. Res. Inst., Tokyo, Japan

Abstract: We have developed a useful rat model for the elucidation of oxaliplatin-induced chronic neuropathy and investigated the action of Goshajinkigan (GJG), a traditional Japanese herbal medicine. GJG has been reported to ameliorate oxaliplatin-induced neuropathy in a placebo-controlled double-blind randomized phase II study in Japan and is also refereed in chemotherapy-induced neurotoxicity guidelines (American Society of Clinical Oncology). A previous report observed that peripheral blood flow (PBF) was altered in oxaliplatin-treated animals, which might correlate with neurotoxicity. GJG and its components have been reported to show vasodilatation in several models partly via increasing nitric oxide production. Therefore, we investigated the efficacy of GJG on oxaliplatin-induced decrease of PBF. The effects of GJG were examined in rat following treatment with oxaliplatin (4 mg/kg, i.p.) twice weekly for 8 wks and with oral administration of GJG five times a week for 8 wks. PBF was measured using a two-dimensional laser speckle Blood Flow Imager. Rats were anesthetized. Body temperature was maintained at 37.5 ±0.5°C using a heating pad. Blood pressure and heart rate were concurrently measured by a tail-cuff apparatus. PBF in the head, ears, forelimbs, hindlimbs and tail of rats was measured at four defined time points (day 3, 10, 26 and 54). Real image and color-coded images were obtained. PBF value is expressed as mean blood flow. The ratio of blood flow rate of treated animals to naïve animals was calculated (%). Regional PBF, except for that in the ears and tail, decreased from 10 days to 4 wks after treatment with oxaliplatin, but then increased back toward normal values after 8 wks. Mean blood flow in the fore- and hindlimbs was significantly decreased at 4 wks. Reduction of mean blood flow in the left hindlimb was significantly inhibited in rats administered GJG at 4 wks after oxaliplatin treatment. No change in blood flow at each site was observed at 8 wks after oxaliplatin treatment. GJG did not affect either systemic blood pressure or heart rate in oxaliplatin-treated rats. Our study suggests that GJG prevents oxaliplatin-induced decrease of PBF which can be a crucial mechanism for preventing oxaliplatin-induced neuropathy.

Title: TRPM8-mediated response to cold in human DRG neurons and its modulation by the chemotherapy agent oxaliplatin

Authors: *A. GHETTI[1], J. ZHANG[1], Y. MIRON[1], J. STRETTON[2], K. MORRISON[2], P. MURDOCK[2], K. PAGE[2], P. MILLER[1];

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN), is a serious dose-limiting adverse effect induced by several chemotherapy agents and can lead to dose reduction or discontinuation of therapy, with consequent negative impact on cancer patients' survival. Manifestations of CIPN include: mechanical and cold allodynia, burning pain and tingling numbness. Following the cessation of chemotherapy, gradual recovery from peripheral nerve damage occurs in most patients but, in a significant number of cases, pain may persist. Cold allodynia is a very common instance with CIPN and growing efforts have been focused on the identification and development of pharmacological agents that can treat cold-related pain in CIPN patients. The mediators of cold pain sensation in human remain poorly characterized, although several ion channel candidates have been proposed. Transient Receptor Potential Cation Channel, Subfamily M, Member 8 (TRPM8) is considered a prime candidate for the transduction of low temperature-induced pain. For this reason, it is a potentially valuable target for the development of novel agents with the potential to treat cold allodynia. We have investigated the expression of TRPM8 in human dorsal root ganglion (DRG) neurons as well as in a variety of other tissues. Expression of TRPM8 mRNA was detectable by qRT-PCR (TaqMan®) not only in the DRG neurons, but also in several other tissues, including prostate, testis and liver. By employing automated branched-DNA *in situ* hybridization and automated immunohistochemistry on sections of fixed human DRG, we were able to localize TRPM8 expression to both large as well as smaller diameter DRG neuron cell bodies. We then conducted functional studies aimed at measuring the amplitude and kinetics of cold-induced responses in human DRG neurons in culture. In these preparations we recorded a rapid and reversible increase in intracellular calcium, following a rapid cooling to temperatures between 8°C and 12°C. Pre-treatment with a TRPM8 blocker resulted in marked, but incomplete, inhibition of the cold-induced responses. Pre-treatment of the cells with the chemotherapy drug oxaliplatin potentiated the response to rapid cooling and reduced the rate of desensitization. The increased duration of the cold-induced response in human DRG neurons, may contribute to the mechanism underlying CIPN-related

cold allodynia and may provide a useful *ex vivo* assay for identifying novel therapeutic agents for treating this condition.

Title: Synergistic interaction of morphine plus clonidine in cisplatin-induced neuropathic pain in rat

Authors: ***A. ZUÑIGA**[1,2], J. REYES-GARCÍA[2], F. FLORES-MURRIETA[2], H. ROCHA-GONZÁLEZ[2];
[1]INER, MEXICO DF, Mexico; [2]Escuela Superior de Medicina IPN, ciudad de México, Mexico

Abstract: Clinical use of anti-neoplastic drugs is associated with the development of numerous adverse effects that many patients find intolerable, including peripheral neuropathy. Cisplatin, an effective anti-neoplastic agent in the treatment of solid tumors, produces a dose-limiting painful peripheral neurophathy in a clinically significant number of cancer patients. The aim of the present study was to investigate the possible synergistic interaction of systemic administration of morphine and clonidine either alone or in combination in an animal model of neuropathic pain evoked by cisplatin. Mechanical allodynia was measured by using von Frey filaments in the hindpaw. Male Wistar rats, weighting 160-180 g, were treated with cisplatin administered intraperitoneally three times a week (Monday, Wednesday, and Friday) at a dose of 0.1 mg/ 100 g weight. Morphine (0.1, 0.3, 3 and 5.6 mg/kg), clonidine (0.03, 0.3, 563 and 30 μg/kg), or equieffective doses of the combination in a ratio 1:1 were administered to obtain the 40% experimental effective doses (ED_{40}) for each drug and for the combination. Isobolographic analysis was performed to examine the interaction. Morphine (ED_{40} = 3.2 +/- 0.7 mg/kg), clonidine (ED_{40} = 0.88 +/- 3.5 μg/kg), and fixed-dose ratio morphine-clonidine combinations showed dose-dependently anti-allodinical effect. Theoretical ED_{40} value for the combination

estimated from the isobologram was 2.05 +/- 0.32 mg/kg, whereas that experimental ED_{40} value was 0.80 +/-0.02 mg/kg. Results indicate that i.p. administration of morphine plus clonidine can interact synergistically in the neuropathic pain model and suggest the use of this combination to relieve pain evoked by anti-neoplastic agents in humans.

Title: The therapeutic effect of Rho kinase inhibitor Y-27632 on protection from chemotherapy-induced peripheral neuropathy in a tumor-bearing mouse model

Authors: *Y. ZHU[1], G. A. HOWARD, IV[2], K. PITTMAN[2], C. BOYKIN[1], K. VERBANAC[2], Q. LU[1];

Abstract: Cisplatin often causes loss of touch sensitivity in the hands and feet of cancer patients as well as tingling, numbness, and a shooting or burning pain; these clinical symptoms are referred to as chemotherapy-induced peripheral neuropathy (CIPN). CIPN frequently results in a reduction or cessation of chemotherapy, and there is currently no effective intervention or prevention for CIPN. Therefore, it is important to understand the mechanism of CIPN pathogenesis and determine associated signaling pathways to identify potential therapeutic targets. Previously, we created a CIPN mouse model in 3 month old C57/BL6 mice by injections of 6μg/g cisplatin every 14 days. Our data indicated that the RhoA signaling pathway was responsible for attenuating CIPN since the preserved touch sensitivity was achieved in cisplatin-treated mice by injecting LM11A-31, a p75 neurotrophin receptor ligand mimetic that serves as an upstream inhibitor of RhoA signaling pathway. In order to fully capture the clinical situation, we extend this approach to CIPN in a syngeneic murine Lewis Lung Carcinoma (LLCab) model

in which mice were concurrently treated with weekly injections of cisplatin and a RhoA pathway inhibitor. In this tumor-bearing CIPN mouse model, we determined the therapeutic effectiveness of Y-27632 that selectively inhibits ROCK, a downstream effector of the RhoA signaling pathway, in peripheral neuroprotection. Von Frey filaments analysis of hind paw touch sensitivity indicated that Y-27632 treatment protected tumor-bearing mice from cisplatin-induced reduction of touch sensation. Furthermore, immunohistochemical analysis of cutaneous nerve fibers in foot pad tissue, which was acquired from the corresponding hind paw, demonstrated that the cisplatin-induced decrease in touch sensory associated-cutaneous nerve fibers could be alleviated by the concurrent treatment with Y-27632. Therefore, Rho kinase inhibitor Y-27632 can potentially protect peripheral nerve function in the tumor-bearing CIPN mouse model.

Title: The role of TLR4 signaling pathway in oxaliplatin-induced peripheral neuropathy in rat

Authors: *P. M. DOUGHERTY[1], A. ILLIAS[2], Y. LI[2], H. ZHANG[2], K.-J. YU[2], J. F. VELASQUEZ[3], J. P. CATA[2];
[1]Pain Med., Univ. of Texas MD Anderson Cancer Ctr., Houston, TX; [2]MD Anderson, Houston, TX; [3]MD Anderson.org, Houston, TX

Abstract: Many efforts have been made to understand the mechanism of Chemotherapy-Induced Peripheral Neuropathy (CIPN) in order to treat or prevent this common complication of cancer treatment, which sometimes persists even after the patient is cured from cancer. Accumulating evidence shows that TLR4 signaling contributes to paclitaxel-induced peripheral neuropathy. In the present study, we test the hypothesis that TLR4 also plays a crucial role in peripheral neuropathy caused by platin agents, Oxaliplatin in particular. Peripheral neuropathy was induced

in a group of Sprague-Dawley rats treated with oxaliplatin. Mechanical hypersensitivity test (von Frey's), biochemical analysis (Western blot), and immunohistochemistry staining results from rats treated with oxaliplatin were compared to a group of control rats and another group of rats who received intrathecal injections of TLR4 antagonist LPS-RS along with intraperitoneal oxaliplatin. Oxaliplatin treated rats expressed decrease in paw withdrawal threshold detected one hour post oxaliplatin injection and continued as long as our experiment was conducted, for 35 days after the first injection, whereas blocking of TLR4 with LPS-RS resulted in a behavior phenotype closer to the control group. Western blot show that TLR4 protein along with its downstream signaling molecule- myeloid differentiation primary response gene 88 (MyD88)- were increased in dorsal root ganglion (DRG) since 7 days after oxaliplatin injection and continued throughout day 35. Furthermore, Immunohistochemistry staining displayed increases in expression of glial fibrillary acidic protein (GFAP) positive cells in dorsal horn of oxaliplatin treated rats with colocalization of TLR4 on these cells. In the same group, TLR4 was also increased in calcitonin gene-related peptide (CGRP) and isolectin B4 (IB4) positive DRG cells. Co-administration of LPS-RS prevented excessive expression of TLR4 as detected by both immunohistochemistry and western blot analysis. Therefore, Blockade of TLR4 might prevent or attenuate pain caused by chemotherapy agents.

Title: Neuroprotectin D1 protects the chemotherapy-induced neuropathy by modulating the function of macrophages

Authors: *S. BANG, Z.-Z. XU, R.-R. JI;
Dept. of Anesthesiol. and Neurobio., Pain Res. Div. ,Department of Anesthesiol. and Neurobiology, Duke Univ., Durham, NC

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is a major side-effect of cancer treatment. Neuroprotectin D1 (NPD1) is derived from omega-3 unsaturated fatty acids and has potent anti-inflammatory and pro-resolution actions. Our previous study showed that NPD1 prevented the nerve injury-induced neuropathic pain by regulating glial activation and neuroinflammation in the spinal cord. In the present study, we examined whether NPD1 would modulate macrophage function following paclitaxel-induced CIPN. Systematic injection of NPD1 effectively prevented paclitaxel-induced mechanical allodynia in mice. Paclitaxel also induced marked infiltration of macrophages to dorsal root ganglia (DRG), but this infiltration was blocked by the NPD1 treatment. NPD1 also reduced the production of proinflammatory cytokines in macrophages from the paclitaxel injected mice. In the primary cultures of macrophages, NPD1 further enhanced the phagocytosis activity and reduced the production of proinflammatory cytokines. Intraplantar injection of the paclitaxel-treated but not control macrophages induced mechanical allodynia, but this allodynia was compromised by pretreatment of paclitaxel-stimulated macrophages with NPD1. These results suggest that NPD1 might protect paclitaxel-induced neuropathic pain through regulation of macrophage function.

Abstract: Paclitaxel chemotherapy induced peripheral neuropathy (CIPN) is a common side effect experienced by patients in chemotherapy. Although the mechanisms remain little understood several lines of evidence indicate that CIPN is associated with hyperexcitability of peripheral and central neurons. Here the role of changes in expression and function of the voltage-gated sodium channel Nav1.7 in DRG and spinal cord in CIPN was tested in rats. Double immunofluorescence staining showed that Nav1.7 was up-regulated in small DRG neurons especially those also expressing CGRP. Meanwhile and in contrast Nav1.7 was down regulated in spinal cord, in particular being reduced in GAD65 and GAD67 positive spinal neurons. Whole-cell patch clamp recordings in DRG neurons and lamina II spinal cord neuron revealed that paclitaxel (1)induced a prominent enhancement of I_{NaT} and (2)increased ramp currents, the persistent sodium current (I_{NaP}), in response to slow depolarization and (3)decreased the frequency of sIPSC in spinal cord dorsal horn neurons. The reduction in spinal neuron sIPSC was rescued by perfusion with the Nav1.7 blocker ProTx II. Intrathecal injection of ProTx II also significantly attenuated the behavioral signs of CIPN. This study suggests that Nav1.7 may provide a potential new target for the treatment of paclitaxel induced peripheral neuropathic pain.

Title: Paclitaxel application leads to long-term changes of presynaptic TRPV1 receptors function in spinal cord dorsal horn

Authors: *P. ADAMEK[1,2], J. PALECEK[1];
[1]Functional Morphology, Inst. of Physiology, Czech Acad. of Sci., Prague, Czech Republic;
[2]Dept. of Physiol., Fac. of Science, Charles Univ., Prague, Czech Republic

Abstract: Antineoplastic drug Paclitaxel (PTX) is the frontline agent widely used in clinical practice for the treatment of multiple solid tumors, such as breast, ovarian and lung cancer. However, the major dose- and treatment-limiting factor of PTX therapy is development of Chemotherapy-Induced Peripheral Neuropathy (CIPN). We have shown previously (Li et al., J. Neurosci., 35:13487-13500, 2015) that acute application of PTX (50 nM) modulated frequency of mEPSC via TLR4 and TRPV1 receptors activation. PTX also significantly reduced tachyphylaxis present after repeated capsaicin application. In extension of these findings we have studied the effect of PTX treatment on the capsaicin response tachyphylaxis and behavioral changes at different time points. Whole-cell patch clamp recordings of miniature excitatory postsynaptic currents (mEPSC) were made from superficial dorsal horn neurons in acute spinal cord slices prepared from adult male mice C57BL/6. CIPN was induced by single dose application of PTX (Mylan, 8 mg/kg; *i.p.*). Von Frey filament measurements were used for behavioral testing to evaluate the presence of mechanical allodynia in the model. In naïve animals mEPSCs frequency evoked by second capsaicin (0.2 μM) application was dramatically reduced to 33 % of the first one. After acute PTX treatment the second response was 91 % of the first one. Our latest data show that PTX significantly changed the second capsaicin response also after incubation in PTX (50 nM) for ~2 hours (80 %) and 1 (72 %) and 8 days (83 %) after single systemic PTX (8 mg/kg; *i.p.*) treatment. The systemic PTX treatment also significantly increased the basal frequency of mEPSC (2.5 Hz and 3.2 Hz vs. 0.9 Hz in controls) and enhanced responses to capsaicin (22.2 Hz and 26.2 Hz vs. 7.8 Hz in controls) at 1 and 8 days after the PTX treatment. Further information about the intracellular signaling pathways involved in the signaling between the TLR4 and TRPV1 receptors after the *in vitro* and *in vivo* PTX treatment will be also presented on-site. Our results suggest that functional interaction between TLR4 and TRPV1 receptors and modulation of TRPV1 receptors properties in the spinal cord dorsal horn may play an important role in the development painful states after PTX treatment. Targeting these receptors may represent a viable option for possible analgesic treatment.

Title: HKP-16 ameliorates chemotherapy-induced neuropathic pain in rats by oral administration

Authors: *H. KIM, S.-H. HWANG, S. ABDI;
Dept. of Pain Med., MD Anderson Cancer Ctr., Houston, TX

Abstract: Chemotherapy agents including taxanes, vinca alkaloids, platinum complexes, and proteasome inhibitor produce peripheral neuropathic pain which is a dose-limiting side effect. Paclitaxel (PAC) is the first choice for breast cancer and produced neuropathic pain. Commonly used pain medications such as opioids, anticonvulsants, antidepressants, and selective serotonin norepinephrine reuptake inhibitors have only modest analgesic effects at best for chemotherapy-induced neuropathic pain. Therefore, we need to develop new drugs. The purpose of this study was to determine the analgesic effects of HKP-16 as a new drug candidate on PAC-induced neuropathic pain in rats. PAC-induced neuropathic pain model was produced by intraperitoneal injections of PAC (2 mg/kg; total doses of 8 mg/kg) on days 0, 2, 4, and 6 in adult male Sprague-Dawley rats. The behavioral tests for mechanical hyperalgesia were foot withdrawal thresholds to von Frey filaments. After the rats developed pain behavior, HKP-16 was orally administered in the suspension in 0.5% methylcellulose in water. The single oral administration of HKP-16 reduced PAC-induced pain behaviors in rats at the doses of 10, 30, and 100 mg/kg. Especially, the 100 mg/kg returned the pain up to no-pain condition. In addition, repeated oral administrations of HKP-16 (twice daily for 4 days at the dose of 30 mg/kg) significantly reduced PAC-induced pain behaviors for 5 days. The single and repeated administrations of HKP-16 did not produce sedation as a side effects. The result indicates that HKP-16 ameliorates PAC-induced neuropathic pain in rats by oral administration. We conclude that HKP-16 may be a potent new drug candidate for chemotherapy-induced chronic neuropathic pain in cancer patients and survivors.

Title: Pentoxifylline decreases inflammatory cytokines in the dorsal root ganglia in chemotherapy-induced neuropathic pain in rats

Authors: *S.-H. H. KIM, H. KIM, S. ABDI;
Pain Med. - Res., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Many chemotherapy agents such as taxanes, vinca alkaloids, and platinum complexes produce peripheral neuropathic pain, which is a dose-limiting side effect. We previously reported that pentoxifylline (PTX) ameliorates paclitaxel (PAC)-induced neuropathic pain in rats. The purpose of this study was to investigate the effect of PTX on PAC-induced inflammatory cytokines in dorsal root ganglia (DRGs). PAC (2 mg/kg on days 0, 2, 4, 6) or vehicle (4% dimethyl sulfoxide and 4% Tween 80 in saline) was intraperitoneally injected in adult male Sprague-Dawley rats. PTX was intraperitoneally infusion for 7 days starting on day 14 after the first PAC injection and the DRG was dissected on day 20. For western blot, the L1-6 DRGs were dissected, homogenized in RIPA lysis buffer, separated in SDS polyacrylamide gel and then transferred to polyvinylidene fluoride membrane. For detection, blot was incubated with the primary antibody to phosphorylated NFκB (p-NFκB), IL-1β, TNF-α, and GAPDH, respectively and then incubated with the horseradish peroxidase-conjugated secondary antibody. The immunoblots were detected by a chemiluminescence detection system and normalized to GAPDH. For immunohistochemistry, the L5 DRG was dissected, post fixed, cryoprotected in 30% sucrose solution, cryosectioned, and mounted on slides. The section was incubated with primary antibodies followed by secondary antibodies conjugated with either Alexa Fluor 568 or Alexa Fluor 488. The primary antibodies used anti-NeuN, anti-glial fibrillary acidic protein (anti-GFAP), and anti-IL-1β. PAC significantly increased the levels of p-NFκB, TNF-α and IL-1β in the DRGs. Further, PAC-induced increase in p-NFκB, TNF-α, and IL-1β protein levels in the DRGs were decreased by PTX treatment. In addition, IL-1β was expressed in the L5 DRG in PAC-injected rats and IL-1β was co-expressed in NeuN-positive neurons and GFAP-positive satellite cells in the L5 DRG. This result indicates that PAC increases the production of phosphorylated NFκB, TNF-α, and IL-1β in the DRGs and inhibition of PAC-induced inflammatory cytokines level in the DRGs may be the mechanisms underlying the analgesic effect of PTX for chemotherapy-induced neuropathic pain in rats.

Title: The Neuronal calcium sensor-1 knockout mouse model and its utility in better understanding chemotherapy-induced neuropathic pain

Authors: E. M. EDWARDS[1], A. FERRAR[1], D. GIUVELIS[1], K. LINDROS[1], I. M. BERGQUIST[1], O. PONGS[3], E. KAFTAN[4], B. EHRLICH[4], *E. J. BILSKY[2];

Abstract: The neuronal calcium sensor gene family encodes calcium-binding proteins (including NCS-1) that are predominantly expressed in neurons and regulate G protein-coupled receptor phosphorylation in a calcium-dependent manner. NCS-1 regulates a number of intracellular functions including synaptic plasticity and transmission. We have previously shown that NCS-1 is critical to the cellular pathway responsible for paclitaxel-induced peripheral neuropathy. Prolonged treatment with paclitaxel induced degradation of NCS-1 and compromised intracellular calcium signaling. An NCS-1 knockout mouse (NCS-1 KO) has been developed to further explore this mechanistically and we are in the process of doing a comprehensive phenotyping, as well as using the model to assess the role of NCS-1 in development of chronic pain. Adult male and female WT and NCS-1 KO mice were run through a battery of standardized sensory, nociceptive, motor and other behavioral assays to determine the KO phenotype in preparation for the more advanced studies that are examining and comparing nociceptive responses to paclitaxel and other injury-induced nociceptive models. In open field locomotor studies, the WT and NCS-1 KO mice were indistinguishable from each other. Similar results were found with rotarod (coordination) and grip strength measures. Trait anxiety measures were normal between the two groups. Responses to acute thermal stimuli (hot and cold) were generally similar across a range of stimuli intensities, as were tactile thresholds. A small difference was observed in response to plantar incision hyperalgesia (thermal) with NCS-1 KO mice showing a reduced response. In female mice, initial results indicate that paclitaxel produced a similar degree of hypersensitivity in WT and KO mice (male mice are currently being tested). The NCS-1 KO mouse displayed a near normal behavioral phenotype compared to corresponding WT controls and should be a useful tool in further exploring the pathophysiology of chemotherapy induced peripheral neuropathies.

Title: Oxaliplatin impairs mechano-sensory encoding by slowly adapting cutaneous afferents

Authors: J. A. VINCENT[1], P. NARDELLI[2], *T. C. COPE[2];
[1]Neuroscience, Cell Biology, and Physiol., Wright State Univ., Dayton, OH; [2]Applied Physiol. and Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Chronic oxaliplatin (OX) neurotoxicity causes debilitating effects including sensory ataxia and paraesthesia. Our *in vivo* studies (Bullinger et al 2011, Vincent et al 2015) of rats weeks after a full treatment course of OX demonstrate that muscle proprioceptors lose their ability to sustain repetitive firing during static muscle stretch. Given this finding and the known effects of OX on cutaneous sensation (Reddy et al 2016), we hypothesize that OX also abbreviates sustained firing to in response to static tactile stimulation of low threshold mechanoreceptors (LTMRs) in the skin. We began testing this hypothesis by measuring LTMR firing responses in 2 rats following OX treatment after first establishing stable characterization of responses in 10 untreated control rats. Firing was measured in terminal experiments on adult female Wistar rats anesthetized with isoflurane. Action potentials were recorded intra-axonally in dorsal roots from single LTMRs responding to tactile stimulation of glabrous skin on the plantar surface of the foot. LTMRs characterized as Aβ based on conduction delay and threshold were selected for detailed study. Receptors were classified as rapidly adapting (RA) when they adapted and ceased firing during the first 3 seconds of sustained skin indentation, whereas slowly adapting (SA) receptors maintained repetitive firing during sustained skin displacement for 10 seconds and up to 60 secs. Further differentiation of RA1 or 2 vs. SA1 or 2 afferents was based on their vibration sensitivity, and the regularity of firing during sustained skin indentation, respectively. Similar to previous studies of rodent LTMRs, RA afferents ceased firing within 3-5 second of sustained indentation; differentiation of RA2 afferents was based on their exquisite sensitivity to high frequency vibration. SA afferents maintained discharge during sustained displacement, SA1 afferent discharge was highly variable, whereas SA2 afferents showed a

highly regular discharge (Leem et al 1993, Woodbury 2007, Wellnitz 2010, Lesnoak 2014). By comparison, preliminary findings for rats following chronic OX treatment indicated that SA2 afferents had difficulty maintaining repetitive firing during sustained skin displacement, SA1 afferents appeared unaffected as did RA afferents. These early results suggest that chronic OX toxicity might selectively impair signaling of static mechanical stimuli for cutaneous afferents as it does for muscle afferents. These results warrant further study as they may help to explain altered cutaneous sensation experienced by patients treated with OX.

Title: Fy-504, a potent and selective nav1.8 antagonist, blocked chemotherapy-induced peripheral neuropathy (cipn)

Authors: *P. CHO;
Physiol. Lab., Seoul, Korea, Republic of

Abstract: The NaV1.8 sodium channel, encoded by gene SCN10A, was initially termed sensory neuron-specific (SNS) due to prominent expression in primary sensory neurons including dorsal root ganglion (DRG) neurons. This Na(v)1.8 sodium channel has tetrodotoxin-resistant property, activation of which contributes to action potential generation in DRG neurons. Recent genetic and pharmacological evidence indicates that activation of Na(v)1.8 channels contributes to chronic pain, such as inflammatory and neuropathic pain. Here we propose a new selective and potent Na(v)1.8 antagonist (FY-504), which is a modified natural compound from Asian sweetleaf. FY-504 potently blocked tetrodotoxin(TTX)-resistant sodium currents (IC(50)=10pM) from small diameter mouse DRG neurons in a voltage-dependent fashion, but not TTX-sensitive voltage-gated sodium channels. In addition, FY-504 potently blocked recombinant human Na(v)1.8 channels in a dose dependent manner(IC50 ~10 pM) and completely blocked Na(v)1.8 at 100 pM, but did not affect the sodium current of HEK cell with Na(v)1.5 or 1.9. Next, we investigated whether FY-504 effectively suppresses chemotherapy-induced peripheral neuropathy (CIPN). CIPN is a major dose-limiting toxicity of potentially curative cancer therapy regimens. Chemotherapy agents, such as cisplatin and vincristin, have a broad spectrum of activity against tumors, but they induce peripheral sensory neuropathy and there is currently no accepted proven prevention or therapy of CIPN. In CIPN model, protein expression of Na(v)1.8

in DRG and spinal cord increased and FY-504 alleviated painful behavior of CIPN model(vincristin-induced peripheral neuropathy). Thus, FY-504 may also be a promising novel candidate for the prevention and treatment of CIPN.

Abstract: We screened nine genetically diverse inbred mouse strains including seven founder lines of the collaborative cross in attempt to discover novel genes and pathways to promote peripheral nerve regeneration. Naïve and conditioned L4 and 5 adult dorsal root ganglion (DRG) explants from A/J, C3H/HeJ, C57BL/6J, DBA/2J, 129S1/SvImJ, NOD/LtJ, NZO/HlLtJ, CAST/EiJ, and WSB/EiJ strains were grown and assayed on Matrigel, mimicking peripheral nervous system (PNS) environment for their ability to extend axons. *In vitro* analysis for total longest axonal length revealed DBA as the most regenerating strain in the PNS environment. In vivo pinch test also showed 1.6 times more axonal growth with DBA in comparison with C57. Full-genome expression profiling of naïve and preconditioned DRGs across all strains revealed Taf7l and Fscn1 as the transcripts whose expressions most closely correlated with axonal growth on Matrigel. Taf7l is a member of the TATA binding protein associated factor 7 involved in forming transcription factor IID complex, and interestingly regulate Fscn1. Fscn1 is an actin filament binding protein which assembles actin filament binding and organizes actin cytoskeleton. Expression of Fscn1 mRNA in the DRG showed upregulation after peripheral nerve injury and in the conditioned primary cultured sensory neurons, increase in Fscn1 protein was observed in the regenerating axons. Our results indicate that Taf7l and Fscn1 could be playing an important role in peripheral nerve regeneration.

Title: Axonal dysfunction in rab7-associated cmt2b peripheral sensory neuropathy

Authors: ***C. WU**[1], X. CHEN[2], X. ZHAO[2], W. YANG[2], C. JOLIVALT[2], L. BAO[3];
[1]Neurosciences MC0624, UCSD Sch. of Med., La Jolla, CA; [2]Univ. of California San Diego, La Jolla, CA; [3]Chinese Acad. of Sci., Inst. of Biochem. and Cell Biol., Shanghai, China

Abstract: CMT2B is a rare but debilitating disease with axonopathy, i.e. axonal dysfunction and degeneration of the peripheral sensory neurons as a major clinical manifestation. Patients with this disease lose pain sensation and frequently need amputation. Genetic analyses have discovered missense autosomal dominant point-mutations at four residues (L129F, K157N, N161T/I, V162M) in Rab7 associated with the disease. Currently, the pathogenic mechanism is unknown, which has hindered the development of treatments. Thus far, studies using cell lines or Drosophila have led to two opposite conclusions: a “gain of toxicity” in mammalian cell lines versus a “loss of function” or haploinsufficiency in flies. They thus suggest two different therapeutic strategies: inhibiting activation of Rab7 for the “gain of toxicity” model and increasing expression or activation of Rab7 for the “halpoinsufficiency” model. Therefore, better models (rodent models, derived human neurons) are pivotal in resolving the differences in defining the disease mechanism(s) to discover critical pathway(s) towards therapeutic treatments. Based on human CMT2B-Rab7V162M patients10, we have generated a Rab7V162M knockin (KI) mouse model to better study the disease. Preliminary behavioral tests demonstrated that the KI Rab7V162M allele has an autosomal dominant effect and the mutant mice show significant deficits in peripheral sensory function. A thorough and careful study of the KI Rab7V162M mutant mice (heterozygotes: KI/+) and wildtype littermate controls (+/+) will yield important insight into the molecular and cellular mechanisms for CMT2B pathogenesis both in vivo and in vitro. We have also obtained human patient CMT2B-Rab7V162M fibroblasts for converting into human neurons1. The mouse model and patient-derived neurons will provide the best possible systems to study CMT2B.

Title: Oral administration of Compound A, which presents anti-inflammatory properties, ameliorates diabetic neuropathy

Authors: *F. H. P. MACEDO[1], R. D. AIRES[2], R. C. M. FERREIRA[3], D. P. D. MACHADO[3], T. R. L. ROMERO[3], J. H. LEAL-CARDOSO[4], J. S. CRUZ[2];

Abstract: Diabetes Mellitus is a common condition that can lead to peripheral neuropathy, which cause painful symptoms in 16-34% of the diabetic patients. Recent studies have indicated that TNF-alpha might be directly correlated with the pain-related symptoms associated to diabetic neuropathy (DN). In an attempt to attenuate the increase in the TNF-alpha serum levels and the resulting DN development, we performed a daily gavage treatment (200 mg/kg) in streptozotocin-induced diabetic rats (65 mg/kg of streptozotocin via i.p. in 28 days old Wistar male rats) with our Compound A, which holds potent anti-inflammatory effects. Streptozotocin-induced diabetic rats (glycemic level > 300 mg/dl) were randomly separated in two groups, treated and untreated. The same was made for control animals. Rats from the groups control treated and diabetic treated received, daily, the Compound A for a period of 7 weeks, and then were euthanized for DRG dissection and neuron dissociation for total sodium current measurement by patch clamp technique. All protocols were approved by the Ethics Committee in Animal Experimentation (CEUA) from Universidade Federal de Minas Gerais (UFMG) - Protocol number 233/2013. Right before euthanasia, the diabetic rats presented increased in glycemic levels and the treatment with Compound A wasn´t able to reduce this glycemia in diabetic rats. In control rats this compound didn´t change the glycemic levels. Mechanical Threshold (g) were accessed by Randal-Selitto test, and before the diabetes induction, the mechanical threshold values were not different between groups. However, before euthanasia, diabetic rats showed lower mechanical threshold value when compared to control rats. The treatment with Compound A raised this threshold but it still was lower than control rats. In addition, the total sodium current density (pA/pF) in DRG neurons from diabetic rats was enhanced. Interesting, Compound A normalized this sodium current densities at control value.

TNF-alpha serum level measured just before the euthanasia was biggest in diabetic rats and the treatment with Compound A reduced this TNF-alpha concentration at same level to the control group. The decrease of the mechanical threshold associated with the increase of the total sodium current density in the diabetic group compared with the control group might be correlated with the elevation of the TNF-alpha serum levels in diabetic group rats. We conclude that the Compound A was able to attenuate the development of DN probably due to its capacity of preventing the elevation in TNF-alpha serum level.

Title: Exosomes derived from schwann cells ameliorates periheral neuropathy in type II diabetic mice

Authors: *A. SZALAD[1], L. WANG[2], M. CHOPP[2], X. LU[2], L. JIA[2], M. LU[2], Y. ZHANG[2], R. ZHANG[2], X. LIU[2], Z. ZHANG[2];
[1]Neurol. Research, E&R Bld 3046, [2]Henry Ford Hosp., Detroit, MI

Abstract: Background: Peripheral neuropathy is one of the major common complications of diabetes. Exosomes, small microvesicles (30~100 nm) containing proteins, lipids and RNAs including microRNAs (miRNAs), mediate intercellular communication by transferring exosomal cargo between source and target cells. Myelin-forming Schwann cells (SCs) interact with axons and blood vessels to regulate peripheral nerve remodeling. Here, we investigated the effect of SC-derived exosomes on diabetic peripheral neuropathy. Methods and Results: Exosomes were isolated from supernatant of SCs cultured under exosome free medium. Male BKS.Cg-*m*+/+*Lepr*^{db}*/J* (db/db) mice at aged 20 weeks (n=10/group) were treated with SC-exosomes ($4x10^{10}$particles/mouse, i.v.) or saline bi-weekly for 8 consecutive weeks. Compared to diabetic mice treated with saline, diabetic mice treated with the exosomes exhibited significant ($p<0.05$) improvement of motor (MCV, 45.9±1.4 m/s vs. 34.3±0.9 m/s in saline) and sensory (SCV, 44.3±1.6 m/s vs. 35.0±1.5 m/s in saline) conduction velocity in the sciatic nerve**.** **H**istopathological analysis shows that the exosome treatment of diabetic mice significantly

($p<0.05$) increased sciatic nerve fiber diameter (9±0.8% vs. 7.7±1.0% in saline) and myelin thickness (1.9±0.3% vs 1.4±0.3% in saline), and robustly ($p<0.05$) reduced g-ratio (axon diameter/fiber diameter, 0.6±0.04% vs. 0.62±0.05% in saline). The exosome treatment also markedly ($p<0.05$) reduced thermal latency (8.0±0.7m/s vs. 11.2±0.7 m/s in saline) and increased of PGP9.5 positive sensory nerve fibers (14.3±0.9% vs. 10.7±0.7% in saline) in footpad epidermal tissue. Moreover, the exosome treatment substantially improved ($p<0.05$) regional blood flow (98±12% vs. 61±9% in saline) and the density of FITC-dextran perfused vessels (23.6±2% vs. 13.2±2% in saline) at the sciatic nerve of diabetic mice. Quantitative RT-PCR and Western blot analysis of sciatic nerve tissue showed that compared to non-diabetic mice, diabetes considerably ($p<0.05$) reduced miR-27a (0.3±0.04 vs. 1.0±0.1 in non-diabetic mice) and increased its target proteins SEMA6A (2.2±0.2 vs. 1.0±0.1 in non-diabetic mice), whereas the exosome treatment overcame the diabetic effect on miR27a (0.75±0.08 vs. 0.3±0.04 in saline) and SEMA6A (1.3±0.1 vs. 2.2±0.2 in saline). Conclusion: Treatment of diabetic mice with SC-exosomes remarkably improved sciatic nerve neurovascular function and ameliorated neurological functional outcome of peripheral neuropathy, suggesting a prominent therapeutic role for SC-exosomes in diabetic peripheral neuropathy.

Title: Sensory weighting in elderly people and neuropathy patients

Authors: *C. F. MAURER;
Neurozentrum, Freiburg, Germany

Abstract: INTRODUCTION: Postural control in elderly people as well as in neuropathy seems to be impaired by some similar factors. Changes in sensory systems include a reduced joint position sense at the ankle. Moreover, the motor system is affected in both conditions. However, few studies have systematically evaluated the role of sensory, motor, and central adaptation mechanisms for abnormal postural control in both, elderly and neuropathy. Using a feedback model-based approach, we aimed to identify, quantify, and compare these basic postural

mechanisms and, in addition, evaluate the effect of balance training on postural control in both conditions. METHODS: 17 elderly, 38 young people and 14 patients suffering from neuropathy were included. All patients underwent thorough clinical examination to exclude any additional deficit or neurological condition contributing to postural control. Balance control experiments were conducted using a continuous external perturbation, in this case, a support surface rotation, which followed a pseudo-random ternary sequence (PRTS). Patients had their eyes either closed or open. We applied perturbations with 0.5 and 1.0 degrees peak-to-peak amplitude. System identification and parameter estimation were used to estimate balance control model parameters describing the balance behaviour, including the sensory weights. RESULTS: Whereas neuropathy patients down-weight proprioceptive information, elderly people up-weight proprioception, and down-weight vestibular information. Balance training influenced the abnormal use of sensory information in both conditions, but in a diametrically opposed way. In elderly people, we identified, in addition, an increase in overall time delay challenging the feedback systems stability, and a decline in the amplitude of the motor feedback. These abnormalities were not found in neuropathy patients and were not influenced by balance training, either. DISCUSSION: The perturbation-based approach used here gives us more insight about postural control mechanisms of elderly people and neuropathy patients than measures of spontaneous sway do. In addition, it allows for a model-based interpretation of the experimental data and a precise identification of the therapeutic effects of balance training. The model parameters that were identified as critical parameters for the abnormal postural control in both conditions, were well correlated with clinical measures of balance which underlines their relevance for characterizing postural abnormalities.

Title: human iPSC-derived neurons to address peripheral concerns: applications beyond neurotoxicity assessment

Authors: G. LUERMAN[1], D. HESS[2], *B. MURPHY[1], A. EHLICH[2], H. BOHLEN[2]; [1]Axiogenesis, Plymouth Meeting, PA; [2]Axiogenesis AG, Cologne, Germany

Abstract: New technologies are needed to address gaps in drug development, not only for neurodegenerative disorders and neurotoxicological liability screens, but also for numerous other

clinically related applications (e.g. BoNT screening, pain, etc). Historically, drug development and toxicology screens have employed classical animal derived *in vitro* and *ex/in vivo* models, but have lacked relevant human cell models until clinical trials. Thus, preclinical biomarkers may have poor translation to the human clinical condition, low sensitivity, or lack of specificity for neuron-specific effects (e.g. astrogliosis). Additionally, human iPS neurons have largely targeted CNS disorders, while not addressing peripheral related endpoints.
To address these concerns, Axiogenesis developed highly pure human iPSC derived (>80% peripherin positive) neurons. Here we show, using microelectrode array analysis, that Axiogenesis neurons are highly spontaneously active cells characterized by prominent burst activity with high signal/noise. Additionally, these cells demonstrated neurite-specific sensitivity to many common chemotherapeutics associated with clinical peripheral neuropathy. Finally, we speculate on the ability of iPS-derived neurons to address pain related endpoints during preclinical development.

Title: Latent pain sensitization is masked by spinal mu and kappa, but not delta, opioid receptor analgesia in male and female mice.

Authors: *L. CUSTODIO-PATSEY, R. R. DONAHUE, W. FU, B. K. TAYLOR;
Univ. of Kentucky, Lexington, KY

Abstract: Tissue or nerve injury elicits a sustained silent form of neuronal plasticity that increases the susceptibility to chronic pain, entitled latent sensitization (LS). Our laboratory previously demonstrated that injury tonically activates spinal μ-opioid receptors, which in turn opposes nociceptive transmission, preventing the transition from acute to chronic pain (Corder et al, Science, 2013). However, whether other opioid receptors contribute to the maintenance of the remission phase of LS remains uncertain. Moreover, preclinical and clinical studies indicate a sexual dimorphism in the responsiveness to the analgesic effects of ƙ-selective agonists. Therefore, we investigated whether there are sex differences in endogenous ƙ- (and also δ- and μ-) opioid receptor-mediated inhibition of LS. To help to answer these questions, we intrathecally administered opioid subtype-selective antagonists after the behavioral hypersensitivity of postoperative pain had resolved, e.g., 21-28 days after surgical incision of the plantar skin plus damage to the plantaris muscle. We found that ƙ-selective antagonists nor-BNI (0.1μg -10μg i.t.) or LY2456302 (0.1μg -10μg i.t.), or the μ-selective antagonist CTOP (0.001μg -0.1μg i.t.), but not the δ-selective antagonists naltrindole (1μg/5μl i.t.) or TIPP [psi] (1μg -10μg i.t.), reinstated pain-like behavior in a dose-dependent manner. Mu and kappa antagonist-induced reinstatement was observed in both male and female mice. There were no significant differences in von Frey thresholds after LY2456302 (10μg i.t.) at 1h (females 0.41 ± 0.11 vs males 0.69 ± 0.21, mean ± SEM), 4h (females 0.41 ± 0.15 vs males 0.69 ± 0.24), and 96 h (females 1.86 ± 0.34 vs males 1.66 ± 0.38) post injection (n=6-7 animals per group); nor on von Frey thresholds after CTOP (0.1μg i.t.) at 30min (females 0.56 ± 0.18 vs males 0.51 ± 0.22), 120min (females 1.23 ± 0.35 vs males 1.04 ± 0.26), and 180min (females 2.00 ± 0.32 vs males 1.80 ± 0.36) post injection (n=8 animals per group). We conclude that mechanical hyperalgesia after plantar incision in the mouse is maintained in state of remission through ƙ- and μ-, but not δ-opioid receptor subtypes, and is sex-independent. We are currently investigating whether lower doses of ƙ- and μ-opioid antagonists will reinstate mechanical or heat hyperalgesia in a sex-dependent manner. We also aim to investigate whether injury up-regulates the expression of opioid receptors on excitatory interneurons within the superficial laminae of dorsal horn.

Title: Agrins may inhibit diabetic neuropathic pain

Authors: *J.-G. CUI[1], D. ERASSO[2], S. ABDI[3];
[1]Dept of PAIN MEDICINE, DIVISION of Anesthesiol., MD ANDERSON CANCER CENTER, Houston, TX; [2]Univ. of Miami, Miami, FL; [3]MD Anderson Cancer Ctr., Houston, TX

Abstract: Neuropathic pain occurs in approximately 50% of diabetic patients, which constitutes 3.2% of the adult population. The mechanisms for neuropathic pain development are complex, involving pathological alterations of gene, neurotransmitters, irons, molecular signaling pathways, and cellular structures. Current medications (e.g., non-steroidal anti-inflammatory drugs, anti-convulsants, anti-depressants, and opioids) for NP often yield unsatisfactory results and are frequently complicated by multiple side effects, including dependency, addiction, and/or abuse. Therefore, there is a pressing need to seek new therapy for NP. Agrin proteins play an important role in pain modulation, which can selectively activate GABA neurons' NMDA receptor NR1 subunits to inhibit sensory neuron excitation with specific associated helper molecules mitofusin 2 and neurofilament 135. In this project, we used a STZ induced diabetic neuropathic pain rat model to assess roles of Agr25, Agr50, and Agr75 in diabetic neuropathic pain. STZ was dissolved in 0.05 M citrate buffer (pH 4.5) at 20 mg/ml. A single STZ intraperitoneal injection of 55 mg/Kg was performed. On the following day, glucose in blood was checked with a glucose meter ACCU-CHEK (Roche, Mannheim, Germany). After STZ IP injection, the rats developed NP within 7-21 days. However, glucose concentrations in blood were not consistent with neuropathic pain development. Agr genes were installed into AAV2 vector and expressed in HEK293 cells. The purified Agr25, Agr50, and Agr75 were injected intrathecally into diabetic neuropathic pain rats. Some of the Agr proteins suppressed neuropathic pain. The experiments are going on.

Title: Lack of effect of diazepam on the presynaptic depolarization of primary afferents in the undernourished rat.

Authors: *M. G. CARREON[1], C. VELÁZQUEZ-DELGADO[1], B. SEGURA-ALEGRÍA[2], S. QUIROZ-GONZÁLEZ[3], I. JIMENEZ-ESTRADA[1];
[1]Dept. of Physiology, Biophysics and Neurosciences, CINVESTAV-IPN, Mexico city, Mexico; [2]Deparment of Biol., Natl. Autonomous Univ. of Mexico, Mexico city, Mexico; [3]Dept. de Acupunctura y Rehabilitacion, Univ. Estatal del Valle de Ecatepec, Mexico city, Mexico

Abstract: It has been demonstrated that Diazepam (DZP) administration increases the amplitude and duration of the positive component (P wave) in the cord dorsum potential (CDP) and the dorsal root potential (DRP) evoked in the rat (Schmidt et al, 1967). Both potentials are representatives of the primary afferent depolarization (PAD). Quiroz and collaborators (2012) have shown that the electrical stimulation of the cutaneous sural nerve (nSU) generates P waves in CDPs and DRPs of small amplitude in chronic undernourished rats. In this study we analyze the changes in amplitude and duration of the nSU-evoked CDPs and DRPs in control and chronically undernourished Wistar rats (60 days old) by DZP administration (2 mg/kg-bw). In both groups of animals, nSU was stimulated by single current pulses (1Hz; 3 times threshold, 0.2 ms duration). The CDP was recorded on the L6 spinal segment and the DRP on a L6 rootlet. The nSU evoked CDP usually contain 4 components: An afferent volley (AV), two negative components (N1 and N2), and one positive component (P wave).Intraperitoneal administration of DZP to control rats increases the amplitude, area and duration of the N1 component (105.58 ± 4.58% , 171.87 ± 18.35 % and 164.34 ± 13.11 %, respectively) and P wave in the CDP (168.11 ± 17.63 %, 276.80 ± 76.54 % and 296.24 ± 44.54 %, respectively), even in the DRP (125.78 ± 6.94 %, 216.16 ± 97.45 % and 316.79 ± 145.21 %, respectively, p= <0.05. n = 6) Meanwhile, in the undernourished animals DZP administration practically had no effect on the CDP and DRP. The results obtained may suggest that chronic undernutrition alters the expression of the α1, α2 , α3 and γ2 subunits (sensitive to benzodiazepines) in GABAA receptors which are involved on the presynaptic depolarization of primary afferents and presynaptic inhibition in the rat .

Title: Calcium-permeable AMPA receptor signaling in dorsal horn contributes to latent pain sensitization after inflammation

Authors: R. R. DONAHUE[1], G. P. SINHA[1], J. A. MORON[3], B. K. TAYLOR[1], *S. DOOLEN[2]; [1]Physiol., [2]Dept. of Physiol., Univ. of Kentucky, Lexington, KY; [3]Anesthesiol., Washington Univ., Saint Louis, MO

Abstract: Central sensitization (CS) in dorsal horn neurons is thought to contribute to chronic pain states. Less appreciated, however, are data which suggest that CS outlasts overt signs of hyperalgesia, in a silent form termed latent sensitization (LCS). LCS can be revealed with numerous interventions including stress or drugs that reinstate hyperalgesia. For example, we reported in Science (Corder et al, 2013)that the opioid receptor inverse agonist naltrexone (NTX) reinstated pain-like behaviors and signs of spinal neuron activation such as glutamate-evoked Ca^{2+} responses when administered long after the resolution of the initial inflammatory hyperalgesia. Ca^{2+} signaling is crucial in the central sensitization that drives chronic pain. Glutamate α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs) are critically involved in excitatory synaptic transmission, and acute inflammatory insult (1-3 days) triggers spinal accumulation of calcium permeable (CP) AMPARs that coincides with inflammatory hyperalgesia. However, whether CP AMPARs contribute to LCS is unknown. To test the hypothesis that blockade of opioid receptor activity with naltrexone (NTX) will reinstate CP AMPAR-mediated Ca^{2+} signaling during LCS, we performed 4 studies: 1) We measured the effect of an antagonist of CP AMPAR, Naspm, on NTX-induced behavioral reinstatement 21d after injection of complete Freund's adjuvant (CFA, 5-10 ul, i.pl). von Frey (vF) measures of tactile sensitivity were assessed 3, 7 or 21 d later. Consistent with our previous studies, 1 ug NTX (*i.t.*) reinstated mechanical hyperalgesia. We found that Naspm (1 nmol, *i.t.*) dose-dependently decreased NTX-induced mechanical hypersensitivity; 2) We used live-cell Ca^{2+} imaging in adult mouse transverse lumbar slices (450 um), bulk loaded with 10 uM fura-2 AM to measure Ca^{2+} signals in response to AMPA 21d after CFA injury. We found AMPA-evoked Ca^{2+} signaling was greater in the presence of 30 μm NTX; 3) We used patch-clamp electrophysiology

of lamina II neurons to study AMPA currents at 3 d (coinciding with acute hypersensitivity) and 21 d after CFA (during LCS). Consistent with previous studies, current-voltage curves obtained from spinal slices taken 3 d after injection of CFA but not saline exhibited a marked inward rectification at positive potentials. Similarly, we observed inward rectification 21d after CFA; 4) Preliminary western blot data suggest CP AMPARs remain at the post-synaptic density 3d and 21 d after CFA. These data suggest that synaptic CP AMPARs are increased soon after injury, and remain at the synapse during LCS. Targeting CP AMPARs may provide relief in chronic inflammatory pain states.

Title: Effects of botulinum toxin on histamine-dependent and histamine-independent pruritus

Authors: *T. L. YAKSH[1], M. J. MARINO[1], S. PAUL[1], Z. WANG[2], N. MASCARENHAS[2], A. DINARDO[2], R. RAMACHANDRAN[1];
[1]Univ. of California San Diego, La Jolla, CA; [2]Dermatol., UCSD, La Jolla, CA

Abstract: Background: Pruriceptive itch as seen in atopic dermatitis originates following the activation of peripheral sensory nerve terminals associated with allergic reactions either induced by insect bites or when pruitogens come in contact with the skin. The transmission of the pruriceptive signals is mediated by the release of neurotransmitters or peptides from the primary afferents. The ability of botulinum neurotoxins (BoNTs) in attenuating neurotransmitter release has been extensively used in clinic in treating several pain disorders thus, providing a rationale for its application in pruritus. Therefore, the present study investigates the effects of BoNT-A1 and BoNT-B1 serotypes on Compound 48/80 and Chloroquine (CQ) induced itch.
Method: C57Bl/6 mice (male, 25–30 gram) were shaven on the dorsolateral aspect of the neck and upper shoulder. The detection band was placed around the hind paw ipsilateral to the shaven area. Animals are then adapted to the testing chambers for 1 hour. To initiate scratching

behavior, intradermal (ID) injection of the compound 48/80 or CQ was made in the middle of the shaven area of skin using a 30gauge needle and the scratching behavior was recorded using the paw motion detector (PWD) for a period of 40 min. To determine the effects of BoNTs on compound 48/80 and CQ induced scratching, unilateral injections of 1.5 U of BoNT-A or BoNT-B or saline were given 2, 7, 14 and 21 days prior to ipsilateral compound 48/80 and CQ treatment

Results: A significant increase in the bouts of scratching was observed following intradermal injection of histamine dependent compound 48/80 and histamine-independent CQ. Pre-treatment with BoNT-A1 and BoNT-B1 significantly reduced compound 48/80 induced scratching behavior on day 2, 7 and 14 but not on day 21 as compared to the saline treated group suggesting a reversal of BoNT effect by day 21. A similar long lasting effect of BoNT-A1 and B1 were observed on CQ induced scratching as well. BoNT-A1 and BoNT-B1 groups were not statistically different from each other either in compound 48/80 or CQ treated groups.

Discussion: The present study for the first time demonstrated the anti-pruritic effects of two well characterized and clinically employed BoNT serotypes, Botulinum Toxin A1 (A: BoTox©) and Botulinum Toxin B (B: MyoBloc©) over time in pruritus model using two different mechanistically driven pruritogens.

Title: New botulinum conjugates targeting NK1 and opiate receptor expressing neurons for the control of chronic pain

Authors: S. M. GERANTON[1], M. MAIARU[1], A. S. MANGIONE[1], C. TASSORELLI[2], E. FERRARI[3], C. LEESE[4], B. DAVLETOV[4], *S. P. HUNT[1];

Abstract: Botulinum neurotoxin/A (BoNT/A) reversibly blocks neuromuscular synaptic transmission by cleavage of the specific target SNAP25 essential for neurotransmitter release. However, there is also growing evidence that BoNT/A will ameliorate chronic pain states although the mechanism remains unclear. Recently, a botulinum A-based molecule (BiTOX) has been developed that maintains neuronal silencing capacity and reduces peripheral neuropathic pain states but without muscle paralysis (Mangione et al.,2016). Here we have extended this approach by conjugating the silencing domain of BoNT/A (BOT) to either substance P or dermorphin to reversibly inhibit key NK1 or mu-opiate receptor-expressing neurons in the pain pathways and ameliorate chronic pain states.
SP-BOT or Derm-BOT conjugates were injected intrathecally in mice either 2 weeks prior to surgery or 5 days after surgery for the spared nerve injury model of neuropathic pain (SNI). Von Frey's filaments were used to monitor mechanical sensitivity. The targeting of conjugates was monitored using immunochemistry. Lumbar spinal cord sections were stained for cleaved SNAP25 using a specific antibody and tyramide amplification followed by mu-opiate receptor antibody or NK1-rceptor antibody.
SP-BOT (100ng/2µl) treatment before surgery attenuated the increase in mechanical sensitivity seen after SNI (55%). Similarly, when the construct was injected after SNI surgery SP-BOT injected mice showed reduced neuropathic sensitivity compared with the vehicle-injected SNI mice (40%). Derm-BOT conjugates (100ng/3µl) also reduced mechanical hypersensitivity when injected intrathecally in mice after SNI surgery. Immunohistochemistry demonstrated subsets of cleaved SNAP 25-positive neurons in the dorsal horn of conjugate injected mice. Double staining with either NK1 or mu-receptor antibodies indicated that up take of conjugates was largely specific: SP-BOT was found in NK1 positive neurons and Derm-SAP in mu-receptor positive neurons.
In conclusion, the data strongly suggests that both BOT constructs have translational potential for the treatment of chronic pain by selectively and reversibly silencing central neurons involved in pain processing.

Title: Inhibition of transient receptor potential vanilloid type 1 (TRPV1) receptor by α2-adrenergic receptors in dorsal root ganglia neurons

Authors: *M. PUOPOLO, S. CHAKRABORTY, Y. LU, M. REBECCHI;
Anesthesiol., Stony Brook Med., Stony Brook, NY

Abstract: The TRPV1 channel is a molecular integrator in the pain pathway preferentially expressed in Aδ- and C-fiber nociceptors. Expression on the central terminals of nociceptors make TRPV1 channels well positioned to interact with neuromodulators released in the dorsal horn of the spinal cord by supraspinal centers. The aim of this project was to investigate whether norepinephrine (NE) could modulate the activity of TRPV1 channels expressed in nociceptors. Experiments were carried out in isolated dorsal root ganglia (DRG) neurons and in horizontal spinal cord slices from P18-28 rats using the patch clamp technique. In DRG neurons, the TRPV1 current was isolated as the capsaicin-activated current during a ramp of voltage from -100 to +100 mV. The external solution was (mM): 151 NaCl, 2.5 KCl, 2 $CaCl_2$, 1 $MgCl_2$, 10 HEPES. The internal solution was (mM): 125 CsCl, 10 NaCl, 2 $MgCl_2$, 10 HEPES, 10 EGTA, 4 MgATP, 0.3 NaGTP, 14 phosphocreatine, pH=7.2. In spinal cord slices, miniature excitatory postsynaptic currents (mEPSCs) were recorded in voltage clamp (V_h= -70 mV) from lamina I neurons. The external solution was (mM): 125 NaCl, 2.5 KCl, 1.25 $NaH_2PO_4.H_2O$, 26 $NaHCO_3$, 2 $CaCl_2$, 1 $MgCl_2$, 20 Glucose, 0.01 bicuculline, 0.005 strychnine, supplemented with 300 nM tetrodotoxin and 200 nM ω-Con-MVIIC. The internal solution was (mM): 125 $CsMeSO_3$, 10 NaCl, 2 $MgCl_2$, 10 HEPES, 10 EGTA, 4 MgATP, 0.6 GDP-β-S, 14 phosphocreatine, 5 QX-314, pH=7.2. In small DRG neurons, 1 μM NE inhibited the capsaicin-activated inward current by 45±9% (n=11). 1 μM clonidine had similar effects (inhibition by 54±10%, n=6), suggesting modulation of TRPV1 channels by α2-adrenergic receptors. Removal of external Ca^{2+} reduced the inhibitory effect of 1 μM NE on the capsaicin-activated inward current to only 8±3% (n=10). The inhibitory effect of 1 μM NE on the capsaicin-activated inward current remained unchanged when the activity of PKA or PKC was blocked with H89 or BIM, respectively. In contrast, when the activity of CaMKII was blocked with KN-93, 1 μM NE inhibited the capsaicin-activated inward current by only 12±7% (n=12). In spinal cord slices, 500 nM capsaicin increased the frequency of mEPSCs from 11±3 to 30±12 Hz, and 1 μM clonidine on top of capsaicin reduced the frequency of mEPSCs to 12±5 Hz (n=6), consistent with inhibition of TRPV1 channels mediated by activation of presynaptic α2-adrenergic receptors. The data presented here suggest that: 1) activation of presynaptic α2-adrenergic receptors down regulates the activity of TRPV1 channels; 2) the effect of NE is dependent on Ca^{2+} influx; 3) the intracellular pathway downstream to α2-adrenergic receptors activation is coupled, in large part, to CaMKII activity.

Title: Tonic inhibition of spinal PKA- and Epac-mediated latent pain sensitization by neuropeptide Y

Authors: *W. FU[1], N. YE[2], J. ZHOU[2], B. K. TAYLOR[1];
[1]Physiol., Univ. of Kentucky, Lexington, KY; [2]Dept. of pharmacology and Toxicology, Univ. of Texas Med. Br., Galveston, TX

Abstract: Our new models of chronic pain in rodents (Solway et al, PNAS, 2011; Corder et al, SCIENCE, 2013) and humans (Pereira et al, PLoS ONE, 2015) indicate that inflammation or nerve injury produces a silent, or latent sensitization (LS) of nociceptive neurons in the dorsal horn lasting several months, after overt signs of hyperalgesia have resolved. After tissue injury (intraplantar CFA model) or peripheral nerve injury (a mild version of spared nerve injury, CpxSx), LS is under the tonic inhibitory control of endogenous spinal neuropeptide Y (NPY), as indicated by our previous studies showing that intrathecal administration of a selective antagonist of the NPY Y1 receptor, BIBO3304, reinstated pain-like behavior in a dose-dependent manner when injected during the remission phase of LS. To determine the cellular signaling mechanisms underlying the LS that is modulated by Y1 activation, we used pharmacological inhibitors, activators, and transgenic mouse models in the setting of BIBO3304-induced pain reinstatement. We found that BIBO3304 reinstatement was absent in mice lacking adenylyl cyclase 1 (AC1), and could be prevented with intrathecal administration of an AC1 inhibitor (NB001), an activity-dependent NMDAR blocker (MK801), and a TRPA1 antagonist (HC030031). Therefore, we next tested the hypothesis that endogenous NPY/Y1 signaling silences the spinal sensitization driven by cAMP effector proteins. We found that the protein kinase A (PKA) activator (6Bnz) reinstated pain-like behavior when administered during remission; conversely, a PKA inhibitor (H89) attenuated BIBO3304-induced behavioral reinstatement. HC030031 reversed 6Bnz reinstatement. Next, we intrathecally administered one of several inhibitors of exchange protein activated by cAMP (Epac), including ESI-09, HJC0350, and HJC0197 during remission. Each Epac inhibitor attenuated BIBO3304-induced behavioral reinstatement. We conclude that injury sensitizes NMDAR-AC1-Epac and NMDAR-AC1-PKA-TRPA1 pain signaling pathways, both of which are latent due to inhibitory NPY-Y1 signaling. Our data suggest that Y1R signaling is part of an endogenous braking mechanism that silences the behavioral manifestations of chronic

pain, such that mammals naturally recover from the LS associated with inflammation or nerve injury.

Title: Lidocaine metabolite, monoethylglycinexylidide, affects synaptic transmission in rat spinal dorsal horn

Authors: ***K. FURUTANI**, Y. KAMIYA, T. KOHNO, H. BABA;
Niigata university, Niigata-city, Japan

Abstract: Background: Analgesic mechanisms of systemic administration of lidocaine (Lid) have not fully elucidated. In recent years, some investigators reported that Lid metabolites could exert analgesic action. Therefore, we hypothesized that the one of the Lid metabolites, monoethylglycinexylidide (MEGX), had the analgesic action on spinal dorsal horn. The purpose of this study was to analyze whether MEGX affected synaptic transmission in rat dorsal horn neurons using whole-cell patch clamp recording.
Methods: Adult male Wistar rats were anesthetized by urethane. Thereafter, dorsal laminectomy was performed and lumbosacral segment of spinal cord with ventral and dorsal root was removed. A transverse slice was cut on a microslicer and placed on a nylon mesh in the recording chamber. The slice was perfused continuously with Krebs solution. The effects of MEGX (10 μM) and Lid (10 μM) on the spontaneous excitatory postsynaptic currents (EPSC) and inhibitory postsynaptic currents (IPSC) were examined in lamina II neurons using the whole-cell patch-clamp technique. Data were expressed mean +/- SD. Statistical analysis was performed using Student's *t*-test.
Results: MEGX (10 μM) decreased the frequencies of spontaneous EPSC (44 +/- 22% of control, $p < 0.001$, $n = 7$) with the inward currents (the average amplitude: 13 +/- 6 pA) without affecting the amplitudes. In contrast, MEGX (10 μM) decreased the frequencies of spontaneous IPSC (55 +/- 24% of control, $p < 0.001$, $n = 12$), but biphasic changes (increase followed by decrease) in frequencies were observed in 6 of 12 cells. Outward currents (the average amplitude: 56 +/- 48 pA) were observed in 6 of 12 cells. MEGX did not affect the amplitudes of spontaneous IPSC.

However, Lid (10 μM) did not affect the amplitudes and frequencies of both EPSC and IPSC. Conclusions: MEGX has the possibility to inhibit the presynaptic release of excitatory neurotransmitters. However, MEGX also temporarily increased the frequencies of IPSC and exhibited outward currents in 50% of recording cells, suggesting that MEGX might partially facilitate the release of inhibitory neurotransmitters. In contrast, Lid at clinically-relevant concentration had no effects on synaptic transmission. The analgesic mechanisms of systemic administration of Lid may be exerted by its metabolites.

Title: Molecular and electrophysiological characterization of neuropeptide Y Y1 receptor-expressing neurons in the substantia gelatinosa of the spinal cord

Authors: ***G. P. SINHA**[1], W. FU[2], K. C. HALMOS[2], B. N. SMITH[2], S. DOOLEN[2], B. K. TAYLOR[2];
[2]Dept. of Physiol., [1]Univ. of Kentucky, Lexington, KY

Abstract: Neuropeptide Y (NPY) receptors are expressed in *substantia gelatinosa* (lamina II) neurons of the spinal cord. NPY reduces behavioral signs of acute and chronic pain, in part through activation of the NPY Y1 receptor (Y1R). However, the cellular mechanism of Y1R-mediated analgesia remains unclear. One outstanding question is whether they are expressed in inhibitory and/or excitatory neurons, and where they fit within the dorsal horn microcircuity of pain transmission and pain control, especially in the setting of chronic pain arising from tissue or nerve injury. Behavioral pharmacology and targeted neurotoxin studies from our laboratory support the hypothesis that Y1R-expressing neurons are excitatory. Furthermore, we report that Y1Rs co-exist with multiple markers of excitatory neurons such as Tlx3, calbindin, calretinin,

and somatostatin, but not a widely accepted marker of spinal inhibitory interneurons, PAX2. Using patch-clamp electrophysiology in current clamp mode we recorded from lamina II neurons in para-sagittal slices from the spinal cord lumbar L4/L5 segment of adult mice. In randomly recorded unlabeled neurons, we observed firing patterns in the following ratios: tonic (35 %), initial burst (28 %), delayed and gap (15 %) and single (22 %). In Y1R- positive cells visualized from slices prepared from Y1R-eGFP mice, the majority of cells exhibited initial burst firing (90%) upon current injection, with a small percentage (10%) exhibiting tonic firing. It is widely assumed that tonic and perhaps initial burst firing patterns represent inhibitory, GABAergic neurons, and preliminary single-cell PCR experiments in Y1-expressing neurons using GAD67 and vGlut2 probes seem to confirm this. Also, dorsal root stimulation (DRS) evoked monosynaptic (putative) EPSCs at A-δ recruiting strengths in Y1R-GFP neurons (n = 2), suggesting that they receive primary afferent input from A-δ sensory neurons. To determine the effects of NPY on Y1R-GFP neurons, we administered NPY via puff application and observed outward currents (n = 4). In current clamp mode, DRS evoked action potentials were abolished by application of NPY, and this was accompanied by a hyperpolarizing shift of the resting membrane potential by ~10 mV. Both recovered after washout. Taken together, our data suggest that endogenous spinal NPY produces analgesia by altering a complex dorsal horn microcircuit in the dorsal horn that includes interneurons that express Y1R.

Title: Underlying mechanisms of acetaminophen in the spinal dorsal horn neurons

Authors: N. OHASHI[1], M. SASAKI[1], M. OHASHI[1], Y. KAMIYA[2], *H. BABA[3], T. KOHNO[1]; [1]Niigata Univ. Grad. Sch. of Med. and Dent. Sci., Niigata, Japan; [2]Uonuma institute of community medicine, Minami-Uonuma, Japan; [3]Niigata Univ, Sch. Med., Niigata, Japan

Abstract: Acetaminophen is one of the most popular and has been widely used as an analgesic agent. Several studies suggest that acetaminophen is metabolized to *N*-acylphenolamine (AM404), which directly acts transient receptor potential vanilloid 1 (TRPV1) and cannabinoid (CB1) receptors in the brain, resulting in analgesia. TRPV1 and CB1 receptors are both present in the superficial spinal dorsal horn, especially the substantia gelatinosa (SG), which is important

as pain pathway. However, no previous studies have reported the analgesic mechanisms of acetaminophen in the spinal dorsal horn. In the present study, we therefore investigated whether clinical level of acetaminophen produces analgesia in the rat spinal dorsal horn using behavioral measures and electrophysiological methods. First, we investigated the effects of AM404 in spinal cord in the radiant heat test. Intrathecal injection of AM404 (0.1, 0.3, 1 nmol) significantly prolonged the withdrawal latency in a concentration-dependent manner, suggesting that AM404 produces analgesia in the spinal cord directly. We then examined the effects of AM404 on primary afferent Aδ and C fibers using spinal transverse slices with the dorsal root attached by whole-cell patch-clamp recording in SG neurons. Monosynaptic excitatory postsynaptic currents (EPSCs) were evoked by Aδ or C fiber stimulation. Bath applied AM404 (30 μM) significantly decreased the amplitude of monosynaptic EPSCs evoked by C fiber stimulation ($P < 0.01$), but not by Aδ fiber stimulation ($P > 0.05$). These effects disappeared in the presence of capsazepine (TRPV1 receptor antagonist), but not AM251 (CB1 receptor antagonist). Taken together, these findings strongly suggest that AM404 metabolized from acetaminophen produces analgesia through TRPV1 receptors expressed on C fibers in the spinal dorsal horn.

Title: Effect of voltage gated sodium channel toxins as therapeutic agents for chronic pain

Authors: N. R. MUNASINGHE[1], J. DEUIS[2], V. HERZIG[2], Z. DEKAN[2], *W. L. IMLACH[3], R. LEWIS[2], G. KING[2], P. ALEWOOD[2], J. KLINT[2], I. VETTER[2], M. J. CHRISTIE[1];
[1]Discipline of Pharmacol., Univ. of Sydney, Sydney, Australia; [2]Institue for Mol. Biosci., Univ. of Queensland, Brisbane, Australia; [3]The Univ. of Sydney, Sydney, Australia

Abstract: In humans, the loss function mutation in the SCN9A gene that codes for voltage gated sodium channel 1.7 ($Na_V1.7$) caused insensitivity to pain, while gain of function mutations resulted in paroxysmal extreme pain disorder and primary erythermalgia. $Na_V1.7$ therefore plays an important role in pain. $Na_V1.7$ channels are abundant in small (<25μm) primary sensory neurons of the dorsal root ganglion (DRG). This project aimed to identify the efficacy of animal

toxins that are selective for $Na_V1.7$, which may serve as potential therapeutic agents in the treatment of pain. In order to identify the role of $Na_V1.7$ channels, whole cell patch clamp electrophysiology was conducted on acutely isolated neurons from male Sprague Dawley rats. Types of DRG neurons were discriminated based on isolectin-B4 binding (peptidergic neurons do not stain) and cell size. The synthetic spider toxin Hs1a inhibited 70% percent of the small peptidergic DRG Na_V neuronal current while only inhibiting about 30% of the small non-peptidergic Na_V neuronal current. Similarly, the synthetic venom peptide 1 was found to be most effective in small peptidergic neurons. When the tetrodotoxin sensitive Na_V current component was isolated, there was about 80-90% inhibition by peptide 1 (1μM) in both peptidergic and non peptidergic, small DRG neurons. Since $Na_V1.7$ is potently blocked by tetrodotoxin, these results show promise that the inhibited Na_V current is primarily due to $Na_V1.7$ blockade. Peptide 1 shows little inhibition in large DRG neurons which are known to express very low levels of $Na_V1.7$. In spinal cord slices, peptide 1 inhibited electrically-evoked afferent transmission (at C-fibre strength) onto dorsal horn neurons. Overall, these results support both Hs1a and peptide 1 as having therapeutic potential to treat pain by selectively inhibiting $Na_V1.7$ in nociceptive neurons.

Title: Peripheral nerve injury increases stimulation-induced neuropeptide Y release as measured by Y1 receptor internalization in the rat dorsal horn

Authors: *B. K. TAYLOR[1], W. FU[1], W.-L. CHEN[2], J. G. MARVIZON[2];
[1]Physiol., Univ. of Kentucky, Lexington, KY; [2]UC Los Angeles, VA Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Peripheral nerve injury greatly increases the expression of neuropeptide Y (NPY) in myelinated afferents and their central terminals in laminae II-IV of dorsal horn. We previously reported that tissue injury increases NPY expression, NPY Y1 receptor (Y1) signaling, and spinal anti-hyperalgesia (Taylor et al., Neuroscience, 2014). However, whether this is associated with an increased release of NPY and Y1 activation has been difficult to study in the absence of a sensitive and reliable assay. Therefore, we developed Y1R internalization as a new *in situ* assay of spinal NPY release. This approach is similar to the extensive use of neurokinin 1 receptor and μ-opioid receptor internalization to measure the release of substance P and opioids, respectively. Receptor internalization has several advantages over other methods to measure neuropeptide release such as microdialysis, antibody microprobes and peptide immunoassays: 1) it allows the localization of the areas of release (segment, side, lamina, etc.); 2) it is an *in situ* measure and thus avoids problems with extracting the peptide; 3) it is sensitive; 4) it is non-invasive; 5) it detects peptide release that is physiologically relevant in terms of receptor activation. We found that NPY concentration-dependently induced Y1R internalization in rat spinal cord slices with and EC_{50} of 43 nM (95% CI 18-100 nM). In spinal cord slices, electrical stimulation of the dorsal horn (1000 pulses of 20 V, 0.4 ms, at 5 Hz and 500 Hz) induced Y1R internalization. In contrast, the same 1000 pulses delivered to the dorsal root (at 5 Hz or 100 Hz) failed to induce a significant amount of Y1R internalization. Y1R internalization induced by dorsal horn stimulation increased 14 days after spared nerve injury (SNI). Next, we substituted electrical stimulation of the dorsal horn with stimulation of the sural receptive field of the plantar skin ipsilateral to SNI. At day 14 after SNI, rats were anesthetized with isoflurane and received a non-noxious (gentle stroke with the experimenter's thumb for 2 sec, repeated every 4 sec for 2 min) or noxious stimulus (application of a 2-cm wide binder clip for 2 min). Rats were euthanized 5 minutes later and used to measure Y1R internalization in the lumbar spinal cord. We found that both non-noxious and noxious stimulation markedly increased Y1R internalization in the dorsal horn ipsilateral but not contralateral to SNI. Therefore, SNI increases NPY release induced by electrical stimulation of the dorsal horn in slices or by sensory stimulation of the hindpaw. We conclude that after nerve injury, sensory stimulation evokes NPY release from A-fibers or from neurons receiving synapses from them.

Title: Inhibition of bone resorption does not contribute to the analgesic effects of Src antagonism in an animal model of cancer-induced bone pain

Authors: *V. HURST[1], D. LAMBERT[2], I. HOLEN[3], K. J. ESCOTT[4], D. ANDREW[1]; [1]OMFS, [2]Biochem. and Cell Biol., [3]Oncology and Metabolism, The Univ. of Sheffield, Sheffield, United Kingdom; [4]Astrazeneca, London, United Kingdom

Abstract: Cancer-Induced Bone Pain (CIBP) is a common and debilitating symptom of patients with advanced disease, and severely reduces their quality of life. Current medical treatments can cause adverse effects or may not produce a significant improvement in symptoms. One proposed mechanism-based therapy is the inhibition of the non-receptor tryrosine kinase Src, which controls N-Methyl-D-Aspartate receptor (NMDAR) activity. The NMDAR plays a key role in the pathophysiology of pain and inhibiting Src is effective in reducing pain in a rat model of CIBP (de Felice et al. 2016). Cancer patients with bone metastases receive bisphosphonates such as zoledronic acid (ZOL) to prevent skeletal related events, such as pathological fractures, spinal cord compression and hypercalcaemia. ZOL also has weak analgesic efficacy as shown in a meta-analysis (Wong & Wiffen 2002). We have investigated whether co-administration of a clinically-relevant dose of ZOL with the Src-inhibitor Saracatinib increased the magnitude of hyperalgesia inhibition in a rat model of CIBP, and whether combined treatment also improved bone preservation. Thirty-six male Sprague-Dawley rats were injected with $6x10^4$ MRMT-1 (rat mammary cancer; Riken, Japan) cells into the left tibia. Seven days later the animals were given a single injection of ZOL (100ug/kg s.c.) or vehicle, and administered either Saracatinib (20mg/kg) or vehicle daily for one week by gavage. Mechanical allodynia and thermal hyperalgesia of the plantar surface of the hind limb paws were measured pre- and post-surgery. The tumour-bearing bones and serum were harvested at day 14 post-surgery for microtomography, histology, and to measure markers of osteolysis. Animals administered Saracatinib (either alone or with ZOL) showed reduced thermal hyperalgesia as compared with animals treated with vehicle alone. There was no effect of ZOL on pain behaviour, nor any additive effects when administered with Saracatinib. Bone resorption markers were reduced and bone volume increased in animals treated with combined ZOL + Saracatinib, but not Saracatinib alone. These data indicate that administration of a clinically-relevant dose of ZOL in combination with Saracatinib does not provide any therapeutic gain in pain relief or bone-preservation.

Title: Sex differences in pioglitazone analgesia for painful diabetic neuropathy

Authors: *D. E. LAIRD, R. R. DONAHUE, R. B. GRIGGS, B. K. TAYLOR;
Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Diabetes affects 9% of the United States population equating to over 25 million adults and children. Approximately one-half of patients with diabetes experience neuropathy, which is characterized by motor, autonomic, and sensory nerve dysfunction. Approximately two-thirds of patients with neuropathy experience pain, commonly referred to as painful diabetic neuropathy (PDN). Maintaining blood glucose in the normal range is first line of defense against PDN. In late-stage type 2 diabetes, however, PDN is difficult to manage. Blood levels of methylglyoxal (MG), a highly reactive dicarbonyl product of glycolysis that accumulates in plasma during hyperglycemia, is elevated in patients with diabetes, and even further elevated in patients with PDN. We found elevated levels of MG in plasma of the ZDF and db/db rodent model PDN. Also, intraplantar injection of MG produced dose-dependent pain-like behaviors in mice and rats (e.g. licking and lifting of the hind paw), hyperalgesia (mechanical and heat hypersensitivity), conditioned place aversion and pERK in superficial laminae of the dorsal horn. PPARγ agonists such as pioglitazone have analgesic properties distinct from their antidiabetic properties. Since PPARγ agonists are already available and have proven beneficial effects in diabetes in humans, testing their mechanisms of action in animal models seems like a reasonable approach. We are currently investigating the therapeutic effects of pioglitazone on MG-induced thermal hypersensitivity in males and females using a hot plate assay, as well as MG-induced mechanical hypersensitivity using von Frey filaments. We found that pretreatment with 100 mg/kg i.p. pioglitazone, but neither 10 mg/kg nor saline, prevented MG-induced (100 µg / 5µl i.pl.) mechanical hypersensitivity in male C57Bl/6 mice. By contrast, 10 mg/kg pioglitazone substantially reduced the development of MG-induced mechanical hypersensitivity in females. Preliminary dose-response data from the lab indicate that low doses (1, 10 mg/kg) of pioglitazone inhibit MG-induced thermal and mechanical hyperalgesia in female but not male mice. These data suggest that pioglitazone is more effective in reducing MG-induced thermal and mechanical hyperalgesia in female than in male mice. Further studies are needed to determine whether this sex difference extends to models of PDN.

Title: Small molecule inhibitors of PSD95-nNOS protein-protein interactions suppress formalin-evoked Fos protein expression and nociceptive behavior in rats.

Authors: *L. M. CAREY, IV[1], P. KULKARNI[2], G. A. THAKUR[2], Y. Y. LAI[1], A. G. HOHMANN[1];
[1]Indiana Univ., Bloomington, IN; [2]Northeastern Univ., Boston, MA

Abstract: Excessive activation of NMDA receptor (NMDAR) signaling within the spinal cord contributes to the generation of central sensitization, a phenomenon which underlies the induction and maintenance of pathological pain states. However, direct antagonism of NMDARs produces a wide range of undesirable side effects (e.g. impairments in learning, memory and motor function) which limit their clinical use. NMDAR activation initiates central sensitization, at least in part, by initiating a signaling cascade that activates the enzyme neuronal nitric oxide synthase (nNOS) and generates the signaling molecule nitric oxide (NO). NMDAR activation of nNOS requires a scaffolding protein, postsynaptic density protein 95 kDa (PSD95), which tethers nNOS to NMDARs. Thus, disrupting the interaction between PSD95 and nNOS may inhibit pro-nociceptive signaling mechanisms downstream of NMDARs and suppress central sensitization while sparing unwanted side effects associated with direct NMDAR antagonists. We examined the impact of two small molecule PSD95-nNOS protein-protein interaction inhibitors, ZL006 and IC87201, on formalin-evoked nociceptive behavior as well as Fos protein expression, a marker of neuronal activation, within the lumbar spinal dorsal horn, using the same subjects. To assess specificity of small molecule inhibitors, comparisons were made with ZL007, an analog of ZL006 that does not disrupt PSD95-nNOS interactions in vivo. The noncompetitive NMDAR antagonist MK-801 was used as a positive control. IC87201 and ZL006 selectively suppressed

phase 2 of formalin-evoked pain behavior whereas ZL007 did not. Moreover, IC87201 and ZL006 similarly decreased the number of Fos-like immunoreactive cells in lumbar spinal cord regions associated with nociceptive processing. PSD95-nNOS inhibitors suppressed the number of formalin-evoked Fos like immunoreactive cells in the superficial dorsal horn (laminae I, II), the nucleus proprius (laminae III, IV) and the neck region of the dorsal horn (laminae V, VI). The pattern of biochemical and behavioral changes induced by PSD95-nNOS inhibitors was also similar to that produced by MK801. The present findings validate the use of small molecule PSD95-nNOS protein-protein interaction inhibitors as novel analgesics and demonstrate, for the first time, that these inhibitors suppress inflammation-evoked neuronal activation at the level of the spinal dorsal horn.

Title: Contribution of presynaptic HCN channels to excitatory inputs of spinal substantia gelatinosa neurons

Authors: ***T. LIU**[1], S. PENG[2], D. ZHANG[2], X. HU[2], L. LI[2], C. XIE[2];
[1]The First Affiliated Hosp. of Nanchang Univ., Jiangxi, China; [2]the First Affiliated Hosp. of Nanchang Univ., Nanchang, China

Abstract: Aim of Investigation: Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are widely distributed in nervous system and are associated with neuropathic pain. HCN channel family comprises four homologous isoforms (HCN1-HCN4). Activation of HCN channel results in an inward mixed cation current. Lamina II in spinal cord (also named substantia gelatinosa, SG) is identified as the primary center to regulate peripheral nociceptive signal, where the excitatory interneurons dominate sensory processing. In order to know in detail about the contribution of HCN channels in regulating nociceptive transmission, the expression of HCN channel isoforms in glutamatergic synaptic terminal and the role of presynaptic HCN channels to excitatory inputs in spinal SG were investigated.**Methods:** We examined the expression of HCN1-HCN4 isoforms in presynaptic terminal using the immunohistochemical

technology. Whole-cell patch-clamp recordings were applied to SG neurons in spinal cord slices prepared from both male juvenile SD rats and GAD67-GFP transgenic C57BL6 mice. Spontaneous and miniature excitatory postsynaptic currents (sEPSCs and mEPSCs) are recorded in whole-cell mode at a holding potential of -70 mV. **Results:** All isoforms of HCN channels were found in superficial spinal dorsal horn. Among them, HCN4 was partly co-expressed with VGLUT2 (marker of excitatory presynaptic terminal). Unlike HCN4, HCN1-HCN3 were seldom co-expressed with VGLUT2. Superfusion of an HCN channel antagonist, ZD7288, dose-dependently decreased the frequency but not the amplitude of spontaneous excitatory postsynaptic currents (sEPSCs) in nearly 70% of SG neurons examined. Moreover, the ZD7288-induced reduction was mimicked by another HCN channel blocker cesium chloride and not affected by tetrodotoxin. On the contrary, 50 μM of forskolin (the activation of adenylate cyclase) superfused for 15 min significantly increased the frequency but not the amplitude of both sEPSCs and mEPSCs. Interestingly, ZD7288 hardly had effect on sEPSCs of GABAergic SG neurons which labeled with GFP in GAD67-GFP transgenic C57BL6 mice. **Conclusions:** We conclude that HCN isoforms are differently expressed in axon terminal of SG neurons. HCN4 but not HCN1-HCN3 is relatively enriched in excitatory presynaptic terminal. Our data also demonstrate HCN channels are involved in decreasing the release probability of glutamate from presynaptic terminal which innervate excitatory but not inhibitory SG interneurons. Thus, inhibition of HCN4 channels may be a novel pathway for suppression of nociceptive transmission.

Title: Spinal sigma-1 receptor mediates dephosphorylation of astrocytic aromatase leading to nociceptive effect in mice formalin model

Authors: M.-J. LEE[1], H.-S. CHOI[1], A. J. BEITZ[2], *J.-H. LEE[1];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Vet. and Biomed. Sciences, Col. of Vet. Med., Univ. of Minnesota, St. Paul, MN

Abstract: Aromatase in central nervous system is a key enzyme that produces estrogen from testosterone, which participates in various biological processes including pain sensation. The short term changes of aromatase activity are known to be regulated with rapid and transient cellular processes, such as phosphorylation of proteins at different activation sites. We have previously demonstrated that Sigma-1 receptor, a unique ligand-regulated molecular chaperone, can affect the phosphorylation states of various receptors and enzymes in pain sensation. In this study, we examined whether spinal Sigma-1 receptor can modulate the activity of aromatase through modifying phosphorylation states of aromatase, leading to nociceptive effect in formalin model. Intrathecal (i.t.) injection of letrozole, an aromatase inhibitor, has dose-dependently reduced the nociceptive responses in the second phase of formalin test and the expression of spinal Fos, as compared with those of control group. After showing that aromatase was co-localized with Sigma-1 receptor in spinal astrocytes, we confirmed through co-immunoprecipitation that the level of phosphorylated serine in spinal aromatase was down-regulated in formalin injected control mice. However, this dephosphorylation of aromatase was significantly restored by i.t. administration of BD-1047. Moreover, sub-effective doses of letrozole and BD-1047 showed anti-nociceptive effect when they were co-administered in formalin injected mice. These results demonstrate that Sigma-1 receptor mediated dephosphorylation of astrocytic aromatase indeed induces nociceptive effect in formalin mice, suggesting Sigma-1 receptor as an important factor for aromatase activity modulation in the spinal cord.

Title: Ifenprodil and agmatine inhibit C-fiber-mediated EPSCs in spinal cord slices from Nav1.8-ChR2 mice.

Authors: J. J. WAATAJA[1], P. A. SÉGUÉLA[3], G. L. WILCOX[1], *C. A. FAIRBANKS[2]; [1]Dept of Neurosci., [2]Depts Pharmaceut, Pharmacol & Neurosci, Univ. Minnesota, Minneapolis, MN; [3]Neurol. and Neurosurg., McGill Univ., Montreal, QC, Canada

Abstract: Background: Agmatine (decarboxylated arginine) is found throughout the CNS and has been shown to play a role in synaptic plasticity. In the spinal cord, changes in the synaptic strength between nociceptive afferents and their neuronal targets are thought to play a role in the initiation of neuropathic pain. Indeed, exogenous application of agmatine has been shown to attenuate hyperalgesisa (Fairbanks et al., PNAS 2000), spinal opioid tolerance, and inhibit spinal LTP Waataja, SfN Abstracts (2014). Little is known, however, of agmatine's effect on specific subunits of the NMDA receptor in spinal cord dorsal horn.
Methods: Transverse spinal cord slices with a 4-7 mm L4 dorsal root attached were prepared from naïve mice with transgenically introduced channel rhodopsin 2 in Nav1.8-expressing sensory neurons. The dorsal root was stimulated optogenetically by LED-generated 470 nm light applied via the 40x objective of an Olympus BX-50WI microscope to evoke glutamate-mediated excitatory post synaptic currents (eEPSCs); all conduction velocities of afferent fiberss were <1 m/s, confirming that they were all C-fibers. Uhelski-ML and colleagues (SfN Abstracts, 2016) have demonstrated that almost 90% of light-activated neurons in these mice are nociceptors. Dorsal horn neurons were patch-clamped and held at a holding potential of +50 mV to maximize NMDA receptor-mediated EPSCs. We expected to observe EPSCs with two distinct components, faster decay times (~500 ms) indicating the participation of NR2A subunits and slower decay times (~1000 ms) indicating the participation of NR2B subunits; EPSCs were recorded and averaged (N=10). The effect of the NR2B subunit-selective antagonist Ifenprodil (1 - 100 uM) was used as a positive control for NR2B subunit activity and compared against that of agmatine (300 uM - 3 mM).
Results: Bath application of ifenprodil concentration-dependently reduced amplitude, eEPSC recovery time and the tau of eEPSCs recorded from spinal neurons following stimulation. Similarly, bath application of agmatine concentration-dependently reduced amplitude, eEPSC recovery time and the tau of eEPSCs in spinal cord neurons. In both cases, bath application of each compound was sequential resulting in cumulative concentration-response curves.
Conclusion: This study supports the hypothesis that agmatine antagonizes NMDA receptors containing the NR2B subunit. Furthermore, these experiments corroborate that agmatine acts on neurons in the dorsal horn of the spinal cord that receive nociceptive information.

Title: Repetitive motor cortex stimulation for the relief of neuropathic pain after nerve injury in rats

Authors: *M. CHA, B. LEE;
Dept. of Physiol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Motor cortex stimulation (MCS) is increasingly reported as an effective surgical option for the treatment of neuropathic pain although its mechanism of action remains poorly understood. We hypothesized that analgesic effects of MCS may be related to plastic changes in the anterior cingulate cortex (ACC) in animals with neuropathic pain and, furthermore, the repetitive MCS could alleviate the neuropathic pain more effectively than single MCS. To test this hypothesis, rodent neuropathic pain model were used and the repetitive MCS stimulation (30 min, 50 μA, 50 Hz; 300 ms pulses) was applied during 10 days. The mechanical threshold on the hind paw of the nerve injured rat was recorded before and after repetitive MCS. As results, MCS suppressed the neuropathic pain in nerve-injured rats and repetitive MCS showed the enhanced analgesic effect. In addition, the analgesic effects of repetitive MCS were blocked by inactivation of PKM ζ(related to LTP maintenance) using zeta inhibitory peptide (ZIP). These findings support our hypothesis and suggest that MCS for neuropathic pain is a safe and efficacious treatment option. This research was supported by the Basic Science Research Program through the National Research Foundation (NRF) funded by the Ministry of Science, ICT & Future Planning (2015R1C1A1A01053484 and 2015021989).

Title: Contribution of ascending serotonin facilitation to neuronal hyperactivity in the anterior cingulate cortex underlying the maintenance of neuropathic pain

Authors: C. BIAN[1], R. HU[1,2], M. LI[1,2], J. LIU[1,3], J.-L. YANG[1], W. GUO[1], S. ZOU[1], K. REN[1], R. DUBNER[1], *F. WEI[1];

Abstract: The neurotransmitter serotonin (5-HT) in the brain stem modulates neuronal activity in the CNS through its descending and ascending projections. Recent studies have shown that active 5-HT-dependent descending facilitation is involved in central mechanisms underlying the maintenance of neuropathic pain. Although functional changes of the ascending 5-HT system are implicated in the pathophysiology of some affective disorders, such as depression, it is less known whether the ascending 5-HT system contributes to cortical mechanisms of persistent pain. Given the efficacy of tricyclic antidepressants but less benefit of selective 5-HT reuptake inhibitors in the treatment of neuropathic pain, it is necessary to understand how cortical 5-HT activity participates in the modulation of the affective dimension of persistent pain. In the present study, we investigated functional changes of the 5-HT system in the anterior cingulate cortex (ACC) of mice after CCI of the infraorbital nerve (CCI-ION), an animal model of orofacial neuropathic pain, and its contribution to the sensory and affective-emotional components of neuropathic pain. First, a wide-spread and equal density of distribution of 5-HT-IR fibers were observed in all laminae of the ACC. A combination of retrograde tracing and immunostaining demonstrated that ACC 5-HT input came from both the dorsal raphe (DR) and median raphe nuclei (MR). We also observed pERK1/2 expression in 5-HT-IR neurons in both the DR and the MR without variance of 5-HT-IR intensity in the ACC at 14 d after CCI when compared with

naïve animals. Next, using whole-cell patch-clamp recording from ACC slices from naïve and 14d CCI-treated mice, we found that nerve injury caused a significant increase of the frequency and the amplitude of spontaneous and miniature excitatory postsynaptic currents in layer V pyramidal neurons, suggesting CCI-induced neuronal hyperactivity in the ACC. Either bath application of the selective 5-HT3A receptor antagonist, Y25130, or the selective 5-HT1A receptor agonist 8-OH-DPAT alleviated the CCI-induced increase of the frequency but not amplitude of sEPSCs in layer V ACC neurons at 14 d after CCI. Finally, microinjection of 2% lidocaine or Y25130 attenuated mechanical allodynia and negative reinforcement in the conditioned place preference test at 14 d after CCI. Together, these findings suggest that the active ascending 5-HT system enhances excitatory neuronal activity in the deep layer of the ACC and contributes to the maintenance of neuropathic pain conditions by presynaptic 5-HT3AR mechanisms. Reduction of ascending 5-HT facilitation in the ACC may be a potential therapy for neuropathic pain.

Title: Chronic pain disrupts the affective response to acute pain through altered neural activities in the anterior cingulate cortex (ACC)

Authors: ***J. WANG**[1], Q. ZHANG[2], A. TONG[2], T. MANDERS[2], A. GARG[2], R. YANG[2], Z. CHEN[2];

Abstract: Chronic pain is known to impair the affective response to acute pain even at anatomically unrelated locations. The neural substrate for such behavior, however, remains elusive. We hypothesize that the anterior cingulate cortex (ACC), a key brain region for processing the affective component of pain, can play a role. We use a laser to provide acute thermal nociceptive stimuli of varying intensity to the rodent paw. Rodents show an aversion to

the chamber paired with high- vs low-intensity stimulus on the conditioned place aversion (CPA) test, demonstrating an ability to distinguish pain intensity. We also measure local field potentials (LFPs) and spikes in the ACC before, during and after acute pain stimuli in freely moving rats. We find that with increasing pain intensity, there is an increase in the power of LFPs at low frequency ranges. There is also a graded rise in the number of pyramidal neurons that demonstrate increased spike rates after a painful stimulus. Optogenetic activation of the ACC, meanwhile, has the same effect as high-intensity pain stimulus in the CPA test. These results indicate that neurons in the ACC can provide a representation of acute pain intensity. We then test acute pain responses in the chronic pain condition by injecting Complete Freund's Adjuvant (CFA) to the opposite paw. Withdrawal latency in the uninjured paw is not significantly altered, indicating intact peripheral and spinal nociceptive pathway. However, rats with chronic pain are unable to distinguish between low and high stimulus intensity on the CPA, suggesting an impairment in the affective response to acute pain. Correspondingly, in the chronic pain state, ACC neurons display a compressed pain intensity tuning curve. This is demonstrated by increased LFP power and spike rates with low-intensity stimulus but not with non-painful or high-intensity pain stimuli in CFA-treated rats. Finally, our optogenetic studies show that activation of the ACC has the same effect as chronic pain on the CPA test. Together, these results indicate that disrupted ACC circuitry is a major cause for altered response to acute pain in the chronic pain state.

Title: Reticular thalamic neuronal activity changes by formalin induced nociception of awake behaving mice

Authors: *Y. HUH, J. CHO;
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: The reticular thalamus (RT), composed mainly of GABAergic neurons, is a structure that wraps around the thalamic structure to provide major inhibitory inputs to thalamic nuclei. Thalamic neurons have characteristic firing mode call the tonic and burst firing mode, and the switch between the two firing mode have been implicated to have roles in modulating sensory information such as vision, touch, and nociception. Of the two firing modes, low threshold calcium spike (LTS) bursts occur only after thalamic neurons have been hyperpolarized. Since the RT provide major inhibitory inputs to thalamic nuclei, RT may play a key role in regulating switch between tonic and burst firing of thalamic neurons, and consequently regulate nociceptive signal processing. This study attempted to study the role of RT in nociception processing by recording RT neuronal activity changes to formalin injection in awake behaving mice. Results showed that most neurons in the RT increased firing right after formalin injection while the rest decreased firing. Group of neurons that increased firing to formalin injection significantly increased firing rate right after formalin injection and over time firing rate gradually decreased. Overall, neurons in the RT responded to formalin, but their role in nociceptive signal processing is inconclusive at the moment.

Title: Lateralized effects of neuropeptide S (NPS) on amygdala output neurons in an arthritis pain rat model

Authors: *G. JI[1], V. NEUGEBAUER[1,2];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Behavioral, electrophysiological and biochemical data suggest right-hemispheric lateralization of amygdala functions in pain (Carrasquillo and Gereau 2007 J Neurosci, 2008 Mol Pain; Ji and Neugebauer 2009 J Neurophysiol; Gonçalves and Dickenson 2012 Eur J Neurosci). The neurobiological principle of hemispheric lateralization of amygdala function in pain remains to be determined. Neuropeptide S (NPS) was shown in our previous work (Ren et al 2013 J Neurophysiol; Medina et al 2014 Mol Pain) to increase feed-forward inhibition of neurons in the amygdala output region (central nucleus, CeA), resulting in the inhibition of pain-related behaviors. The aim of the present study was to determine potentially differential roles of NPS in pain-related activity of amygdala neurons in the left and right hemisphere. Extracellular single-unit recordings were made from CeA neurons in the left and right hemisphere of anesthetized adult male rats. Responses to brief (15 s) stimulation (compression) of the knee, background activity, and receptive field size were measured before and during stereotaxic application of an NPS receptor antagonist (SHA68) into the CeA by microdialysis. SHA68 increased the evoked responses of left and right CeA neurons under normal conditions. In the arthritis (kaolin/carrageenan) pain model, however, SHA68 significantly increased only the responses of CeA neurons in the left, but not right, hemisphere. These data suggest lateralized effects of neuropeptide S receptor activation in amygdala neurons in an arthritis pain model.

Title: Affective components of chronic pain reflect circuit-specific changes in the anterior cingulate cortex

Authors: *K. S. MEDA[1], T. PATEL[2], J. M. BRAZ[1], A. I. BASBAUM[1], V. S. SOHAL[2];
[1]Anat., [2]Psychiatry, UCSF, San Francisco, CA

Abstract: Aims: We aimed to identify a neural circuit that encodes affective salience of pain in the anterior cingulate cortex (ACC). The ACC is densely innervated by the mediodorsal thalamus (MD) and the basolateral amygdala (BLA). Although studies have focused on intrinsic changes in the ACC as the main driver of aberrant pain affect in chronic pain, the contribution of afferent information from the MD and BLA to the ACC has been largely unexplored. Here we tested the hypothesis that these long-range inputs to the ACC are physiologically altered in the setting of chronic pain, and that these changes contribute to changes in the behavioral manifestation of pain affect.
Methods: In two models of neuropathic pain- spared nerve injury and chemotherapy (Taxol) induced neuropathy, we used whole-cell patch clamp recordings in slice preparations of the ACC to identify changes in intrinsic properties of ACC pyramidal neurons, as well as in their response to stimulation of excitatory inputs from the MD and BLA. To stimulate these inputs selectively, we injected an AAV5-CaMKII-ChR2 into the MD or BLA. To inhibit these inputs selectively, an AAV5-Synapsin-Arch was injected into the same regions. The same optogenetic approach was used to stimulate or inhibit these projections *in vivo*, in a conditioned place preference paradigm.
Results: We found that layer V pyramidal cells of the ACC are hyperexcitable in the two models of neuropathic pain. We also recorded a significant reduction in the excitatory responses of ACC pyramidal neurons to optogenetic stimulation of MD inputs in nerve-injured or Taxol animals, compared to controls. In contrast, there was an increase in the excitatory responses of ACC pyramidal neurons to optogenetic stimulation of BLA inputs in the nerve-injured condition, compared to control mice. Behaviorally, we found that animals with chronic pain avoided contexts in which they received optogenetic stimulation of MD inputs to the ACC; control animals showed neither preference nor avoidance. Inhibiting MD inputs produced the opposite effect, i.e, preference in animals with chronic pain. Stimulating BLA inputs produced preference in both animals with chronic pain and controls, while inhibiting the same inputs produced aversion in animals with chronic pain only.
Conclusions: These findings demonstrate that nerve injury induces long-term physiological changes in a circuit containing the ACC, MD and BLA. It appears that these changes may be differentially implicated in the behavioral manifestation of pain affect. Thus, targeting particular components of this circuit may offer a novel therapeutic approach to treating maladaptive pain affect in chronic neuropathic pain.

Title: Characterizing the sensitivity of laser-evoked EEG potentials to stimulus intensity using signal detection analysis

Authors: *B. BECK[1], G. IANNETTI[2], P. HAGGARD[1];
[1]Inst. of Cognitive Neurosci., [2]Dept. of Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Laser-evoked potentials (LEPs) are considered an indirect measure of activity in afferent nociceptive pathways. However, they are also sensitive to factors that are not specific to nociception, such as stimulus novelty and saliency. We investigated the extent to which LEP components are sensitive to a sensory property of the nociceptive stimulus, namely, the stimulus intensity. We measured LEPs while participants discriminated between a higher level and a lower level of laser stimulation of A-delta afferents on the hand dorsum. A multiple linear regression method was used to automatically estimate single-trial amplitudes and latencies of the main LEP components (i.e., N1, N2, and P2). These measures were used to calculate neurometric measures of perceptual sensitivity (d') for each LEP component. A range of possible cutoffs in the amplitude or the latency of each component was used to classify each trial as either a neural "high" response or a neural "low" response. In a separate experimental session, EEG was recorded while the same participants discriminated between two levels of non-nociceptive transcutaneous electrical stimulation of A-beta afferents. The non-nociceptive somatosensory-evoked potentials (SEPs) from this condition were subjected to the same analysis, to address questions of nociceptive specificity. Preliminary findings suggest that the amplitude of the N2 LEP component contains information about stimulus intensity that is relatively independent of "bias" (i.e., the chosen amplitude cutoff for a "high response"). The equivalent N2 component of the non-nociceptive SEP does not exhibit the same sensitivity to stimulus intensity, despite having a signal-to-noise ratio similar to the laser-evoked N2. This suggests that the N2 component may contain more information about the intensity of nociceptive stimuli than the intensity of non-nociceptive somatosensory stimuli.

Title: Neural signatures of pain in animal models

Authors: *C. Y. SAAB, B. LEBLANC;
Neurosurg. & Neurosci., Brown/RIH, Providence, RI

Abstract: Pain is known to disrupt brain rhythms in humans. By contrast, little is known regarding the neural dynamics of spontaneous pain in awake animals. Here, we identify EEG signatures of pain and analgesia in rodents. Our data show increased power within the low frequency (3-10 Hz) range in primary somatosensory cortex (S1) and prefrontal cortex (PFC) in awake, freely-behaving rats with acute (intradermal capsaicin), inflammatory (intradermal CFA) or neuropathic pain (chronic constriction injury of the sciatic nerve). In the neuropathic pain model, coherence between PFC and S1 significantly increases at a late, but not early, time point during the development of nociceptive behavior. Treatment with ibuprofen, pregabalin or mexiletine at a clinically-relevant dose attenuates power and S1-PFC coherence. Our data suggest that cortical synchrony and cortico-cortical connectivity correlate with pain, analgesia and the transition from acute to chronic pain. We are currently investigating the thalamic origin of these neural signatures using a multi-channel recording system combined with optogenetic neuromodulation in awake mice.

Title: Anterior cingulate cortex (ACC) representation of aversive pain intensity

Authors: *Q. ZHANG[1], A. TONG[1], T. MANDERS[1], A. GARG[1], R. YANG[1], L. URIEN[1], Z. CHEN[2], J. WANG[1];
[1]Anesthesiol., [2]Psychiatry, New York Univ., New York, NY

Abstract: The anterior cingulate cortex (ACC) is well known to play a role in affective pain processing. It is less clear, however, if neural activities in the ACC can code aversive pain intensity. To address this question, we combine extracellular recordings in awake, behaving rats using tetrode arrays with optogenetic activation of the ACC during acute pain episodes. We use a laser to provide acute thermal pain of controlled intensity to the hindpaw. We also use a sharp 25g needle to provide acute mechanical pain and light touch as a negative control. With increasing laser intensity, rats demonstrate decreased paw withdrawal latency. Meanwhile, both spike rates and local field potentials (LFP) in the ACC respond to acute pain stimuli in a graded fashion. The percentage of neurons that increase their firing rates is inversely proportional to paw withdrawal latency. Furthermore, there is an increase in the LFP power at low frequencies with increasing pain intensity. Detailed analysis reveals that only a small fraction of the neurons in the ACC are truly pain-specific. We characterize such pain-specific neurons as cells that do not respond to non-nociceptive warmth or light touch, but increase their firing rates proportionally with increasing thermal pain intensity and also increase their firing rates to mechanical pain. Spike phase-locking analysis reveals that these neurons show significant phase synchrony to the LFP phase, indicating the role of timing code in response to transient pain stimuli with varying intensity. As LFPs originate from synchronous synaptic inputs into the local neural circuit, such phase synchrony suggests that a small fraction of pain-specific neurons communicate with local ACC neuronal population to provide pain-intensity coding. To further verify the role of ACC in pain coding, we perform decoding analysis using support vector machine (SVM) and K nearest neighbor classifiers (KNN). By selecting features with binned firing rate and low frequence LFP power, these machine-learning approaches can discriminate painful vs non-painful stimulus or low- vs high-intensity pain stimulus with high accuracy (up to 90%). Finally, we show that optogenetic activation of the ACC during the presentation of an acute pain stimulus increases conditioned place aversion (CPA) to that stimulus. Furthermore,

ACC activation during the presentation of a low-intensity pain stimulus has the same effect as a high-intensity stimulus. Together, our results indicate that the ACC plays a critical role in coding aversive pain intensity.

Title: Dorsal and ventral parts of the thalamic nucleus submedius provide two independent inputs to different areas of the rat orbitofrontal cortex: A single neuron-tracing study using virus vectors

Authors: *E. KURAMOTO[1], H. IWAI[1], A. YAMANAKA[1], S. OHNO[2], R. SENDO[2], K. KOYANAGI[3], S. TOYODOME[1], T. FURUTA[4], H. HIOKI[4], T. GOTO[1];
[1]Dept. of Oral Anat. and Cell Biol., [2]Dent. Anesthesiol., [3]Orthodontics and Dentofacial Orthopedics, Kagoshima Univ., Kagoshima, Japan; [4]Morphological Brain Sci., Kyoto Univ., Kyoto, Japan

Abstract: The orbitofrontal cortex is reported to have a role in various cognitive and behavioral functions, such as flexible behavior, outcome expectation, pain modulation, and fear conditioning. These orbitofrontal functions might be mediated not only by neuronal circuitry in the orbitofrontal cortex, but also by network between the orbitofrontal cortex and subcortical

structures, the striatum and thalamus. The thalamic nucleus submedius (Sm) is known to intensely project to the orbitofrontal cortex. The aim of this study is to define the underlying circuits connecting the Sm to the orbitofrontal cortex for the better understanding of the mechanisms of orbitofrontal functions. Thus, the axonal arborization of single Sm neurons was examined in rat brain using Sindbis virus vectors expressing membrane-targeted fluorescent proteins. First, the Sm was subdivided into dorsal part and ventral part: dorsal part was innervated by vesicular glutamate transporter 2-immunopositive afferents derived from the spinal trigeminal nucleus and spinal dorsal horn, but ventral part was not. We then visualized and reconstructed 5 dorsal Sm and 5 ventral Sm neurons at a single-cell level, and analyzed the difference of the axonal arborization between dorsal and ventral parts of the Sm. When the axons exited from the thalamus, the reconstructed Sm neurons always emitted axon collaterals to the thalamic reticular nucleus. In the cerebral cortex, both of the dorsal and ventral Sm neurons sent axons mainly to layers 2/3 and layer 5, and formed dense axon bushes. The spread of each axon bush was approximately 500 μm in diameter in the tangential direction to the cortical surface. Interestingly, the dorsal Sm neurons formed single axon bush restrictively in the ventrolateral orbital area, whereas ventral Sm neurons made 2 axon bushes in ventral, medial, and lateral orbital areas, as well as agranular insular areas, but not in ventrolateral orbital area. These results suggest that the dorsal and ventral Sm neurons play different roles in the orbitofrontal functions. The dorsal Sm might be able to activate neurons in ventrolateral orbital area and involved in pain modulation, because ventrolateral orbital area is known to modulate pain sensitivity through activation of a periaqueductal gray-brainstem descending pathway that inhibits the nociceptive inputs at the spinal and trigeminal dorsal horn. The ventral Sm neurons would be involved in fear conditioning by activation of neurons in ventral and medial orbital areas, and agranular insular areas, since these cortical areas are known to innervate the amygdala.

Sci. and Technolog, Aalborg Univ., Aalborg, Denmark; [4]Ctr. for Chiropractic Res., New Zealand Col. of Chiropractic, Auckland, New Zealand; [5]Hlth. & Rehabil. Res. Institute, Fac. of Hlth. & Envrn. Sci., Auckland Univ. of Technol., Auckland, New Zealand

Abstract: It has been demonstrated that after chiropractic spinal manipulation neural plastic changes occur in different areas of the brain. Different methods have been utilized to assess these changes, but the majority of the measurements to find the involved brain areas have been indirect. The objective of this study was to determine the changes in brain activity during tonic pain after single session of chiropractic care in a sub-clinical pain population by using source localization of the EEG.
Fifteen healthy volunteers (10 males, 32.1 ± 7.2 years) participated in two experimental sessions on separate days; chiropractic or control (sham) session in random order. The EEG was recorded continuously using a 61-channel system before and after either intervention during 72s of cold pressor test at 2°C (left hand). The pain and unpleasantness ratings were obtained on two separate numeric scales (range: 0 = no unpleasantness/pain to 10 = maximum unpleasantness/pain). The EEG was divided into 9 epochs (8s each), which were separated into four frequency bands: delta (1-4 Hz), theta (4-8 Hz), alpha (8-12 Hz) and beta (12-32 Hz). Subsequently, standardized low resolution brain electromagnetic tomography (sLORETA) was done on these frequency bands.
In the control experiment, the brain activity decreased in all frequency bands (all $p \leq 0.05$), whereas no change in activity was seen after the chiropractic session (all $p > 0.05$). The decrease in activity in the control arm was specifically seen in the limbic (delta), frontal (theta) and temporal (alpha and beta) lobes. There were no significant differences in pain and unpleasantness scores between pre and post-sessions in either of the two arms.
The decrease in brain activity in the control arm reflects central habituation which occurs due to repetitive painful stimulation. The lack of this phenomenon in the chiropractic arm could imply that the chiropractic care normalizes the central nervous system leading to central dishabituation following the session.

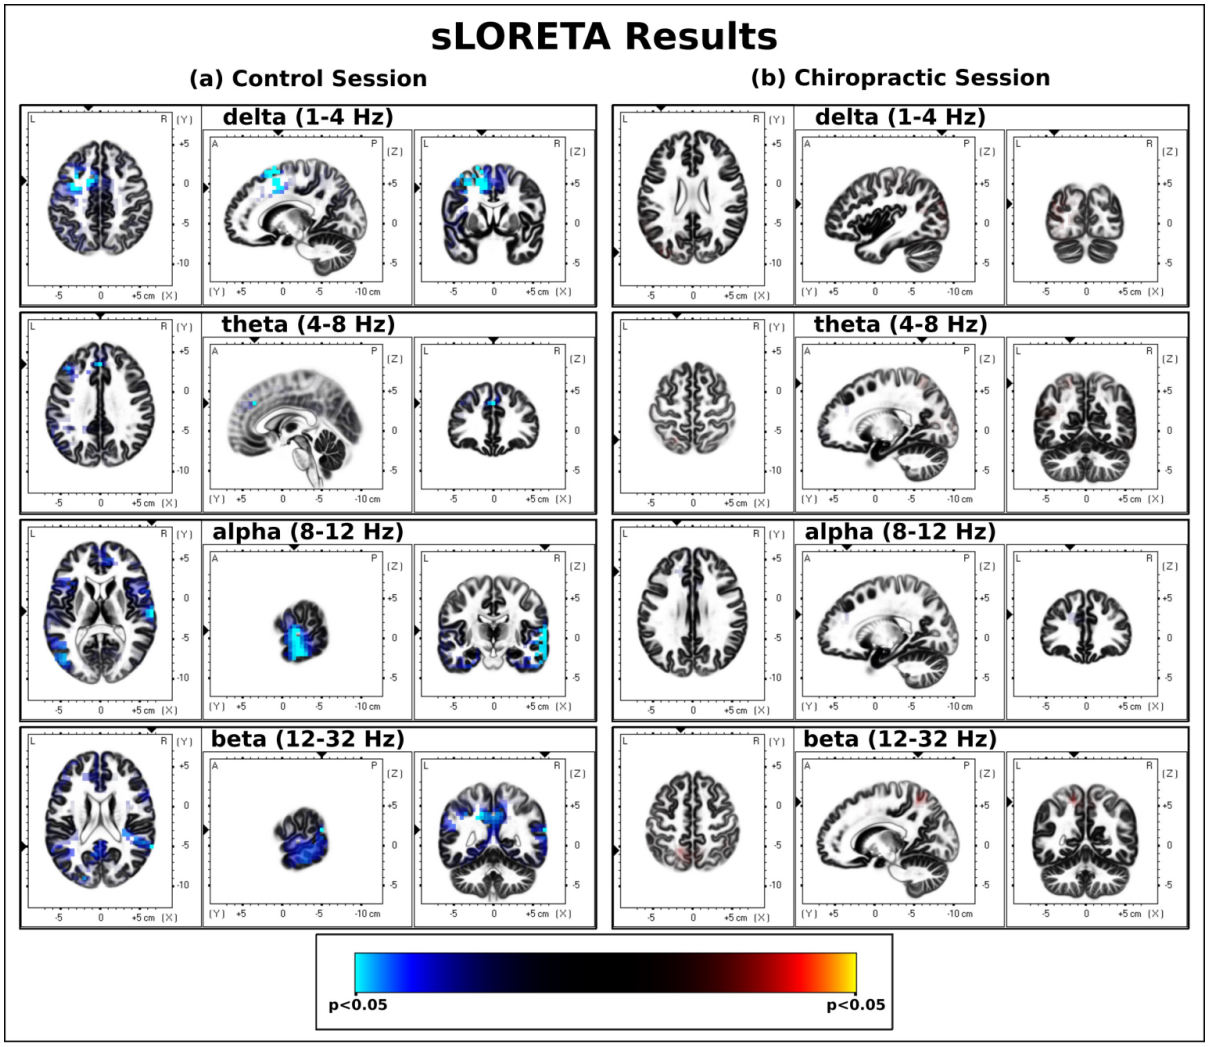

Figure: Slice views of source locations with the changes in activity for each frequency band after (a) control session and (b) chiropractic session compared to respective pre-session activity. Significant decrease in activity in all frequency bands can be seen in (a) (p≤0.05).

Title: Effects of chronic pain on the cortical circuitry implicated in pain and endogenous analgesia

Authors: *J. CHERIYAN[1], P. L. SHEETS[1,2];
[1]Dept. of Pharmacol. and Toxicology, Indiana Univ. Scool of Med., South Bend, IN; [2]Dept. of Biol. Sci., Univ. of Notre Dame, Notre Dame, IN

Abstract: The central nervous system elicits endogenous analgesia via an extensive descending network. The periaqueductal gray (PAG), a key midbrain node within this network, is essential for suppressing ascending nociceptive signals and is a major pharmacological target of opioid based analgesics. The PAG receives significant input from the medial prefrontal cortex (mPFC) which is a cortical region that contributes to the affective and attentional components of pain. Functional and structural changes occur within the mPFC in human pain patients and in animal models of pain. However, pain-induced changes in defined mPFC neurons remain unclear. We hypothesized that cortico-PAG (CP) neurons would display altered local circuitry in the chronic constriction injury (CCI) model of neuropathic pain in mice. At post-operative day (POD) 7, a significant decrease in paw-withdrawal threshold (PWT) was observed for CCI animals compared to sham. At POD7, we targeted retrogradely labeled mPFC-CP neurons for local circuit mapping using glutamate uncaging in combination with laser scanning photostimulation (glu-LSPS). We found that the CCI resulted in significantly reduced local excitatory and local inhibitory inputs to CP neurons in both the prelimbic (PL) and inframbic (IL) regions of the mPFC. Although the input strengths were reduced throughout the cortical layers, inputs from layer 2 were significantly reduced in CCI CP-neurons. For the first time in a neuropathic pain model, we describe local circuit alterations to defined mPFC neurons within a key descending analgesic network. Our current efforts are focused on using optogenetics to dissect changes of long-range inputs to CP neurons in the CCI model. Collectively, circuit changes in the cortical control of PAG circuits could alter the homeostasis of the endogenous analgesic network and thereby diminish the intrinsic capability of the nervous system to suppress ascending nociceptive information.

Title: SK channel function in CRF-containing amygdala neurons in a neuropathic pain rat model

Authors: *V. A. YAKHNITSA[1], T. KIRITOSHI[1], V. NEUGEBAUER[1,2];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The central nucleus of amygdala (CeA) plays a key role in the regulation of the emotional-affective component of pain. The CeA is rich in neurons containing corticotropin releasing factor (CRF). Activation of CRF-CeA neurons and projecting pathways alters anxiety-like behavior and emotional responses. Our previous work showed that increased activity in CeA neurons in pain models drives emotional-effective responses and anxiety-like behaviors. Here we tested the hypothesis that dysfunction of small-conductance calcium-activated potassium (SK) channels contributes to increased tonic activity and excitability of CRF-CeA output neurons in rat model of chronic neuropathic pain. Whole-cell voltage- and current-clamp recordings were made from latero-capsular CeA neurons in brain slices from behaviorally tested normal/sham rats (controls) and neuropathic rats 3-4 weeks after spinal nerve ligation (SNL). Recorded cells were filled with biocytin and stained for co-localization with CRF. Neuropathic rats had developed mechanical hypersensitivity, increased vocalizations, and anxiety-like behavior by the time brain slices were obtained. CRF-positive CeA neurons recorded in brain slices from neuropathic rats lacked an apamin-sensitive medium afterhyperpolarization (mAHP) and showed increased excitability measured as the number of spikes in response to depolarizing current injections (F-I function) compared to CRH-positive neurons from control rats. The results suggest that loss of SK-channel function contributes to increased activation in amygdala CRH-positive output neurons mediating emotional responses in a neuropathic pain model.

Title: Brain-network mechanisms underlying the analgesic effect of electrical stimulation of periaqueductal gray

Authors: *N. WANG[1], Y.-L. SU[2], J.-Y. WANG[1], F. LUO[1];
[1]Inst. of Psychology, Chinese Acad. of Sciences; Key Lab. of Mental H, Beijing, China; [2]Dept. of Applied Psychology, Wenzhou Med. Univ., Wenzhou, China

Abstract: Clinical studies have proved that deep brain stimulation (DBS) can produce therapeutic benefits for neurologic diseases. DBS has been employed as an important application to treat chronic intractable pain for many years. Periaqueductal gray (PAG) is a traditional stimulation target of DBS. Numbers of studies have proved the analgesia effect of PAG stimulation in animals with experimental pain and patients with chronic pain. However, the neural basis underlying PAG stimulation produced analgesia remains unclear, especially at the supraspinal level. In this study, neuronal activity within thalamocortical circuits in rats has been recorded using a multichannel single unit recording technique. Four brain regions in the lateral and medial pain systems have been focused in this study, including the primary somatosensory cortex (SI), anterior cingulate cortex (ACC), medial dorsal thalamus (MD), and ventral posterolateral thalamus (VPL). We attempted to explore the effects of ventrolateral PAG (vlPAG) stimulation on the discharge of single units as well as the functional connections between these regions. Some important findings emerged from this study: (1) vlPAG stimulation could inhibit the nociceptive behavioral responses of noxious thermal-induced acute pain. In the four recorded areas, vlPAG stimulation inhibited the nociceptive responses of single neurons by reducing the fraction of responding neurons and decreasing the neuronal response magnitude. The correlation between paw withdrawal latency and response magnitude was also inhibited by vlPAG stimulation. (2) Functional connection analysis revealed that vlPAG stimulation suppressed the pain-evoked changes in the information flow from ACC to MD and from SI to VPL. These results suggested that the inhibitory effect on both sensory and affective dimensions of pain may contribute to the analgesia effect of vlPAG stimulation on acute pain.

Title: Prefrontal cortical feedforward inhibition of amygdala output neurons in arthritic and neuropathic pain rat models

Authors: *V. NEUGEBAUER[1,2], T. KIRITOSHI[1];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Hyperactivity in the amygdala output region (central nucleus, CeA) accounts for pain-related emotional responses and affective states. Direct excitatory inputs and feedforward inhibition modulate activity of CeA neurons. Feedforward inhibition is centered on a cluster of inhibitory neurons in the intercalated cell mass (ITC). Evidence suggests that the medial prefrontal cortex (mPFC) can modulate amygdala activity, but synaptic mechanisms and pain-related effects remain to be determined. Our previous work showed beneficial effects of restoring mPFC output on pain behaviors. Here we used optogenetics and patch-clamp in brain slices to determine mPFC-driven synaptic transmission onto CeA neurons and pain-related changes in this pathway. rAAV5/CaMKIIa-hChR2 (H134R)-eYFP vector was injected into the mPFC to express light sensitive channel rhodopsin 2 (ChR2) in mPFC pyramidal cells and their axons. Whole-cell patch clamp recordings were made from CeA neurons in brain slices from control rats and from arthritic (kaolin/carrageenan model) or neuropathic (spinal nerve ligation model) rats. Light activation (blue laser) of ChR2-expressing mPFC axons in the amygdala brain slice evoked glutamate-driven polysynaptic inhibitory postsynaptic currents (IPSCs) in CeA neurons; these IPSCs were blocked by bicuculline or NBQX. Largest IPSCs were usually evoked by light stimulation centered on the ITC area, suggesting activation of cortical fibers onto ITC cells. mPFC-driven feedforward inhibition was found under normal conditions and in the pain models. The data provide direct evidence for mPFC-driven feedforward inhibition of CeA neurons using optogenetics. Further, this control mechanism is available in pain conditions to inhibit amygdala output.

Title: Monomethyl fumarate (MMF) inhibits pain behaviors of arthritic rats: involvement of the amygdala

Authors: ***H. KIM**[1], J. M. THOMPSON[1], V. GANAPATHY[2], V. NEUGEBAUER[1,3]; [1]Pharmacol. and Neurosci., [2]Cell Biol. and Biochem., [3]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Pain is the number one reason for patients to seek health care. To contribute to mitigating this major health care problem with significant emotional and affective components, we investigate novel and improved therapeutic interventions to restore or strengthen normal brain functions in pain models. Evidence suggests beneficial neuroprotective effects of fumarate-containing pharmaceuticals on cellular resistance to oxidative damage in central nervous system cells, potentially via up-regulation of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) pathway. Dimethyl fumarate (DMF) has been clinically used to treat relapsing forms of multiple sclerosis and psoriasis, and it is rapidly hydrolyzed to monomethyl fumarate (MMF) in the body. However, the beneficial neuroprotective effects of DMF and its primary metabolite MMF in pain management remain to be determined. Hence, we examined the ability of MMF to inhibit emotional-affective pain behaviors through an action in the amygdala output region (central nucleus, CeA), which plays a key role in emotional-affective dimensions of pain and pain modulation. Systemic (intraperitoneal, i.p.) or stereotaxic (into CeA) administration of MMF inhibited audible (nocifensive response) and ultrasonic (averse affective response) vocalizations of adult male Sprague-Dawley rats 5 to 6 hours postinduction of arthritis in the left knee joint (kaolin-carrageenan model). Systemic, but not intra-amygdala, application of MMF also inhibited spinal reflexes significantly, increasing hind limb withdrawal thresholds. MMF had no effect in control rats. These data indicate that MMF can inhibit arthritis pain behaviors, and its effects on emotional-affective responses are mediated by an action in the amygdala (CeA).

Title: Vesicular Gamma-aminobutyric Acid transporter (VGAT) expression in the ventral posterior thalamus can modulate hypersensitivity following varicella zoster virus (VZV) infection of rat whisker pad

Authors: ***M. UMORIN**[1], C. STINSON[1], M. DENG[2], M. RAO[1], M. YEE[3], L. L. BELLINGER[1], P. KINCHINGTON[3], P. R. KRAMER[1];

Abstract: Gamma-Aminobutyric acid (GABA) stored with the help of VGAT in synaptic vesicles is one of the main inhibitory neurotransmitters found in mammals. The thalamus plays an important relay function in the central transmission of orofacial nociception. This study aimed at answering the question: can a decrease in VGAT expression in ventral posterior thalamus increase orofacial hypersensitivity following VZV infection in the whisker pad of male rats? Seven male Sprague-Dawley rats were injected into the right ventral posterior thalamic nucleus with adeno-associated virus containing VGAT shRNA or random shRNA construct under U6 promoter. One week later the left whisker pad was injected with either VZV-infected MeWo cell or non-infected cells. A week after the VZV injection the rats were tested with a place escape/avoidance paradigm test for the presence of nociception in the area around the injected whisker pad. After the second week of testing the rats were sacrificed and brain tissues were collected for immunohistochemistry of the thalamic tissue and VGAT expression analysis. Rats with VGAT expression inhibited by expression of shRNA exhibited increased and longer

orofacial hypersensitivity compared to the rats with normal VGAT expression. The results indicate that modulation of orofacial nociception signaling in the ventral posterior thalamus can occur through change in release of the inhibitory neurotransmitter GABA.

Title: Lateralized feedforward inhibition of amygdala output neurons in an arthritis pain rat model.

Authors: ***T. KIRITOSHI**[1], V. NEUGEBAUER[1,2];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Synaptic plasticity and increased responsiveness of neurons in the amygdala output region (central nucleus, CeA) have been consistently found in acute and chronic pain models. Behavioral, electrophysiological and biochemical studies showed right-hemispheric lateralization of CeA function in pain models, but underlying mechanisms remain to be determined. In this study, we sought to determine potential differences in excitatory and inhibitory synaptic transmission onto the left and right CeA under normal conditions and in an arthritis pain model. Whole-cell patch clamp recordings were made from CeA neurons in brain slices from normal and arthritic rats (5-6 h after intraarticular injections of kaolin and carrageenan into the left or right knee). Slices from the left and right hemisphere were used and compared in each animal. Excitatory and inhibitory postsynaptic currents (EPSCs and IPSCs) were evoked by electrical stimulation in the basolateral amygdala (BLA). Electrical stimulation of the BLA evoked monosynaptic EPSCs and polysynaptic IPSCs in CeA neurons. IPSCs were blocked by

bicuculline but were also sensitive to a non-NMDA receptor antagonist (NBQX), suggesting that they reflect glutamate-driven feedforward inhibition. Under normal condition, peak amplitude of IPSCs and the IPSC/EPSC ratio were larger in right than left CeA neurons. In the arthritis pain model, peak amplitude of IPSCs and the IPSC/EPSC ratio were decreased in right but increased in left CeA neurons. Importantly, the difference was independent of the side (left-right) of arthritis induction. The results suggest a baseline difference in the inhibitory control of CeA neurons between the left and right hemisphere, and a dramatic change in a pain model. Increased feedforward inhibition of the left CeA and loss of feedforward inhibition of the right CeA may account for pain-related hemispheric lateralization.

Title: Hyperexcitability of somatosensory cortical neurons in CK1d migraine mutant mice.

Authors: *P. S. SURYAVANSHI[1,2], P. A. SAWANT-POKAM[2], K. C. BRENNAN[2];
[1]Univ. of Utah, Salt Lake City, UT; [2]Neurol., Univ. of Utah, Salt lake city, UT

Abstract: A mutation in casein kinase 1delta (CK1d) was identified in two families with advanced sleep phase syndrome and typical migraine with aura. Mice genetically engineered to express this mutation showed a reduced threshold for cortical spreading depression (a phenomenon that underlies both migraine aura and brain injury) and an increased sensitivity to nitroglycerine-induced mechanical and thermal hyperalgesia (both considered migraine relevant pain phenotypes). The cellular mechanisms underlying this network excitability are unclear. We examined the intrinsic and synaptic properties of layer 2/3 neurons of mouse somatosensory cortex, using *in vivo* and *in vitro* whole-cell current and voltage-clamp recordings in wild-type (WT) and CK1d mutant mice. *In vivo* intrinsic membrane properties were different in neurons of CK1d mice, showing a significant hyperpolarizing shift in resting membrane potential, and a trend towards increased input resistance compared to WT littermate neurons. Due to higher input resistance, CK1d neurons even with hyperpolarized Vm showed similar frequency of APs firing

(or slope of F/I slope) and rheobase. To characterize synaptic network-dependent activity, we recorded post-synaptic potentials in current clamp recordings *in vivo*. We observed decreased frequency, but increased duration, amplitude and rise slope of post-synaptic potentials in CK1d vs WT neurons. To determine the contribution of excitatory synaptic currents to these differences, neurons were voltage clamped at a holding potential of -70 mV, with a cesium-based internal solution *in vivo*. We found that excitatory currents in CK1d neurons had reduced frequency but increased amplitude compared to WT neurons, suggesting that changes in post-synaptic potentials were driven by excitation. We further characterized synaptic differences between CK1d and WT neurons in *in vitro* using voltage-clamp recordings. Consistent with our *in vivo* recordings, we observed a reduction in the frequency of AMPA-receptor mediated excitatory currents in CK1d, relative to WT neurons. In conclusion, we observed intrinsic and synaptic characteristics in CK1d neurons that may account for the excitable network phenotype: particularly an increased amplitude and duration of postsynaptic potentials, likely accounted for by increases in excitation. Hyperpolarized membrane potential and decreased frequency of events may represent an adaptation to chronic increases in synaptic excitability. As CK1d mice represent a transgenic model of *non*-hemiplegic migraine, these data may be helpful in elucidating mechanisms that are relevant to normal migraineurs.

Title: 5-HT_{2C}R blockade in the amygdala conveys analgesic efficacy to SSRIs in a neuropathic pain rat model

Authors: ***T. T. DANG**[1], G. JI[1], T. A. GREEN[3], V. NEUGEBAUER[1,2];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci. and Therapeut., Texas

Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [3]Pharmacol. & Toxicology, The Univ. of Texas Med. Br., Galveston, TX

Abstract: Neuropathic pain is a serious chronic condition associated with negative affective states, anxiety, and depression. Current treatments, including selective serotonin reuptake inhibitors (SSRIs), have shown only variable efficacy. Our hypothesis is that serotonin 5-HT_{2C} receptor (5-HT_{2C}R) in the amygdala accounts for the limited effectiveness of serotonin. The amygdala plays a critical role in the emotional-affective dimension of pain. 5-HT_{2C}R is widely distributed in the human and rat brain, particularly in the basolateral amygdala (BLA). A $G_{q/11}$ protein-coupled receptor, 5-HT_{2C}R has been found in GABAergic, glutamatergic, and dopaminergic neurons. 5-HT_{2C}R in the amygdala has been associated with anxiogenic effects. Here we tested the hypothesis that 5-HT_{2C}R blockage in the BLA improves the efficacy of an SSRI (fluvoxamine) in reducing emotional-affective behaviors in a neuropathic pain rat model (spinal nerve ligation, SNL). Spinal reflex thresholds, supraspinally organized audible (nocifensive response) and ultrasonic (emotional-affective response) vocalizations, elevated plus maze and open field test (EPM and OFT, anxiety-like behaviors), and immobility in the forced swim test (depression-like behavior) were measured in male Sprague Dawley rats, 4 weeks after ligation of the left L5 spinal nerve (SNL model). Behaviors were compared in rats with stereotaxic injection of 5-HT_{2C}R shRNA-AAV vector into the BLA for local knockdown of 5-HT_{2C}R and rats with stereotaxic control viral vector injection. The protocol was as follows. Hindlimb withdrawal thresholds and vocalizations were measured before and after administration of fluvoxamine (30 mg/kg, i.p.). Elevated plus maze, open field, and forced swim tests were performed the next day after another administration of fluvoxamine. Fluvoxamine increased reflex thresholds, decreased vocalizations, increased open arm preference (EPM), and increased center duration and decreased number of entries into the center (OFT) in neuropathic rats with 5-HT_{2C}R knockdown compared to control viral vector treated neuropathic rats. The results suggest that 5-HT_{2C}R knockdown can enhance the pain inhibiting effect of SSRIs.

Title: SK channel-mediated electrophysiological and behavioral effects of riluzole in the amygdala in a neuropathic pain rat model

Authors: *J. M. THOMPSON[1], V. YAKHNITSA[1], G. JI[1], V. NEUGEBAUER[1,2];
[1]Pharmacol. and Neurosci., [2]Ctr. of Excellence for Translational Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Chronic pain, including neuropathic pain, is a prevalent and expensive healthcare issue, but in spite of its clinical importance, treatment remains a challenge. Therapeutic strategies are limited and characterized by variable efficacy and severe side effects. Complicating treatment further are emotional affective aspects of pain. The amygdala is a limbic brain region that plays a key role in mediating the emotional affective dimension of pain. Here we tested the beneficial effects of riluzole, a clinically available compound that can activate small conductance calcium activated potassium (SK) channels. We hypothesized that riluzole would inhibit pain-related changes in the amygdala output region (central nucleus, CeA), resulting in the inhibition of pain behaviors in a rat model of neuropathic pain (spinal nerve ligation, SNL). Whole cell current clamp recordings of regular firing CeA neurons were made in brain slices from control and SNL rats. Spinally organized hindlimb withdrawal reflex thresholds and supraspinally organized audible (nocifensive response) and ultrasonic (emotional affective response) vocalizations were measured in control and SNL rats. Measurements were made 4 weeks after left sided L5 spinal nerve ligation. CeA neurons in brain slices from SNL rats showed increased action potential frequency-current (F-I) relationship, which corresponded to increased vocalizations and mechanical hypersensitivity. Riluzole application inhibited neuronal firing, increased the SK channel mediated medium afterhyperpolarization (mAHP), and induced an inhibitory synaptic response to stimulation of the parabrachial input into the CeA in some but not all neurons. Systemic (i.p.) and stereotaxic (into CeA) application of riluzole inhibited vocalizations with little effect on withdrawal thresholds. However, these effects were variable and failed to return responses to normal levels. Inhibitory effects of riluzole on vocalizations were blocked by stereotaxic (into CeA) coapplication of an SK channel blocker (apamin), but not ACSF (control), indicating the contribution of SK channels to the effects of riluzole. The results suggest that riluzole has inconsistent electrophysiological and behavioral effects on SK channels in the CeA in a neuropathic pain model.

Title: Neuronal encoding of modality and intensity of somatosensory stimuli in the mouse S1 cortex

Authors: *Y. KIM[1], C.-E. KIM[1], H. YOON[2], S. KIM[2], S. KIM[1];
[1]Dept. of Physiol., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [2]Kyunghee Univ. Col. of Korean medicine, Seoul, Korea, Republic of

Abstract: The function of the primary somatosensory (S1) cortex is to discriminate various somatic sensations including touch and pain. Unlike other sensations, such as vision, hearing, taste and smell, how such somatic sensations are encoded at the cellular level in the S1 cortex is poorly understood. Using *in vivo* two-photon calcium imaging, we investigated the tuning profiles of layer 2-3 neurons in the mouse S1 cortex in response to distinct modality (i.e. innocuous press vs. noxious pinch) and intensity (i.e. different pinch intensity) of somatosensory stimuli. We found that S1 cortex neurons show mixed selectivity for different stimulation modality with co-existence of wide dynamic range neurons and low/high threshold cells. In contrast, a majority of neurons showed the similar response properties to different intensities of pinch stimulation while selective responses were observed only in a small subset of neurons. These results suggest that S1 cortex neurons process modality and intensity of somatosensory stimuli using differential encoding strategies.

Title: Short-term effect of transcranial direct current stimulation (tdcs) in healthy subjects: somatosensory and pain threshold

Authors: *M.-S. HUNG[1,2];
[1]Physical therapy of Rehabil., China Med. Univ. Hosp., Taichung (City), Taiwan; [2]Dept. of Physical Therapy, China Med. Univ. Hosp., Taichung, Taiwan

Abstract: Background: Primary motor cortex hand (M1) area is the common site to set as tDCS stimulate target. It can alleviate pain in patients who suffered from neuropathic pain. But rare investigate can demonstrate the sensory and pain modulate of tDCS. We seek to test how the single-session anodal tDCS alleviate acute pain immediately in healthy subject. **Hypothesis**: Single-session tDCS stimulation can (1) modulation of the pain threshold (2) reduce the grade of moderate pain stimulus before tDCS stimulus and (3) it also reflected in cerebral activity as measured with evoked potentials (EPs). **Materials and Methods**: There have 48 healthy subjects (Female:Male=1:1) attended the experiment. Each one receive once 20 minutes or 30s tDCS stimulation. Somatosensory and pain threshold (including electrical and heat stimulus) were recorded before and after tDCS stimulus. Contact heat evoked potentials (CHEPs) for the moderate pain temperature also were recorded before and after tDCS sessions. **Results**: Single session anodal tDCS over M1 can significant elevated electrical and thermal pain threshold but not sensory threshold. It means for (1) anodal tDCS has improved short-term effect even if on normal neural activity, (2) Once tDCS session used in M1-F4 montage can modulate pain threshold independently, or pain threshold were easier to modulated then sensory thresholds. **Conclusions**: There has no side effect in all subjects. In healthy subjects, once 20minutes anodal M1 tDCS stimulus can alleviate pain threshold (including electrical and heat pain) but the sensory threshold still stable. The mechanisms of pain reduce might not due to sensory threshold modulate. The short-term pain alleviate effect is effectively on healthy subject, it worth to investigate the long-lasting pain reduce effect.

Title: The neurochemistry of thalamic reticular cells and its relationship with cell physiology and synaptic connectivity

Authors: R. MARTINEZ-GARCIA, B. VOELCKER, S. L. PATRICK, B. W. CONNORS, *S. J. CRUIKSHANK;
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Neurons of the thalamic reticular nucleus (TRN) are the main source of inhibition in the thalamus. These GABAergic cells receive input from both thalamic and cortical neurons and are critical nodes in thalamocortical processing. TRN cells are thought to mediate synchronized activity during sleep and some types of seizures, and may be critical for selective attention. Previous studies have shown diversity in TRN cell physiology, morphology and synaptic connectivity, yet there is no generally accepted scheme for classifying TRN neurons. The neurochemistry of TRN cells may provide a basis for taxonomy, as it has for cortical interneurons. Whereas virtually all TRN cells seem to express the calcium binding protein parvalbumin (PV), we have observed that only subsets express calbindin (Calb1), or somatostatin (SOM), or both. Here we are testing whether TRN cell subtypes, defined by expression of these neurochemical markers, have distinct anatomical, functional, or synaptic properties in the somatosensory thalamus of mice. Anatomically, we observed that Calb1-expressing TRN cells were most concentrated in the central tier of the somatosensory sector of TRN, whereas SOM-expressing cells dominated the outer edges. Previous reports indicate that TRN cells projecting VPM thalamus vs. VPL/POM thalamus have a similar central vs. edge topography (Pinault, Br. Res. Rev., 2004). This suggests that neurochemically distinct TRN cell types differentially interact with the three main somatosensory relay nuclei, and may receive distinct cortical inputs as well. To investigate whether TRN subtypes differentially process synaptic inputs from thalamic or cortical sources, we are using optogenetics to control specific afferent populations while recording synaptic currents in pairs of neurochemically contrasting TRN cells (identified by fluorescent reporters in established knock-in lines). For example, we have used SOM-Cre x tdTomato mice to investigate synaptic input from corticothalamic cells onto SOM+ and SOM- TRN cells. We found that optogenetically activated corticothalamic inputs to SOM+ cells had lower thresholds than those to SOM- cells. Corresponding postsynaptic excitatory currents (EPSCs) were also larger in SOM+ than in SOM- cells for near-threshold stimuli. Curiously, the EPSC sizes in the two cell types converged at higher stimulus intensities. We are now studying inputs from thalamic relay nuclei, as well as the intrinsic cellular properties of TRN cells, to further characterize the relationship between neurochemical diversity of TRN and thalamic processing.

Title: Infrabarrels: Ensembles of structurally and functionally distinct neurons in layer 6a of mouse somatosensory cortex

Authors: *S. R. CRANDALL, S. L. PATRICK, S. J. CRUIKSHANK, B. W. CONNORS; Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Neurons of layer 6 (L6) are in a unique position to control the flow of information to and from the neocortex. The organization of L6 circuits is poorly understood, however. Here we used L6 corticothalamic (CT) specific Cre driver mice (Ntsr1-Cre) crossed to various reporter lines to study the circuit organization of L6a of the mouse primary somatosensory cortex, in particular the region representing the large mystacial vibrissae. Notably, we found that L6a contains discrete cytoarchitectonic units aligned with the barrels found in L4; we call these infragranular structures “infrabarrels”. Infrabarrels were not evident in L5 or L6b. Somata of excitatory CT pyramidal cells in L6a tended to cluster within infrabarrels, while non-CT excitatory neurons were densest within the septa between infrabarrels. The somata of parvalbumin- and somatostatin-expressing inhibitory interneurons were evenly distributed across L6a. Paired whole-cell recordings suggested that all CT and non-CT types of L6a excitatory neurons respond to ‘lemniscal’ input from the ventral posterior medial nucleus, with non-CT types receiving stronger input. In contrast, only non-CT types of L6a excitatory neurons responded to ‘paralemniscal’ input from the posterior medial nucleus of the thalamus. Our results show that the projection neurons of L6a are somatotopically organized into discrete ensembles, or infrabarrels. The structure and function of infrabarrel circuits will provide a foundation for understanding how parallel streams of sensory information are received and processed within the infragranular layers.

Title: Contextual modulation of spatial coding during active sensation

Authors: *E. LYALL[1], S. R. PLUTA[2], E. RYAPOLOVA-WEBB[3], G. I. TELIAN[3], D. E. TAYLOR[2], H. ADESNIK[2];

Abstract: Sensory context transforms how stimuli are represented in the neocortex, altering spatial representations, suppressing redundant information, and facilitating the encoding of higher order stimulus features. Despite the wealth of data on how sensory context influences neural computation under passive conditions, due to technical challenges, our understanding of the role of contextual modulation during active sensation is extremely limited. To address this gap, we probed how surround input influenced spatial coding in the rodent somatosensory system while animals actively explored space with their whiskers. By combining electrophysiological recordings and two photon imaging across four stages of the thalamocortical system, we found that surround whisker input imposes a dramatic transformation on how cortical neurons encode space. Unlike for thalamic neurons, surround suppression dominates L4 responses, and shifts spatial representations backwards in space. In layer 2/3 and layer 5 surround input provides a distributed mixture of facilitation and suppression that locally diversifies and globally distributes the cortical map of space. These data suggest that during active sensation contextual input increases spatiotemporal contrast in cortical population codes which may facilitate spatial localization and haptic perception.

Title: Mapping cortical mesoscopic networks linked to the firing of single cortical and sub-cortical neurons

Authors: *D. XIAO[1], M. P. VANNI[1], C. MITELUT[1], A. CHAN[1], Y. XIE[1], A. CHEN[2], N. SWINDALE[3], T. H. MURPHY[1];

Abstract: Understanding the basis of brain function requires knowledge of cortical operations over wide-spatial scales, but also within the context of single neurons. In vivo, simultaneous wide-field of view GCAMP imaging and sub-cortical/cortical cellular electrophysiology were used in mice to investigate relationships between spontaneous single neuron spiking and mesoscopic cortical activity using a spike-triggered mapping procedure. The procedure extends spike-triggered averaging methods to wide areas of cortex and provides selectivity by also employing genetically targeted indicators of neuronal activity. Spiking thalamic neurons was correlated with complex cortical spatiotemporal map features not predicted from consensus intra-cortical networks. Dynamically, single thalamic neurons predicted and reported specific cycles of wide-scale cortical inhibition/excitation. In contrast, spike-triggered maps from single cortical neurons tended to yield spatio-temporal maps expected for regional cortical consensus function. This approach can define network relationships between any point source of neuronal spiking and mesoscale cortical maps and may have use for identifying novel brain stimulation targets to affect connected areas.

Title: Modeling the vibrotactile responses of excitatory and inhibitory neurons in the hindpaw representation of rat SI cortex

Authors: *B. VARDAR, B. GÜÇLÜ;
Inst. of Biomed. Engin., Bogazici Univ., Istanbul, Turkey

Abstract: We have recently characterized the vibrotactile responses of regular-spiking (RS) and fast-spiking (FS) neurons in the hindpaw representation of rat SI cortex before and after bicuculline ($GABA_A$ receptor antagonist) microinjections. At all tested frequencies, the tonic responses of RS (excitatory) neurons increased, but the phasic responses did not change. Both phasic and tonic responses of FS (inhibitory) neurons were not influenced by bicuculline. We modified a computational model for whisker barrels (Pinto et al., 1996; J. Comput. Neurosci. 3, 247-264) to simulate vibrotactile responses of cortical neurons during bicuculline application. Specifically, our model included a thalamocortical input based on previous experimental data (de la Rocha and Parga, 2008; J. Comput. Neurosci. 25, 122-140), and generated by 5-Hz and 40-Hz sinusoidal bursts with 500-ms duration. Inhibitory weights on both excitatory and inhibitory populations were probabilistically decreased according to drug effects. In order to mimic the random variation among neurons, all weights were sampled from their particular probability distribution functions. We simulated firing rates of 14 RS and 11 FS neurons to compare with our experimental data recorded from the SI cortex. Percent changes in firing rate from the sham condition were calculated for both phasic responses (R_o: during the initial 100 ms of stimulus duration) and the tonic responses (R_d: during the entire stimulus duration of 500 ms). The results were analyzed by independent two-sample t-tests. For the 40-Hz stimulus, relative firing-rate changes due to bicuculline were very similar in simulation results compared to the experimental data (R_o: p=0.55 for RS, p=0.79 for FS; R_d: p=0.86 for RS, p=0.51 for FS). However, for the 5-Hz stimulus, the relative tonic firing-rate increase in the simulation results of RS neurons were significantly lower than the experimental data (R_o: p=0.28, R_d: p=0.006). On the other hand, the simulations were able to reproduce the experimental results of FS neurons for the 5-Hz stimulus (R_o: p=0.66, R_d: p=0.75). Overall, the modified computational model was successful for quantitatively simulating the relative excitatory/inhibitory interactions due to thalamacortical inputs driven by vibrotactile stimulation and the effects of bicuculline. It is important to note that the original model in the literature was established for mechanical ramp-and-hold stimuli on the

whiskers. The current work shows that our modified model still needs further improvement, especially at low frequencies, for incorporating vibrotactile stimuli applied on the skin.

Title: Pom thalamocortical input drives layer-specific response transformations

Authors: ***N. AUDETTE**[1], J. URBAN-CIECKO[1], M. MATSUSHITA[2], A. L. BARTH[1]; [1]Dept. Biol. Sci. and Ctr. for Neural Basis of Cognition, [2]Dept. Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Higher-order thalamic nuclei, such as the posterior-medial nucleus (Pom) in the somatosensory system or the pulvinar in the visual system, densely innervate the cortex and can influence perception and plasticity. To systematically evaluate how higher-order thalamic nuclei can drive cortical circuits, we optogenetically activated Pom axons in mouse primary somatosensory (barrel) cortex during genetically-targeted whole-cell recordings in acute brain slices. We find that ChR2-evoked thalamic input is differentially distributed across four major cell types in the neocortex, revealing layer-specific modules for the summation and processing of Pom input. Specifically, we find that direct Pom input to parvalbumin-expressing (PV) neurons is strong in L5a but absent in L2, where Pom activity drives firing in 5HT3a-expressing (5HT) cells. In both layers, direct synaptic input to somatostatin (SST) neurons was negligible. Evoked activity in pyramidal neurons from deep layers is fast and synchronized by rapid, PV-mediated feedforward inhibition, and activity in superficial layers is weaker and prolonged, facilitated by slow inhibition from 5HT neurons. A longer integration window for incoming sensory information in L2 may facilitate stimulus detection and plasticity over long time scales, requiring coincident inputs from multiple pathways to drive action potentials. Our data also recapitulate some cell-type-specific features of sensory-evoked activity – SST neuron hyperpolarization, and the initiation of recurrent network activity – that have been observed *in vivo*, indicating that Pom activity is sufficient to generate these phenomenon in acute brain slices with only local connections preserved.

Title: Corticothalamic neurons target fast-spiking and somatostatin containing interneurons with different short-term dynamics

Authors: *A. AGMON[1], H. HU[2];
[1]Dept Neurobiol & Anat, [2]Neurobio. and Anat., West Virginia Univ. Sch. of Med., Morgantown, WV

Abstract: The corticothalamic (CT) pathway is a massive feedback projection from pyramidal neurons in cortical layer 6 to the thalamus, in which CT axons make facilitating excitatory synapses on both thalamocortical relay neurons and reticular thalamic neurons. Corticothalamic neurons also emit intracortical collaterals which make excitatory synapses in layers 5/6 and in layer 4; however, data on the intracortical targets of these collaterals and on the short-term dynamics of these connections are inconclusive. To resolve these questions, we crossed the NtsR-Cre mouse line and the Ai32 Cre-responder line to express channelrhodopsin exclusively in CT neurons. Using thalamocortical slices from mouse somatosensory cortex, we performed dual whole-cell recordings from excitatory neurons (regular spiking, RS) or inhibitory interneurons (fast-spiking, FS or somatostatin-containing, SOM) in layers 4-6, while using blue light stimulation to depolarize CT axon terminals in the vicinity of the recorded neurons. Adding TTX and 4AP to the bath solution eliminated spiking and polysynaptic activity, revealing the direct postsynaptic targets of the CT neurons. We observed strong excitatory responses (EPSPs and EPSCs) in both FS and SOM interneurons in both layer 4 and layers 5/6, but only weak or no responses in Layer 4 RS neurons. To determine the short-term dynamics of these synapses, we recorded from connected CT-FS and CT-SOM pairs in layers 5/6. In response to 10-80 Hz trains of CT spikes, EPSPs in SOM interneurons facilitated, but those in FS interneurons underwent depression. We conclude that CT activation is likely to generate net inhibition in the cortical network; this inhibition will switch from proximally targeting to distally targeting as the firing frequency of CT neuron increases.

Title: Understanding optogenetic stimulation strategies: a study of opsin-neuron models and their spiking behaviors

Authors: *A. WILLATS;
Georgia Inst. of Technol. & Emory Univ., Atlanta, GA

Abstract: Optogenetics is a powerful tool for eliciting a wide range of patterns of neural activity with genetic and anatomical precision. Paired with closed-loop stimulation, it is possible to produce desired dynamic firing rates with high precision and reliability. However, the choice of stimulus protocol greatly impacts neural response and careful design relies on understanding nonlinear, nonstationary response properties which depend strongly on neuron type. For example, thalamic neurons tend to burst in response to sharp increases of light, but this bursting can be alleviated by maintaining a constant DC-bias. By altering the stimuli along an axis from smoothly modulated, to sharp pulsatile stimuli, an experimenter can manipulate the proportion of burst responses in this neuron.In this work we develop the foundations of optogenetic stimulation waveform design by exploring algorithmic approaches to fitting mathematical models of spiking responses and characterizing the output behavior of model neuron types with distinct mathematical structures. The results of this investigation suggest practical design guidelines for stimulation waveform design that depend on the neuron response properties and the task goals, with a particular emphasis on closed-loop stimulation strategies for dynamically controlling firing rate.Specifically, we build a map from stimulus features and model types to resulting spiking behaviors. Our investigations explore stimuli which are informed by current experimental practice and include sinusoids, ramps, noise waveforms, and square pulses of light. Our preliminary work consists of predicting in-vivo extracellular responses to optogenetic stimulation in closed- and open-loop contexts. We demonstrate genetic algorithm approaches as a flexible tool for fitting diverse classes of models, including phenomenological (linear-nonlinear-poisson), biophysical (4-state opsin dynamics coupled to a leaky-integrate-and-fire-or-

burst model), and models of intermediate complexity (a simple opsin model coupled with an Izhikevich neurons). We quantify behaviors including fine and coarse temporal features. Given the importance of bursting in sensory pathways and the challenges it presents in controlling firing rate, we perform a detailed comparisonof bursting vs. tonic response properties.Our results provide practical algorithms for model fitting, a taxonomy of model neural response behaviors under different stimulation strategies, and guidelines for stimulation design under task-dependent criteria (e.g., synchronous responses, bursting behaviors, etc.).

Title: Closed loop optogenetic control of neural circuits *In vivo*: Developing design principles for controlling patterns of neural firing rate

Authors: *M. F. BOLUS[1], A. A. WILLATS[1], C. J. WHITMIRE[1], Z. COSTELLO[2], M. B. EGERSTEDT[2], C. J. ROZELL[1,2], G. B. STANLEY[1];
[1]Wallace H Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol. & Emory Univ., Atlanta, GA; [2]Sch. of Electrical & Computer Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: The rapid advancement of genetic tools has enabled control of neuronal activity at fast timescales in an anatomically targeted manner with cell type specificity. Until recently, an ‘open loop’ strategy in which stimuli are designed a priori has been the de facto method for optogenetic control of neural activity. However, this method is prone to error due to unaccounted for variability in evoked neural activity. In the face of these challenges, a better strategy is to ‘close the loop’ around the activity being controlled, using feedback to guide stimulation in real-time. Recently, our group demonstrated the use of closed loop optogenetic control (CLOC) to drive single unit firing to desired constant firing rates in vivo (Newman et al. 2015). In this paradigm,

extracellularly recorded spikes are isolated in the somatosensory thalamus of the anesthetized rat and sorted in real-time. Firing rate is estimated online using a fixed-bandwidth filter and compared to a target rate. The resulting error signal is filtered through a proportional-integral (PI) controller and used to continuously modulate optical stimulation of neurons expressing channelrhodopsin (ChR2). Using this approach, we have since demonstrated effective control of dynamic patterns of firing rate. To generalize these results to the control of arbitrary patterns of firing rates, a systematic method for designing closed loop optogenetic systems is required. To this end, we are developing design principles for controlling temporally dynamic patterns of firing rate while rejecting disturbances that are band-limited from 0-25 Hz, a frequency range relevant to active sensation in rodent somatosensory thalamus. Specifically, we focus on tuning parameters for firing rate estimation and control as a function of control task. To estimate instantaneous firing rate from spikes online, we employ an exponential filter, whose time constant determines the filter bandwidth. Computationally, we have found that the optimal filter time constant decreases nonlinearly as the frequency content in the control task increases. To design the controller, we implemented a linear-nonlinear-Poisson model which was sufficient to capture optogenetic response in certain operating regimes. In simulation, controller gains are tuned by maximizing closed loop performance on sinusoidal firing rate tasks, sweeping across frequencies. Tuned parameters are then tested experimentally. Principled CLOC design demonstrated here will enable precise control of rhythmic oscillations and will form the basic building block required for more complex spatiotemporal control of activity such as sensory representations in cortex.

Title: Intracortical network effects preserve thalamocortical input efficacy in a cortex without layers.

Authors: ***J. GUY**[1], A. SACHKOVA[1], M. MÖCK[1], M. WITTE[1], R. J. WAGENER[2], J. F. STAIGER[1];

[1]Univ. Med. Ctr., Goettingen, Germany; [2]Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland

Abstract: Layer IV of the rodent somatosensory cortex contains the somatotopic barrel field. Barrels receive much of the sensory input to the cortex through innervation by thalamocortical axons (TCAs) from the ventral posteromedial nucleus (VPM). In the *reeler* mouse, the absence of cortical layers results in the formation of mispositioned barrel-equivalent clusters of layer IV fated neurons. Although functional imaging suggests that sensory input activates the cortex in a correct somatotopic fashion, little is known about the cellular and synaptic properties of identified excitatory neurons of the *reeler* cortex. We examined the properties of thalamic input to spiny stellate (SpS) neurons in the *reeler* cortex with in vitro electrophysiology, optogenetics and subcellular channelrhodopsin-2 (ChR2) assisted circuit mapping (sCRACM). Our results indicate that *reeler* SpS neurons receive direct input from the VPM, in line with their well-documented function as a main class of thalamorecipient neuron. Thalamic input, however, was more spatially dispersed along the somatodendritic arbors of *reeler* SpS neurons, and was also weaker with respect to wild-type controls. In spite of its relative weakness, thalamic input reliably recruited network dynamics including recurrent excitation and feedforward inhibition. These results raise the possibility that an increase in cortical amplification, either through enhanced recurrent excitation or weaker feedforward inhibition, rescue a weakened thalamic input to the *reeler* cortex, thereby ensuring sensory input efficacy.

Title: Neural dynamics of single units and local field potentials in mouse barrel cortex underlying detection at perceptual threshold

Authors: *H. SHIN, S. R. JONES, C. I. MOORE;
Brown Univ., Providence, RI

Abstract: Detection at perceptual threshold is a neocortex-dependent process. To study the neural dynamics underlying successful sensory processing, we employed a well-controlled vibrissae deflection detection task in mice. Here we describe preliminary results from large-scale chronic electrophysiology recordings in the barrel cortex, the vibrissae region of the primary sensory area of the neocortex (2 mice, 34 sessions of high psychometric performance). Consistent with prior studies (Cauller & Kulics 1990; Jones et al., 2007), the somatosensory evoked potential showed a larger surface negativity (N1, thought to reflect feedback activity from higher sensory areas) at ~70ms after sensory stimulus onset on threshold-level hit (detected) trials compared to stimulus amplitude matched miss (non-detected) trials. Closer examination of the evoked potential further revealed a larger early surface positivity (P1, thought to reflect feedforward activity) at ~20ms on threshold level hits. Next, we characterized single and multi unit activity by quantifying the stimulus probability (SP, a measure of whether the unit was sensory driven; >0.5 if stimulus evoked, <0.5 if stimulus suppressed) and the detect probability (DP, a measure of whether the unit had differential activity in detected and non-detected trials; >0.5 if more activity on threshold level hits, <0.5 if more activity on threshold level misses). Well-isolated single units were classified into regular spiking (RS; n=76) and fast spiking (FS; n=69) units based on the spike waveform. Sensory-modulated RS units had a mixed distribution of sensory enhanced (4 out of 12 RS with SP significantly different from 0.5) and sensory suppressed units (8/12), whereas the majority of sensory-modulated FS units were excited by the sensory input (20/20). For both RS and FS units, DP during the evoked period (0~100ms, before the animals' reaction times) was positively correlated with SP during the same period, replicating previous studies (Yang et al., 2015). Interestingly, pre-stimulus DP and post-stimulus SP had a slightly negative trend in both populations. The majority of FS had hit-predictive post-stimulus DP (8 out of 9 FS with DP significantly different from 0.5 had DP significantly greater than 0.5), which manifested in the population average post-stimulus time histogram as higher evoked firing rate on hits than misses. For FS cells with hit predictive evoked DP, the activity on hits and misses started diverging at ~20ms, which coincides with the P1 of the evoked potential. This implies that feedforward excitation of barrel cortex FS neurons has an important role in perceptual modulation of detection.

Title: Human beta rhythm modulation with perception and attention reflects the density of rhythmic transients across trials

Authors: *S. R. JONES[1], S. TSUTSUI[2], R. LAW[1], H. SHIN[1], C. I. MOORE[1];
[1]Dept. of Neurosci., [2]Brown Univ., Providence, RI

Abstract: Neocortical beta (15-29Hz) is one of the most prominent signatures of neural activity measured non-invasively in humans. Beta power is a strong predictor of healthy and pathological perceptual and motor performance. Yet, its precise causal role in function is unknown. Key to discovering beta's impact on function is a proper characterization the nature of beta in the un-averaged, unfiltered, time domain signals. We have previously shown that functionally relevant beta rhythms measured with magenetoencephalography (MEG) from primary somatosensory cortex (SI) and frontal cortex are transient in un-averaged data, emerging in high-power as brief events that last ~150ms. We have also shown that, on average, increased beta power predicted inattention and failed tactile detection (Jones et. al., J. Neurosci. 2010), and beta-band synchrony between SI and frontal cortex increased during inattention (Sacchet et. al., J. Neurosci. 2015). Here, we quantify beta in un-averaged data to uncover features that underlie the observed power differences with perception and attention across trials. We show that continuous bands of beta activity apparent in averaged data reflect the accumulation of discrete beta events across trials. Further, correlations between increased pre-stimulus beta power and decreased tactile perception and attention are driven primarily by an increase in the number of discrete beta "events" in the pre-stimulus period, rather than an increase in event amplitude or the duration of individual events. These results are consistent with other recent studies of local field potentials in monkeys that showed differences in averaged power across behavioral conditions reflect a change in the density of transients across trials (Feingold et. al., PNAS 2015, Lundqvist et. al., Neuron 2016), supporting the idea that this is a generalizable beta phenomena across tasks and species. In summary, our results suggest the transient nature of beta is an important feature to consider in developing models of beta's causal impact on function, and in designing stimulation paradigms aimed to modulate beta to improve function.

Title: Mechanisms of sensory inhibition induced by neocortical beta rhythms

Authors: *R. LAW[1], S. TSUTSUI[2], S. R. JONES[2];
[1]Neurosci., [2]Brown Univ., Providence, RI

Abstract: Beta frequency rhythms (15-30hz) are prominent throughout the brain and correlate with perception and attention as well as motor action. In human primary somatosensory cortex (SI), beta band magnetoencephalographic (MEG) spectral power in the prestimulus period inversely correlates with detection of a tactile stimulus (Jones et al 2010). Neural mechanisms that may link beta with perception, however, are not captured by contemporary models.
We have previously shown that beta in human SI is event-like, emerging for periods of ~150ms with a stereotypical waveform. Combining MEG, computational modeling and laminar recordings in animals, we also showed that beta can emerge from the integration of brief bouts of excitatory synaptic input to the proximal and distal dendrites of cortical pyramidal neurons, where the beta frequency is set by the duration (~50ms) of strong distal excitation.
Building on these results, we use a computational model of neocortical dynamics that accounts for the biophysics of MEG to study circuit mechanisms that connect beta rhythmicity to decreased tactile detection. We show that early tactile evoked potentials (<100ms) associated with high and low prestimulus beta power have distinguishable waveforms consistent with differences associated with detection. In a companion study (see Jones, Tsutsui, Law et al., SFN 2016), we also show that prestimulus spectral power differences with detection corresponds better to differences in the density of beta "events" than to differences in amplitude or duration of these events. Taken together, these results raise the possibility that beta's perceptual interference effect may result from the coincidence of an exogenously driven beta event with a tactile stimulus.
We model tactile stimuli occurring at several phases of a beta event as well as outside a beta event, finding that stimulation during a beta event can recruit a gamma cycle (~80Hz) in superficial layers, which inhibits the later (~70ms) network response that correlates with detection, generating current dipoles that qualitatively match early components of the event-related MEG signal. This effect depends on the phase of the underlying beta waveform. Our results provide a mechanistic link between beta rhythms and perception that may generalize to other sensory and motor processes.

Title: Developing a bio-electronic nose by interfacing to the early olfactory system

Authors: E. SHOR[1], T. BOZZA[2], *D. RINBERG[1];
[1]New York Univ., New York, NY; [2]Northwestern Univesity, Evanston, IL

Abstract: The mammalian olfaction sense is capable of detecting and classifying odors in a quick, reproducible and sensitive manner even in rapidly changing environment where many odorants are present and odor concentrations vary. This detection capability is superior to any electro-chemical detector technology present today. Consequently, animals are used to detect and sense odor response of various substances for a variety of healthcare, agriculture and homeland security tasks. However, although animals can detect and classify odors, we rely on behavioral training to allow those animals report which odors were detected. Here, we attempt to develop a bio-electronic nose by interfacing to the early olfactory system using high resolution ECoG array implanted on the olfactory bulb. By obtaining LFP recording in high spatial and temporal resolution of awake mice presented with various odors in different concentrations we develop a machine learning odor classification algorithm. The performance and sensitivity of this approach is compared to the sensitivity of other detection devices. This technology is also used to investigate the circuitry of the olfactory system.

Title: Onset latency analysis of odor-evoked calcium response in the juxtaglomerular cells of mouse olfactory bulb

Authors: *R. HOMMA[1], X. LV[2,3], S. ZENG[2,3], S. NAGAYAMA[1];
[1]Univ. of Texas Med. Sch. at Houston, Houston, TX; [2]Wuhan Natl. Lab. for Optoelectronics, [3]Dept. of Biomed. Engin., Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: Olfactory glomeruli are the relay center where the principal neurons (i.e. mitral and tufted cells) receive the glutamatergic inputs from the olfactory sensory neurons. Different types of interneurons including both excitatory and inhibitory enclose each glomerulus and contribute to the odor information process within the glomerulus. These interneurons are collectively referred to as juxtaglomerular cells. Thanks to the past studies including slice preparation physiology and histology, major types of juxtaglomerular cells at least have been decently characterized. On the other hand, it is still far from clear how these neurons are coordinated to shape the glomerular inputs to the principal neurons. To fill this gap of understanding, it is important to look at ensemble activity patterns of population of juxtaglomerular cells that are associated with the same glomerulus. In this study, we used *in vivo* calcium imaging method to record odor response of multiple juxtaglomerular cells with Acousto-Optic Deflector (AOD) two-photon microscope. Anesthetized mice were used for this experiment. Neurons expressed a calcium indicator GCaMP6f through an AAV injection into the olfactory bulb preceding the optical recording. Odor-evoked calcium transients from 12 to 15 neurons surrounding a few glomeruli were recorded with a random-access scanning mode at a sampling rate of 667 to 833 Hz. We especially focused on the juxtaglomerular cells that were supposed to receive the inputs from the same glomerulus. These neurons were identified based on their odorant selectivity and the location of cell body (adjacent to the same glomerulus). Interestingly, neurons which presumably belong to the same glomerulus showed quite similar temporal patterns of calcium response. We carefully estimated the time at which odor-evoked calcium transient started rising from the baseline. We limited our analysis to the responses that are strong enough for accurately estimating the latency. Onset of odorant response of these neurons vary across stimulus-glomerulus pairs. Median across the cells within the glomerulus ranged from 18 to 235 ms after the estimated onset of first inhalation following stimulus presentation (25 stimulus-glomerulus pairs; mean 151 ms, SD 59 ms). The difference between the shortest and the longest latency within a trial was distributed between 10 and 79 ms (mean 33 ms, SD 15 ms). These distributions imply that the onset latency of juxtaglomerular neurons probably follow the time course of inputs from the olfactory sensory neurons and is less variable across the neurons within a glomerulus.

Title: Control of mitral/tufted cell output by selective inhibition among olfactory bulb glomeruli

Authors: ***M. WACHOWIAK**[1], T. BOZZA[3], K. R. HANSEN[2], M. N. ECONOMO[1];
[1]Dept. of Neurobio. and Anat., [2]Dept. of Bioengineering, Univ. of Utah, Salt Lake City, UT;
[3]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Inhibition is fundamental to information processing by neural circuits. In the olfactory bulb (OB), glomeruli are the functional units for odor information coding and contain multiple inhibitory circuits that shape glomerular output via mitral and tufted (MT) cells. How this inhibition is organized with respect to the glomerular map and how it manifests in response to odorant stimulation remains poorly characterized. Here, using ultrasensitive calcium reporters targeted to MT cells in combination with two-photon imaging from MT somata or apical tufts in awake and anesthetized mice, we were able to monitor odorant-evoked excitation and suppression of MT cell output. We found that MT cell response polarity was distributed across all MT cells innervating the same glomerulus, allowing us to relate patterns of MT excitation and suppression to the glomerular map. Odorants elicited unique patterns of excitation and suppression across glomeruli, and MT cells from any one glomerulus were excited or suppressed by different subsets of odorants. Excited and suppressed glomeruli were spatially intermingled, with both excitation and suppression sparsely distributed at low odorant concentrations and more densely distributed at higher concentrations. Using odorant mixtures, we found that this suppression is sufficiently strong to gate excitatory responses to other odorants and is mediated, at least in part, by interglomerular inhibitory interactions that differentially impact deep versus superficial MT cells. The specificity, concentration-dependence and spatial distribution of glomerular suppression are not easily explained by recently-proposed models of intensity-dependent feedforward inhibition or scaled global inhibition by inhibitory OB circuits. Instead, these results support a model of selective and nonrandom inhibition among glomerular ensembles and reveal that inhibitory OB circuits nonlinearly transform odor representations.

Title: Structural basis for cholinergic regulation of neural circuits in the mouse olfactory bulb

Authors: M. HAMAMOTO, E. KIYOKAGE, *K. TOIDA;
Kawasaki Med. Sch., Kurashiki, Japan

Abstract: Odor information is regulated by olfactory inputs, bulbar interneurons, and centrifugal inputs from other brain regions. We have recently shown a unique distribution pattern of serotonergic neurons, one of the centrifugal inputs to the olfactory bulb. In this study, we focused on cholinergic regulation of the olfactory bulb (OB) and analyzed projection pathways of cholinergic neurons in detail. Cholinergic neurons in the nucleus of the horizontal limb of the diagonal band of Broca and the magnocellular preoptic nucleus project to the OB. Single cell imaging of a specific neuron within dense fibers is critical to evaluate the structure and function of the neural circuits. We labeled cholinergic neurons by infection with virus vector and then reconstructed them. We also examined the ultramicrostructure of synapses by electron microscopy tomography. To further clarify the function of cholinergic neurons, we performed confocal laser scanning microscopy to investigate whether other neurotransmitters are present within cholinergic axons in the OB. Our results show the first visualization of complete cholinergic neurons, including axons projecting to the OB, and also showed frequent axonal branching within the OB where it innervated multiple glomeruli in different areas. Furthermore, the synapse structure was found to be similar to that in serotonergic neurons. Although we have not yet detected the presence of other neurotransmitters, the diversity of synaptic morphology suggests multiple modes of transmission. Our present study elucidates the ways that cholinergic neurons could contribute to the elaborate mechanisms involved in olfactory processing in the OB.

Title: Dynamics of neuronal ensembles in the main olfactory bulb

Authors: S. WADDLE[1], E. LYMAN[1], *K. PADMANABHAN[2];
[1]Univ. of Delaware, Newark, DE; [2]Neurosci., Univ. of Rochester, Rochester, NY

Abstract: Spontaneous activity across ensembles of neurons can reveal important features of network architecture, the responses of networks to inputs, and ultimately the encoding and decoding of sensory stimuli. In the olfactory system of the mammal, the main olfactory bulb is one of the first processing centers for sensory information. Complex interactions between the principle excitatory cells, the mitral and tufted cells, and local inhibitory neurons, govern the dynamics of activity, shaping how information is transmitted to higher processing centers. Understanding the dynamics of activity among these neurons, and the effect of those dynamics on olfactory coding remains an open question. Using high-density recordings in the main olfactory bulb, we characterized the dynamics of neuronal ensembles of mitral/tufted cells during epochs of sensory independent spontaneous activity. Complex interactions among populations of neurons were uncovered using maximum entropy models, providing important insight into structure of activity within the bulb. In addition to examining the features of activity across ensembles of neurons, we also developed a new approach to examine the effect that previous patterns of activity had on shaping future patterns of activity. Together, our work provides an important clue into how activity patterns in the bulb are evolved from the interactions between neurons, and how this activity is affected by the history of activity that preceded it.

Title: Increased olfactory bulb BDNF does not enhance the normal survival of new granule cells and does not prevent deprivation-induced cell death

Authors: *K. M. GUTHRIE[1], R. BERGER[2], B. MCDOLE[2];
[1]Dept Biomed Sci., [2]Florida Atlantic Univ., Boca Raton, FL

Abstract: The adult subventricular zone (SVZ) harbors progenitor cells that give rise to new olfactory granule bulb granule cells throughout adulthood. Normally about half of these new cells survive to become functionally integrated into bulbar circuitry. A variety of molecular cues are known to regulate the survival of new granule cells in vivo, and sensory activity plays an important role as well. Olfactory deprivation by naris occlusion increases the number of new granule cells lost by apoptosis during a critical developmental window spanning ~14-21 days of cell age. The neurotrophin brain-derived neurotrophic factor (BDNF) exhibits activity-dependent expression and secretion in the CNS, and has well characterized effects on neuronal maturation and dendritic spine morphology during development and in adulthood. Augmenting BDNF availability in the adult rodent ventricular ependymal (VZ/SVZ) has been shown to promote the production and survival of adult-born granule cells in vivo. In contrast, studies employing knockout of the BDNF receptor TrkB in SVZ-born cells have reported no significant effect on granule cell survival. The aims of the present study were to determine 1) if increasing endogenous BDNF levels in the olfactory bulb, rather than the SVZ, enhances the survival of adult-born granule cells as they integrate into the granule cell layer (GCL), and 2) if increased BDNF can rescue new granule cells from sensory deprivation-induced apoptosis. We used adult transgenic mice that express increased BDNF throughout the olfactory bulb GCL. Elevated BDNF expression was confirmed by ELISA, and control and unilaterally-deprived mice were treated with bromodeoxyuridine (BrdU) to label dividing SVZ progenitor cells. Mice survived for 2, 4, or 8-9 weeks. Bulb sections were processed for co-localization of Brdu+/Neu+ to quantify numbers of new neurons in the GCL. Potential changes in SVZ cell proliferation were assessed by immunostaining for Ki-67, and levels of apoptotic cell death in the GCL were assessed with TUNEL labeling. In non-deprived mice, no significant differences in the numbers of BrdU+/Neu+ granule cells, Ki-67+ SVZ cells, or TUNEL+ bulb cells were found between transgenic mice and wild-type controls. Increased bulbar BDNF did not suppress apoptosis caused by sensory deprivation, or increase the number of new granule cells present in the

deprived bulb at 8 wks post-BrdU. Our findings support the view that while BDNF has significant morphological effects on granule cells (Bergami et al., 2013; McDole et al., 2015), its increased availability in the bulb has little impact on the survival of adult-born cells.

Title: Dynamic regulation of mitral cell spike synchronization and phase-locking by external tufted cells in a glomerular network model

Authors: ***C. RAPP**[1], F. FROHLICH[2], T. A. CLELAND[3], G. LI[2];
[2]Psychiatry, [1]Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [3]Psychology, Cornell Univ., Ithaca, NY

Abstract: External tufted (ET) cells are glutamatergic interneurons within the glomerular layer of the olfactory bulb (OB) that recently have been shown to serve multiple important functions in the coding and processing of olfactory sensory information. ET cells possess striking dynamical characteristics such as spontaneous bursting at respiratory theta frequency, highly correlated activity, and burst entrainment to patterned olfactory input. By providing feedforward excitation to other juxtaglomerular interneurons and to principal output neurons (mitral cells), ET cells may regulate important OB computation such as signal amplification and glomerular synchronization. However, the functional roles of ET cells may critically depend on how olfactory information is transmitted to the mitral cells (MCs). In the traditional model, MCs are predominantly activated by olfactory sensory neurons (OSNs), while in a recent model, most or even all afferent excitation to MCs is delivered via intermediating ET cells. The computational implications of these two relay models in olfactory information processing remain unclear. To address this issue, we developed a biophysical model of the OB glomerular network consisting of OSNs, ETs, MCs and inhibitory periglomerular (PG) cells. The ET cell model contains multiple ionic currents as observed experimentally and accurately replicates the salient properties such as spontaneous bursting at theta frequency band and burst entrainment to olfactory input. The OSN is modeled as tonic spiking neuron and both MC and PG cell models are taken from previous study. We simulated both the traditional OSN-routing network and the ET-routing network under three

different sniffing frequencies (2, 4 and 8 Hz) and observed that MC spike synchronization and phase-locking to inhalation are dynamically regulated by ET bursting in the ET-routing network. When the sniffing frequency is low (e.g, 2 Hz), ET bursting is loosely entrained to the sniffing input, leading to weak MC synchronization and phase-locking. As the sniffing frequency increases, more ET bursting is entrained and the maximal entrainment is achieved at 8 Hz. Consequently, MC spike synchronization and phase-locking is the largest in response to 8 Hz sniffing input. In contrast, in the OSN-routing network, MC spike synchronization and phase-locking decreases with sniffing frequency. Thus, as sniffing frequency increases, the glomerular network may switch from an OSN-based computation to an ET-based computation that enhances the fidelity and precision of odor coding.

Title: Reconstruction of neuronal activity and connectivity patterns in the zebrafish olfactory bulb

Authors: *A. A. WANNER, C. GENOUD, R. W. FRIEDRICH;
Friedrich Miescher Inst. For Biol. Res., Basel, Switzerland

Abstract: In the olfactory bulb (OB), odors evoke distributed patterns of activity across glomeruli that are reorganized by networks of interneurons (INs). This reorganization results in multiple computations including a decorrelation of activity patterns across the output neurons,

the mitral cells (MCs). To understand the mechanistic basis of these computations it is essential to analyze the relationship between function and structure of the underlying circuit.
We combined *in vivo* twophoton calcium imaging with dense circuit reconstruction from complete serial block-face electron microscopy stacks of the larval zebrafish OB (4.5 dpf) with a voxel size of 9x9x25nm. We set up a high throughput neuron reconstruction pipeline with >30 professional tracers that is available for the scientific community (ariadne-service.com). To assure efficient and accurate circuit reconstruction, we developed PyKNOSSOS, a Python software for skeleton tracing and synapse annotation, and CORE, a skeleton consolidation procedure that combines redundant reconstruction with targeted expert input.
Using these procedures we reconstructed all neurons (>1000) in the larval OB. Unlike in the adult OB, INs were rare and appeared to represent specific subtypes, indicating that different sub-circuits develop sequentially. MCs were uniglomerular (see image) whereas inter-glomerular projections of INs were complex and biased towards groups of glomeruli that receive input from common types of sensory neurons. Hence, the IN network in the OB exhibits a topological organization that is governed by glomerular identity.
Calcium imaging revealed that the larval OB circuitry already decorrelates activity patterns evoked by similar odors. The comparison of inter-glomerular connectivity to the functional interactions between glomeruli indicates that pattern decorrelation depends on specific, non-random inter-glomerular IN projections. Hence, the topology of IN networks in the OB appears to be an important determinant of circuit function.

Title: Mechanisms and functions of the offset response in insect olfaction

Authors: ***S. HANEY**[1], D. SAHA[2], B. RAMAN[2], M. BAZHENOV[3];
[1]Med., UCSD, Los Angeles, CA; [2]Washington Univ., St. Louis, MO; [3]Med., Univ. of California, San Diego, CA

Abstract: Insects respond to the olfactory stimuli with a strong transient response at odor onset followed by a moderate response during long odor presentations. Surprisingly, the neural response to the removal of olfactory stimulus, the offset response, is nearly as strong as the response to the application of olfactory stimulus, the onset response. We have previously found that this offset response: 1) governs stimulus termination behavior, 2) involves a disjoint (orthogonal) set of neurons from the onset response, and 3) is a common neural strategy to encode stimulus termination also employed in marmoset auditory cortex. However, little is known about the neuronal mechanisms of the offset response. What neural circuits generate the offset response? What effects might this have on the downstream neural targets? How might this impact the formation of memories? To address these questions, we have developed biophysically accurate computational model of the insect olfactory system. Based on the finding that odors can inhibit cognate receptors and depress firing rates of certain Olfactory Receptor Neurons (ORNs), we implemented odor-specific inhibition of a subpopulation of ORNs and synaptic adaptation at the ORN-AL synapse. We found that these two mechanisms are sufficient to produce offset responses that are a) orthogonal to the onset response and b) lacking in oscillatory behavior as seen *in vivo*. We next modeled the downstream Mushroom Body (MB) neurons, a region important in olfactory memory, and found that the onset and offset responses remain orthogonal in the high dimensional space of the MB neurons. MB neurons synapse with neurons in the beta lobe and these synapses are known to undergo spike timing dependent plasticity (STDP). Our study predicts that the offset response may contribute to meaningful and odor-specific synaptic

changes after multiple odor presentations. It remains, however, to be explored whether the odor offset activity may contribute to olfactory learning. The offset response exists in multiple different organisms and multiple different sensory systems but has gone largely unstudied. Our work presents a novel foundation for understanding this intriguing feature of sensory processing.

Title: Modulatory convergence of serotonin and dopamine in an olfactory network.

Authors: *K. M. LIZBINSKI, A. M. DACKS;
Biol., West Virginia Univ., Morgantown, WV

Abstract: Neuromodulation optimizes nervous system function by altering the synaptic efficacy and biophysical properties of individual neurons. The effects of neuromodulation are dictated by receptor expression patterns, receptor types and second messenger systems. Thus, the convergence of multiple neuromodulators on a single neuron involves the integration of several second messenger cascades, leading to potential non-linear effects on neuronal biophysical properties. Every neural network is influenced by a dynamic cocktail of neuromodulators that vary in their time course of action. For instance, serotonin (5-HT) and dopamine (DA) are both released by extrinsic neurons within the antennal lobe (AL) of the moth *Manduca sexta*, however they are associated with different physiological contexts. As a result, the extent to which they simultaneously affect olfactory processing is variable. Broadly, the integrated effects of multiple neuromodulators on sensory processing is not well understood. Here, we determined the consequences of integrating both 5-HT and DA on olfactory processing in the AL of *Manduca*. Using multichannel extracellular electrophysiology, we recorded the effects of 5-HT, DA and a combination of both modulators on odor-evoked responses of AL neural ensembles. DA and 5-HT affected overlapping populations of AL neurons, generally enhancing odor-evoked firing. However, each modulator had distinct effects on temporal structure of odor-evoked responses, with 5-HT extending response duration and DA shortening phases of post-excitatory inhibition. As a consequence the integrated effect of both modulators was overall excitatory, yet non-linear. Our data suggests that olfactory processing is contextually modulated based on a variable network state.

Title: Integration of olfactory and mechanosensory stimuli in the projection neurons of antennal lobe in the moth Manduca sexta

Authors: ***H. LEI**[1], J. KIM[2], J. G. HILDEBRAND[2];
[1]Univ. Arizona, Tucson, AZ; [2]Univ. of Arizona, Tucson, AZ

Abstract: Olfactory receptor neurons (ORN) on the moth antennae sense environmental odors and transmit information to the interneruons, projection neuron (PN) and local neuron (LN), in the primary olfactory center, the antennal lobe (AL). The information about odors is synaptically processed within dense neuropil called glomerulus, which houses ORN terminals and dendrites of PNs and LNs, before sending out to higher olfactory centers in the protocerebrum. Additionally, mechanic stimuli, such as wind, are known to be an important sensory modality in moths' odor-seeking behaviors. Integration of mechanosensory and olfactory stimuli seems a beneficial feature, but where are these two modalities integrated? Our recent experiments suggest that the integration may occur as early as on the PNs. We recorded intracellularly from PNs' somata and stimulated moth antenna with odors carried by air puffs of different velocities, in addition to controls, i.e. air puffs alone. We found that increasing air velocity resulted in stronger responses to odors, and this phenomenon could not be explained by increased odor flux rate. While intermediate wind velocity caused significant increment of responses, both to odor and to control, higher velocity failed to enhance response further. It's still unknown what functional significance of mechanosensory responses in PNs might be, but we are currently testing a hypothesis that these responses may amplify odor signal. Title: The connectivity of the serotonergic input to the olfactory system of *Drosophila*

Authors: *K. COATES, A. AUDA, C. MICHAEL, S. MICHAELS, T. SIZEMORE, A. MAJOT, A. DACKS;
Biol., West Virginia Univ., Morgantown, WV

Abstract: From one moment to the next, neuromodulators dynamically tune sensory processing to match the needs of the animal. By altering the biophysical and synaptic properties of individual neurons, neuromodulators alter the way that networks process information, which allows for adjustment of behavior. Neuromodulators strongly influence sensory processing, however the context in which neuromodulators are released within sensory networks is often complex. Modulatory nuclei are typically comprised of highly heterogeneous neurons that project to and receive input from many diverse brain regions, making it challenging to understand how modulatory systems affect sensory processing. Therefore, we sought to characterize the connectivity of two identified modulatory neurons in the olfactory system of *Drosophila melanogaster.* The contralaterally-projecting, serotonin-immunoreactive deutocerebral neurons, or CSDs, project broadly throughout the olfactory system, innervating both the ipsi-and contralateral antennal lobe, mushroom body calyx, superior lateral protocerebrum, and lateral horn. Moreover, they are the sole source of serotonin-immunoreactivity in the antennal lobe and lateral horn. Using a dendritic marker Dscam-GFP, we found that CSD neuron dendrites are found predominantly in higher order brain areas, including the antler and superior clamp. Using the axon marker synaptotagmin-GFP, we found that the CSD neurons have axon terminals in four olfactory processing regions, including the antennal lobe. Within the antennal lobe, the CSD neurons innervate the glomeruli to different extents. We therefore used the active zone marker Brp_{short} to quantify glomerulus specific differences in synaptic input from the CSDs. The density of active zones was consistent within identified glomeruli and lateral horn regions across animals. However, different glomeruli and lateral horn regions varied widely in CSD synaptic density. Taken together, our data suggest that the CSD neurons provided a unified source of modulatory input to several olfactory regions, yet their synaptic input may vary in an odotopic manner.

Abstract: In the olfactory system of *Drosophila melanogaster*, sensory transduction activates olfactory receptor neurons (ORNs) housed in the antennae and maxillary palps. These sensory neurons provide input to the antennal lobe, where the structural unit is the glomerulus. Each glomerulus is associated with at least three classes of neurons: excitatory local neurons (eLNs), inhibitory local neurons (iLNs), and projection neurons (PNs). PNs provide the output from the antennal lobe, sending axon terminals to the mushroom bodies and lateral horn, while the local neuron aborizations are confined to the antennal lobe.
In this work, we construct a conductance-based neuronal network model of the *Drosophila* antennal lobe, based on experimental data for *Drosophila* channel kinetics and constrained by specific odor stimulus/response characteristics described by Bhandawat et al. [1,2]. We use computational studies to investigate the role of interglomerular and intraglomerular connectivity patterns in the antennal lobe, where ORN inputs to the antennal lobe are modeled with Poisson spike trains, and model synaptic connections are mediated by chemical synapses and gap junctions as described in the *Drosophila* antennal lobe literature [3,4]. We find that in the case of homogeneous synaptic connection strengths, the model suggests that the eLN network facilitates odor detection in the presence of weak stimuli. Excitatory local neurons can spread excitation from PNs, amplifying weak inputs. However, depending on connectivity strength, excitatory LNs may decrease the ability of the network to discriminate between odors. In addition, computational studies suggest that gap junctions play a prominent role in facilitating synchronization of glomerular electrical activity. Various electrical connectivity regimes are explored to elucidate the role of gap junctions in the dynamical behavior of the antennal lobe network and the functional roles of different classes of neurons in odor detection and odor discrimination.

Title: Serotonergic modulation of inhibitory input to lateral horn modifies olfactory attraction in *Drosophila*

Authors: ***A. H. AUDA**, K. COATES, T. SIZEMORE, A. DACKS;
Biol., West Virginia Univ., Morgantown, WV

Abstract: An organism must adjust its behavior based on the continuously changing environment. In response to the change in external conditions, network parameters are adjusted to generate different internal network states. These adjustments are often implemented via a variety of neuromodulators. Serotonin (5-HT) is widely distributed across the central nervous system and activates several receptor types. These receptors have different effects on biophysical and synaptic properties, thus allowing 5-HT to differentially target individual populations of neurons within a neural network. For instance, within the antennal lobe (AL), 5-HT enhances odor-evoked responses of projection neurons (PNs) and local interneurons (LNs), however the individual 5-HT receptors in the olfactory system responsible for the modulatory effects of 5-HT are not known. Using Drosophila, we have investigated the contribution of a specific 5-HT receptor expressed by a specific population of PN to the modulation of the lateral horn (LH), a second order olfactory network associated with processing innately important odor information. The ALs provide input to the LH via two types of PNs. We found that the GABAergic ventral projection neurons (vPNs) express the 5-HT1A receptor. Using GFP reconstitution across synaptic partners (GRASP), we found that the sole source of 5-HT to the AL and LH synapses onto vPNs in both regions, but not onto a subset of LH output neurons. To determine the functional role of the 5-HT1A receptor expressed in vPNs on odor-attraction, we reduced the expression of the 5-HT1A receptor in vPNs and tested olfactory sensitivity. The vPNs have been shown to respond to innately attractive odors and GABA release by vPNs in the LH is necessary for eliciting olfactory attraction. Consistent with these studies, we found that knocking down the inhibitory 5-HT1A receptor expression in the vPNs resulted in enhanced odor attraction. Therefore, our results suggest that 5-HT modulates innate odor-guided attraction by regulating the inhibitory tone exerted by the AL on the LH via the GABAergic vPNs.

Abstract: The olfactory system of animals is charged with identifying and discriminating familiar and novel odors which are complex mixtures drawn from a very high dimensional space of volatile molecules (perhaps 10^6 or more). Thus, the olfactory system must invest a limited number of genetically encoded receptor types (~50 in the fly, ~400 in humans, ~1500 in mice) wisely, to sense a much higher dimensional and highly variable signal. The responses are normalized (at the antennal lobe in insects and the olfactory bulb in mammals) and then projected, apparently randomly, to higher brain areas involved in learned behavior (mushroom body in insects and piriform cortex in mammals). We propose a new interpretation of the functional logic of this circuit pathway that is rooted in a key simplifying property of natural odors -- a typical odor is “sparse” in that it contains only 50-100 molecular components, a tiny fraction of the total number of volatile molecules. Drawing on the mathematics of random projections and on receptor response data, we demonstrate that the nervous system exploits the sparsity of natural odors by using disordered responses of olfactory receptors to create an efficient, distance-preserving embedding of the high-dimensional odor space in a low dimensional neural space. This efficient embedding is replicated by the subsequent random projections to the cortex, creating redundant and compact copies of the information that facilitate flexible learning. The theory makes striking new predictions, e.g. that arbitrary and small subsets of cortical neurons can provide complete representations of odor space to support complex animal behaviors. This prediction can be tested by optogenetic manipulation of the olfactory

cortex. In light of these results, we argue that the olfactory circuit pathway should be regarded as a novel scheme for compressive sensing of odors that developed through natural selection.

Title: Odor-evoked responses in both olfactory bulb and brain stem in a perfused preparation of the rat olfactory system

Authors: F. PEREZ DE LOS COBOS PALLARES[1,2], D. FARMER[3], D. STANIC[3], M. LUKAS[1], M. DUTSCHMANN[3], *V. EGGER[1];

Abstract: To explore the mechanisms underlying network oscillations in the olfactory bulb (OB) and olfactory processing in the brain stem (BS), we adapted an established technique, the semi-intact *in situ* BS preparation, to develop a preparation with preserved anatomy of the olfactory system from the nasal cavities to the olfactory bulb and preserved respiratory circuitry. While the BS is oxygenated via the basilar artery, the OB is perfused in parallel via the ophthalmic artery. Although the forebrain is completely removed, the anatomical integrity of the nasal trigeminal afferents innervating the BS is not compromised.
In local field potential (LFP) recordings from the perfused OB, we observed robust spontaneous oscillations, mostly in the theta range. Odor application to the nasal epithelium with an olfactometer resulted in an increase in oscillatory power in higher frequency ranges, stimulus-locked LFPs, and excitation or inhibition of individual bulbar neurons that were established in multi-unit recordings, similar to odor responses reported from in vivo recordings.
Stimulation of the nose with room air caused weaker activation of the OB than odorant exposure. Moreover, irrigation of the nose with cold water did not evoke field potentials in the bulb but

triggered a breath hold signal in the simultaneous recordings of phrenic nerve activity due to the protective diving reflex. Moreover, such simultaneous recordings from the phrenic nerve and the OB also showed that odors can trigger significant and specific respiratory modulations via the trigeminal pathway. A non-trigeminal odor (rose oil) did not evoke significant respiratory modulation (n = 11 preparations), whereas trigeminal odors (menthol, lavender; n = 12) changed inspiratory activity in duration and amplitude in two phases: First, short inspiratory bursts were elicited in all recordings with parallel OB LFP responses, evocative of fictive sniffing. Second, specifically upon menthol application the respiratory frequency decreased compared to baseline activity. These changes were followed by an immediate recovery of the eupneic inspiratory activity after stimulation offset.
Since this preparation lacks cortico-limbic networks, our study demonstrates for the first time direct respiratory modulation via the trigeminal pathway in relation to odor sensing. We conclude that our method constitutes the first viable in situ preparation of a mammalian system that uses airborne odor stimuli, preserves characteristic features of odor processing and allows to to study odor-evoked signals within the olfactory bulb network and interactions between olfactory sensing and respiration.

Title: Assaying the spatial and temporal structure of olfactory bulb inhibition using paired recordings

Authors: *H. A. ARNSON, B. W. STROWBRIDGE;
Neurosciences, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstract: Inhibitory synaptic interactions play a central role in the processing of sensory information within the olfactory bulb. While the primary synaptic connections between principal cells and GABAergic interneurons, such as granule cells (GCs), have been described, less is known about the spatial and temporal scales over which these circuits operate. Previous work provides support for a wide potential range of spatial scales of inhibitory function mediated by

GCs. Individual GCs may influence principal cells spanning hundreds of microns if action potentials routinely drive GABA release throughout the entire dendritic arbor or may act in a spatially restricted manner (over several microns) if individual dendritic spines operate independently in response to highly localized sodium or calcium spikes. The spatial and temporal domains over which individual interneurons can functionally link principal mitral cells (MCs) and tufted cells (TCs) likely play a critical role governing how emergent network behaviors are generated during sensory processing.
In this study, we performed simultaneous intracellular recordings in acute rat olfactory bulb brain slices from MC - MC and MC - TC pairs to address the questions of temporal and spatial synchrony of GC activity. We found that ~40% of sampled pairs of MCs received low levels of coincident IPSCs greater than expected by chance as measured by the clipped cross-intensity function ($p<0.05$ threshold). Coincident IPSCs occurred in both proximal pairs and pairs separated by up to 350 μm, consistent with filtering properties of MC and TC lateral dendrites. In pairs of MCs separated by < 350 μm (and presumably sharing a common GC), we found little correlation between inhibitory connection probability and spatial scale. We also observed statistically significant synchronous activity in approximately 20% of MC - TC pairs separated by up to ~200 μm, suggesting that GCs functionally connect different sensory processing streams. The rate of synchronous activity is highly correlated to the baseline IPSC rate recorded in TTX, suggesting a reflection of intrinsic GC - MC circuitry. We find that IPSC synchrony occurs primarily over short time scales (< 2 ms) implicating coordination of GABA release sites by sodium-dependent spiking mechanism rather than through a slower, calcium-dependent mechanism. These results suggest that MCs and TCs appear to form random connections with GCs, enabling inhibitory postsynaptic responses to functionally link diverse subgroups of principal neurons during olfactory processing.

Title: Mimicking natural stimulation patterns to the olfactory bulb

Authors: *C. E. VAAGA, G. L. WESTBROOK;
Vollum Inst., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Understanding how external stimuli are encoded in neuronal activity is a primary interest in sensory neurophysiology. In the olfactory bulb mitral cells and external tufted cells have unique physiological profiles to a single, brief afferent stimulus; however, their responses to afferent impulse patterns are less well understood. Odorant stimulation *in vivo* produces three distinct afferent impulse patterns: phasic, phasic-tonic and burst-pause-rebound (Savinger et al., 2009; Tan et al., 2010). Here, using single glomerulus stimulation in olfactory bulb slices, we examine the responses of principal neurons to "naturalistic" stimulation paradigms. Our stimulation protocol consisted of a transient phase that peaked at 100 spikes per sec and a tonic spiking rate of 60 spikes per second, which lasted for 0.5 seconds. In voltage clamp recordings, the monosynaptic afferent current in mitral and external tufted cells rapidly attenuated to the high stimulation frequencies, consistent with high release probability of afferent nerve terminals (Murphy et al., 2004). Furthermore, naturalistic stimulation resulted in long lasting depression of afferent responses in external tufted cells. In current clamp, mitral cells showed sustained firing despite the reduction in the monosynaptic response. Interestingly, the firing of mitral cells persisted well beyond the afferent stimulation, suggesting that these cells amplify afferent input. Conversely, the firing in external tufted cells followed the attenuation of the monosynaptic current, resulting in much briefer response profiles. Our results suggest that natural stimulation patterns result in different patterns of activation in mitral and external tufted cells, consistent with the view that these cells serve as unique, parallel input pathways with distinct function.

Title: BDNF augmentation *In vivo* increases spine density in adult-born olfactory granule cells

Authors: *B. MCDOLE[1,2], C. ISGOR[2], K. GUTHRIE[2];
[1]Biomed. Sci., [2]Florida Atlantic Univ., Boca Raton, FL

Abstract: Brain-derived neurotrophic factor (BDNF) promotes the maturation, plasticity and maintenance of dendritic spines during development and in adulthood. In the main olfactory bulb, granule cells form a large population of inhibitory interneurons that regulate the activity of the bulb's excitatory projection neurons (mitral/tufted cells) through dendrodendritic synapses,

ultimately controlling the relay of sensory information to the primary olfactory cortex. Using Golgi staining, we previously have shown that over-expression of BDNF in the bulb granule cell layer increases spine density on granule cells throughout this layer. New granule cells are continuously generated from progenitor cells in the adult forebrain subventricular zone (SVZ). Knockout of the BDNF receptor TrkB in adult-born granule cells has been shown to impair their normal spine formation, implicating BDNF/TrkB signaling in the morphological development and integration of these new cells. The present study tested the hypothesis that spine development/maintenance in new granule cells can be promoted by increasing bulbar BDNF in vivo. Adult male transgenic mice over-expressing BDNF in the granule cell layer (TgBDNF mice), and their wild-type (WT) littermates, received SVZ-targeted injections of a lentivirus encoding a tau-mCherry fusion protein. In order to capture different stages of granule cell maturation, bulb tissue was collected at several time points post-infection. Using confocal microscope z-stack images, labeled granule cells were reconstructed in their entirety using Neurolucida software (MicroBrightfield Inc.). By 60 days post-infection, the latest time point examined, adult born-granule cells in TgBDNF mice exhibited a significant increase in apical dendritic spine density overall, as well as an increase the density of headed, mushroom-type spines, in comparison to WT controls. This included apical segments in the external plexiform layer (EPL) where dendrodendritic synapses with mitral/tufted cells are located. Additionally, estimates of GABAergic synapse number in the EPL, counted from immunolabeled confocal images, showed a significant increase in the density of gephyrin-positive puncta in TgBDNF mice relative to WT controls. Taken together with the evidence that TrkB knockdown impairs spine development in adult-born granule cells, these results provide insight into how BDNF/TrkB signaling contributes to the morphological integration of new granule cells by controlling spine maturation and maintenance.

Title: The role of olfactory bulb adult neurogenesis in olfactory representation and behavior

Authors: *W. L. LI[1], I. IMAYOSHI[3,4], T. KOMIYAMA[1,4,2];
[1]Biol. Sci., [2]Ctr. of Neural Circuits and Behavior, Univ. of California San Diego, La Jolla, CA; [3]Inst. for Virus Res., Kyoto Univ., Kyoto, Japan; [4]Presto, Japan Sci. and Technol. Agency, Tokyo, Japan

Abstract: Perceptual learning, a process that leads to improved ability to discriminate between and/or categorize similar sensory stimuli, is fundamental to complex cognitive processes and animal survival. Here we study mechanisms mediating olfactory perceptual learning in mice, focusing on the olfactory bulb(OB), where the initial olfactory information processing occurs. We have recently found that olfactory perceptual learning involves changes of principal neuron population dynamics in the OB, but the cause of these changes is unknown. In the adult OB, thousands of newly-born neurons arrive daily and differentiate into inhibitory interneurons. These adult-born neurons form extensive reciprocal connections with principal neurons and transiently display a higher level of plasticity. We hypothesize that they play an important role in mediating circuit plasticity underlying olfactory perceptual learning. Here we test this hypothesis using an inducible genetic method to ablate adult neurogenesis and testing their ability to discriminate between odors in a two alternative-choice discrimination task. We found that mice without adult-born neurons could discriminate two very distinct odors as accurately as control mice. However, in a task in which mice were required to categorize eight highly similar odors and respond accordingly, learning of animals with adult neurogenesis ablation was significantly slower. These results indicate that adult neurogenesis is important for olfactory perceptual learning. We are currently in the process of testing the hypothesis that these young adult-born neurons facilitate perceptual learning through modulating local principal neurons. Taking advantage of the chronic in vivo two photon imaging technology, we are recording the activity of principal neuron ensembles throughout the days of learning. Comparing the plasticity of principal neuron odor representations during learning between mice with and without adult-born neurons, we hope to shed light on the role of adult neurogenesis in perceptual learning and the underlying mechanism. Our preliminary data suggest that the discriminability of the principal neuron population is impaired in the absence of young adult-born neurons. We will present the latest results from these experiments.

Title: Synaptic distribution of individually labeled mitral cells in the external plexiform layer of the mouse olfactory bulb

Authors: T. MATSUNO, *E. KIYOKAGE, K. TOIDA;
Kawasaki Med. Sch., Kurashiki, Japan

Abstract: Mitral cells are major projection neurons of the olfactory bulb. They receive olfactory inputs, regulate information, and send their axons to the olfactory cortex. To understand the regulation of the output of mitral cells, we established a method for visualization of individual projection neurons and examined the distribution of their synapses quantitatively. Individual mitral cells were labeled by viral injection, 3D-reconstructed with light microscopy and serial-sectioned for electron microscopy. Secondary dendrites of mitral and tufted cells were distributed within the inner and outer halves of the external plexiform layer respectively. Electron microscopically-reconstructed mitral cell bodies, proximal and distal secondary dendrites and primary dendrites were examined in approximately 100 to 370 serial thin sections each and their synaptic distributions were analyzed. The ratio of presynaptic sites (60%), reciprocal synapses (60% of presynaptic and 80% of postsynaptic sites) and neuronal profiles forming synapses with mitral cells and including reciprocal pairs (50%) were similar in each region. On the other hand, the density of synapses on the primary dendrites decreased with distance from the soma. The distributions of symmetrical synapses on mitral and tufted cells were also analyzed using synaptic and neuronal markers such as parvalbumin, vesicular gamma-aminobutyric acid transporter and gephyrin. Neurons immunoreactive for parvalbumin tended to form synapses on proximal secondary dendrites of mitral cells. In conclusion, we clarified the unique synaptic distributions on mitral and tufted cells and showed that local synaptic circuits of

these cells are restricted in the inner and outer halves of the external plexiform layer, respectively.

Abstract: The neuronal circuitry of the olfactory bulb glomerulus is the first site for sensory integration in the mammalian olfactory system. Across a mouse olfactory bulb approximately 1200 glomeruli are responsible for integration and transmission of the sensory input to projection neurons and thus olfactory cortex. Therefore understanding the details of both composition and connectivity of the glomerular circuit will be the basis of accurate models of early olfactory function. Here, we have sought to explore this question by performing serial block-face scanning electron microscopy (SBEM) analysis of a genetically defined glomerulus.
Automated EM volumetric approaches including serial block-face EM offer an outstanding platform to resolve these questions. Using a Merlin/3View SBEM we can acquire stacks of OB tissue with 32 nm slice thickness, 13 nm pixel size and 20 nm effective x-y resolution imaging with a 2 kV electron beam and current doses of 20 e^-/nm^2. Acquisition at these parameter sets requires 8 days per $(100\mu m)^3$ cube. While acquiring a high resolution stack from a glomerulus ($(180\ \mu m)^2 * 230\ \mu m$) together with a low resolution stack ($(500\ \mu m)^3$, 80 nm isotropic voxels,

imaging at 3 kV) through external plexiform and mitral cell layer is thus feasible within 72 days, this points to the need to target EM acquisition to the very region of interest as sampling larger areas for alignment at the EM level becomes prohibitively time consuming. A key challenge is thus to obtain focussed region-specific maps in a reproducible manner. Samples stained forSBEM typically become too dark to be aligned at the light microscope level; obtaining EM images on the other hand is associated with sample destruction. This points to a need for a volumetric technique that allows sample alignment and is compatible with EM-prepared tissue. By using correlative X-ray tomography - EM imaging we have been able to precisely target the high-resolution long-lasting acquisition of a specific olfactory bulb glomerulus at synapse resolution: The intensely heavy metal-loaded SBEM-prepared samples offer good contrast for imaging with a SkyScan 1172 microCT system. Therefore, the tomography contains 3D information of the histology of a large olfactory bulb sample (0.6 * 0.6 * 1.5 mm^3, at 5 μm resolution). This allows targeting a specific glomerulus, both narrowing the high-resolution acquisition in 3D and ensuring successful SBEM imaging from glomerular to mitral cell layer. This is the first step towards understanding the diversity of patterns of synaptic connectivity of the glomerular circuit and will pave the way for investigations into mechanisms of structural plasticity in this sensory system.

Title: Control of the granule cell-short axon cell local circuit in the olfactory bulb by direct feedforward and feedback axonal inputs

Authors: *F. R. POUILLE, N. E. SCHOPPA;
Dep. of Physiol. & Biophysics, Univ. of Colorado, AMC, Aurora, CO

Abstract: GABAergic granule cells (GCs) in the olfactory bulb have been widely implicated in altering the activity of output mitral cells (MCs), for example in mediating lateral inhibition and synchronization. Recent studies have suggested that GC activity may itself be regulated by GABAergic deep short-axon cells (dSACs) located in the granule cell layer. We examined the

circuitry involved in modulating the GC-dSAC local circuit by performing whole-cell patch-clamp recordings in olfactory bulb slices from various mice, including two transgenic lines that express channelrhodopsin-2 (ChR2) in specific cell types. Light stimulation of tufted cells (TCs) in cholecystokinin-Cre-ChR2 mice elicited large monosynaptic excitatory post-synaptic currents (EPSCs) in both GCs (n = 6) and dSACs (n = 7). The rapid kinetics of the TC-to-GC EPSC together with the localization of the light pulse (around the GC soma) suggested that the feedforward excitatory signals originated from axon collaterals that terminate close to GC somata (Schoppa, 2006). Rapid monosynaptic EPSCs were also elicited in GCs (n = 22) and dSACs (n = 71) by stimulation of cortical feedback axons, either optogenetically in neurotensin receptor 1-Cre-ChR2 mice or via electrical stimulation in the anterior piriform cortex. If feedforward and feedback axons can directly excite both GCs and dSACs that inhibit GCs, we next wondered whether specific factors could alter the weighting of GC excitation versus inhibition. One such factor for the feedback pathway appeared to be cannabinoid (CB) receptors, as a 5-second conditioning depolarization of test dSACs resulted in a 36 ± 6 % (n = 41, p < 0.001) reduction of the feedback EPSC that was sensitive to the CB receptor type 1 (CB_1) antagonist SR 141716. Furthermore, the CB receptor agonist WIN 55,212-2 reduced feedback EPSCs in dSACs (by 62 ± 5 %, n = 5, p = 0.012), while also causing a transient increase (by 102.5 ± 27 %, n = 10) in the frequency of inhibitory PSCs in MCs evoked by feedback stimulation. Thus, by reducing feedback excitation of dSACs, activation of CB_1 receptors can favor excitation of GCs. Together, these results indicate that feedforward and feedback axons can directly excite both GCs and dSACs and that the net effect on GC-to-MC inhibition could depend on the depolarizing state of the network.

Title: A model of experience-dependent odor construction in the olfactory bulb

Authors: ***A. BORTHAKUR**, T. A. CLELAND;
Psychology, Cornell Univ., Ithaca, NY

Abstract: Reciprocal interactions between mitral and granule cells in the external plexiform layer (EPL) of the olfactory bulb transform the odor representation before transmitting the information to targets such as piriform cortex. However, the nature of this transformation remains unclear. Specifically, while the basic synaptic connections within the EPL are known, the topology of connectivity is not. Given that lateral inhibitory synaptic weights do not correlate with physical proximity (Fantana et al., 2008, Neuron 59:802-814), what then determines the distribution of synaptic weights among mitral cell principal neurons and inhibitory granule cells? We propose that the topology of connectivity arises from statistical learning based on olfactory experience. The question then is twofold. First, how does learning modify EPL topology in a way that contributes to odor perception and is consistent with existing data? Second, by what individual synaptic rules can the network generate the appropriate patterns of statistical learning? Current theory indicates that mitral cells can excite granule cells at any distance, but that granule cells can only effectively inhibit neighboring mitral cells (McTavish et al., 2012, Front Comput Neurosci 6:3; McIntyre and Cleland, 2016, J Neurophys), establishing some important topological constraints. Moreover, the principle that granule cells functionally inhibit mitral cell output by delaying their spikes rather than eliminating them adds to the accumulating evidence that odor representations at this level depend on fine-timescale spike timing differences. We began by assessing the effects of timing-dependent learning rules on mitral-to-granule synapses. We demonstrate that an asymmetric STDP rule generates higher-order receptive fields in granule cells that are more diagnostic for specific odors than are principal neurons. This constructive process enables olfactory bulb interneurons to learn patterns of covariance derived from the external environment. Critically, patterns of feedback inhibition mediated by granule cells can orthogonalize odor representations even for very similar odors, enabling very fine discrimination. The degree of discrimination is dependent upon the order of granule cell receptive fields, which are regulated by the maximum synaptic weight, synaptic connection probability, interneuron membrane time constant and spiking threshold, STDP parameters, and the amount of learning, in principle enabling the appropriate allocation of generalization and discrimination among specific odor representations.

Title: Electrical stimulation of the locus coeruleus enhances signal to noise ratio in the olfactory bulb of anesthetized rats

Authors: *L. C. MANELLA, N. PETERSEN, C. LINSTER;
Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: Among other neuromodulatory inputs, the olfactory bulb (OB) receives abundant noradrenergic (NE) inputs from the locus coerulus (LC). Behaviorally, noradrenergic modulation in the OB has been shown to decrease odor detection thresholds and enhances odor discrimination at low concentration odors. It is hypothesized that NE does this in part through increasing signal to noise ratio of odor representations in the OB. We here test this hypothesis by electrically stimulating the LC in anesthetized rats to study how NE affects OB-dependent processing. We found that a majority of mitral cells show a significant modulation of spontaneous firing response to LC stimulation, with a subset of cells showing enhanced firing rates. In the presence of NE receptor antagonists, LC evoked modulation of firing rates is absent. The observed modulation of firing rate is strongly dependent on initial levels of spiking with low rates being increased and high rates decreased; the net result is a reduction in spread of spontaneous rates across mitral cells. Responses to odorants at three concentrations corresponding to vapor partial pressures of 0.01, 0.01 and 0.001 Pa were also modulated by LC stimulation. After LC stimulation, the number of significant excitatory responses to odors was somewhat increased, while inhibitory responses to odorants was decreased. Modulation of odor responses correlated strongly with that of spontaneous activity, suggesting that enhanced overall excitatory odor responses are due to the overall reduction of spontaneous firing rates, producing enhanced ability for excitatory responses to be seen, and inhibitory responses to be diminished. At the population level, neural representations across odor concentration were rendered more similar to each other by LC stimulation, suggesting an effect of concentration invariant representations. Similar results are shown by direct noradrenergic pharmacological manipulations within the olfactory bulb. These results together show that LC activity influences signal to noise ratio in the OB, and thus influences near threshold odor responsiveness.

Title: Middle tufted cell drive the mitral cell spatiotemporal firing patterns through glomerular and granule cell microcircuits

Authors: *F. CAVARRETTA[1,2], M. MIGLIORE[1,3], M. L. HINES[1], K. M. IGARASHI[4], G. M. SHEPHERD[1];

Council, Palermo, Italy; [4]4Department of Anat. and Neurobiology, and Ctr. for the Neurobio. of Learning and Memory, Univ. of California, Irvine, CA

Abstract: The olfactory bulb (OB) is a dual layer system, consisting of many glomerular units (GU) extending across the glomerular (GL) and the granule cell layers (GCL). The principal neurons are middle tufted (MT) and mitral cells (MC), whose activity encodes odor representation which is sent on the olfactory cortex (OC) through their axons. In turn, their activity is modulated by inter-glomerular lateral interactions which occur at both layers. Previously, our 3D biophysically and morphologically accurate OB models have included only MCs, GL, and GCL. It has been predicted that the GL microcircuits transform a dense and disorganized spatial glomerular activation, such as that exhibited by natural odors, into a sparse, normalized and contrast-enhanced one. Together, the GCL, over time, decreases the spatial representation overlaps of different odors after learning (Cavarretta et al., 2016). However, many questions remain open, especially regarding the role of MTs. In this work, we have implemented MTs in our 3D model. We show that both MTs and MCs contribute to the columnar organization of the GCL, in particular demonstrating that they must be inhibited by the same GL neurons, in order to generate learning-dependent columns (Migliore et al., 2007) which conform to those observed in the experiments (Willhite et al., 2006). The inclusion of MTs in the model also allowed an estimation of the relative proportion of the 3 subtype of granule cells (Woolf et al., 1991), for which there are no quantitative data. In addition, we found that MT membrane properties facilitate their precise inter-glomerular synchronization, which would be a key-feature to realize a fine temporal code relying on the inter-glomerular interactions in the GCL. Finally, assuming the MTs excite the deep short axon cells by their axon collaterals, we have inferred a plausible connection scheme in which the MTs could orchestrate the lateral inhibition produced by the GCL. These results provide insights into the role of the MTs in spatial and temporal odor coding, which will eventually lead to also include the OC in the 3D OB model, starting from those regions that are targeted from MCs and MTs axons and could act as a gate connecting the OB and OC, such as the anterior olfactory nucleus.

Title: Possible roles for dopamine and vasoactive intestinal polypeptide in the circadian rhythms of the mammalian olfactory bulb

Authors: *K. S. KORSHUNOV[1], L. J. BLAKEMORE[2], P. Q. TROMBLEY[2];
[2]Biol. Sci., [1]Florida State Univ., Tallahassee, FL

Abstract: Circadian rhythms influence nearly every daily biological process, from genetics to behavior, and are synchronized by the master circadian pacemaker, the suprachiasmatic nucleus (SCN). SCN ablation leads to the desynchronization of circadian rhythms of nearly every part of the body, with the exception of the retina and olfactory bulb (OB), which are proposed to maintain circadian rhythm synchrony due to their own circadian clocks. In the OB, circadian rhythms manifest in expression of certain genes, neuronal excitability, and odor sensitivity. However, the neuronal mechanisms that allow the OB to maintain independent circadian rhythms are not well understood. The OB's endogenous dopamine (DA) neurons play multiple roles in regulating OB circuit function and likely influence these rhythms, as DA neuron activity in the OB has been shown to vary with time of day as indicated by higher diurnal than nocturnal DA content and release. Also, DA is responsible for proper expression of circadian proteins in the retina, a structure that closely parallels the OB. In the SCN, where vasoactive intestinal polypeptide (VIP) is endogenous, VIP neurons synapse with hypothalamic DA neurons and regulate the circadian release of prolactin. This, as well as the finding that the VIP receptor, VPAC2, is important in synchronizing the expression of circadian genes in the OB, has led us to hypothesize that VIP regulates OB DA neurons. We have pilot data showing that VPAC2 is highly expressed in the glomerular layer of the OB and is co-localized with at least a subset of DA neurons. Additionally, we have found that VIP may affect the neuronal activity of DA and other OB neurons by influencing outward K^+ currents. We are currently working with a tyrosine hydroxylase green-fluorescent protein (TH-GFP) transgenic rat line to better target DA neurons for electrophysiological/pharmacological experiments so we can further establish the effects of VIP on the neuronal activity of DA neurons. Neuronal regulation of OB DA neurons by VIP may be one of the mechanisms that contribute to the endogenous circadian clock of the OB and to rhythmic olfactory functions.

Title: Functional mapping of circuits mediating inhibition of olfactory bulb interneurons

Authors: *A. SANZ DÍEZ, N. BENITO, D. DE SAINT JAN;
INCI CNRS, Strasbourg, France

Abstract: Olfactory sensory neurons (OSN) carry odor information from the nasal epithelium to the olfactory bulb (OB) where it is transmited to Mitral and Tufted cells, the principal output neurons, within spherical structures called glomeruli. Each glomerulus is surrounded by periglomerular (PG) cells that mediate intraglomerular inhibition. PG cells have been classified as type 1 if they receive direct synaptic inputs from OSN terminals or type 2 if they do not. PG cells also receive inhibitory postsynaptic currents (IPSCs) but the circuits mediating this inhibition are unknown. We examined this question using whole-cell voltage-clamp recordings in mouse horizontal OB slices. Stimulation of OSN producing excitatory postsynaptic currents (EPSCs, holding potential Vh = -75mV) also evoked polysynaptic IPSCs in 6/11 type 1 PG cells (at Vh = 0mV). In contrast, OSN stimulation did not evoke IPSCs in type 2 PG cells (n=19), suggesting that inhibitory inputs onto type 2 PG cells are not generated by the glomerular network. However, distant stimulation within the glomerular layer (n=19) or in the internal plexiform layer (n=5) produced monosynaptic IPSCs in type 2 PG cells in the presence of NBQX and D-AP5 (amplitude 81.45 ± 44.92 pA; 20-80% rise time (RT) 0.77 ± 0.69 ms, decay time (DT) 17.23 ± 12.31 ms) with similar kinetics than spontaneous IPSCs. These results suggest that type 2 PG cells are inhibited by neurons with axons in deep layers and in the glomerular layer. Interestingly, we found that type 2 PG cells recorded in a transgenic mouse line expressing channelrhodopsin-2 (ChR2) under the control of the thy-1 promoter (Thy1-ChR2-YFP, Jackson Laboratory) responded with a TTX-sensitive monosynaptic IPSC to a short light pulse (490 nm, 1-10 ms) (n=17, amplitude 127.39 ± 151.38 pA (range 9-659 pA); RT 0.72 ± 0.34 ms and DT time 17.9 ± 28.16 ms, in the presence of NBQX and D-AP5). Light stimulation also evoked TTX-sensitive monosynaptic IPSCs in granule (n=5) and deep short axon cells (n=24) in this mouse. However, none of these OB interneurons (PG, dSA and granule cells) expressed ChR2 in Thy1-ChR2-YFP mice, suggesting that ChR2 is expressed in GABAergic centrifugal afferences projecting to the OB. Consistent with this idea, we have detected ChR2-YFP expression in GABAergic neurons of the Horizontal limb of the Diagonal Band of Broca (HDB), an area that sends dense GABAergic projections to the OB. HDB might thus be a major source of inhibition

of OB interneurons, an hypothesis that we are currently exploring using selective AAV-ChR2 transfection of HDB GABAergic neurons.

Title: Reconstructing odor identity from olfactory bulb sequences using patterned optogenetics

Authors: *J. V. GILL[1,2], **J. M. KAPPEL**[2], E. CHONG[2], G. SERRANO[3], D. RINBERG[3]; [1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Neurosci. Inst., New York Univ. Langone Med. Ctr., New York City, NY; [3]Neurosci. Inst., New York Langone Med. Ctr., New York City, NY

Abstract: In mammalian olfaction, the transmission of odor information relies on the activation of defined subsets of individual glomeruli located in the olfactory bulb. Odor cues are translated into complex patterns of glomerular activity and relayed to downstream regions in the cortex. To what extent these patterns contain odor information on a fine scale in space (single glomeruli) and time (milliseconds) is largely unknown due to limitations in manipulating glomerular activity. We used patterned optogenetics for instant generation and precise manipulation of glomerular activity to investigate spatiotemporal features of the glomerular code. Mice were trained to respond to 'artificial odors' composed of glomerular patterns generated with digital micromirror device (DMD)-driven optics. By observing the responses of mice to fine changes in patterns along spatial and temporal dimensions, we have identified features of glomerular activity that are critical to odor identity.

Sch. at Houston, Houston, TX; [5]Dept. of Neurobio., Northwestern Univ., Evanston, IL

Abstract: Olfactory glomeruli are innervated by interneurons, which control glomerular excitability and cross-talk. The interneurons in the glomerular layer are very diverse and it has been difficult to understand exactly how they contribute to olfactory information processing. We are therefore studying the population activity of glomerular layer interneurons using different methods of olfactory and optogenetic stimulation. Our experiments were initially conducted in transgenic mice that express GFP in GABAergic (GAD65 and GAD67) and dopaminergic interneurons. These interneurons were bulk-loaded with AM calcium dyes, and their stimulus-evoked activities measured via acute *in vivo* two-photon calcium imaging. We determined that most interneurons responded preferentially to odor stimuli delivered at high concentrations; their numbers and signal sizes decreased as odors were presented at lower concentrations. Furthermore, interneuron responses also changed as odor stimulation lengths were varied. Specifically, short odor presentations (2-5 sec) elicited interneuron signals that were tightly coupled to the signals recorded from adjacent glomeruli, but prolonged odor exposures (20 sec) often triggered more diverse, decoupled cellular signals. We conducted similar experiments in mice that express channelrhodopsin in a single glomerulus (M72>S50-IRES-hChR-Venus). Optogenetic activation of this glomerulus at different intensities and durations replicated our findings from odor stimulation experiments, thus allowing us to map the interneuron population connected to a single glomerular unit. In a final set of experiments, we are combining calcium imaging with post-mortem immunocytochemistry targeted against the calcium-binding proteins calretinin, calbindin, S100 and neurocalcin. Consistent with previous results, we found that calcium binding proteins are expressed in subpopulations of GABAergic and dopaminergic

interneurons. We are now studying if molecularly distinct interneuron subpopulations comprise some of the physiologically identifiable interneuron pools that were identifiable based on their unique response patterns during various types of olfactory and optogenetic stimulation.

Title: Independent attentional modulation of compound auditory feature integration and segregation

Authors: *K. N. O'CONNOR, A. J. PRABHU, J. S. JOHNSON, M. L. SUTTER;
Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: Attention plays a significant role in sensory detection. Although auditory scene analysis relies largely on the preattentive segregation and grouping of features based on their temporal and spectral attributes (Bregman 1990), attention also plays an important role in focusing on particular sound sources or streams (Cherry 1953). Auditory perceptual grouping and segregation depend on Gestalt-like rules (such as similarity and proximity along one or more dimensions), however little is known of attention's effects on perception in feature integration or segregation, when the differences between features are held constant. Intuitively it would seem that, the more readily that features may be segregated or independently processed, the greater their resistance to integration and grouping.
To address this question, we assessed human subjects' sensitivity for detecting one or two acoustic features presented simultaneously, using psychophysical methods. The features, broadband sinusoidally amplitude-modulated (AM) noise and bandwidth restricted noise (BWr), were chosen for minimal physical interaction. In an experiment designed to assess feature segregation, subjects were required to selectively attend to *either* AM or BWr during a session while ignoring the other feature. In the experiment designed to evaluate feature integration, subjects were required to detect a feature compound. Sensitivity in both cases was compared to single feature (SF) detection under either mixed (randomly interleaved trials) or blocked (SF only) sessions. A yes-no procedure was used: The subjects indicated using a joystick whether a

test stimulus was different than a previously presented standard stimulus (400-ms stimulus duration and interval). To date, three subjects have been tested in the selective attention (SA) experiment and two in the feature integration (FI) experiment.
Thresholds for feature detection were estimated from psychometric function fits using percentage of correct responses at seven levels of modulation /restriction, normalized for comparisons across condition. All subjects in the SA experiment were able to detect the attended feature with relatively low losses in accuracy (~0-20%), relative to SF stimuli, regardless of the magnitude of the unattended feature. However, both subjects in the FI experiment displayed relatively large drops in relative threshold (~10-50%) when detecting compound as compared to SF stimuli. These results support that, for relatively independent compound acoustic features, feature integration and segregation operate largely independently and are subject to attentional modulation.

Title: Prefrontal and sensory correlates of auditory spatial attention in the macaque

Authors: *C. R. CAMALIER, A. BROWN, J. JACOBS, M. MISHKIN, B. B. AVERBECK; Lab. of Neuropsychology, NIH, Bethesda, MD

Abstract: Auditory spatial attention is critical for everyday interactions, especially hearing in noisy environments. In addition, attention is thought to be a largely “amodal” resource, but to test this assumption it is important to understand whether spatial attentional mechanisms differ across modalities (e.g. vision vs audition), particularly at the single-neuron level. Though fundamental to our understanding of attention and auditory processing, the neural correlates of spatial auditory attention remain poorly understood. This is due in part to the lack of a robust animal model, particularly one that shares key similarities with humans.
To address this, we have developed a novel spatial auditory selective attention task for macaques (n=2), based closely on human paradigms. In this task, a macaque monkey is cued to a particular side and must report the presence of a difficult-to-detect auditory target (embedded in noise) only

if it appears on the cued side. If it appears on the uncued side, he must ignore it. In this way, we are able to compare attention effects under identical auditory conditions.
We have begun collecting single neuron data from from two key areas implicated in the control of auditory spatial attention : prefrontal cortex (caudal principal sulcus; n = 163) and caudal auditory cortex (A1/CM/CL/TPT; n = 64) in one monkey during this task. In both areas, attention deployed to contralateral space significantly affected baseline firing rates in about 20% of the responsive neurons and also significantly affected 20-40% of responses to the masking noise. These early results are consistent with some of the hypothesized mechanisms reported during visuospatial attention, suggesting at least some attentional mechanisms are truly amodal.

Title: Sensory coding properties predict selective attention effects on single units in primary auditory cortex

Authors: Z. P. SCHWARTZ, *S. V. DAVID;
OHRC, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Auditory selective attention is required to discern behaviorally relevant information in crowded acoustic environments. Studies of attention and related behaviors during single-unit recording in animals have revealed diverse behavior-related effects, which have yet to be integrated into a coherent theory of how attention influences neural coding. In order to better understand the diversity of behavioral effects, we asked whether the baseline sensory coding properties of neurons in auditory cortex predict whether they will be modulated by attention. We trained three ferrets to perform an auditory selective attention task. Animals responded to a target tone embedded in one of two simultaneous narrowband noise streams and ignored catch tones in the other. The target stream was switched between blocks, and selective attention was verified by comparing responses to targets versus catch tones. After training, we recorded single-unit

activity in primary auditory cortex (A1) during behavior and during passive presentation of task stimuli (*n*=52). One noise stream was centered at neural best frequency and contralateral to the recording site. Thus, the task alternated between attention directed into the receptive field (*attend RF*) and away from the RF (*attend away*). Identical noise stimuli were played in all behavioral conditions. We compared spiking activity evoked by the noise and tone stimuli in each behavioral condition. During the attend RF condition, the average noise-evoked response decreased. Tone responses did not change. Because only the RF stream evoked neural activity, this change represents a suppression of noise responses at the locus of attention. Distractor responses were suppressed in only about half of recorded units. To test whether a neuron's sensory coding properties predicted modulated by attention, we computed a nonlinear spectro-temporal receptive field (STRF) for each unit. The STRF included a nonlinear input term that accounted for short-term plasticity (STP, depression or facilitation) of sensory inputs. Neurons that showed evidence for STP were less likely to undergo attention-mediate changes. Thus the nonlinear temporal integration properties of A1 neurons predict whether they will undergo changes in tuning during selective attention.

Title: A gradient frequency neural network model of auditory scene analysis

Authors: *J. C. KIM, E. W. LARGE;
Psychological Sci., Univ. of Connecticut, Storrs, CT

Abstract: Acoustic environments typically include multiple sound sources, and it is a central function of the auditory system to segregate individual sounds in an acoustic mixture. This capability, called auditory scene analysis, is important both for understanding how the auditory system works and for developing computational systems capable of detecting and identifying relevant sound events in real-world environments. Computational models of auditory scene analysis commonly employ signal processing techniques to analyze and segregate frequencies in mixture signals. However, a common criticism of the current modeling efforts has been the lack of evidence for biological mechanisms performing such computations. Here we present a

computational model of auditory scene analysis based on the neural processes observed in the auditory system. We model the auditory system as a dynamical system consisting of gradient frequency neural networks (GrFNNs), which are tonotopically organized networks of neural oscillators. We show that self-organizing patterns of synchronized oscillations in GrFNNs provide a biologically plausible account of auditory scene analysis. Oscillators tuned to harmonically related frequencies resonate with each other by mode-locking in integer ratios, so that separate groups of mode-locked oscillators emerge when the GrFNN model is driven by a signal containing multiple harmonic sounds. We show that dynamic pattern formation in the GrFNN model replicates existing empirical data on concurrent sound perception, including the fusion and segregation of concurrent harmonic sounds, the discrimination of concurrent pitches, and the pop out of a mistuned harmonic. This study shows that auditory scene analysis can be achieved by GrFNNs, neural processes known to exist in the auditory system, without introducing external computations based on signal processing techniques.

Title: Reward cues direct auditory attention and modulate fMRI activations in monkey auditory cortex

Authors: P. WIKMAN[1], T. RINNE[1], *C. I. PETKOV[2];
[1]Inst. of Behavioural Sci., Univ. of Helsinki, Helsinki, Finland; [2]Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Training nonhuman animals on active auditory tasks is notoriously difficult and time consuming, typically requiring hundreds of daily training sessions. Advancing and developing animal models for human auditory cognition critically depends on innovating the approaches for

training nonhuman animals and assessing how auditory-attention related effects influence cortical networks. In this study, we tested whether a novel paradigm based on reward incentive cues, which was originally used to show that monkeys learn a visual categorization task in tens of trials (Minamimoto et al. 2010, *Neuron*), could be adapted to speed up auditory task training and to direct monkeys' auditory attention. First, we trained monkeys to respond to a 400-ms "coo" target sound to receive a juice reward. Then at trial onset, we introduced either high (HiRe) or low (LoRe) reward incentive cues indicating that a correct response would be associated with, respectively, a big and immediate juice reward or a small and delayed reward. We hypothesized that monkeys' performance in the simple auditory target detection task would be systematically better during HiRe than LoRe trials after they learned to discriminate the cues from each other. We compared monkeys' auditory target detection performance when the HiRe and LoRe cues were either two different sounds or visual patterns. Further, in the condition with visual cues, a 2 s tone was played to redirect monkey's attention to the auditory modality after the presentation of the visual cue but before the onset of the "coo" target sound. We found that after only a few training sessions with 100-300 trials, monkey performance showed a significant difference between HiRe and LoRe trials with both auditory and visual cues. However, this difference was systematically bigger, more reliable and faster to achieve when visual incentive cues were used. Thus during fMRI we used the auditory target detection task with visual cues. We hypothesized that the monkeys would attend to the sounds more during HiRe than LoRe trials and, as a result, fMRI activations in auditory cortex would be higher during the HiRe trials. Our results showed that the reward incentive cues significantly biased monkeys' auditory task performance during fMRI. Moreover, activations in auditory cortex were significantly stronger during the HiRe than LoRe trials. Thus, this novel behavioral paradigm successfully revealed activation modulations in the monkey brain associated with focused listening. Remarkably, these results were obtained after less than 15 days of task-specific behavioral training.

Title: Using deep networks to generate naturalistic stimuli reveals shared higher-level perceptual space among wild-caught starlings

Authors: *M. THIELK[1], T. SHARPEE[2], T. GENTNER[1];
[1]Neurosci., UCSD, San Diego, CA; [2]Salk Inst., San Diego, CA

Abstract: To date, the neural basis of auditory processing is understood primarily in terms of simple sine tones and other artificial signals, and the few cases that have used conspecific natural stimuli rely on serendipitous use of natural variation. This use of clearly impoverished stimuli reflects the failure to understand the relevant acoustic dimensions along which categorical perception varies, which has until now prevented parametric control over the more complex acoustic features composing natural complex stimuli. This lack of control has prevented the application of psychophysical experiments on natural stimuli. Exploiting recent developments in machine learning, we've implemented a novel method to parameterize and explore the auditory stimuli space using a Deep Neural Network. This compressed quantitative representation allows me to generate "morph" motifs between any two arbitrarily chosen song elements (motifs) in a continuous manner which allows me to perform the more complex behavioral manipulations and neurophysiological experiments.
This project explores the neural mechanisms that mediate the recognition of ambiguous auditory objects in European starlings (Sturnus vulgaris) during a categorical perception task. Leveraging this parameterization of the stimuli, we explore how motif categories are encoded within the learned space. We do this by sampling points in this space and constructing categories the birds must learn. We train the subject to associate 4 motifs with right responses and another 4 motifs with left responses using 2AC operant training. We then generate morphs between each of the left motifs and each of the right motifs using my interpolation method giving a total of 16 independent continuous axes to probe along and estimate of their natural perceptual boundary between the left and right category for each morph. We find that the psychometric curves are highly variable within subject across different morph dimensions, yet highly conserved across subjects, which suggests a shared perceptual space between birds. Furthermore, differences in the initial training category parameters result in characteristic and predictable differences in the boundaries. Then, using the pre-trained subjects under anesthesia, we then record from neural populations in different auditory regions to estimate the neurometric functions in response to the morphed stimuli.

Title: Primate BOLD data demonstrating fundamental bases for auditory figure-ground analysis

Authors: *P. DHEERENDRA[1,2], F. BALEZEAU[1], S. KUMAR[1,2], A. BLAMIRE[1], A. THIELE[1], T. D. GRIFFITHS[1,2];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Wellcome Trust Ctr. for Neuroimaging, Inst. of Neurol., Univ. Col. of London, London, United Kingdom

Abstract: A critical aspect of auditory scene analysis is the ability to extract a sound of relevance (figure) from a background of competing sounds (ground) such as when we hear a speaker in a cafe. Previous work on this has used high-level stimuli with stochastic elements like speech in noise or deterministic stimuli like that developed by van Noorden. We have developed a stimulus based on the detection of elements in frequency space in a random background that are repeated over time - a form of sequential grouping of spectral patterns. Functional imaging in humans [1] demonstrates a network that includes auditory cortex and the intraparietal sulcus (IPS).
The stochastic figure ground stimulus we have developed examines fundamental mechanisms for figure ground perception that are equally relevant to the rhesus macaque, in which we can carry out both system level and systematic neuronal specification of the system. We investigated the neural bases of pre-attentive stimulus-driven auditory segregation in rhesus macaques using functional magnetic resonance imaging.
Stimuli were made of 5-15 randomly chosen pure tone components (ground) that change for every chord. This ground segment is overlaid with 10 additional components that are either coherent (figure) or incoherent (control), presented at the middle 2 s of the 6 s long exemplars. EPI images were acquired using a sparse acquisition protocol on 4.7T upright Bruker scanner (TR/TA/TE = 10s/2.01s/21ms) while the animal performed a stimulus irrelevant visual fixation task. 360 volumes (135 each for figure & control) were acquired per session per animal. Analysis was carried out using SPM software (SPM12). Single subject inference was carried out by applying a generalized linear model (GLM).
We observed significant activation in core auditory cortex, anterior and posterior superior temporal sulcus (STS). Our results suggest that analogous to human IPS, macaque posterior STS is involved in mediating pre-attentive auditory segregation identified using an identical stimulus

to that used in previous human study [1].
The data support the use of the macaque as a model for human auditory scene analysis that allows both system-level and neuronal characterisation.

Title: Dynamics of cortical activity during behavioral engagement and auditory perception

Authors: *I. CARCEA, M. N. INSANALLY, R. C. FROEMKE;
Skirball Inst., NYU Med. Ctr., New York, NY

Abstract: Changes in brain state can control perceptual abilities by modulating the detection of sensory input in a background of ongoing activity, and the recognition of behaviorally relevant inputs over less relevant or distracting inputs. Neurophysiologially, many aspects of cortical activity and representations can be modulated to affect sensory processing including the structure of neuronal receptive fields, population dynamics, spike rates or spike timing during periods of stimulus presentation, or patterns of spontaneous activity. Depending on the demands of behavioral tasks, there are different modes and levels of engagement that can result in different performance scores. It is not clear how different forms of engagement modulate activity in the auditory cortex to impact perceptual detection and discrimination. Here we examine this question using two different variants of a frequency recognition task while monitoring neural activity in rat auditory cortex.
We recorded 80 single units from the auditory cortex of five rats performing a self-initiated go/no-go auditory task. Self-initiation transformed tuning curves and activity patterns in the auditory cortex. In 55/80 neurons, tone-evoked responses were suppressed while in the rest of the cells they were enhanced. In some cells, self-initiation modulated responses to target and non-

target tones in opposite directions, leading to sharpening of frequency tuning profiles ('self-initiated' $\sigma = 5.6 \pm 1.4$ versus uncued trials $\sigma = 12.5 \pm 3.0$; two-tailed paired t-test, $p<0.02$, n=41 cells). In other cells, self-initiation changed responses to target and non-target tones in the same direction, adjusting thus the gain of the response. Trial self-initiation decreased the rate and the variability of spontaneous activity in 63 of the 80 recorded cells. Optogenetic disruptions of activity patterns in the auditory cortex during the self-initiated trials showed that these changes in spontaneous activity were important for sound perception ('light ON' hit rate, 0.78 ± 0.14 of 'light OFF' trials, $p < 0.05$, two-tailed paired t-test). Thus, behavioral engagement can prepare cortical circuits for sensory processing by sharpening receptive fields and controling the pattern of spontaneous activity.

Title: Inactivation of primate dorsolateral prefrontal cortex during auditory working memory.

Authors: *L. M. ROMANSKI[1], B. PLAKKE[1], T. LINCOLN[1], A. POREMBA[2], J. BIGELOW[3]; [1]Dept Neurosci., Univ. of Rochester Sch. of Med. and Dent., Rochester, NY; [2]Psychology, Univ. of Iowa, Iowa City, IA; [3]Dept. of Otolaryngology-Head and Neck Surgery, Univ. of California, San Francisco, San Franscisco, CA

Abstract: We have previously shown that inactivation of the ventrolateral prefrontal cortex (VLPFC), including areas 12/47, 45, and ventral 46 results in impaired performance during audiovisual working memory with dynamic vocalization movies as the memoranda. We have also demonstrated that VLPFC inactivation impairs performance when only the auditory stimulus, the vocalization has to be remembered. These experiments demonstrate that VLPFC is crucial in auditory and audiovisual working memory. However, it is also possible that our inactivation may have included portions of the dorsolateral prefrontal cortex (DLPFC). Furthermore, DLPFC may also be involved in these working memory paradigms due to its general role in the process of working memory, and goal directed behavior. We therefore trained

animals to perform an auditory match-to-sample task using 3 categories of complex sounds: macaque vocalizations, other vocal sounds and non-vocal auditory stimuli. Cylinders were aligned over the DLPFC in order to allow for the use of cortical cooling which inactivates the area within the cylinder. For each experimental session the monkeys were brought to the testing room and the auditory match to sample task was started. The subjects performed 100 trials to establish the baseline prior to cooling (WARM trials) then the cooling process was started and the brain was cooled to 20 degrees Celsius in order to reduce synaptic activity and temporarily inactivate the cortex. After 100 trials during cooling (COLD trials) the temperature was returned to normal and the subject was returned to their home cage. Warm and Cold trials were compared in order to determine if cooling of DLPFC has an effect of auditory working memory.

Title: The impact of parvalbumin deficiency on auditory function in aging mice

Authors: *J. BURIANOVA[1], R. TURECEK[1], B. SCHWALLER[2], J. SYKA[1];
[1]Dept. of Auditory Neurosci., Inst. of Exptl. Medicine, CAS, Prague, Czech Republic; [2]Anat. Unit, Dept. of Med., Univ. of Fribourg, Fribourg, Switzerland

Abstract: The lack of parvalbumin (PV) leads to behavioral deficits such as impaired social interaction, behavioral flexibility, or altered patterns of locomotor activity. In comparison with wild type mice (WT - C57Bl/6J), parvalbumin-deficient (PV-/-) mice exhibit alterations in acoustic startle response (ASR) and prepulse inhibition (PPI). It remains to be elucidated, however, whether these changes persist throughout the life span of the mouse or whether they manifest any age dependent specificity. The present study was aimed at exploring the effects of PV deficiency on ASR and PPI using juvenile (1 month-old), young adult (5 month-old) or aged (16 month-old) mice. The ASR in response to a broad-band noise impulse or a tone pip (4, 8, 16 kHz) and the PPI of ASR elicited by a broad-band noise impulse or 4, 8, or 16 kHz tones over a

range of 20-80 dB SPL were recorded. Hearing function in the mice was evaluated by recording the auditory brainstem responses (ABRs). In juveniles and young adults, no difference was found between WT and PV-/- mice in their ABRs. Unexpectedly, aged PV-/- mice showed ABR thresholds similar to young adults while aged WT mice had their hearing thresholds elevated across all frequencies tested. The ASR and PPI of the juveniles were comparable in both groups. In young adults, WT mice exhibited increased ASR to broad-band noise and 8 kHz tones, while PV-/- mice responded more to 16 kHz tones. Furthermore, PPI of ASR was more efficient in WT than PV-/- young adult mice across all used prepulse frequencies and intensities. In aged animals, the pattern of ASR and PPI results was found to be reversed. The PV (-/-) mice exhibited more efficient PPI (particularly when using a broad-band noise impulse) and significantly pronounced ASR to 120 dB pips, which might suggest the appearance of hyperacusis. Taken together, the data supports the importance of parvalbumin for auditory functions and suggests the novel role of this protein in processes associated with aging of the mammalian auditory system. The underlying mechanisms deserve to be explored in more detail.

Title: DREADD-mediated silencing of projections from basolateral amygdala to nucleus accumbens disrupts pre-pulse inhibition in rats.

Authors: ***B. L. AGUILAR**[1,2,3], E. WICKER[3,1], L. MALKOVA[3,1,2], P. A. FORCELLI[2,3,1]; [2]Interdisciplinary Program in Neurosci., [3]Dept. of Pharmacol. & Physiol., [1]Georgetown Univ., Washington, DC

Abstract: Sensorimotor gating is a fundamental process through which the central nervous system filters motor responses to redundant or irrelevant stimuli; this process can be assessed operationally through measurement of prepulse inhibition (PPI) of the acoustic startle response (ASR). PPI is a well-conserved effect across species in which the magnitude of ASR is attenuated by presentation of a low-intensity prepulse prior to the startle-inducing stimulus. PPI deficits have been reported in a number of neuropsychiatric disorders. Investigations of circuitry underlying PPI have relied primarily on lesion and pharmacological inactivation studies, both of

which lack the ability to target circuitry in a projection-specific manner. The use of chemogenetic technology allows pathway specific targeting through the use of designer receptors exclusively activated by designer drugs (DREADDs). These receptors allow for the selective inactivation of DREADD-expressing neurons by otherwise inert compounds (clozapine-n-oxide, CNO, hM4D agonist). Our lab has previously reported (Forcelli et al., 2012) that inhibition of basolateral amygdala (BLA) disrupts PPI, and that this effect is mediated by the ventral pallidum (VP). However, BLA does not project directly to VP, but rather through a relay in the nucleus accumbens (NAcc). Here, we sought to test the hypothesis that inhibition of projections from to NAcc would be sufficient to impair PPI, providing functional evidence for the proposed circuit. 12 Long Evans rats were injected unilaterally into BLA with AAV-hSyn-hM4D(Gi)-mCherry DREADD construct paired with an ipsilaterally placed cannula targeted to the NAcc. Using an SR-LAB rodent startle response system, we determined that silencing of BLA projections terminating in the NAcc disrupted sensorimotor gating as measured by a reduction in PPI. Rats were treated with either systemic CNO (10mg/kg) or with intra-NAcc injection of CNO (1nmol). The former treatment was intended to silence all BLA projections, while the latter targeted BLA terminals in NAcc. Intracerebral microinfusions of 1mM CNO resulted in a significant decrease in PPI at prepulse intensities of 3 and 6dB above background ($p<0.05$). Additionally, systemic injections at a dose of 10mg/kg CNO yielded a significant decrease in PPI at a prepulse of 3dB above background ($p<0.05$). These results demonstrate that DREADD-mediated silencing of the direct BLA to NAcc pathway results in a disruption of sensorimotor gating function as quantified by a loss of prepulse inhibition to the acoustic startle, and suggest that projections from BLA to NAcc are sufficient to account for the PPI-disruptive effects of BLA silencing.

Title: Attenuated responses to self-generated sounds in auditory cortex

Authors: B. RUMMELL, J. KLEE, *T. SIGURDSSON;
Goethe Univ. Frankfurt, Frankfurt, Germany

Abstract: Many of the sounds that we perceive are caused by our own actions, for example during speech or movement, and must be distinguished from sounds caused by external events. Studies using macroscopic measurements of brain activity in human subjects have consistently shown that responses to self-generated sounds are attenuated in amplitude. However, the underlying manifestation of this phenomenon at the cellular level is not well understood. In order to address this, we recorded the activity of neurons in the auditory cortex of mice in response to sounds that were generated by their own behavior. We found that the responses of auditory cortical neurons to these self-generated sounds were consistently attenuated, in comparison to the same sounds generated independently of the animals' behavior. This effect was observed, with differences in magnitude, in upper and lower layers of auditory cortex as well as in putative pyramidal neurons and interneurons. Downstream of the auditory cortex, we found that responses of hippocampal neurons to self-generated sounds were almost entirely suppressed. Responses to self-generated optogenetic stimulation of thalamocortical terminals were also attenuated, suggesting a cortical contribution to this effect. Further analyses revealed that the attenuation of self-generated sounds was not simply due to the non-specific effects of movement or behavioral state on auditory responsiveness. However, the strength of attenuation depended on the degree to which self-generated sounds were expected to occur, in a cell-type specific manner. Taken together, these results reveal the cellular basis underlying attenuated responses to self-generated sounds and suggest that predictive mechanisms contribute to this effect.

Title: Behavioral uncertainty in tone-in-noise and speech-in-noise detection tasks reflected in neuronal responses in ferret auditory and frontal cortices

Authors: ***J. B. FRITZ**[1], C. BIMBARD[2], D. D. DUQUE[1], D. DELGUEDA[3], S. V. DAVID[4], S. A. SHAMMA[3];
[1]Inst. For Systems Res., College Park, MD; [2]Cognitive Sci., Ecole Normale Superieure, Paris, France; [3]Inst. for Systems Res., Univ. of Maryland, College Park, MD; [4]Oregon Hlth. Sci. Univ., Portland, OR

Abstract: The detection of faint sounds in the presence of background noise is a ubiquitous acoustic challenge in active hearing for humans and animals. In a previous study (Atiani et al., 2009) ferrets (*Mustela putorius*) were trained on a conditioned avoidance go-nogo task to detect a tone embedded in noise. The level of difficulty of the tone-in-noise (TIN) task was parametrically varied by changing the signal-to-noise ratio (SNR) of the pure tone relative to background noise. Ferrets took longer to recognize the presence of the tone as SNR decreased, reflecting rising difficulty of extracting signals from increasingly noisy surroundings and uncertainty in low SNR as to whether the tone was present. We also observed rapid task-related plasticity in primary auditory cortex (A1) that may enable better TIN detection. Other work (Mesgarani et al., 2014) has shown a noise-robust representation of speech, suggesting that extraction of signal from noise can be studied in the ferret for more complex acoustic stimuli such as speech (Doncos et al., 2016). The objective of the present study was to explore neural responses in higher auditory cortical areas beyond A1 during task performance and elucidate contributions of different areas to neuronal recognition of the target tone (TIN task) or speech token. We recorded neuronal activity extracellularly, with high impedance electrodes, from A1, higher order auditory cortex (the ventral posterior area (VP)), and from dorsolateral frontal cortex (dlFC) in four female adult ferrets trained on the TIN and the speech-in-noise task. We recorded over 110 single units in dlFC under quiescent conditions and in two behavioral task conditions of pure tone detection, and TIN, with variable SNR. Frontal neurons during TIN behavior showed: (1) similar selective responses to the tonal target, even when embedded in noise, (2) greater latency of target response in the TIN task compared to target latency in pure tone detection reflecting greater processing time to detect the TIN, (3) diminished amplitude of target responses in the TIN task compared to target responses in pure tone detection, reflecting a greater degree of uncertainty about the presence of target tonal stimuli. Similar responses in the TIN task were also observed in 40 cells recorded in VP. Results were also obtained from A1, VP and dlFC in one female ferret trained on the speech-in-noise task with variable SNR. The intriguing parallel between task performance and neural responses in frontal cortex and VP and the adaptive A1 receptive field responses suggests that all areas contribute to a broader auditory network for extraction of relevant signals from noise.

Title: Higher age-related decline in behavior discrimination of amplitude modulation frequencies compared to auditory evoked potentials

Authors: *J. LAI[1], E. L. BARTLETT[2];
[2]Biol. Sci. and Biomed. engineering, [1]Purdue Univ., West Lafayette, IN

Abstract: Age-related hearing loss, or presbyacusis, causes a reduction in speech understanding which could eventually result in self-isolation, loneliness and depression. Speech consists of complex and rapid amplitude modulation (AM) and frequency modulation, so the ability to discriminate between modulation frequencies is important for discrimination of speech and other complex sounds. It is known that age-related differences in temporal processing assessed physiologically by envelope following responses (EFRs) of the auditory midbrain and brainstem are significant at more rapid AM frequencies. A typical assumption is that a decline in EFR responses will necessarily result in corresponding perceptual decline. To test this assumption, we investigated behavior discrimination abilities of AM frequencies in young and aged Fischer-344 rats. Comparison of physiological and behavior results should aid in reflecting the relationship of AM processing and AM perception. For AM processing, we measured EFRs of temporal modulation transfer function (tMTF) using sinusoidal AM (SAM) 8 kHz tone at AM frequencies of 16-2048 Hz in 0.5-octave step. For behavior AM discrimination, we used a modified version of prepulse inhibition (PPI) of acoustic startle reflex (ASR). In a typical trial of AM discrimination task, pulses of SAM tone at 128 Hz AM frequency were presented sequentially and a prepulse of SAM tone at the same or different SAM frequency (e.g. 32, 256 Hz, etc.) was presented right before a sudden brief loud noise that induced ASR. Larger PPI intrinsically indicates a higher sensitivity in discriminating SAM frequency of the prepulse from 128 Hz. Comparable behavior PPI results were observed in the young and the aged when the AM discrimination task was performed at 100 % AM depth even though age-related differences in EFR amplitudes of tMTF at 100 % depth were large. At 50 % AM depth, age-related decline of EFR amplitudes was small but aged animals' AM discrimination performance was highly compromised. In contrast, young animals were able to discriminate AM frequencies at 50 % depth though their EFR amplitudes were slightly higher than the aged. Even at 25 % depth, young animals were still able to discriminate AM frequencies that are about 3 octaves away from 128 Hz. Overall, the results reveal a complex relationship between EFRs and behavioral age-related differences, suggesting that EFR amplitude or changes in EFR amplitude alone are not enough to predict behavioral performance.

Title: Parallel processing by cortical inhibition in auditory cortex enables flexible behavior and learning

Authors: *K. KUCHIBHOTLA[1], J. V. GILL[1], G. W. LINDSAY[2], E. PAPADOYANNIS[1], T. A. H. STEN[1], R. E. FIELD[1], K. D. MILLER[2], R. C. FROEMKE[3];
[1]Skirball Inst., New York Univ. Sch. of Med., New York, NY; [2]Columbia Unviersity, New York, NY; [3]NYU Sch. of Med., New York, NY

Abstract: Neocortical inhibitory neurons are remarkably diverse in terms of lineage and connectivity, but little is known about how this diversity supports perception and behavior. Here we show that during a stimulus recognition task, excitatory neurons in auditory cortex exhibit a continuum of responses about a mean suppression, with high variance including some response facilitation. With whole-cell recording, two-photon calcium imaging and optogenetics during behavior, we found that synaptic inhibition gated these changes, with PV, SOM+ and VIP+ interneurons dynamically balancing inhibition and disinhibition within the network. Cholinergic axons increased activity during behavior, directly depolarized all interneuron subtypes, and were necessary for behavioral performance. Stimulating the cholinergic system elicited fictive behavioral responses even out-of-context. A network model captured the complex neural dynamics across neuronal subtypes only when cholinergic activity coincidently depolarized all interneurons. Differential responses of cortical interneurons to neuromodulation may thus enable circuits to have distinctive responses during behavior. We next explored excitatory neural dynamics during the acquisition of this flexible task. Neural correlates to stimulus recognition and behavioral context emerged early, well before the animal could behaviorally report task contingencies correctly in the active context. This suggests that sensory learning may be dissociable from complete task acquisition.

Title: Acoustic environmental enrichment prolonged natural lifespan of mice

Authors: *Y. YAMASHITA[1], N. KAWAI[2], O. UENO[1], T. OOHASHI[2], M. HONDA[1];
[1]Natl. Inst. of Neuroscience, Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan; [2]Dept. of Res. and Develop., Fndn. for Advancement of Intl. Sci., Tsukuba, Japan

Abstract: Environmental enrichment (EE) has been reported to have positive effects on experimental animals including prevention of frailty signs, prolongation of lifespan, and accelerations of developments and functions of the brain. A standard experimental setting of EE consists of the interaction of complex factors including larger cages with variety of objects enhancing animal's physical activity and larger groups of animals with the opportunity for more social interaction. In such complex factors, diversity of sensory stimuli may be one of the essential factors of enriched environment. For example, recent studies have demonstrated that enrichment of acoustic environment promotes plasticity and recovery of the auditory cortex. In the current study, we focused on the effects of enrichment of acoustic environment and investigated whether acoustic enrichment affects lifespan and voluntary movements in mice. Ninety-six 8-week old C57Bl/6J mice were assigned to two groups with different acoustic environments throughout the experiment: (1) acoustically enriched environment with sounds of tropical rain forest (AEE group, n=64, 32-male and 32-female), and (2) standard environment without any exposure to stimulation (control: CNT group, n=32, 16-male and 16-female). In AEE condition, tropical rain forest sounds were presented through two speakers fixed at the top of the cage. Other properties of environment including cage size (a standard plastic cage) were standard rearing condition of experimental animals. Body weights were monitored once every week, and voluntary movements were continuously monitored with a computerized system throughout lifespan.
The mice of AEE group lived significantly longer (nearly 12%) than those of CNT group. In addition, the voluntary movements of AEE group significantly increased compared to those of CNT group. However, no correlation between the lifespan and voluntary movements was observed. There was no significant difference in body weights between AEE group and CNT

group.
The results showed that additional acoustic stimuli with standard rearing condition prolonged natural lifespan of the mice. One may argue that prolonged lifespan might result from increased voluntary movements. However, there was no significant correlation between the voluntary movements and lifespan, suggesting that the increase of voluntary movements was not a primary cause of prolongation of lifespan. These observations suggest that acoustic sensory enrichment may be one of the essential elements of EE. This work could contribute to providing clues regarding underlying mechanisms of the positive effects of EE.

Title: Shared mechanisms of mismatch activity in common marmosets and macaque monkeys

Authors: ***M. KOMATSU**, N. FUJII;
RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: Mismatch negativity (MMN) is a component of event-related potentials evoked by violations of the regularity in sensory stimulus-sequences in human. MMN has been receiving attentions as a clinical and translatable biomarker of psychiatric disorders such as schizophrenia. Recently many studies are focusing on MMN of several species to develop the animal models of these psychiatric disorders. In this study, we investigated shared mechanisms of MMN in two species of non-human primates, common marmosets and macaque monkeys. We recorded the electrocorticograms (ECoGs) from four common marmosets and three macaque monkeys with implanted electrodes covering a wide range of a hemisphere. The 28-64 channel ECoG arrays were epidurally implanted on the hemispheres of each marmoset (two on the left and two on the right hemispheres) and the 128 channel arrays were subdurally implanted on the brains of the

macaque monkeys (one on the left and two on the right). ECoG recordings were conducted in passive listening condition with a roving oddball paradigm. Repetitive tone-sequences with 20 types of frequency (250-6727 Hz with an interval of 1/4 octaves) are randomly presented. We considered the last tones of sequences as standard, and the first tones of sequences as deviants. First, we calculated ERPs for standards and deviant stimulus, respectively. Then, difference wave is obtained by subtracting the deviant stimulus ERP from the standard stimulus ERP. We observed significant negative components of the difference wave lasting 40-150 ms after the onset of the stimuli, around the lateral sulcus of both the species. This result suggested that shared mechanisms of mismatch activity exist in information processing around the lateral sulcus of both the species. Furthermore, we investigated the functional connectivity between electrodes of a marmoset. We calculated direct Directed Transfer Function (dDTF) during 0-100 ms after the onsets of the standard and deviant stimuli, respectively. At the high frequency band (56~ Hz), intra connections appeared in the temporal area during both the period, while prominent connections in the frontal area appeared for the deviant stimuli period, but not for the standard stimuli period. These results suggested the high-gamma activity reflected different roles of temporal and frontal generator.

Title: Task-related plasticity in the inferior colliculus of the marmoset monkey

Authors: ***S. J. SLEE**, S. V. DAVID;
Oregon Hearing Res. Ctr., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Recent evidence suggests that neurons in the inferior colliculus (IC) undergo receptive field changes during auditory behavior in carnivores (Slee and David, 2015. J Neurosci.). In this study, we tested for similar effects in the marmoset monkey, a primate species that uses vocalizations to communicate. Two marmosets were trained to detect a pure tone target embedded in a background of random spectral shape (RSS) distractor stimuli. The level of the

target was manipulated to vary task difficulty. Both marmosets accurately performed this task over a 5-octave range of target frequencies (0.625-20 kHz). As the signal to noise ratio of the target was decreased, we found a significant decrease in hit rate and an increase in false alarm rate. We measured the effects of task engagement by recording from single neurons in the IC. Neural responses to both targets and RSS distractors were compared between conditions when the marmoset performed the detection task or listened passively. The target frequency was presented near the best frequency (BF) of the neuron under study. Responses to the distractors were suppressed in about half of the neurons during task engagement relative to passive listening. The median global gain change (-14%) in these neurons was comparable to our previous study in the ferret (median=-20%). To measure local tuning changes, responses to the RSS distractor stimuli were also used to fit linear and nonlinear spectral weighting models. Spectral weights were tuned around BF for most neurons in the central nucleus of the IC. In about 1/3 of these neurons we found a significant decrease in the spectral weight at BF (target frequency) during task engagement. The median weight change (-25%) was also similar to previous measurements in the ferret (-32%). Finally, we computed the discrimination index (*d'*) between the distributions of neural responses to the target and distractor stimuli in both behavioral conditions. We found that while most IC neurons can discriminate between the task stimuli (*d'*>1), discrimination *does not* improve during task engagement. These results support a model with task-related plasticity in the IC as a prerequisite for the improved neural discrimination that has been reported in auditory cortex.

Title: Contribution of population activity in the auditory cortex to the cocktail-party problem

Authors: *K. L. CHRISTISON-LAGAY[1], S. BENNUR[2], Y. COHEN[2];
[1]Perelman Sch. of Med. At the Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: One of the fundamental functions of the auditory system is to transform acoustic stimuli into discrete perceptual representations (sounds). However, this task is often complicated

by our listening conditions: rarely do we listen to sounds against silence. Instead, our auditory system often must extract and segregate a “target” stimulus from a noisy background (e.g., isolating your friend’s speech from the rest of the sounds in a restaurant). This ability is frequently referred to as figure-ground segregation or, more informally, as the cocktail-party problem. The neural underpinnings of this ability, specifically those in the auditory cortex, have not yet been fully elucidated. To address this issue, we recorded from the auditory cortex while rhesus monkeys simultaneously reported whether they heard a target stimulus that was embedded in a noisy background. The target stimulus was a tone burst, whose frequency was set to the best frequency of the recording site, and the noisy background was comodulated broadband noise. On a trial-by- trial basis, we varied the “target-in-noise” ratio (TNR) between 0 and 25 dB. On approximately of 50% of the trials, we presented the noise alone; these trials served as catch trials. Although most auditory-cortex neurons were driven by the auditory stimuli, only a small fraction of neurons was significantly modulated as a function of TNR levels. Further, we could not identify a significant population of neurons that was modulated by the monkeys’ choices (detection versus no detection of the target stimulus). Because of these two sets of findings, it seemed that very few individual neurons contributed sensory evidence to the task’s perceptual decision. However, the heterogeneity of neural responsivity suggested that population activity might provide more stimulus- and/or task-related information. To test this hypothesis, we constructed a support vector machine and tested how well neural activity in response to different stimulus and/or task attributes could be discriminated using a linear-decision- boundary. With populations as small as ~100 neurons, this classifier could reliable decode TNR level, discriminate between the target and noise stimulus, and discriminate between variability that was modulated by the monkeys’ choices. Overall, these findings are consistent with the hypothesis that auditory cortex does contribute directly to the cocktail-party problem. However, this contribution is not seen in individual neurons but the overall activity of the population.

Title: The role of auditory thalamo-striatal and cortico-striatal neurons in amplitude modulation frequency discrimination

Authors: *N. D. PONVERT, S. JARAMILLO;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Multiple parallel neural pathways link information about sounds with behavioral responses. The striatum, a brain structure involved in movement and reward-related learning, receives neuronal projections from both the auditory thalamus and the auditory cortex. It is unclear whether sound information that reaches the striatum through these two parallel pathways is redundant or complementary. To test whether both pathways are required for auditory discrimination of amplitude modulated sounds, we first performed transient pharmacological inactivations of auditory cortex in mice trained to perform a two-alternative choice auditory task. We then used optogenetic techniques to tag neurons in the thalamo-striatal and cortico-striatal pathways, allowing us to identify them during extracellular recording. We characterized the responses of identified neurons in each pathway to pure tones and to amplitude-modulated noise stimuli. Consistent with previous studies, we found that inactivation of auditory cortex largely impaired the ability to discriminate between different amplitude modulation frequencies. We also found that neurons in the thalamo-striatal and cortico-striatal pathways have largely overlapping tuning for sound frequency, but display different coding strategies for amplitude modulated sounds. These results suggest that the thalamo-striatal pathway carries sufficient information to support discriminations of sound frequency, but that fundamental differences exist between the cortico-striatal and thalamo-striatal pathways with respect to their contribution to discrimination of temporal modulations in amplitude.

Abstract: The frontal cortex has been previously associated with enhancement of relevant information for goal-directed behavior. Neuronal responses in the frontal cortex (FC) of the behaving ferret have been shown to be behaviorally gated and highly selective for target stimuli during auditory and visual discrimination tasks (Fritz et al., 2010). This suggests a selection in the flow of sensory information by frontal cortex in tasks in which ferrets rapidly categorize reference and targets. However, in a more natural and cluttered environment, accumulating relevant evidence to produce an adequate behavior is critical. Here we investigate how FC can extract targets embedded in continuous sound stream, and how FC is involved in a complex task demanding accumulation of sensory evidence. For this purpose we trained ferrets on a change detection paradigm where animals have to constantly monitor a stochastic and continuous acoustic stream to detect subtle statistical changes. In an attempt to characterize the extraction of relevant sensory information performed between sensory cortices and frontal areas, we gathered electrophysiological data in the primary auditory (A1) cortex and the dorso-lateral FC (dlFC) of the behaving ferret. A1 neurons exhibited strong onset responses and reduced change-related discharges, whereas dlFC neurons presented an enhanced response to change-related events during behavior, possibly being the signature of accumulation of sensory evidence. These area-specific responses to sound are consistent with EEG recordings done in humans performing the same task. All together this suggest a behavior-dependent sensory 'gating' mechanism leading to decision making.

Title: Contribution of correlated neural activity in the auditory cortex to the cocktail-party problem

Authors: F. RODRIGUEZ-CAMPOS[1], T. BANNO[1], *Y. E. COHEN[2], S. BENNUR[1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. Otorhinolaryngology-Head Neck Surgery, Univ. of Pennsylvania Dept. of Otorhinolaryngology, Philadelphia, PA

Abstract: One of the fundamental functions of the auditory system is to transform acoustic stimuli into discrete perceptual representations (sounds). However, often, because we listen in noisy environments, our auditory system needs to extract and segregate a "target" stimulus (e.g., your friend's speech) from a noisy background (e.g., the sounds that are formed by other talkers in a restaurant). This ability is often referred to as figure-ground segregation or, more informally, as the cocktail-party problem. However, it is unknown whether and if coordinated correlated auditory contributes to the computations underlying the cochtail-party. To address this issue, we recorded from the auditory cortex while rhesus monkeys simultaneously reported whether or not they heard a target stimulus that was embedded in a noisy background. The target stimulus was a tone burst, whose frequency was set to the best frequency of the recording site, and the noisy background was comodulated broadband noise. On a trial-by-trial basis, we varied the "target-in-noise" ratio (TNR) between 0 and 25 dB. On approximately 50% of the trials, we presented the noise alone; these trials served as catch trials. We recorded with Plexon u-probes and were able to isolate several neurons in each recording session. In general, we did not identify any changes in correlated activity with changes in TNR level. However, changes in correlated activity did emerge as a function of the monkeys' performance. In particular, we found that signal correlation was modulated as a function of task performance (hits versus misses). Similarly, noise correlation was modulated as function of whether the monkeys' reported a hit versus a miss. Finally, we found that the Fano factor (an index of spiking variability) was smaller on hit trials than on miss trials. These findings suggest changes in coordinated population activity may limit a listener's performance on tasks like foreground-background segregation. They also suggest that changes in Fano factor may be an underlying mechanism.

Title: Decoding the white matter geometrical structure by encoding connectomes in multidimensional spaces

Authors: *F. PESTILLI[1], C. F. CAIAFA[2];
[1]Psychology, Neuroscience, Cognitive Sci. and Network Sci., Indiana Univ., Bloomington, IN;
[2]Psychological and Brain Sci., Indiana Univ. / CONICET, Bloomington, IN

Abstract: A growing body of scientific evidence suggests the inner workings of the brain cannot be simply understood at the level of single neurons or isolated brain areas; rather, modern efforts must focus on brain networks and circuit behavior. The full network of brain connections, commonly referred to as the connectome, is comprised of both grey matter regions representing neural units of information processing, and white-matter tracts serving as structural communication pathways. To date, large-scale human brain networks can be mapped in-vivo by using diffusion- weighted magnetic resonance imaging and fiber tracking methods (Bullmore and Sporns 2009). Standard methods for mapping connectomes operate on data based on the naturally occurring geometry of the brain white matter. This geometry is complex and difficult to handle computationally. As a result a majority of algorithms for mapping connectomes rely on sets of ad-hoc rules and heuristics that identify white matter pathways one fascicle at the time. This is a computationally suboptimal process prone to failure because no rule is expected to be optimal in all brain locations or across multiple brains (Takemura et al., 2016). Computational limitations restrict our ability to routinely measure the accuracy of connectome models (Pestilli et al., 2014).We introduce an approach that uses multidimensional arrays to encode anatomical properties of connectomes in a computationally-efficient way. The method allows performing neuroanatomical operations on the geometric organization of the brain's white matter. We analyzed 1,040 brain connectomes generated using multiple tractography algorithms on publicly available datasets (Human Connectome Project, purl.stanford.edu/ng782rw8378). Results show that the framework: (1) Can be used to establish approaches for precision connectomics by allowing building highly reliable within-brain and highly discriminable between-brain connectomes; (2) Allow efficient estimation of distributions of crossing angles between white matter fascicles (Van Wedeen et al., 2012; Catani et al., 2012). In sum, we show a connectome encoding framework with important computational advantages for decoding fundamental features of the human brain.

Title: Towards a standard cortical observer model in human V1-V3

Authors: C. OLSSON, 10003[1], N. C. BENSON[2], *J. WINAWER[2];
[1]Ctr. for Neural Sci., [2]Psychology, New York Univ., New York, NY

Abstract: A goal of visual neuroscience is to be able to predict neural responses to arbitrary images. There has been considerable success modeling signals in human visual field maps at the level of fMRI. Population receptive field ('pRF') models can predict responses in a voxel to a wide variety of images (e.g., Kay et al, 2013, 10.1371/journal.pcbi.1003079). These models are solved independently for each voxel by learning the pRF parameters that best fit fMRI measurements. Retinotopic templates are a complementary type of model. They can predict the preferred position in the visual field of all voxels in V1-V3 from anatomy alone, but cannot predict responses to arbitrary images (Benson et al, 2014, 10.1371/journal.pcbi.1003538). Here we integrated a pRF model with an anatomical template to create a first generation 'Standard Cortical Observer Model of Human V1-V3'. The pRF component is based on the two-stage cascade model of Kay et al (2013), and has been extended to handle multiple spatial frequency bands. The pRF parameters summarize the voxel's sensitivity to a variety of image features, including spatial location, spatial frequency, and second order contrast. The V1-V3 template component is an extension of Benson et al (2014). The complete model takes visual images and an anatomical MRI as input. It outputs the predicted BOLD response of each voxel in V1-V3 for each image. The model accomplishes this by: (1) identifying voxels in V1-V3 and deriving their retinotopic coordinates from the anatomical MRI, (2) inferring additional pRF parameters from the retinotopic coordinates, and (3) applying the pRF model at each voxel to the images. The mapping between retinotopic coordinates and other pRF parameters was learned by identifying systematic variation of pRF parameters across voxels in training data. Once learned, the mapping is applied to new subjects and new images with no further fMRI measurements. The model and training data are publicly available, with code on GitHub and a working version packaged in a Docker. The code is structured to facilitate model comparison, such that other researchers can easily extend or modify the model, or apply it to their own data. In preliminary testing, we predicted responses in all voxels in one subject's V1, V2, and V3 to a set of 57 images. The inputs to the model were the images and the subject's unlabeled anatomical MRI. The accuracy of the predicted responses averaged across V1 was 61% (R^2). The model has the combined

advantages of a pRF model and a template, in that it predicts responses to arbitrary images, can be computed from anatomy alone, and takes advantage of the fact that model parameters are distributed systematically on the cortex.

Title: A fully computable model of bottom-up and top-down processing in high-level visual cortex

Authors: *K. N. KAY[1], J. D. YEATMAN[2];
[1]Univ. of Minnesota, Twin Cities, Minneapolis, MN; [2]Univ. of Washington, Seattle, WA

Abstract: Specific regions of ventral temporal cortex (VTC) appear to be specialized for the representation of certain visual categories: for example, the visual word form area (VWFA) for words and the fusiform face area (FFA) for faces. However, a computational understanding of how these regions process visual inputs is lacking. Here we develop a fully computable model of responses in VWFA and FFA. We measured BOLD responses in these regions to a wide range of carefully controlled grayscale images while subjects performed different tasks (fixation task: judge color of a small central dot; categorization task: report perceived stimulus category; one-back task: detect image repetitions). Using cross- validation to control for overfitting, we developed a model that accurately accounts for the observed data. The first component of the model is a two-stage cascade of visual processing in which the bottom-up response in VTC (fixation task) is computed as the degree to which low-level stimulus properties match a category template. This reveals how high-level representations are constructed from simple stimulus properties. The second component of the model addresses top-down enhancement of VTC responses produced by performance of a task on the stimulus (categorization and one-back tasks). We show that the enhancement is stimulus-specific and can be modeled as a scaling of the bottom-up representation by the intraparietal sulcus (IPS). The third and final component of the model shows that the IPS response to a given stimulus reflects perceptual decision-making and can be quantitatively predicted using a drift diffusion model. Thus, the top-down scaling induced

by the IPS is directly related to the behavioral goals of the subject. In sum, these results provide a unifying account of neural processing in VTC in the form of a model that addresses both bottom-up and top-down effects and quantitatively predicts VTC responses.

Title: Preserved information in multivoxel patterns despite significant decrease in mean signals following surgical removal of human inferior occipital cortex

Authors: *K. S. WEINER[1], J. JONAS[2], L. MAILLARD[2], G. HOSSU[3], S. COLNAT-COULBOIS[2], K. GRILL-SPECTOR[1], B. ROSSION[4];

Abstract: The stable and plastic features of cortical repair following damage to the human brain are a major topic in systems neurobiology. However, there is little understanding regarding how partial removal of a brain region affects the functionality of the remaining region due to the rarity of acquiring brain measurements pre-damage in humans. Here, we had the unique opportunity to fill this gap in knowledge with pre- and post-operative functional magnetic resonance imaging (fMRI) in a patient (SP) requiring focal resection of the inferior occipital cortex in the right hemisphere. Despite the focality of the surgery, four brain regions were partially resected: a majority of hV4 (66.2%) and less than a quarter of VO-1 (16.1%), pFus-faces/FFA-1 (23.3%), and LOS-limbs/EBA-1 (21.7%). We asked: (1) How does the resection affect mean signal and multivoxel patterns (MVP) in the tissue adjacent to the resection? (2) Do these effects differ in regions that are category-selective (e.g. pFus-faces/FFA-1 and LOS-limbs/EBA-1) compared to

those that are not (e.g. hV4 and VO-1). In four fMRI sessions (two before surgery and two after surgery), SP participated in two experimental runs during which she viewed images from four categories (faces, limbs, places, objects), as well as phase-scrambled images. We measured and compared both mean responses and MVPs in SP pre- and post-operatively, which revealed two main findings. First, partial resection detrimentally affects global processing: the mean signal within each region significantly decreases post-resection irrespective of both the proportion of brain tissue removed, as well as the functional selectivity of the region. Second, distributed representations to object categories were preserved despite a decrement in the mean signal: representational similarity among MVPs is preserved and comparable to pre-resection representations if less than a quarter of the region was removed but not if more than 2/3 of the region was removed (as in hV4). These rare data indicate that the functional assessment of regions surviving cortical resection varies across spatial scales and is sensitive to the amount of the functional region that has been removed. Together, these results caution conclusions of diminished function of a brain region based solely on global reductions in the mean fMRI signal following cortical resection or damage.

Title: Population receptive field attraction by spatial attention varies across cortical depth in human V1

Authors: ***B. P. KLEIN**[1], A. FRACASSO[2,3], S. O. DUMOULIN[1,2];
[1]Helmholtz Inst., Utrecht, Netherlands; [2]Spinoza Ctr. for Neuroimaging, Amsterdam, Netherlands; [3]Dept. of Radiology, Univ. Med. Ctr., Utrecht, Netherlands

Abstract: Introduction:
Attention is the mechanism through which we select relevant information from our visual environment. Recently, we have demonstrated that voluntary spatial attention attracts population receptive fields (pRFs) towards its focus in humans across the visual hierarchy, including primary visual cortex (V1) (Klein et al, 2014). Data from non-human primate histology shows

that in V1, visual processing is functionally segregated across different cortical layers at the level of the first synapse. Central layers predominantly receive ascending feedforward inputs, whereas descending feedback inputs mainly terminate in deep and superficial layers. Because of the separation between feedback and feedforward inputs in V1, we expect that attention affects pRF positions in human V1 differently between cortical layers.
Methods:
We acquired sub-millimeter (0.7 mm isotropic, TR = 4s) ultra-high field (7T) functional MRI data while participants viewed an expanding, contrast-defined ring, centered on fixation (±5.5 degrees radius). Concurrently, participants performed an endogenous attention demanding contrast discrimination task on one of two locations, either left or right outside the stimulus range. We estimate pRF positions from the BOLD-fMRI time-series elicited by the expanding ring stimulus for both task locations separately and compare these estimates between the two conditions. We obtain estimates of cortical depth for every fMRI voxel by using a distance map based upon a gray matter/white matter manual segmentation. This segmentation is derived from a combination of the mean image of reconstructed fMRI amplitude and unwrapped phase (equivalent to anatomical T2*weighted images, Duyn et al, 2007).
Results:
Replicating our earlier study, we found that pRFs are attracted towards the task location when averaged across all layers in V1. Furthermore, pRF attraction varied across cortical depth. Specifically, we observed that pRF attraction near the white matter border (i.e. deeper) was larger compared to attraction further away from the white matter border (i.e. more superficial).
Conclusions:
We found that spatial attention affects pRF position more at greater cortical depth in human V1. These results can be explained by a stronger effect of attention at this location in V1, where descending feedback connections terminate. These results extend earlier results on pRF attraction across different visual field maps and demonstrate that laminar imaging helps to bridge the gap between neurophysiology and functional imaging, indicating sites near the white matter border in V1 as the main target of endogenous attentional modulation.

Title: Neural variability is an individual trait

Authors: *A. ARAZI[1], G. GONEN - YAACOVI[1], I. DINSTEIN[2];
[1]Dept. of brain and cognitive science, [2]Dept. of psychology, Ben Gurion Univ., Beer Sheva, Israel

Abstract: Introduction: The mammalian brain is an unstable system where neural responses to repeated presentations of an identical stimulus exhibit considerable trial-by-trial variability. Previous studies have reported that such neural variability is reduced (i.e., quenched) by the presentation of a stimulus, suggesting that the brain enforces stability when processing external stimuli. Does neural variability and variability quenching differ across individuals? Do some individuals exhibit reliably larger levels of variability than others? To address these questions we recorded neural responses with EEG from human subjects while they performed several cognitive and sensory tasks in two experimental sessions that were separated by a year. We quantified individual levels of trial-by-trial variability and variability quenching and assessed the reliability of between-subject differences across sessions and across the different tasks. **Methods:** Twenty four subjects completed two experimental sessions. Each session included four experiments: 1) Presentation of a checkerboard stimulus in the periphery while subjects performed an orthogonal color-detection task at fixation. 2) A choice reaction time task containing two visual stimuli. 3) A go-no-go response-inhibition task containing the same two visual stimuli. 4) A 2-back working memory task containing four visual stimuli. Neural responses were recorded with EEG and trial-by-trial neural variability was quantified before and after stimulus presentation to quantify neural variability and quenching in each subject. **Results:** Neural variability and variability quenching levels were positively correlated across experimental sessions and tasks ($0.65<r<0.93$, $p<0.01$). Furthermore, variability quenching was significantly smaller in the first visual task (where attention was diverted away from the checkerboard stimulus) in comparison to the other three tasks (where attention was focused on the stimulus). This demonstrated that attentional demand increased neural variability quenching, yet showed that between subject differences were much larger than those due to attentional modulation. **Conclusions:** The results revealed that trial-by-trial variability and variability quenching are stable individual traits that remain consistent regardless of the task being examined or the state of the subject.

Title: Contextual modulation in human visual cortex: orientation tuning of surround suppression varies with the spatial extent of the surround

Authors: *S. WARDLE[1,2], K. SEYMOUR[1,2];
[1]Dept. of Cognitive Sci., Macquarie Univ., Sydney, Australia; [2]ARC Ctr. of Excellence in Cognition and its Disorders, Sydney, Australia

Abstract: It is well-established that the response to visual stimuli placed within a neuron's receptive field can be modulated by stimuli placed in the surround regions outside the classical receptive field. Contextual modulation has also been demonstrated at the population level in human V1 using fMRI: the BOLD response to a central target grating is suppressed by the addition of a large annular surround grating. Surround suppression is orientation-tuned: greater suppression occurs when the target and surround gratings have the same orientation, and suppression is reduced when the target and surround gratings are orthogonal. Recent results in macaque V1 and human psychophysics suggest that the orientation-tuning of surround suppression is modulated by the spatial extent of the surround [Shushruth et al., 2013, J. Neuroscience]. Here we examine the spatial range of orientation-tuned surround suppression at the population level in human visual cortex with fMRI. In an optimized block design we presented target and surround gratings that varied both in their relative orientation (parallel or orthogonal) and importantly, in the spatial extent of the surround (near or far). We used independent localizer runs to isolate voxels in V1 that responded preferentially to the target. Consistent with previous results, greater suppression of the BOLD response to the target occurred for a parallel near surround than for an orthogonal near surround. However, the results differed for the far-surround, and facilitation of the BOLD response to the target occurred for the orthogonal far-surround. Our results in human V1 are consistent with previous findings in macaque V1 and human behavior suggesting differential orientation tuning of near and far surround suppression in early visual cortex.

Title: The phase of ongoing delta oscillations predicts eye movements and visually evoked responses in striate cortex during visual search

Authors: *N. N. THIGPEN;
Psychology: Behavioral and Cognitive Neurosci., Univ. of Florida, Gainesville, FL

Abstract: In recent animal work, oscillations in the delta range have been shown to align with the temporal structure of an attended stream of visual stimuli, suggesting delta oscillations may reflect a mechanism for attentional selection. Here, we investigate whether delta oscillations in the human visual cortex temporally align with eye movements and steady-state visual evoked potentials (SSVEP) during visual search. Thirty participants attempted to identify a hidden target in 80 natural scenes, while undergoing dense array EEG and eye tracking recordings. Each scene was luminance modulated at a rate of 30 Hz, to produce SSVEPs. SSVEP power was quantified as time-locked and phase-locked oscillations at the luminance-modulation frequency, using time frequency transforms of event-related EEG segments, whereas ongoing delta oscillations were quantified in the continuous data. At occipital electrode sites, delta oscillations were phase-coupled with eye movement onset, suggesting that delta phase alignment reflects a mechanism underlying oculomotor sampling of the environment during visual search. Delta oscillations were also phase-coupled with an increase in SSVEP power in the absence of an eye movement, suggesting visual information processing at the population level is facilitated during specific phases of the delta cycle. Taken together, these results suggest delta oscillations reflect a mechanism for active oculomotor and visual sampling of the environment during visual search behavior.

Title: V1 & V2 receive high-level scene information via cortical feedback.

Authors: *A. T. MORGAN, L. S. PETRO, L. MUCKLI;
Inst. of Neurosci. & Psychology, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Introduction: Neurons in early visual cortex receive highly selective feedforward input that is amplified or disamplified by contextual feedback and lateral connections (Phillips, 2015). Many cortical areas feed back to early visual cortex, yet measuring feedback channels presents a central challenge to fully understanding neural computations (Muckli and Petro, 2013). To isolate feedback during scene processing we blocked feedforward input to subsections of human retinotopic visual cortex with a uniform visual occluder covering one quarter of the visual field (Smith and Muckli, 2010) while participants viewed 24 real-world scenes. We probed the information characteristics of feedback by selecting scenes spanning two abstract features that modulate V1 responses: scene category and depth (Kravitz, et al. 2011; Walther, et al. 2009). This allowed us to investigate whether feedback contains information about these features. **Methods:** We localized subsections of V1 and V2 in an fMRI experiment responding to either an occluded or non-occluded portion of the visual field, yielding four regions of interest: Occluded and Non-Occluded V1 and V2. We used multivariate pattern analyses (support vector machines [Smith and Muckli, 2010] and representational similarity analysis [RSA; Kriegeskorte, et al. 2008]) to compare and visualize scene response profiles in each region. **Results:** Using pattern classification techniques we found that response patterns in Occluded V1 and V2 contain individual scene, category and depth information. By testing classifiers on scenes withheld from training we found that category information was generalizable across scenes while depth information was not. Feedback to early visual cortex is therefore specific to individual scenes while concurrently conveying some high-level structure. Using RSA we show that Occluded V1 and V2 responses differed from each other, indicating that feedback to these two areas has unique information content. Additionally, Occluded and Non-Occluded V1 and V2 represented scenes differently than three popular biologically-inspired computational models (Weibull, Gist, and H-MAX-C2). **Conclusions:** Our results show that feedback to early visual cortex contains individual scenes, category and depth information. Moreover, feedback to V1 and V2 has unique information content. Additionally, these areas represent scenes differently from three popular biologically inspired computational models. Together these results highlight that a true

understanding of the neural computations of early visual cortex will involve understanding how and what information is conveyed by feedback.

Title: Array coils for ultra-high resolution columnar imaging in visual cortex

Authors: ***A. BECKETT**[1], A. T. VU[1,2], S. SCHILLACK[3], D. A. FEINBERG[1,2];
[1]Univ. of California, Berkeley, CA; [2]Advanced MRI Technologies, Sebastopol, CA; [3]Virtumed, Minneapolis, MN

Abstract: Innovations in hardware, such as the progression to ultra-high magnetic fields, and sequence development, i.e. accelerated image acquisition, have greatly increased the available resolution available for fMRI, and allowed the capability for the imaging of neural architecture at sub-millimeter resolutions. Specialized receiver hardware may be necessary to routinely allow sufficient SNR for this kind of high-resolution imaging. As part of our NIH BRAIN Initiative project (1R24MH106096-01), new coil designs have been developed to increase SNR specifically in the cortex, rather than more balanced SNR across both superficial and deep brain regions. We tested the utility of these new coils by focusing on a known fine-scale feature of human visual cortex: ocular dominance columns (ODCs).
ODC fMRI data were collected on a Siemens 7T scanner using a prototype coil: 8-channel receive, 1-channel transmit, with 4cm diameter loops in receiver array to optimize SNR in cortex. Data were collected using simultaneous multi-slice (SMS) EPI (resolution 0.5 mm isotopic, SMS-factor 2, in-plane IPAT 2, Matrix Size 180x160, 60 slices, 0% distance factor, flip angle 67, partial Fourier 5/8, TR=3000ms, TE=25.2ms, B/W=817 Hz, FOV 90x80.) The dedicated cortical imaging coil was combined with slice dithering for enhanced resolution (SLIDER), in which the slice thickness was doubled and slice positions overlapped to maintain closer slice spacing. This decreased aliasing and increased high spatial frequencies in the slice direction relative to 1mm isotropic voxels, with the benefit of increased SNR relative to 0.5mm slice thickness, leading to a net gain in sensitivity to ODCs.
Ocular dominance mapping was done using colored moving dot stimuli in three different colors:

red, green and yellow. Using custom anaglyph spectacles (using Kodak Wratten filters No. 25 (red) and 44A (cyan)) these dots stimulated either a single eye or both eyes simultaneously (Nasr 2016). Blank blocks (uniform black screen) were interspersed amongst the colored dot blocks. The use of the higher density coil array increased signal in peripheral brain regions, including cortex, , yielding increased tSNR and BOLD contrast at high resolution for 3D cortical fMRI. These gains allowed the potential for high-resolution, columnar scale imaging in timeframes much reduced than previous. The potential for high-resolution 3D columnar scale imaging in such a reduced time allows the potential to both localize and test the response properties of such features in a single scanning session, increasing the accuracy, reducing the need for combining data between sessions.

Title: Luminance modulates the contrast response in human visual cortex

Authors: *L. VINKE[1,2], S. LING[2,3,4];
[1]Grad. Program in Neurosci., [2]Ctr. for Systems Neurosci., [3]Psychological and Brain Sci., Boston Univ., Boston, MA; [4]Donders Inst. for Brain, Cognition, and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: The vast majority of models in vision downplay the importance of overall luminance in the neural coding of visual signals, placing emphasis instead on the coding of features such as relative contrast. Given that the visual system is tasked with encoding surfaces and objects in scenes, which often vary independently in luminance and contrast, it seems likely that luminance information is indeed encoded and plays an influential role in visuocortical processing. However, the cortical response properties that support luminance encoding remain poorly understood. In this study, we investigate the interaction between contrast response and luminance in human visual cortex, using fMRI. We assessed BOLD responses in early visual cortex (V1-V3) while participants viewed checkerboard stimuli that varied in contrast and luminance. Specifically, we utilized an adaptation paradigm that allowed us to reliably measure contrast responses at multiple

spatial scales (voxel-wise and retinotopic), and across a set of luminance levels. To control for changes in pupil diameter with varying luminance levels, stimuli were viewed monocularly through an artificial pupil. We found that the extent to which the overall luminance of a signal modulates responses in visual cortex is contrast dependent, with reliable increases in responses along with increasing luminance levels, but only occurring at low levels of contrast. These results reveal that the visuocortical neural code does indeed retain and utilize information about the luminance of a visual signal, but appears to preferentially modulate the response only at low-to-zero contrast levels. This finding suggests that luminance likely plays a dominant role in visual tasks such as our perceptual encoding and segregation of surfaces.

Title: Cortical depth dependent 7T BOLD responses to parametrically varied luminance contrast

Authors: ***I. MARQUARDT**, M. SCHNEIDER, O. GULBAN, D. IVANOV, K. ULUDAG; Dept. of Cognitive Neurosci., Maastricht, Netherlands

Abstract: Introduction
High-resolution functional MRI (fMRI) studies at high field strength (7 Tesla) have demonstrated the feasibility of sampling functional signals at different cortical depth levels [1, 3, 5, 6, 7, 8]. However, laminar specificity of the neuronal response is degraded by the hemodynamic response. Here, we demonstrate that cortical depth specificity in V1 can be recovered by measuring responses to parametrically varied luminance contrast levels of a grating stimulus.
Methods
Human participants (n=3) were presented with visual grating stimuli at four different luminance contrasts. Retinotopic mapping was performed using population receptive field estimation, allowing delineation of V1 [2]. Functional MRI data were acquired on a 7 Tesla scanner using a gradient-echo EPI sequence (resolution 0.7 mm isotropic). We also acquired T1 images with identical distortions using a multi-inversion time inversion recovery sequence, allowing for an unbiased sampling of the cortical ribbon [4].

Results

Figure 1A shows the mean percent signal change (PSC) change at each depth level for each stimulus luminance contrast averaged across all trials in all participants. A two-way AVNOVA showed a significant effect of stimulus luminance contrast ($F(3, 5148) = 272.9$, $p < 0.001$) and cortical depth level ($F(8, 5148) = 67.4$, $p < 0.001$), as well as an interaction ($F(24, 5148) = p < 0.001$). As expected, stronger stimulus luminance contrast led to a stronger PSC at all cortical depth levels (Figure 1B).

Conclusion

Our results demonstrate that high-resolution fMRI at 7T in conjunction with a parametric experimental design can detect differences in the response properties across cortical depths in human participants.

Title: Extra-classical receptive field effects on visual processing in the awake rodent

Authors: *F. LUONGO, L. LIU, D. TSAO;
Caltech, Pasadena, CA

Abstract: Traditionally, methods for describing the responsiveness of visual neurons in the mouse have centered around responses within a neuron's receptive field. However, neurons are often modulated by context outside of this traditional receptive field also termed the extra-classical receptive field. Such contextual modulation e.g. figure-ground and border ownership modulation provide valuable insights into the underlying computational machinery that the brain uses to segment and identify discrete objects in the visual world. Determining to what extent some of these computations in the extra-classical receptive field are conserved across animals is an important step in establishing the strength and limitations of the rodent as a model of visual computation. We presented a battery of figure ground and border ownership stimuli to rodent's while observing the activity of ~100 neurons simultaneously using 2-photon calcium imaging. We relate the activity of these neurons to modulation that occurs both within and outside the traditional receptive field. Neurons show varied responses to stimuli and exhibit contextual modulation outside of the traditional receptive field. We observe these responses in both primary and extra-striate visual areas as defined using widefield calcium imaging. This work lays the foundation for understanding the types of computations performed in the rodent visual hierarchy and its relation to previous work in cat and primate models.

Title: Binocular integration in mouse using stereoscopic cues to guide behavior

Authors: *V. CHOI[1], S. JOO[2], J. M. SAMONDS[1], A. C. HUK[2], N. J. PRIEBE[1];
[1]Dept. of Neuroscience, Ctr. for Perceptual Systems, Ctr. for Learning a, [2]Dept. of Neurosci. and Psychology, Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: Despite the presence of disparity selective neurons in mouse primary visual cortex (Scholl et al. 2013), there has been little evidence that mice integrate binocular cues to guide behavior. Previous work has demonstrated that rodents can estimate the size of a gap (Legg & Lambert, 1990; Kerr et al., 2013), but it is unclear whether the binocular or monocular depth cues were used. To determine whether binocular cues can drive behavior, we trained animals to distinguish between toward and away motion in depth. Drifting vertical gratings were presented to each eye using a stereoscopic projector and mice were trained to stop for the toward condition and walk for other conditions. "Toward" stimuli are generated by presenting the left eye with a rightward grating and the right eye with a leftward grating; “away” stimuli are generated by presenting the left eye with a leftward grating and the right eye with a rightward grating. We also presented frontoparallel motion in which the gratings moved same direction. Trained mice walked significantly faster for the away and frontoparallel conditions than the toward condition. The behavior depended critically on the binocular depth cues we employed with our stereoscopic projector: the difference in walking speed was abolished when the polarizing glasses used for stereoscopic stimulation were removed and walking speed for toward and away conditions reversed when the position of the polarized glasses are swapped. To determine whether activity in primary visual cortex (V1) impacts this behavior we inactivated V1 using optogenetics while animals performed the motion in depth task. Inactivating V1 eliminates the difference in walking speed for toward and away conditions. These results indicate that binocular cues are used to guide behavior in mice, as in other mammals, and that signals in V1 are essential for the expression of this behavior.

Title: Locomotion enhances information represented in mouse visual cortex both by increasing firing rates and decreasing correlations

Authors: ***M. C. DADARLAT**, M. P. STRYKER;
Physiol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Locomotion is a behavioral state that increases stimulus-evoked responses in mouse primary visual cortex (V1); the response changes have previously been characterized as changes in gain. But spikes cost metabolic energy; is something purchased at this price? As more visual information is available to an animal moving through the environment, perhaps locomotion enhances the information represented in the visual system. To test this hypothesis, we made simultaneous extracellular recordings from 40-83 single neurons in the primary visual cortex of each of 6 awake mice that were presented with moving gratings in the monocular visual field contralateral to the recording site. Mice were free to run or stand stationary on a spherical treadmill floating on an air stream, and we monitored locomotion speed and heading direction. We found that V1 does encode information more accurately during locomotion, and not merely by way of increased firing rates. Locomotion-induced increase in firing rates enhanced the "stimulus-specific information" of individual neurons, as well the population-based discriminability of stimuli. Furthermore, discriminability was improved even when population firing rates did not change with locomotion because locomotion also decreased noise correlations across the population. These improvements were both realized by a particular type of neuron: broad-spiking presumptive excitatory neurons with high multiplicative gain. Together, these

results suggest a computational function for locomotion-induced modulation in neural firing and explain how this function is achieved.

Title: Thalamocortical and intracortical contributions to binocular matching of orientation preference in mouse visual cortex

Authors: ***Y. GU**, J. CANG;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Binocular neurons in the visual cortex are tuned to similar orientations through the two eyes. In mice, the developmental process that gives rise to binocularly matched tuning takes place in a critical period in early life (approximately postnatal day 20-30, Wang et al., 2010 and 2013). In this study, we used in vivo whole cell recording in urethane-anesthetized mice to investigate the synaptic and circuit mechanisms of binocular matching.
First, we found that in adult mice, the subthreshold membrane potential (Vm) responses of individual layer 4 cortical neurons are binocularly matched in their orientation preference to drifting sinusoidal gratings (the difference in preferred orientation through the two eyes: ΔO = 21.1±3.2°, n= 14 cells). In contrast, in juvenile mice (P15-21) before the critical period, the orientation preference of Vm responses are mismatched between the two eyes (ΔO = 50.5±3.8°, n = 25), consistent with our previous studies of spiking responses (Wang et al., 2013).
Next, by comparing visually-evoked excitation under voltage clamp between before and after optogenetically silencing visual cortex, we were able to isolate thalamocortical and intracortical excitatory input to individual layer 4 neurons. In adult mice, we found that both thalamic and cortical excitatory inputs are tuned to similar orientations through the two eyes, leading to binocularly-matched total excitation (thalamic ΔO = 19.4±5.5°, cortical ΔO = 17.2±3.2°, total ΔO = 20.6±4.3°, n = 15). Furthermore, for each eye, the thalamic input predicts the orientation tuning of cortical excitatory inputs (the orientation difference between thalamic and cortical tuning: ΔO = 17.0±4.4° for contra response, and ΔO = 24.4±6.0° for ipsi responses, n = 15). This result is consistent with the recent studies that used similar techniques for contralateral responses

and supported the feed-forward model of thalamocortical transformation (Lien and Scanziani, 2013; Li et al., 2013). In young mice before the critical period (P15-21), on the other hand, both thalamic and cortical excitation onto layer 4 neurons are mismatched in their orientation tuning. Interestingly, the thalamic input appears to be slightly better matched binocularly than the cortical input (thalamic $\Delta O = 35.9 \pm 6.3°$, cortical $\Delta O = 49.4 \pm 6.6°$, $n = 15$). Further experiments and analysis are ongoing to investigate the relative contributions of thalamocortical and intracortical circuits in the matching process. Together, our experiments will begin to reveal the synaptic and circuit mechanisms of how critical period plasticity matches eye-specific inputs in the cortex to achieve normal binocular vision.

Title: Basal forebrain projections to different rat visual cortical areas

Authors: F. HUPPÉ-GOURGUES, K. JEGOUIC, S. BOUHABEL, *E. H. VAUCHER; Univ. of Montreal, Montreal, QC, Canada

Abstract: Acetylcholine is an important neurotransmitter for the regulation of the visual attention, plasticity and perceptual learning. The acetylcholine is released in the visual cortex predominantly by the cholinergic fibers projecting from the basal forebrain. The stimulation of this region may provide a beneficial potentiation of visual processes. However, little is known about the topographical organization of these basalocortical projections, i.e. if there are fine topographical projections from the different basal forebrain nuclei to the primary and secondary visual cortical areas. The aim of this study is to map these basalocortical projections. Small injections of retrograde tracers (fluorescent cholera toxin b fragment) in different quadrants of the primary and secondary visual cortex of long Evans rats were performed (n=8). The retrogradely labelled cell bodies in the nucleus basalis, substantia innominanta and diagonal band of Broca were mapped ex-vivo with a computer-assisted microscope stage controlled by stereological software suite (Microbrightfield). Choline acetyltranferase immunohistochemistry

was used to identify cholinergic cells. Our results show a predominance of projections coming from the horizontal band of Broca's neurons. The projections were not clearly topographically organized, each location of the nucleus innervating every cortical areas observed. Our preliminary results confirm that these cells are cholinergic. The absence of a clear topography of the horizontal band of Broca projections to the visual cortex opens the possibility to stimulate a large cortical region upon stimulation of the cholinergic cells of the horizontal limb of the diagonal band of Broca.

Title: The entropy of neural ensemble firing patterns in mouse primary visual cortex correlates with behavioural performance

Authors: *M. TOLKIEHN, A. BERDITCHEVSKAIA, S. R. SCHULTZ;
Imperial Col. London, London, United Kingdom

Abstract: Simultaneous in-vivo electrophysiological recordings in populations of neurons are a widespread technique to investigate neural activity. To this end there has been much research into single cell properties and their link to behavioural outcome, whilst the contribution of statistical properties of cell assembly firings has been neglected. A prominent model to examine this is mouse primary visual cortex (V1), as it is located at an early cortical processing stage, allowing us to relate neural activity to the stimulus more directly.
To investigate how simultaneously recorded activity patterns relate to task performance, we trained head-fixed, water-restricted mice to respond to vertical and horizontal moving gratings, which were associated with a positive reinforcement (water supplement) or a punishment (air puff to flank). This paradigm required the mouse to initiate a response (lick) or to withhold a lick. Analysis of Multi-Unit-Activity (MUA) recorded by in-vivo multi-shank multi-laminar electrophysiology in V1 of the awake behaving animal indicated a correlation between task

performance and spatial pattern distribution. In particular, the results reveal a negative correlation between (spatial) pattern entropy and the animal's task performance. In addition, response clusters for correct responses appear closer in high performance regimes, particularly for correct decisions (True Positive, True Negative). This means the pattern dissimilarity, estimated with Jensen-Shannon Divergence, decreases at higher accuracy levels. Independent Poisson surrogate data are able to capture this to an extent, but fail to fully explain this relation, which suggests this relationship cannot be explained by firing rate differences alone. The entropies in surrogate data seem to slightly exceed those of the real data ($p<=0.001$ signed rank), and the JS divergences of the surrogate data consistently underestimate those of real data ($p<0.001$, signed rank). To understand what additional features may explain this relationship, we fit (Energy-based) models that allocate a probability to each observed spatial firing pattern. Our results show that including couplings between sites increases the likelihood of our data over the independent model by around 0.2 bit/spike, while also decreasing the divergence between empirical and model distribution. This suggests that laminar interactions in V1 may play a role in behavioural performance.

Title: Sculpting the dynamics of neuronal networks in the mouse cortex with optogenetic tools

Authors: T. TSUBOTA, D. LYAMZIN, *A. BENUCCI;
RIKEN Brain Sci. Inst., Wako City, Saitama, Japan

Abstract: The fine tuning of the connectivity patterns among neurons is what confers upon them the computational power needed to perform complex operations. However, the biological processes underlying such changes are not fully understood. Spike-timing dependent plasticity (STDP) has been hypothesized to play a key role, but whether or not and to what extent STDP can indeed change the functional architecture of cortical networks in adult animals is largely unknown.

Here we used an in-vivo preparation for simultaneous optogenetic stimulation and two-photon imaging of neuronal populations in awake mice. We expressed a red-shifted channelrhodopsin (ChrimsonR) in excitatory neurons in the dorsal cortex of mice (n=3 animals). We then used a digital micro-mirror device (DMD) for spatially patterned excitation of ChrimsonR-expressing cells. We paired DMD stimulation of an individual cell (the driver) with a delayed stimulation (10ms) of several tens of nearby cells (the followers) to induce driver-followers STDP. Using two-photon GCaMP imaging we studied the population dynamics of the followers after the driver's firing, either induced by optogenetic stimulation or occurring during spontaneous activations, and compared the neural dynamics before and after the pairing protocol.
We found that the responses of the followers (n=128 cells) changed in a complex fashion. After paired stimulation, the correlation strength with the driver increased in some cells (45%), at various time-lags, while it decreased in others (33%). Other neurons (22%) were mostly unaffected. To understand this heterogeneity at the network level, we studied the population responses in a reduced dynamical space using principal-component analysis (PCA). In this representation, the network dynamics showed consistent changes across animals; the dynamics of the followers became closer to that of the driver cell after optogenetic pairing. Strikingly, these effects persisted also for a few hundreds of milliseconds after spontaneous firings of the driver.
In conclusion, our methodology provides an effective in-vivo experimental tool to study activity-dependent functional changes in cortical networks of adult animals. Preliminary results demonstrate that although changes induced by paired optogenetic stimulation are diverse at the level of single cells, the overall population dynamics has a tendency to be "attracted" toward the dynamics of the driver cell. Such optogenetic-induced changes might reflect a STDP-based dynamic mechanism of synaptic-weight scaling aiming to efficiently process information in view of novel behavioral demands.

Abstract: In an effort to understand the full diversity of cell types in mouse primary visual cortex (V1), the Allen Institute for Brain Science established an in vitro single cell characterization pipeline, designed for the collection of electrical and morphological properties from 100s -1000s of neurons.
Selectivity and coverage across cell types has been maximized by targeting both Cre-positive and Cre-negative neurons for patch recordings and biocytin labeling in layer- and interneuron-selective Cre mouse lines. A subset of neurons with electrical recordings were reconstructed in 3D. Dendrite only reconstructions were prioritized for spiny, pyramidal neurons, while full reconstructions of both dendrites and local axon were prioritized for aspiny and sparsely spiny interneurons. Both qualitative and quantitative approaches have been pursued to understand the range of morphological types that exist in V1. Qualitative analyses provide a benchmark dataset to which more rigorous quantitative analyses can be compared. Thus far most of the previously described rodent V1 types have been observed in our dataset. Morphological types are also compared to quantitatively identified electrical types. For particularly unique types, such as neurogliaform cells, we see very good correspondence, and in most cases electrical types support morphological types. Recently we have also begun comparing morpho-electrical types to transcriptomically-defined types (Tasic et al., Nature Neuroscience, 2016). Together these analyses will be used to establish a comprehensive, multimodal taxonomy of neurons in mouse V1. These data are all made publicly available on our Allen Institute Cell Types Database (www.brain-map.org).

Title: Behavioral state modulates 3-5 Hz membrane potential oscillations in mouse visual cortex.

Authors: *M. EINSTEIN[1], P.-O. POLACK[3], P. GOLSHANI[2];
[1]Neurol., UCLA, Playa Del Rey, CA; [2]Neurol., UCLA, Los Angeles, CA; [3]Rutgers Univ., Newark, NJ

Abstract: 3-5 Hz oscillations in visual cortex have been implicated as important during reward expectation and working memory. Here, we demonstrate the underlying membrane potential changes that drive local field potential changes in primary visual cortex (V1) during 3-5 Hz oscillations by measuring the membrane potential (Vm) from V1 L2/3 excitatory, PV+, and SOM+ neurons of awake and behaving mice. During oscillation epochs, excitatory neurons reduced their spontaneous and visually evoked firing rate while PV+ and SOM+ inhibitory neurons fired rhythmically with each cycle of the oscillation. 3-5 Hz oscillation timing was also drastically different when animals were passively viewing stimuli versus when they engaged in a visual discrimination task. But, when animals performed a similar non-visual discrimination task, oscillations were rare. Altogether, our results indicate that 3-5 Hz oscillations decrease the gain of excitatory neurons, and oscillation recruitment relies on both visual stimulation and an animal's internal state. Our findings suggest that 3-5 Hz oscillations may act as a mechanism to decrease visually evoked L2/3 cortical neuron firing rates, potentially to prevent interference of the sensory driven responses with internally generated representations.

Title: Invariant and abstract perceptual representations in mouse decision-making

Authors: *R. AOKI, D. LYAMZIN, M. ABDOLRAHMANI, M. J. MORAIS, A. BENUCCI; RIKEN Brain Sci. Inst., Wako City, Saitama, Japan

Abstract: The ability to form abstract perceptual representations that are invariant to physical transformations of sensory stimuli (e.g. size, luminance, etc) is a hallmark of primate high-level cognition. Such ability is critical to efficiently interact with a continuously changing natural environment, but little is known about its neural basis.
To study this problem, we trained mice in a visual decision-making task that required the animal's ability to form an abstract and invariant representation of a stimulus' orientation. More specifically, in a two-alternative forced choice task, the animal had to choose which of two grating stimuli was more vertical. Crucially, neither of the orientations were vertical.
To train the mice in this complex task, we used a fully-automated training setup for voluntary head fixation which allowed us to train ~30 mice/day (10^4 trials/day). During the time course of 3-4 weeks, mice increased their performance (n = 4 mice), with evidence for both procedural and perceptual learning, as quantified by a decrease in lapse rate (84% ± 6%, $p < 0.05$) and bias (74% ± 9 %, $p < 0.05$), and an increase in sensitivity (76% ± 19 %, $p < 0.05$) of the psychometric curves from naïve to expert animals (> 85% correct rate).
To verify the hypothesis that mice solved this task by resorting to an abstract and invariant representation of the target orientation, we demonstrated that mice did not utilize low-level features e.g. local luminance or contrast, nor memorized the luminance patterns. Moreover, the performance remained unchanged when introducing novel orientations or when changing the spatial frequency of the gratings. Finally, mice trained with a horizontal target orientation performed equally well.
Taking advantage of our automated setup for voluntary head fixation, we are combining behavioral observations with wide-field GCaMP imaging of all 10 retinotopically identified visual areas. Preliminary results reveal a significant correlation between the GCaMP signal and several learned task-related events.
In conclusion, our results strongly constrain the pool of possible functional principles underlying this cognitive task, and suggest a more fundamental, robust mechanism that can be conserved even across dramatic differences in putative neural resources, as evident in view of the three orders of magnitude fewer neurons in the mouse relative to the primate brain.

Title: Identification of neuronal ensembles from primary visual cortex *In vivo* using probabilistic graphical models

Authors: *S. HAN[1], L. CARRILLO-REID[1], E. TARALOVA[1], T. JEBARA[2], R. YUSTE[1]; [1]Biol. Sci., [2]Computer Sci., Columbia Univ., New York, NY

Abstract: The coordinated firing of neuronal populations is considered to be the substrate of sensory, behavioral and cognitive functions. In particular, neuronal ensembles in primary visual cortex represent specific features of visual stimuli. However, how the functional connectivity in local microcircuits relate to their function has been difficult to elucidate *in vivo*. The development of recording and stimulation techniques with single cell precision has opened the possibility of testing the function and computation principles of cortical ensembles during physiological processes. To address these questions, it is necessary to identify online the most representative elements from a given neuronal ensemble. Here we used two-photon calcium imaging to record the responses to drifting gratings of layer 2/3 neurons in primary visual cortex of awake behaving mice, and then applied probabilistic graphical models to find the most representative neurons from each cortical ensemble. We demonstrate that the activity of the most representative neurons identified from each cortical ensemble is sufficient to predict a given visual stimuli. We anticipate that our approach will allow the design of close-loop two-photon optogenetic experiments with single cell resolution to test the physiological role of cortical ensembles during behavioral tasks.

Title: Cholinergic modulation of an inhibitory microcircuit changes dendritic integration after the visual critical period

Authors: *C. E. YAEGER, K. L. KWAN, J. T. TRACHTENBERG;
Neurobio., UCLA, Los Angeles, CA

Abstract: We find that changes in cholinergic input to somatostatin-expressing (SST) interneurons alters dendritic encoding of layer 5 excitatory neurons. Using fast resonant scanning two-photon microscopy in combination with genetically-encoded calcium indicators, layer 2/3 inhibitory interneurons and apical dendrites of layer 5 excitatory neurons were imaged in the primary visual cortex of awake, behaving mice during the visual critical period (p28) and after critical period closure (p60). While SST cells responded to visual stimulation in both groups of awake behaving mice, there was a divergence in SST response between age groups during locomotive events: during the critical period, SST cells are active during movement, but in adults, SST cells are suppressed. These findings were corroborated with slice recordings of SST interneurons and cholinergic stimulation. Furthermore, SST cells target layer 5 pyramidal cell apical dendrites, and local dendritic calcium events were also altered depending on the age and activity of the mouse: during the presence of greater inhibition from SST interneurons, more local dendritic calcium events occurred. This age-dependent shift in dendritic coding is expected to contribute to the large-scale plasticity characteristic of the juvenile cortex.

Title: PV interneurons in visual cortex control contrast sensitivity and spatial integration of pyramidal cells

Authors: *M. FIORINI[1,2,3], S. ERISKEN[1,2,3], A. VAICELIUNAITE[1], O. JURJUT[1], S. KATZNER[1], L. BUSSE[1,3];

Abstract: In primary visual cortex (V1), the largest neuronal population mediating GABAergic inhibition is represented by fast-spiking parvalbumin-positive interneurons (PV+ INs). Previous studies suggested that PV+ INs influence low-level visual processing by controlling contrast gain and shaping spatial integration of pyramidal cells. Interestingly, altered contrast perception and spatial integration are associated with schizophrenia, where one theory proposes that hypofunctioning NMDA-glutamate receptors (NMDAR) might cause deficient excitatory drive to PV+ INs (Marin, 2012). Following this model, we investigated whether selective ablation of NMDAR in PV+ INs was sufficient to alter sensory processing at early stages of the visual pathway.
We crossed PV-Cre mice with mice carrying floxed alleles of the obligatory NMDAR NR1 subunit and compared visual responses between transgenic (NR1-PVCre$^{-/-}$) and control animals. We recorded extracellular single unit activity from V1 and dorsolateral-geniculate nucleus (dLGN) of head-fixed mice placed on a spherical treadmill. For the analysis of neural activity, we concentrated on periods in which animals were stationary. Based on spike wave-shapes, we classified V1 neurons as broad- or narrow-spiking.
To assess how the reduction of NMDAR-mediated PV+ excitation changes baseline response properties in the V1 population, we first considered spontaneous activity. As expected, NMDAR ablation in PV+ INs led to lower firing rates in narrow-spiking and higher firing rates in broad-spiking neurons. We then restricted our analyses to broad-spiking, putative excitatory neurons and probed the role of NMDAR in PV+ INs for spatial integration: we observed that receptive field center sizes of V1 cells in mutants were smaller as compared to controls, and suppression strength was increased. Since it is well known that spatial integration depends on stimulus contrast, we tested the hypothesis that NMDAR dysfunction in PV+ INs could contribute to the processing of contrast. We found that broad-spiking V1 cells in NR1-PVCre$^{-/-}$ mice had significantly higher contrast sensitivity across all cortical layers as compared to controls. This increase in sensitivity seems to be a cortical phenomenon as contrast responses were similar between genotypes for neurons in dLGN.
Together, our results demonstrate a critical role of PV+ INs for shaping contrast sensitivity and spatial integration of pyramidal cells. We speculate that reduced glutamatergic excitation of cortical PV+ INs increases the effective stimulus drive in the V1 network, which in turn translates into a regime of more focused spatial integration.

Title: 2-photon imaging of task-dependent cortical population dynamics during a visual discrimination

Authors: *J. B. WEKSELBLATT, R. D. DI RICCO, C. M. NIELL;
Biol., Univ. of Oregon, Eugene, OR

Abstract: Neuronal responses in primary visual cortex (V1) are modulated by behavioral relevance. We sought to understand how information about specific features relevant to a task are encoded across populations of neurons. We therefore performed recordings of activity evoked by identical visual stimuli while mice performed one of two visual discrimination tasks (an orientation discrimination or a spatial location judgment) as well as during passive viewing of these same stimuli. 2-photon imaging using a transgenic mouse, expressing GCaMP6s in excitatory neurons throughout cortex allowed us to measure activity in hundreds of neurons simultaneously in order to extract the tuning properties of individual neurons as well as the dynamics of large ensembles on individual trials.
In these experiments, head-fixed mice were trained on a 2-alternative forced choice behavior to report either the orientation or location of a square-wave grating patch, using their direction of locomotion on a freely rotating track ball. Widefield imaging showed dramatic changes in mesoscopic response patterns over the course of learning the task. Once mice achieved a threshold level of performance, we imaged responses of hundreds of simultaneously recorded neurons in the functionally defined region of V1 representing the stimulus locations, during the behavioral tasks and during passive viewing of the same stimuli. Neurons in layer 2/3 of visual cortex show diverse coding properties including both classical orientation selective responses as well as non-specific suppression of responses based on retinotopic location. Analysis of population-wide encoding revealed dramatic shifts in large-scale dynamics with engagement in specific tasks. These findings extend our understanding of how encoding of visual stimulus

properties is integrated with task-related cortical dynamics.

Title: Neuromodulatory axon activity in the visual cortex

Authors: *R. S. LARSEN, J. ZHUANG, D. OLLERENSHAW, T. DAIGLE, J. WATERS; Neural Coding, Allen Inst. For Brain Sci., Seattle, WA

Abstract: Visual cortical neuron responses are strongly influenced by behavioral state. Neuromodulatory projections from subcortical nuclei have been hypothesized to be important in modulating cortical responses to various behavioral states, but how and when these systems influence the visual cortex is just beginning to be understood. Previous studies have demonstrated that cholinergic, noradrenergic, and serotonergic projections innervate the visual cortex. To study the influence of these projections during visually-guided behavior, we sought to achieve widespread expression of the genetically-encoded calcium sensor GCaMP6 in neuromodulatory axons which innervate the visual cortex. We found that reporter mice expressing Cre-dependent GCaMP6 from the ROSA-26 allele drove only weak expression of GCaMP6 in neuromodulatory axons in the visual cortex. Similarly, triple transgenic mice expressing a neuromodulatory Cre, Cre-dependent tTA, and a tetO promoter-driven GCaMP6 from separate alleles failed to express any GCaMP6 in the somata of some neuromodulatory cell types. In contrast, recently developed Ai148 (TIT2L-GCaMP6f-tTA2) reporter mice which drive both Cre-dependent GCaMP6 and tTA expression from the TIGRE locus resulted in enhanced GCaMP6 labeling in neuromodulatory axon types when these reporter mice were crossed to neuromodulatory Cre lines, such as Chat-IRES-Cre. We have utilized these new tools to correlate mouse behaviors with the activity of neuromodulatory axons both across cortical areas using widefield imaging, and with cellular resolution using *in vivo* 2-photon imaging of the

cortex of awake mice. By imaging the activity of neuromodulatory projections into the visual cortex during behavior, we aim to determine mechanisms for how the cortex modulated by changes in behavioral state.

Title: Robust electro-physiological type identification using co-clustering analysis of clustering tree

Authors: ***C. LEE**[1], N. GOUWENS[1], K. LEPAGE[1], V. MENON[1], T. BAKKEN[2], S. SUNKIN[3], A. ARKHIPOV[1], M. HAWRYLYCZ[1];
[1]Modeling, Analysis, and Theory, Allen Inst. For Brain Sci., Seattle, WA; [2]Human Cell Types, [3]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Identification of neuronal cell-types is one of the most fundamental step toward understanding and modeling of neuronal activity. As a part of our cell-type identification effort at the Allen Institute for Brain Science, we present a fully data-driven approach to a robust electro-physiological (ephys) type neuronal identification in the mouse primary visual cortex (V1) using transcriptomics, morphology, and ephys data.
1111 neurons were collected from V1 over all layers using 12 Cre-lines. The recordings are made with various stimuli to characterize their ephys properties. Overall 311 features including single action potential features, action potential train features, and cell level ephys features were calculated. Clustering trees were built by iterative PCA or by Gaussian mixture model. Robust cluster assignment was made by co-clustering analysis over multiple clustering runs using a 10 fold cross validation resampling strategy. Applying these methods to an initial data set collected from mouse V1 resulted in 10 cluster clustering tree. The initial branch separated inhibitory and excitatory neurons. Subsequent branches further distinguished the clusters into 3 fast spiking, 2 moderate width spiking, and 5 regular spiking groups. These groups were also assessed by comparing intrinsic ephys properties, cortical layer, and Cre-line composition to other cell-type classifications of cortical neurons previously reported in the literature. These comparisons with earlier studies revealed areas for further investigation and refinement. Keywords : Cell-type, Ephys-type, Clustering, Co-clustering, iterative PCA, Gaussian mixture model

Title: A modern approach to labelling and visualizing the central visual pathway

Authors: ***J. L. BALSOR**, K. M. MURPHY;
McMaster Integrative Neurosci. Discovery and Study, McMaster Univ., Hamilton, ON, Canada

Abstract: Recent tissue clearing protocols provide exciting opportunities for studying connections from the eye to the brain. There is a problem, however, combining pathway tracing with the see-through brain because traditional tracers (e.g. proline, WGA-HRP) are not compatible with tissue clearing. Here we describe a simple and reliable solution that takes advantage of a new tracer using wheat germ agglutinin labelled with a fluorescent dye (CF dyes, Biotium Inc.). WGA is actively taken up by retinal ganglion cells, anterogradely transported to LGN and superior colliculus, and moves trans-synaptically to label inputs to visual cortex. The fluorescent dye is water soluble, highly photostable, bright and comes in a rainbow of 20 colours from blue (350nm) to far-red (770nm).Our protocol combines eye injections with CF dye-labelled WGA and PAssive Clarity Technique (PACT) to visualize the central visual pathway. We did an injection of 5% CF dye-labelled WGA (CF770R or CF680R) into the posterior chamber of each eye. The timeline was: injections on days 1 and 3, then perfusion with PBS on day 5. The retinae were removed and imaged to verify labelling of retinal ganglion cells. Both cortical hemispheres were resected, then unfolded and flattened by removing white matter and making a medial and lateral cut to relieve the intrinsic curvature. The cortex was gently flattened between glass slides and fixed in 2% PFA for 30 minutes. A dissection was done to remove the intact subcortical visual pathway, including optic nerves, optic radiations, LGNs and superior colliculi. This was post-fixed in 2% PFA at 4°C for 5 hours. The PACT procedure was used to clear the tissue. Briefly, tissue was placed in a hydrogel monomer solution (4% acrylamide) and incubated at 4°C for 2 days, then polymerized at 37°C for 5 hours and cleared with a mild detergent (8% SDS) at 37°C until tissue was transparent (range 4-14 days). We did regular low magnification imaging using LiCor Odyssey NIR Scanner to see labelling before, during and after clearing. We found bright labelling of the visual pathway at all stages, including before

tissue clearing. As the tissue cleared more details of the pathway became apparent. These features include layers in LGN, and patches in colliculus and visual cortex. We also did high magnification imaging using confocal microscopy and found lots of vesicularly packaged label in axons, dense clumps of label at presumptive synapses but no label in blood vessels.This modern protocol is fast and easy, plus the label is compatible with cutting-edge techniques (super resolution), making it ideal for studies spanning questions from nano- to macroscales.

Title: Interneurons derived from the caudal ganglionic eminence are preferentially connected to callosal projecting pyramidal cells in deep cortical layers

Authors: *J. C. WESTER[1], C. J. MCBAIN[2];
[2]NICHD, [1]NIH, Bethesda, MD

Abstract: Inhibitory interneurons are crucial regulators of cortical activity, acting to gate the flow of excitatory activity and regulate network oscillations. Although highly diverse, cortical interneurons can be segregated into two non-overlapping subgroups based on their embryonic lineage from either the caudal or medial ganglionic eminences (CGE and MGE). Similarly, cortical excitatory principal cells (PCs) can be segregated based on the target of their long-range axonal projection: those projecting to cortex/striatum (intratelencephalic ICPNs) and those projecting to the brainstem, thalamus, and spinal cord (subcerebral SCPNs). ICPNs and SCPNs form local parallel overlapping microcircuits and recent evidence indicates that they may be differently regulated by CGE or MGE interneurons. Here, we tested the hypothesis that CGE-derived interneurons and ICPNs form preferential synaptic connections. We used dual whole-cell patch clamp recordings to test for synaptic connections in layer 5 of mouse visual cortex, where ICPNs, SCPNs, and CGE- and MGE-derived interneurons are intermingled. We used the *Htr3a*-GFP mouse line to target CGE-derived interneurons, and retrobead injections into the contralateral visual cortex or ipsilateral superior colliculus to target ICPNs or SCPNs,

respectively. We found that CGE-derived interneurons indeed formed synaptic connections onto ICPNs with greater probability than SCPNs, but in both cases was low (7% vs. 3% connectivity). Interestingly, the most striking difference was the connectivity from PCs to interneurons. Specifically, the probability of finding an excitatory synaptic connection from an ICPN to a CGE-derived interneuron was 11%, compared to 0% for SCPNs. In order to confirm the apparent absence of excitatory input from SCPNs, we injected g-deleted rabies encoding channelrhodopsin (ChR2) and the fluorophore mCherry into superior colliculus. Optical excitation of a local population of SCPNs resulted in only 4 of 14 CGE-derived interneurons exhibiting monosynaptic excitatory input, which was on average less than 10 pA in amplitude when observed. Thus, SCPN input onto CGE-derived interneurons exists but is very sparse and weak. Finally we used paired whole-cell recordings to test synaptic connectivity in layer 2/3, where all PCs are ICPNs and CGE interneurons are in the majority compared to those from the MGE. We found that CGE interneurons innervated PCs with a probability of 12%, and PCs innervated CGE interneurons with a probability of 23%. Thus, excitatory drive from ICPNs to CGE-derived interneurons is prevalent throughout cortical layers and likely represents an important canonical circuit motif.

Title: Learning changes the selectivity and interactions of GABAergic interneuron classes in visual cortex

Authors: *J. POORT[1], A. G. KHAN[2], A. BLOT[2], S. B. HOFER[2], T. D. MRSIC-FLOGEL[2]; [1]Univ. Col. London, London, United Kingdom; [2]Biozentrum, Basel, Switzerland

Abstract: Neural representations of sensory stimuli can be modified by experience. In the mouse primary visual cortex (V1), responses become increasingly selective when animals learn the behavioural relevance of visual stimuli. However, it is unclear how learning reorganises the activity of the different cell types, including excitatory pyramidal (PYR) neurons and different classes of GABAergic interneurons. Although pyramidal cells provide the output from the local circuit to other cortical areas, different interneuron classes can inhibit pyramidal cells as well as each other, and thus exert a powerful influence on circuit activity. To understand how learning changes the responses and co-activation patterns of the different cell types, it is necessary to measure their activity at the same time.

We used two-photon calcium imaging of GCaMP6f signals to record responses of neuronal populations in layer 2/3 of V1 as mice learned to discriminate two visual patterns while running through a virtual corridor, by selectively licking in response to only one of the patterns to obtain a reward. After the behavioural experiments we co-registered immunostained brain sections with in-vivo recording sites to identify simultaneously imaged parvalbumin (PV), somatostatin (SOM) and vasoactive intestinal peptide (VIP) interneurons.

Within and across cell classes, neurons exhibited a large degree of heterogeneity in their responses to the task-relevant stimuli, as well as how the amplitude of their responses changed with learning. Response selectivity for task relevant stimuli increased preferentially in PYR and PV cells. Interestingly, PV cells became as selective as PYR cells after learning. Moreover, response correlations decreased over learning not only between cells belonging to the same class, but more strikingly, between cells from different classes. SOM cells in particular exhibited a marked reduction in correlations with all other cell classes, and a subset developed negatively correlated activity fluctuations with VIP and PV cells.

To determine whether these changes were specific to learning, we trained the same mice to switch between attending to or ignoring the visual stimuli. Although we observed comparable changes in selectivity, we found that learning and attentional switching modulated responses in different sets of PYR cells, and that attentional switching, in contrast to learning, was not associated with strong reductions in correlated activity. These results demonstrate how learning the behavioural relevance of visual stimuli leads to specific and concerted changes in the selectivity and co-activation patterns across multiple cell classes.

Title: How does behavioral relevance affect neural responses in mouse primary visual cortex and thalamus?

Authors: *A. WAL[1,2], A. VAICELIUNAITE[1], P. GEORGIEVA[1], L. BUSSE[1,3], S. KATZNER[1]; [1]Ctr. For Integrative Neurosci., Univ. of Tuebingen, Tuebingen, Germany; [2]Grad. Sch. of Neural and Behavioural Sci., Intl. Max Planck Res. Sch., Tuebingen, Germany; [3]Div. of Neurobiology, Dept. Biol. II, LMU Munich, Munich, Germany

Abstract: In the mouse early visual system, neural responses can reflect the behavioral relevance of a visual stimulus (Poort et al., 2015; Wimmer et al., 2015). Current work aims at understanding the circuit-level mechanisms, by which behavioral relevance can shape sensory processing. Here, we ask how behavioral relevance affects responses of inhibitory interneurons in primary visual cortex (V1). In addition, we ask whether it can influence sensory responses already at the level of the dorsolateral geniculate nucleus (dLGN). We designed a visual foraging paradigm, in which two stimuli provide identical drive to V1 neurons, but differ in reward contingencies. Head-fixed mice were placed on a spherical treadmill, where they could start a trial by moving forward. The stimuli consisted of a single drifting grating, which could appear either behind a square or diamond aperture. For one stimulus, mice could earn a fluid reward by running for an additional 4 s; the other stimulus had no consequences. At any point in time, mice could reject a stimulus by slowing down and thereby terminate the current trial. We recorded extracellular activity with multi-contact silicon probes spanning the depth of V1 or dLGN. In a passive viewing condition, we measured sensory responses to the two stimuli outside the context of the task. We used these measurements to exclude from further analyses all neurons that showed any difference in their sensory response to the two stimuli. We recorded, during task performance, from ensembles of V1 neurons and used optogenetic tagging to identify inhibitory interneurons expressing parvalbumin (PV+). We compared responses to the two stimuli within a time window of 500 ms following stimulus onset, and identified two classes of neurons: some increased the stimulus-driven response if the animal could earn a reward (‘positive modulation’), others if there was no prospect of reward (‘negative modulation’). Identified PV+ neurons tended to show negative modulation. Responses of putative pyramidal cells, on the other hand, seemed more balanced, showing positive as well as negative modulation. These cells were spread across

the depth of cortex, including the thalamo-recipient layer 4. Consistent with such a laminar pattern, we found that task performance already modulated responses of dLGN neurons. Our findings show that the visual foraging paradigm can be used to manipulate behavioral relevance while keeping the sensory input for single neurons constant. These manipulations can affect sensory processing within the mouse early visual system, potentially including inhibition by PV+ interneurons and thalamic responses.

Title: Generation of biophysically-detailed models that reflect diverse intrinsic properties of cortical neuron types

Authors: ***N. W. GOUWENS**, J. BERG, T. DESTA, D. FENG, T. FLISS, K. GODFREY, T. JARSKY, C. LEE, S. SORENSEN, S. SUNKIN, Z. ZHOU, A. BERNARD, C. DANG, L. NG, H. PENG, J. PHILLIPS, H. ZENG, M. HAWRYLYCZ, C. KOCH, A. ARKHIPOV;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Cortical neurons exhibit a variety of intrinsic electrophysiological properties that can shape their roles in the cortical circuit. Network models built to investigate these effects on cortical processing require models of individual neurons that reflect this diversity across cell types. To address this need, we have used the experimental data contained in the Allen Cell Types Database to construct biophysically detailed models that reproduce the characteristics of action potential firing of individual neurons. These models are based on whole-cell electrophysiological recordings from mouse visual cortical slices, as well as the 3D morphologies reconstructed from biocytin fills of the same cells. The majority of the recorded cells were labeled by a variety of Cre driver lines, including ones that exhibit enriched expression in specific cortical layers. We fit the models using the NEURON simulation environment by placing at the soma a set of ~10 mechanisms describing active conductances and intracellular calcium dynamics, then adjusting the densities of these mechanisms via a genetic algorithm until 12 firing property features (e.g., action potential width, action potential peak, average firing rate) matched the original experimental data. We identified a standardized set of techniques that produced well-fit models reliably across our data set, which encompassed a

variety of firing patterns and dendritic morphologies. We also automated these techniques with open-source software packages, including the Allen Software Development Kit (AllenSDK). Models fit by these methods generalized well to a variety of stimuli, such as noisy current injection and current ramps, which we assessed by comparing the model to responses from the recorded cells evoked by identical stimuli. In addition, we used unsupervised clustering methods on the broader Allen Cell Types Database to identify data-driven classes based on electrophysiological properties. We found that the models could be reliably assigned by a supervised learning method to the classes of the original cells, suggesting that our model set preserves diversity in intrinsic properties found experimentally. Finally, we have made these 150+ models publically available online, in addition to providing the source code to run them as part of the AllenSDK.

Title: Circuit models with multiple types of inhibitory neurons based on a brain-wide map of cell density

Authors: ***G.-Y. R. YANG**[1], L. C. GARCIA DEL MOLINO[1], Y. KIM[2,3], P. OSTEN[2], X.-J. WANG[1,4];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Cold Spring Harbor Lab., Cold Spring

Harbor, NY; [3]Penn State Univ., Hershey, PA; [4]NYU-ECNU Joint Inst. of Brain and Cognitive Sci., Shanghai, China

Abstract: The brain consists of various types of interneurons that differ in their morphology, physiology, and connectivity. In the mammalian cortex, 80% of all interneurons are accounted by three major non-overlapping cell types: neurons expressing parvalbumin (PV), somatostatin (SST), or vasoactive intestinal peptide (VIP). The physiological properties of single interneurons are relatively well known at this point. These interneurons form a canonical circuit motif that was recently mapped in several areas. Yet the dynamics of such an interneuronal circuit is-as we show-far from being well understood.

In particular, the circuit dynamics depend critically on the cell density of each type of interneuron. For one type of neuron, having a higher density can lead to stronger output connections on the population level. We quantitatively measured the density of PV-, SST-, and VIP-expressing interneurons across the whole mouse brain (Kim et al. SFN 2015). Our data show that the density of each type of interneuron varies greatly across cortical areas, with the PV neuron density varying more than five-fold, and SST-neuron density more than three-fold.

We investigated the functional implications of this density variation in both simple population-based models and biological-realistic spiking neural circuit models. Through numerical simulation and mathematical analysis, we found that varying the density of interneurons can have counterintuitive impacts on the circuit dynamics. Specifically, we studied the effective connectivity and synaptic current from one class of neuron to another. One paradoxical effect we uncovered, for example, was that when external inputs target PV neurons, elevating the density of SST neurons will decrease the effective connectivity yet increase the synaptic current from PV to excitatory neurons.

Connecting these local circuits through quantitative long-range connections, we built a large-scale dynamical circuit of the mouse cortex. We report that the uneven interneuron density across cortex greatly alters the functional connectivity between areas, including stronger functional couplings within frontal areas. This finding suggests that models of large-scale cortical circuits need to take into account the heterogeneity of interneurons across areas.

Title: Cortical microcircuit endowed with three interneuron subtypes exhibits a repertoire of multiple dynamical regimes.

Authors: *L. GARCIA DEL MOLINO, G. R. YANG, X.-J. WANG;
New York Univ., New York, NY

Abstract: Recent anatomical studies in mice have revealed a recurrent pattern in the connectivity among excitatory pyramidal neurons and three major subpopulations of inhibitory neurons expressing parvalbumin, somatostatin or vasoactive intestinal peptide, respectively. Dissecting the dynamics of this canonical microcircuit is essential to our understanding of the mammalian cortex.
To this goal, we built a computational model that reproduces accurately the single-neuron behavior of each class of neurons based on physiological data and used it to study the impact of different connection weights on the collective circuit dynamics. We explored systematically the connectivity space and analyzed the network behavior for both spontaneous and input driven activity. We find that, in comparison with classical networks composed of one excitatory and one inhibitory population, networks with several classes of interneurons have a much richer repertoire of dynamical behaviors, some of them highly counterintuitive. For example, under certain condition
We conducted a systematic mathematical analysis of a simpler neuronal model that predicts and explains our observations, showing that they are reproducible and robust.
This new network paradigm opens a new playground for studying recurrent neuronal network dynamics. Our work also provides suggestions and predictions for future experiments on systems that include multiple interneuron populations.s for the circuit connections, the activity of the excitatory population may decrease with an increase in its external input.

Title: Stimulus-specific response enhancement in mouse primary visual cortex depends on locomotion

Authors: *M. KANEKO[1], Y. FU[2], M. P. STRYKER[1];
[1]Physiol. and Ctr. for Integrative Neurosci., Univ. of California, San Francisco, CA; [2]Singapore Bioimaging Consortium, Agency for Sci. Technol. and Res., Singapore, Singapore

Abstract: Many experiments have found that responses in adult mammalian visual cortex are stable over long periods. Direction selectivity is the only property widely reported to be malleable (Wu *et al.*, *J Neurosci*, 2011), but evoked potential recordings through implanted electrodes in adult mice are reported to reveal a rapid and persistent increase in response to repeated stimuli (Frenkel *et al*., Neuron, 2006; Cooke & Bear, *J Neurosci*, 2010). Here, we used intrinsic signal imaging through the intact skull, a completely non-invasive technique, to investigate whether repeated exposure to specific stimuli would enhance visual responses in adult mouse primary visual cortex (V1). After acclimating to the setting, wild type adult (postnatal day 70 - 90) C57B6/J mice were allowed to run on Styrofoam balls floating on air while viewing one of three different, high-contrast visual stimuli 2 hours per day for 5 days, as described previously (Kaneko and Stryker, *eLife*, 2014). We found that V1 responses to the stimuli that were viewed by the animal were specifically enhanced, leaving responses to other stimuli unaffected. The enhancement was prevented by an NMDA receptor antagonist and persisted for at least a week following cessation of 10 days of stimulus exposure. Similar exposure in mice that were not walking or running did not significantly enhance responses. When animals were given little opportunity for locomotion, the response enhancement was observed in mice walking for only 40 - 60 minutes over 10 days.

To start to understand cellular mechanisms underlying this enhancement, we followed responses of single neurons in layer 2/3 before and after the daily exposure to one of 8 different directions of drifting gratings with 2-photon calcium imaging using virus-mediated GCaMP6s expression. In majority of cells, the response magnitude to the exposed orientation was significantly increased, while that to the orthogonal orientation was unchanged. Moreover, the preferred orientation in most cells that were originally selective for orientations near the one to which they were exposed shifted slightly but significantly toward the exposed stimulus. In control animals that experienced locomotion without exposure to high-contrast visual stimuli, orientation tuning was stable in nearly all cells.

These findings indicate that stimulus-specific plasticity in the adult visual cortex depends on concurrent locomotion, presumably as a result of the high-gain state of visual cortex induced by locomotion (Fu *et al*., *Neuron*, 2014).

Title: Role of CREB, SRF and MEF2 in ocular dominance plasticity

Authors: ***N. S. PULIMOOD**, A. E. MEDINA;
Pediatrics, Univ. of Maryland Baltimore, Baltimore, MD

Abstract: The transcription factors CREB (cAMP Response Element Binding factor), SRF (Serum Response Factor) and MEF2 (Myocyte Enhancer Factor 2) play critical roles in neuronal plasticity, and have been shown to differentially affect underlying plasticity mechanisms like LTD and LTP. Additionally, a recent study showed that CREB, SRF and MEF2 control the expression of the early gene Arc, which is required for the expression of ocular dominance plasticity (ODP), by binding to the synaptic activity responsive element (SARE). However the role of the activation of these transcription factors in the different components of plasticity *in vivo* is not well known. We used Visually Evoked Potentials (VEPs) in awake mice to investigate the role of CREB, SRF and MEF2 on the depression and potentiation components of ODP (dc-ODP and pc-ODP). We infected animals with a Herpes Simplex viral (HSV) vector expressing dominant negative forms of CREB (CREB-DN), SRF (SRF-DN) or MEF2 (MEF2-DN), then chronically implanted electrodes in the binocular zone of the mouse visual cortex. We then recorded VEPs before and after a period of monocular deprivation (MD). Since the two components of ODP express in a temporally distinct manner in the mouse visual cortex, we used 3 days of MD to isolate dc-ODP and 7 days of MD to investigate pc-ODP. Our results show that these three transcription factors have different effects on dc-ODP and pc-ODP; CREB and MEF2 seem to block both dc-ODP and pc-ODP, whereas SRF seems to block only dc-ODP. Our results can elucidate the role of these key players in the two components of ODP, therefore better informing future attempts to create therapeutic targets for diseases such as amblyopia where ODP is defective.

Title: Orientation tuning curves and selectivity in V1: influence of the past stimulus

Authors: *F. ETINDELE SOSSO, V. BHARMAURIA, L. BACHATENE, S. CATTAN, A. OUELHAZI, N. CHANAURIA, S. MOLOTCHNIKOFF;
Biol. Sci., Univ. of Montreal, Montreal, QC, Canada

Abstract: The knowledge of past influences the way we experience the world. That is, any visual stimulus although extinguished leaves a trace that affects responses of the next stimulus. It has been demonstrated that neuronal responses of visual neurons are largely dependent upon the visual background and the stimuli properties that precede the actual tested light visual stimulus. Many investigators have explored the effect of adaptation (more than 6 min) on the orientation tuning of neurons, but to our knowledge, there is no documentation of how the orientation selectivity of visual neurons is influenced to the application of an initial short (ms level)random or short fixed stimulus before the test (experiencing) stimulus. To this goal, in the primary visual cortex of urethane anaesthetized mice, using orientation tuning curve as a model, we investigated the impact of a briefly applied (250 ms duration, history stimulus) oriented grating (BAOG) on the responses evoked by the succeeding oriented tested grating lasting 4 s (OTG). Two basics protocols were employed and compared: in the first, the BAOG had a fixed angle (that is, it remained unchanged). In the second, the BAOG randomly varied prior to the experiencing grating. The stimuli properties were same in either case. In both cases, the orientation tuning curves were investigated prior to- and post-BAOG. The results demonstrated that the fixed BAOG (analogous to adaptation) significantly shifted the peak of the tuning curve (mean shift = 35.5°, t-test, $p < 0.0001$), increased the OSI (Δ OSI = 0.09, t test $p < 0$, 0001) and decreased the bandwidth (Δ bandwidth =1.4, t-test $p < 0.0001$) of neurons. On the contrary, the random BAOG significantly lead to a decreased OSI (Δ OSI = 0.05, t test $p < 0.0001$), increased responses in the flanked orientation (Δ FR = 18.98, t test $p < 0.0001$) without a change in optimal responses (Δ FR = 0.048), and increased bandwidth (Δ bandwidth = 1.0°, t-test $p < 0.0001$). These results suggest that the previous stimuli differentially affect the dynamics of neuronal responses and their selectivity. ***This research is supported by Natural Sciences and Engineering Research Council of Canada***

Title: The role of Neuregulin1/ErbB4 signaling in transplant-induced cortical plasticity

Authors: *X. ZHENG[1], T. IKRAR[2], X. XU[2], S. P. GANDHI[3];
[2]Dept. of Anat. and Neurobio., [3]Dept. of Neurobio. and Behavior, [1]Univ. of California, Irvine, Irvine, CA

Abstract: In postnatal development, the maturation of GABAergic interneurons promotes the experience-dependent refinement of cortical circuits. Previously, we have shown that transplantation of embryonic GABAergic interneurons reactivates a new critical period for ocular dominance plasticity in adult visual cortex. Here, we investigate the cellular and molecular mechanisms that mediate interneuron transplant-induced plasticity. Neurotrophic factor neuregulin 1 (NRG1) and its receptor ErbB4 have been shown to play a key role in the developmental strengthening of excitatory synapses onto inhibitory neurons, as well as in maturation of the inhibitory synaptic transmission. In this study, we investigated the role of neuregulin1/ErbB4 signaling in transplanted-induced ocular dominance plasticity. First, we transplanted embryonic GABAergic interneurons into adult primary visual cortex. Thirty-five days after transplantation, the animals underwent 4 days of monocular deprivation while receiving either daily injections of soluble NRG1 or saline control. Intrinsic signal optical imaging revealed that NRG1 blocked the reactivation of ocular dominance plasticity by transplanted interneurons. The synaptic locus of the blocked reactivation of plasticity is being investigated using *in vivo* 2-photon Ca^{2+} imaging of visual responses and *in vitro* circuit mapping. Altogether, these results are consistent with the hypothesis that excess NRG1 prevents the reopening of critical period for ocular dominance plasticity by accelerating the maturation of transplanted inhibitory neurons.

Title: Cholinergic enhancement accelerates recovery of vision after optic nerve damage.

Authors: *M. CHAMOUN[1], E. SERGEEVA[2], P. HENRICH-NOACK[2], S. JIA[2], L. GRIGARTZIK[2], J. MA[2], Q. YOU[2], F. HUPPÉ-GOURGUES[1], B. A. SABEL[2], E. VAUCHER[1]; [1]Optometrie, Univ. De Montreal, Montreal, QC, Canada; [2]Inst. of Med. Psychology, Otto-von-Guericke Univ., Magdeburg, Germany

Abstract: Enhancing cortical plasticity and brain connectivity following a visual impairment may improve residual vision. It is possible that these plasticity changes could be achieved by perceptual training or activation of the cholinergic transmission, acetylcholine being a neuromodulator involved in attention and neuronal plasticity. Here we study whether the cholinergic activation improves vision restoration by examining the effect of the acetylcholinesterase inhibitor donepezil on behavioral, electrophysiological and morphological parameters of visual function after the partial optic nerve crush in adult rats. Residual vision recovery was measured by following the rat's performance in a brightness discrimination task for 4 weeks. Neuronal activity was evaluated by quantification of visually evoked potentials once a week for the 4 weeks post-lesion. Visual cortex reactivity was evaluated by thallium autometallography post mortem. Cholinergic enhancement by donepezil induces faster recovery of brightness discrimination performance in rats with optic nerve crush compared to controls. However, visually evoked neuronal activity was not restored. This finding is compatible with the view that restoration of visual function may involve mechanisms beyond the area of primary damage and opens a new perspective for improving visual rehabilitation in humans.

Title: Brain-wide analysis of parvalbumin, somatostatin and vasointestinal peptide levels in cortical interneurons of sighted and enucleated mice using a newly developed imaging tool

Authors: *M.-E. LARAMEE, S. VREYSEN, L. ARCKENS;
KU Leuven, Leuven, Belgium

Abstract: ***Introduction:*** Monocular enucleation (ME) in mice causes a decrease of activity in the contralateral monocular visual cortex, which is gradually reactivated over the course of 7 weeks (Van Brussel et al. 2011; Nys et al. 2014). Parvalbumin interneurons were shown to be key regulators of the reactivation (Nys et al. 2015). In this study, we aimed at identifying the relation between excitation and inhibition using *in situ* hybridization (ISH) for the activity marker *zif268* and for markers of the three main inhibitory neuron populations: parvalbumin (PV), somatostatin (SOM) and vasointestinal peptide (VIP) in ME mice. ***Method:*** To provide a complete overview of the brain-wide expression with high spatial resolution, we built a software tool which allows us to register series of ISH coronal slices from adult C57BL/6J mice that were either sighted controls or enucleated. This tool allows mapping areal borders, segmenting the cortex and calculating the optical densities of the signal within these segments. The segmented cortex is reconstructed in 3D and projected to a horizontal plane creating a top view of the brain. Quantification of the differences between the top view images between ME and control mice is performed using a pseudo t-test to match the need for a non-parametric testing approach. ***Results:*** The developed tool generated high-resolution top view images comparable with optical imaging images. The expression patterns of the activity marker *zif268*, and of the inhibitory markers *pv*, *som* and *vip*, were visualized over the entire mouse visual cortex before and after ME. Complementary expression patterns were found between the different markers in sighted control mice. Surprisingly however no effect of ME was found on the expression levels of the three inhibitory markers, whereas the *zif268* expression was strongly affected, consistent with our previous results (Van Brussel et al. 2011; Nys et al. 2014). ***Conclusion:*** The tool designed is versatile and powerful as it allows combining information from different stainings from the same animal or condition to facilitate the interpretation of correlations between different molecular

patterns across the cortex with high spatial resolution. In our present study, it allowed us to describe the complementary patters of the different markers and to statistically compare expression patterns between different experimental groups. The lack of changes in expression of the inhibitory markers in our ME mice could indicate that changes occur at the protein level rather than at the mRNA level.

Research to Prevent Blindness

Title: Cortical representation of a myopic peripapillary crescent: evidence against fill-in of retinal lesions

Authors: ***D. L. ADAMS**, J. R. ECONOMIDES, J. C. HORTON;
Ophthalmology, UCSF, San Francisco, CA

Abstract: Subjects who become myopic often develop a crescent-shaped region of retinal damage around the temporal border of the optic disc, due to axial stretching of the globe. This region is known as a myopic peripapillary crescent. There are no photoreceptors in this atrophic zone, and partial or complete absence of other retinal layers. Consequently, the blind spot becomes enlarged. It is unknown whether enlargement of the blind spot, a process that occurs after the critical period for plasticity of ocular dominance columns, can be detected in the primary visual cortex. We examined the cortical representation of the blind spot in three macaque monkeys using cytochrome oxidase (CO) histochemistry and/or [^{3}H]proline autoradiography. Two animals were normal, but the third had acquired peripapillary atrophy from high myopia. At age 2 years its refraction was +0.50 sphere OU and the optic discs appeared normal. At age 8, the refraction was -12.50 sphere in the right eye, -13.75 sphere in the left eye. The optic discs were tilted, and bordered temporally by a zone of peripapillary atrophy nearly half the width of the optic disc itself. In the visual cortex there was a zone where CO histochemistry revealed a few pairs of alternating dark and light ocular dominance columns. The

dark and light columns were equal in width. The density of the dark columns matched the background level of cortical CO activity. The ocular dominance columns were situated in the retinotopic map at precisely the location in striate cortex where the temporal side of the optic disc is represented. The most likely inference is that peripapillary damage from high myopia caused loss of retinal drive, resulting in down regulation of metabolic activity within ocular dominance columns serving the contralateral eye. The cortical defect matched the myopic peripapillary crescent in size and shape, indicating that "fill-in" of the retinotopic map by visual input from healthy surrounding retina does not occur, even for a lesion only a few degrees wide.

Title: Short-term deprivation of the amblyopic eye, combined with physical exercise, promotes long-term visual recovery in adult anisometropic patients.

Authors: *C. LUNGHI[1], A. SALE[4], A. LEPRI[2], A. SFRAMELI[3], A. DENDRAMIS[2], D. LISI[2], M. LEPRI[2], M. C. MORRONE[1];

Inst., Natl. Res. Council, Pisa, Italy

Abstract: We have recently shown that the adult visual cortex retains a high degree of neuroplasticity: short-term monocular deprivation (2h) unexpectedly boosts the deprived eye signal during binocular rivalry (Lunghi et al 2011), and decreases intracortical GABAergic inhibition (Lunghi et al, 2015). Interestingly, the effect of short-term monocular deprivation is further enhanced by moderate levels of physical activity (Lunghi & Sale, 2015). As boosting brain plasticity is fundamental for the treatment of amblyopia, especially in adulthood, we attempted a counterintuitive experiment where we deprived the amblyopic instead of the dominant eye, to promote the recovery of visual function in adult amblyopic patients, combining

monocular patching and physical activity. In five adult anisometropic patients (mean age 29±4 years, mean amblyopic eye acuity 0.32±0.24 LogMar), with no associated strabismus, who had not had treatment in the last 10 years, we patched the amblyopic eye for two hours over three consecutive days, then once per week over the next three weeks. During the patching period patients watched a movie while intermittently cycling on an exercise bike. Before and after each patching session we measured binocular rivalry (orthogonal gratings, size 2°, SF: 2 cpd with different contrast for the two eyes to achieve balanced dominance), visual acuity (ETDRS charts), stereoacuity (TNO test) and letter contrast-sensitivity. Surprisingly, we found that the perceptual dominance of the patched eye increased after deprivation similar to the effect found in normal subjects. During the four weeks of testing, visual acuity and contrast sensitivity improved in all four patients (average visual acuity improvement: 0.18 LogMar), and 3/5 patients also recovered stereopsis (two of these patients were stereoblind before the procedure). Strikingly, the improvement in both visual acuity and stereopsis was preserved for at least 1 month after testing. These results demonstrate that amblyopic eye vision can be improved by transiently depriving the weak rather than the strong eye (Zhou et al, 2013), probably by activating homeostatic plasticity. Physical exercise may be crucial for the recovery by potentiating the plastic potential of the visual cortex as observed in animal models (Baroncelli et al, 2012).

Title: Intriguing! Auditory stimulus shifts orientation selectivity of visual neurons in cat V1

Authors: ***N. CHANAURIA**[1], V. BHARMAURIA[1], L. BACHATENE[1], S. CATTAN[1], F. A. ETINDELE-SOSSO[1], J. ROUAT[2], S. MOLOTCHNIKOFF[1];

Abstract: Multisensory stimulation can have a substantial impact on the basic visual perception. Non-visual input such as auditory stimuli can affect visual functioning in a myriad of ways. Numerous studies have demonstrated these alluring cross-modal relationships. For example,

anatomical and electrophysiological approaches in non-human primates (*Ghazanfar & Schroeder, 2006; Driver & Noesselt, 2008*) have provided evidence that multisensory interactions can be observed at early stages of sensory processing (*Adeli et al. 2014*). This body of evidence suggests that projections from the auditory cortex reach deeper layers of the visual cortex and vice versa. Another study by *Muckli et al. 2013* highlights the existence and importance of non-geniculate input to V1 by associated areas such as auditory cortex. Moreover, an fMRI report by *Vetter et al. 2014* displayed through task-based approaches in blindfolded healthy adults that, by solely performing an audio task, a response in the visual cortex could be observed. Therefore, primary areas such as V1 and A1 showcase high multisensory interaction, predominantly a modulatory influence in response to a complementary stimulus. In a recent study, (*Ibrahim et al. 2016*) authors have shown that auditory stimulus sharpens the selectivity of visual neurons. In the present investigation, we further examined the effect of sound on the shifts of orientation selectivity of simultaneously recorded supra- and infragranular layer visual neurons by presenting an auditory stimuli for 12 minutes. The recordings were performed in area 17 of the visual cortex in anaesthetised cats using tungsten multichannel depth electrode. The auditory stimulus (3s 74 dB SPL) was broadband noise-like (*Fritz et al. 2003*) and consisted of temporally orthogonal rippled combinations (TORC's) with varying frequency components. The stimulus was presented continuously and uninterruptedly for 12 min and was delivered by a pair of external loudspeakers positioned perpendicularly to the fixation axis of the animal. Our data show that, after 12 min presentation of the auditory stimulus, a population of visual cortical neurons attain new orientation selectivities. In addition, few layer II-III and V neurons lose their selectivity and become untuned. Further, layer II-III and layer V neurons exhibit functional synchronisation (as computed by crosscorrelograms) prior to- and post- auditory stimulus exposure. These results suggest that, visual neurons in either layers change their properties on application of an auditory stimulus which highlights the cross-modal interactions between visual and auditory systems and a robust reconfiguration of visual cortex.

Title: Evidence for an intact retinotopic organization of early visual cortex but impaired extrastriate processing in sight recovery individuals

Authors: *S. SOURAV[1], D. BOTTARI[1], R. BALACHANDAR[2], R. KEKUNNAYA[2], B. RÖDER[1];

Abstract: Congenital visual deprivation has been shown to cause extensive structural and functional changes in the brain. In periods when neural systems are particularly sensitive for experience (so called sensitive periods), visual deprivation can irrecoverably impair the ability to acquire visual functions if vision is subsequently restored. Some recent findings, however, have suggested that some neural systems emerge in the absence of developmental vision. Humans with a history of bilateral, dense congenital cataracts (CC) who subsequently underwent cataract-removal surgeries to restore vision provide a unique window into sensitive phases of visual development in humans. Using event-related potentials, we investigated the retinotopic organization of early visual cortex in CC individuals with a period of visual deprivation ranging from several months to several years.
Participants looked at grating stimuli flashed either in the upper or the lower visual field. The task of the participants was to detect rare gratings differing in orientation. Cataract individuals showed typical C1 waves of opposing polarities in response to visual stimulation from upper vs. lower visual fields, indicating that the retinotopic organization in the visual cortex is spared in the CC individuals. By contrast, the P1 wave, arising from extrastriate cortical sources, was attenuated in the CC group compared to their matched controls. The findings are in agreement with present brain imaging data suggesting intact retinotopy in congenitally permanently blind adults. We extend these results by demonstrating that the early visual cortex can be activated with the same latency after sight restoration as in healthy controls and thus, indeed is functional. Moreover, the findings are in accord with early suggestions of Hyvarinen et al. (1981) and permanently impaired visual function after visual restoration following a congenital blindness.

Title: Increasing Arc prolongs the critical period for juvenile plasticity in primary visual cortex

Authors: *T. KIM[1], E. D. PASTUZYN[3], K. R. JENKS[3], H. OKUNO[4], J. ICHIDA[3], H. BITO[5], M. F. BEAR[2], J. D. SHEPHERD[3];

Abstract: A defining feature of early postnatal brain development is the activity-dependent winnowing of synaptic connections. This process is readily demonstrated by the response of visual cortical circuits to temporary monocular deprivation (MD) during early life. When MD is initiated during an early sensitive period, the synapses serving the deprived eye in visual cortex lose strength and eventually are eliminated. Deprived-eye depression diminishes with age such that by the onset of adolescence, circuits are no longer vulnerable to deprivation. A question of extraordinary interest concerns the mechanisms that bring this critical period to a close. Clues into the molecular basis for the decline in juvenile plasticity have come from several diverse experimental treatments that can alter sensitivity to MD across the lifespan. It has been suggested that a common thread connecting these varied treatments might be an increase the ratio of excitation to inhibition. However, it is completely unknown how, at the molecular level, general increases in cortical activity increase deprivation-induced synaptic plasticity. We hypothesize that a key molecular determinant of juvenile synaptic plasticity—as demonstrated in visual cortex by depression of deprived-eye responses following MD—is expression of the activity-

regulated gene for Arc. Here we asked if activity-dependent overexpression of Arc prolongs into adulthood the sensitivity of visual cortical synapses to deprivation and if so, how. Using a novel genetically engineered mouse, in which an Arc transgene is expressed under the control of the activity-dependent Arc promoter, we show that augmenting Arc expression renders visual cortical synapses vulnerable to deprived-eye depression in adults. Further, we show in wildtype mice that Arc expression in visual cortex normally declines with age coincident with the loss of juvenile plasticity. Finally, we show that genetic deletion of Arc and chronic inhibition of protein synthesis in juvenile visual cortex, which eliminate ocular dominance plasticity, also disable the mechanism of homosynaptic long-term depression (LTD). The fact that Arc is activity-regulated provides an elegant explanation for how crude manipulations of the excitation-inhibition ratio can, under some circumstances, restore the sensitivity of visual cortex to MD.

Title: Cortico-fugal output from visual cortex promotes plasticity of innate motor behavior

Authors: ***B. LIU**[1], A. HUBERMAN[1], M. SCANZIANI[2];
[1]UCSD, La Jolla, CA; [2]UCSD/HHMI, La Jolla, CA

Abstract: The cerebral cortex of mammals massively innervates the brainstem, a phylogenetically older structure, via cortico-fugal axonal projections. Many cortico-fugal projections target brainstem nuclei that mediate innate motor behaviors and yet, the function of these projections remains obscure. A prime example of such innate behaviors is the optokinetic reflex (OKR), a compensatory eye movement that stabilizes the image on the retina as the animal moves through the environment. This behavior is mediated by the brainstem nuclei of the accessory optic system (AOS) which receive direct visual input from the retina as well as visual cortex. The OKR is plastic throughout life as the organism matures and ages, and can be continuously readjusted relative to other oculo-motor reflexes. Although the cerebellum and

vestibular nuclei are known to be involved in the adaptive changes of the OKR, visual cortex could also contribute to this plasticity through cortico-fugal projections to the AOS. To experimentally induce OKR plasticity we performed vestibular lesions, a manipulation that leads to a persistent potentiation of the amplitude of the OKR. OKR potentiation was strongly reduced by optogenetically silencing visual cortex. Furthermore, targeted ablation of cortico-fugal neurons projecting to the AOS severely impaired OKR potentiation. Finally, we showed that OKR potentiation results from an enhanced drive exerted by visual cortex onto the AOS. Thus, cortico-fugal projections to brainstem enable visual cortex to plastically adapt the execution of innate motor behaviors. These findings expand our understanding of how the innervation of phylogenetically older structures by the mammalian cortex can improve the performance of reflexive behavior in an experience dependent manner.

Title: High-dimensional structure of inhibitory population activity in visual cortex

Authors: ***C. STRINGER**[1], M. PACHITARIU[2], M. DIPOPPA[2], M. OKUN[2], M. CARANDINI[2], K. HARRIS[2];
[1]Gatsby Computat. Neurosci. Unit, [2]Univ. Col. London, London, United Kingdom

Abstract: A fundamental feature of cortical circuits is the balance of excitation and inhibition. Intracellular recordings reveal that inhibitory synaptic inputs track fluctuations in excitatory inputs; similarly, in extracellular recordings, both putative inhibitory and excitatory neurons track the overall activity of the local network.
The activity of an excitatory neuron, however, is not fully summarized by a single population rate: for example, different neurons fire in response to different sensory stimuli or as part of different spontaneous ensembles. Describing the activity of an excitatory population thus requires a high-dimensional vector. For inhibitory neurons, it is unclear whether population

activity is high dimensional. Because inhibitory neurons receive dense, non-specific input from excitatory neurons, one might expect their firing to track the excitatory population rate, resulting in a one-dimensional space of inhibitory neuron activity.
To address this question, we analyzed population recordings made from mouse V1 with 2-photon calcium imaging, in which all neurons expressed the calcium indicator, and selected classes of inhibitory neurons (Pvalb, Sst, or Vip) were labelled with tdTomato. Contrary to expectation, we found that inhibitory population activity tracked excitatory activity along multiple dimensions. Using canonical correlation analysis, we found multiple subspaces of excitatory and inhibitory activity that were significantly aligned to each other. This property held for all three classes of inhibitory neurons. Preliminary evidence suggests that this property also holds for putative inhibitory neurons recorded electrophysiologically.
To provide insight into the possible mechanisms of this phenomenon, we analyzed multiple variants of a recurrent spiking network model. Model networks with purely random connectivity exhibited a single dominant mode of activity that included all excitatory and inhibitory cells. Adding structure only to the excitatory connectivity did not match our experimental data, as excitatory activity switched between full activation of discrete subnetworks, while inhibitory activity remained approximately constant. However, when we matched the inhibitory and excitatory connection structure the activity showed multiple inhibitory modes, matching our experimental findings.
We conclude that the high dimensional structure of inhibitory population activity may reflect organization of inhibitory synaptic networks. Our modelling work suggests that this structured inhibition permits stable high-dimensional computation.

Title: Visual cortical activity during a virtual foraging task in mice

Authors: *A. RESULAJ[1], S. R. OLSEN[2], M. SCANZIANI[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Neural electrical activity in the brain represents the external world and guides our future actions. Although much is known about how sensory areas represent sensory information, little is known about how this information is used to guide behavior. Here, we recorded neuronal responses in primary visual cortex (V1) in mice while they performed a virtual foraging task. In this task, head-fixed mice ran on a circular treadmill while visual stimuli (circular patches of gratings rotated at either 45 or 90 degrees) shown on a monitor passed by at a speed that was proportional to their running speed. Mice were rewarded with water for stabilizing a specific image (the target stimulus) on the center of the monitor for about one second. We recorded evoked spiking activity in individual neurons by inserting a multichannel linear probe in V1 at the beginning of a behavioral session in trained mice. Although the probe spanned almost all layers of V1, the majority of units recorded during the task were found in the deeper layers of V1. After the behavioral session ended, we presented circular patches of gratings rotated at various angles. We found that units in the upper layers of V1 preferred orientations close to zero degrees. This preference, together with their low spontaneous firing rate, explained why units in the upper layers of V1 were not very responsive during the task. These results represent a first step in dissecting the role of visual cortical circuits in perceptual decisions.

Title: Recordings from 10,000 neurons reveal high dimensionality in cortical activity

Authors: *M. PACHITARIU, C. STRINGER, S. SCHRODER, M. CARANDINI, K. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: Neural circuits impose constraints on the possible patterns a population of neurons can express. Understanding these constraints would provide insight into the underlying computations, but such understanding has been limited by the small size of recorded populations, which involve at most a few hundred neurons.
To overcome this limitation, we devised a calcium imaging protocol to record ~10,000 excitatory neurons simultaneously and we applied it to the visual cortex of awake head-fixed mice. The protocol involved imaging 10 planes (1 x 1 x 0.3 mm) at 3 Hz in mice expressing the calcium indicator GCaMP6s in selected neural populations, and identifiying cells with a novel cell detection algorithm (github.com/cortex-lab/Suite2P). Many of our findings would not have been possible by recording fewer (e.g. 300) neurons.
We found that spontaneous neuronal activity occupies a "spontaneous subspace" of at least a few hundred dimensions. The two leading singular vectors of this activity aligned with the average population rate and with fluctuations in arousal, respectively. Fluctuations in arousal, indicated by running or by pupil dilation, switched between two large populations of neurons that were spatially interspersed, while leaving the total firing rate mostly unchanged. The other dimensions reflected sparse sets of neurons and a variety of spatial and temporal timescales, from a few hundred microns to the entire 1 mm2 recorded surface, and from a few hundred milliseconds to tens of seconds.
To investigate the relationship of stimulus-driven responses to spontaneous activity, we presented sets of natural images while recording the same populations. Trial-averaged visual responses spanned a "stimulus subspace" approximately orthogonal to the spontaneous subspace. Trial-to-trial variability in population responses was dominated by fluctuations in the spontaneous subspace, but also contained substantial power in the stimulus subspace. Furthermore, the variability extended along dimensions of activity corresponding to all stimuli in our assay, not just those of the presented stimulus as would be expected from a multiplicative variability model.
We conclude that the large-scale structure of spontaneous activity is organized into a few hundred dimensions with varying spatial and temporal scales. Stimulus response patterns inhabit a different high-dimensional space with its own trial-to-trial variability. The large, internally-generated variability along this response subspace provides a possible substrate for the subjective, internally-biased interpretation of visual scenes demonstrated in human psychophysical experiments.

Title: The recovery of ocular dominance and visual acuity in murine amblyopia are limited by NgR1 in distinct components of the visual circuitry

Authors: *C.-E. STEPHANY[1], H. M. DORTON[2], A. W. MCGEE[1];
[1]Children's Hosp. of Los Angeles, Los Angeles, CA; [2]USC, Los Angeles, CA

Abstract: The brain is profoundly impacted by life experience during development, especially during specified 'critical periods' early in life. In the visual system, abnormal vision during the critical period induces amblyopia, also known as "lazy eye". This common visual disorder is characterized by poor binocular vision and diminished acuity. The closure of this critical period limits recovery from amblyopia by inhibiting developmental plasticity and consolidating existing neural circuitry. In mice, the neuronal Nogo-66-receptor (NgR1) is required to close the critical period. NgR1 mutants display developmental visual plasticity as adults, and exhibit spontaneous recovery of ocular dominance as well as visual acuity in a mouse model of amblyopia, long-term monocular deprivation (LTMD). Yet, it is unclear if or how the recovery of these two forms of visual function is linked. Here, we demonstrate that the recovery of binocularity and visual acuity in murine amblyopia are distinct. Interestingly, deleting NgR1 only in thalamus and layer 4 of cortex yields a complete recovery of visual acuity, but does not rescue ocular dominance. In contrast, deleting NgR1 in all cortical excitatory neurons does not improve visual acuity following LTMD. Thus, NgR1 operates within the thalamocortical component of visual circuitry to regulate the capacity of experience to improve acuity.

Title: Reprograming of neuronal ensembles in primary visual cortex with two-photon optogenetics *In vivo*

Authors: *L. CARRILLO-REID[1], W. YANG[2], D. PETERKA[2], R. YUSTE[2];
[1]Biol. Sci., [2]Columbia Univ., New York, NY

Abstract: Cortical ensembles in primary visual cortex are groups of neurons with coordinated activity that represent specific features of visual stimuli. The functional connectivity of these ensembles gives rise to activity patterns that generate an internal representation of the surrounding world. In this way neuronal ensembles recalled by sensory stimulation make use of imprinted patterns of activity stored in the cortical circuitry. However, whether it is possible to imprint and recall artificially created neuronal ensembles has been difficult to investigate. We used simultaneous two-photon optogenetics and imaging of neuronal populations in vivo to activate specific groups of neurons termed photoensembles whose members can be identified and manipulated with single cell resolution. Recurrent activation of the same photoensembles imprinted them in cortical microcircuits. Once established, single neuron photostimulation is able to recall a complete ensemble. Artificially imprinted photoensembles alternate their activity with visually evoked ensembles and can be used to alter mice behavioral tasks. Our findings demonstrate the possibility to reprogram ad libitum neuronal ensembles and observe the behavioral correlate of changes in the functional connectivity of cortical microcircuits.

Title: Rem2 is required for normal critical period ocular dominance plasticity of the visual cortex.

Authors: *S. E. RICHARDS, A. R. MOORE, K. KENNY, S. PARADIS, S. D. VAN HOOSER;
Neurosci., Brandeis Univ., Waltham, MA

Abstract: The fact that sensory experience contributes to the development of cortical circuits is well-established in the visual system. However, the identity of molecules responsible for transducing visual experience into proper development, maintenance, and plasticity of synaptic connections remains unclear. Recent work has suggested that the small GTPase Rem2 is a candidate molecule in this process. Rem2 is a known positive regulator of spine and synapse formation. Additionally, Rem2 function is regulated by CaMKII phosphorylation, placing Rem2 downstream of this critical molecule for long term potentiation (LTP). Previous work has also placed Rem2 in a signaling cascade upstream of CaMKIV, a proposed regulator of homeostatic plasticity. Furthermore, Rem2 expression is upregulated following brief exposure to light in the *Xenopus Laevis* optic tectum and mouse primary visual cortex, indicating that Rem2 expression can be altered *in vivo* by visual experience. Taken together, these results suggest that Rem2 has the potential to play a role in both Hebbian and homeostatic mechanisms that govern proper development and plasticity of visual circuits.
Here, we tested the hypothesis that Rem2 is necessary for activity-dependent changes in functional circuit responses to sensory stimulation in mouse visual cortex. We generated transgenic mice harboring a Rem2 null allele ($Rem2^{-/-}$) or a Rem2 conditional knockout allele ($Rem2^{flx/flx}$) and investigated critical period ocular dominance plasticity (ODP) induced by monocular lid suture, an extensively-studied cortical plasticity paradigm. ODP is characterized by a decrease in visual cortical responsiveness to stimulation of a deprived eye followed by an increase in responsiveness to input from the spared eye. We find that $Rem2^{-/-}$ mice show only a

partial ocular dominance shift, resulting primarily from a failure to reduce responsiveness to deprived eye input. This suggests a deficiency in the initial, Hebbian plasticity that results in decreased responsiveness to the obscured eye. Furthermore, by crossing cell type-specific Cre driver lines to our $Rem2^{flx/flx}$ line, we find that Rem2 is specifically required in excitatory pyramidal cells of the cortex, but not Parvalbumin-positive interneurons, for normal ODP to occur. Ongoing experiments aim to investigate the involvement of Rem2 in both Hebbian and homeostatic plasticity mechanisms required for ODP.

Title: A surprising transient period of synaptic imbalance exists in the rat visual cortex during postnatal development

Authors: H. ZHANG[1], *M. T. WONG-RILEY[2];
[1]Cell Biology, Neurobio. and Anat., [2]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: The mammalian visual cortex is not mature at birth, but undergoes a period of structural and functional adjustments. As abnormal development can lead to a host of visual impairment, it is important to take an in-depth look at the normal process of synaptic development. The goal of the present study was to record spontaneous excitatory and inhibitory postsynaptic currents (sEPSCs and sIPSCs) in the visual cortex of normal Sprague-Dawley rat pups *daily*, from the time of eye opening (P14) to P36, when neurons have presumably reached their maturity. We found, to our surprise, that the development of excitatory and inhibitory synapses did not follow straight, smooth paths. Instead, they exhibited three periods of development during this time: (1) From P14 to P27, the amplitudes of both sEPSCs and sIPSCs assumed a plateau, whereas the frequencies of both exhibited a gradual rise; (2) from P28 to P33, both the amplitudes and frequencies of sEPSCs fell precipitously and significantly below those of the previous period, whereas the amplitudes and frequencies of sIPSCs rose suddenly and significantly above those of the earlier period; and (3) from P34 to P36, both the amplitudes and frequencies of both sEPSCs and sIPSCs resumed the same, respective levels as those at P27.

These unexpected, striking results indicate that the visual cortex undergoes a drastic synaptic readjustment during the fifth postnatal week in the rat. This period falls within the critical period of the rat's visual system development.

Title: Dichoptic perceptual training in juvenile amblyopes with or without patching history

Authors: *J.-Y. ZHANG[1], X.-Y. LIU[2], C. YU[1];
[1]Peking Univ., Beijing, China; [2]Tengzhou Central People's Hosp., Tengzhou, China

Abstract: Dichoptic training is becoming a popular tool in amblyopia treatment. Here we investigated the effects of dichoptic training on juvenile amblyopia no longer responsive to patching treatment (PT group) or never patch treated (NPT group).
Training consisted of three stages. (1) 10 PT and 10 NPT amblyopes (8-17 years, 15-anisometropic, 3-ametropic, 1-strabismus, 1-mixed) received dichoptic de-masking training for 40 hours. They used AEs to practice contrast discrimination of Gabors that were dichoptically masked by a band-filtered noise pattern simultaneously presented in NAEs. Dichoptic learning is indexed by the increase of maximal tolerable noise contrast (TNC) for AE contrast discrimination. Training improved maximal TNC by 350% in PT and 480% in NPT, which translated to stereoacuity improvements by 4.6-lines in PT and 3.0-lines in NPT, and AE visual acuity improvements by 1.3-lines in PT and 2.1-lines in NPT. (2) The amblyopes further received stereopsis training for another 40 hours. Training improved stereoacuity by 2.4-lines in PT and 0.5-lines in NPT, and AE acuity by 0 line in PT and 0.5 lines in NPT. Seven PT amblyopes regained normal stereoacuity (20~50 arcsec) after two stages of training. (3) Extra monocular AE grating acuity training (30 hours) failed to improve grating acuity in both groups. Neither did it produce further AE acuity and stereoacuity gains. After training the visual acuity and stereoacuity gains persisted for at least one year.
Dichoptic training improved vision in both PT and NPT juvenile amblyopes. The PT group with

milder amblyopia benefited substantially more in stereoacuity (7.0-lines), probably because improved AE acuity (1.3-lines) could translate to greater balance of binocular vision and thus better stereoacuity. The NPT group benefited more in visual acuity (2.6-lines), consistent with our previous report (Liu et al., 2011). Our study confirmed the effectiveness of dichoptic training approaches in the treatment of juvenile amblyopia.

Title: EEG/fNIRS as biomarkers for neural activation in humans during motor tasks

Authors: *T. H. CRUZ[1], T. BULEA[2], T. S. MOULTON[3], A. C. DE CAMPOS[4], A. SHARMA[2], T. HUPPERT[5], D. DAMIANO[2];
[1]NICHD/NIH, Bethesda, MD; [2]Clin. Center/ Rehabil. Med. Dept., NIH, Bethesda, MD; [3]Physical Therapy and Human Movement Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [4]Physiotherapy, Rehabil. Medicine, Developmental Psychology, Univ. Federal de Sao Carlos, Sao Carlos, Brazil; [5]Radiology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The ability to combine mobile neuroimaging techniques, e.g. electroencephalogram (EEG) and functional near-infrared spectroscopy (fNIRS), during a movement task could improve mapping of brain activation underlying motor activity. These techniques have complementary strengths and weaknesses: EEG has high temporal resolution but low spatial resolution due to volume conduction; whereas fNIRS has low temporal resolution due to the hemodynamic response, but higher spatial resolution. The challenges in combining these methods are both physical and computational. To this end, we compared brain activation using EEG and fNIRS during movement by 9 healthy volunteers (4 M; 26 ± 7 yrs, 8 right-handed) under an IRB-approved protocol. Each performed unilateral lower limb tasks with the dominant leg (ankle dorsiflexion and cycling) on two separate days, with the order of EEG and fNIRS randomized. 64-channel EEG was collected using a wireless active-electrode system (Brain Products, Morrisville, NC) with electrodes placed according to the 10-20 system. fNIRS (TechEn, Inc., Milford, MA) was recorded from 44 channels (8 sources & 16 detectors) placed in

a custom probe (Moulton et. al, 2014) optimized to detect signals from primary motor and dorsal premotor cortices. Motion capture was used to measure movement and to co-register locations of the EEG and fNIRS probes. EEG and fNIRS data were processed using EEGLAB (Delorme and Makeig, 2004) and the +NIRS Toolbox (Huppert, 2016), respectively. We examined traditional measures of cortical activation from each modality, i.e. event-related potentials and spectral perturbations from EEG and changes in oxygenated (HbO) and de-oxygenated (HbR) hemoglobin from fNIRS. The fNIRS data, analyzed in block averages, showed significant increases in HbO and decreases in HbR in the contralateral medial motor cortex, as expected for a unilateral lower limb task. Changes in HbO and HbR scaled with the difficulty of the task. In the EEG, movement-related changes were most prominent along midline motor areas, with a more diffuse presentation in the multi-joint cycling task. Interestingly, cortical areas displaying neurovascular coupling during blocks of fNIRS were correlated with EEG channels showing activation on a much faster timescale. Our results demonstrate the potential of multi-modal, portable imaging as a biomarker for localizing neural activity during movement. Such biomarkers are promising for identification of cortical regions underpinning movement in individuals with brain injury, many of whom are unable to remain still for fMRI, because these could provide well-defined, individualized targets for neurorehabilitation.

Title: EEG signals related to movement-related cortical potential by direction-cue and go-cue

Authors: *A. FUNASE[1,2], S. TAKAGI[1], I. TAKUMI[1];
[1]Nagoya Inst. of Technol., Nagoya, Japan; [2]Brain Sci. Inst., RIKEN, Wako, Japan

Abstract: [Purpose] We have been studying the movement-related cortical potential on voluntary movements in the point of temporal patterns of brain activity. In this research, we perform the experiments using by the Direction-Cue and the Go-Cue (this experiments are called “Direction-Cue task”). We can distinguish between the brain activity of decision-making related to direction of movements and the brain activity of connecting between the direction-cue and

movements and the brain activity of preparation on movements. [Experiment] We perform the auditory direction-cue task and the visual direction-cue task. The direction-cue show the direction of movements and the go-cue show the start timing of movements by a beep sound. Experimental order in the visual direction-cue task is as following. 1) A subject watches a fixation point on a computer display. 2) After 4.5-6.0 [sec], a direction-cue is presented to a subject. 3) After 2.5-3.0 [sec], a go-cue is presented to a subject. 4) A subject pushes a bottom. When the direction-cue is shown as the right-arrow on a computer display, a subject pushes a right-side bottom. When the direction-cue is shown as the left-arrow, a subject pushes a left-side bottom. In the auditory direction-cue task, direction-cues are shown as a beep sound. When the beep sound is shown from a right hand side speaker, a subject pushes a right-side bottom. When the beep sound is shown from a left hand side speaker, a subject pushes a left-side bottom. This order is one trial flow. We perform 50 right trials and 50 left trials. We record the EEG signals during these tasks. We focus on the C3, C4, Cz electrode. EEG signals are processed by the ensemble averaging. On-set of the ensemble averaging is at starting time of the direction-cue. [Results and Discussion] From a figure, we obtain two features (a), (b) in the visual direction-cue task and three features (c), (a'), (b') in the auditory direction-cue task. The (c) is a feature related to understanding auditory stimuli. The (a) and (a') are related to decision-making of movement-direction. The (b) and (b') are related to preparation of movements.

Title: Children with cerebral palsy have uncharacteristic beta cortical oscillations during a visuomotor target matching task

Authors: *M. J. KURZ[1,2], A. L. PROSKOVEC[2], J. E. GEHRINGER[1,2], E. HEINRICHS-GRAHAM[2], T. W. WILSON[2];
[1]Physical Therapy, [2]Ctr. for Magnetoencephalography, Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: The literature on cerebral palsy (CP) has predominantly focused on identifying the potential faults that exist within the musculoskeletal system, with little regard for aberrations that may exist within the key cortical networks that serve the uncharacteristic motor actions seen in these children. In this study, we interrogated the beta (15-30 Hz) cortical oscillations as a cohort of children with CP (N=13; Age = 15 $\pm$ 3 yrs; GMFCS levels II-III) and typically developing children (N=15; Age = 14 $\pm$ 3 yrs.) performed an isometric knee extension target matching task. The isometric forces generated by the child elevated an animated box vertically in order to match visual targets that were between 5-30% of the child's maximum force. The epochs of each trial were 10 seconds in duration (-5.0 s to +5.0 s), with the onset of the isometric force defined as 0.0 s. The reaction time, amount of target overshoot, and time to match the target were used to assess the child's motor performance. Magnetoencephalography (MEG) was concurrently collected to assess cortical oscillatory activity during the 120 target matching trials. The resulting MEG data was noise corrected, coregistered to the child's MRI, filtered and subjected to standard artifact rejection methods. A beamformer analysis was performed to image the beta oscillatory activity that was present during the motor planning (-500 to 0 ms) and motor action stages (0 to 500 ms). Our results showed that the children with CP had slower reaction times, a greater amount of overshoot, and took longer to match the targets (*Ps* <0.03). The children with CP also had a stronger beta event related desynchronization (ERD) during the motor planning stage in the SMA, left premotor cortices and primary motor cortices ($P < 0.01$, cluster corrected). During the motor action, the children with CP continued to have a stronger beta ERD within the SMA and left premotor cortices ($P <0.01$, cluster corrected). In addition, the children with CP had a weaker beta event related synchronization (ERS) in the left prefrontal, MT/V5 visual area, and bilaterally in the occipital cortices during the motor action ($P<0.01$; cluster corrected). These results indicate that the uncharacteristic motor actions seen in children with CP may partially be

related to abnormalities in neural computations that are involved in planning a goal directed motor action. Furthermore, movement in children with CP may be further compromised by deficient or inaccurate visuomotor transformations, which are necessary for matching a desired motor goal.

Title: Orthogonalising parameters of predictive coding within a visuomotor adaptation task

Authors: *C. E. PALMER[1], S. ONDOBAKA[2], J. M. KILNER[1];
[1]Inst. of Neurology, Univ. Col. London, London, United Kingdom; [2]Inst. of Neurology, Univ. Col. London, Wellcome Trust Ctr. for Neuroimaging, London, United Kingdom

Abstract: Perturbations introduced in visuomotor adaptation tasks produce prediction errors, which are used to update forward models to generate more accurate sensorimotor predictions. Prediction errors are precision-weighted meaning an estimate of the inverse variance of the afferent signal (sensory precision) and the motor prediction (prior precision) is used to determine how readily prediction errors update forward models. These parameters are modulated during adaptation however their neurophysiological correlates are not fully understood. It has been suggested that beta oscillatory activity over sensorimotor cortex encodes this Bayesian updating process (Tan et al, 2014, 2016; Torrecillos et al, 2015). However, within the paradigms studied it was difficult to dissociate prediction errors from their precision weighting. The current study uses a paradigm designed to orthogonalise prediction error, prior precision and sensory precision in order to identify whether beta oscillations are correlated with any of these parameters. In this study, EEG was recorded whilst 18 subjects completed a visuomotor adaptation task. Subjects were instructed to move a cursor from a start position into a target. Perturbations in the visual feedback of the cursor forced subjects to generate online corrective movements to reach the target. Each perturbation remained the same for 10-15 trials to allow for adaptation. Certainty in motor predictions (prior precision) was modulated by altering the probability with which the next trial would require the same movement; this pattern was dissociable from that of prediction error

modulation. Sensory precision was also orthogonally modulated by introducing random error into the position of the cursor on the screen in a block design; adding noise into the sensory input made the signal more uncertain and decreased sensory precision in noisy vs non-noisy blocks. EEG data in the time period before trial onset was analysed to determine the state of the system prior to moving and after each trial to examine the role of the PMBS in adaptation. Each parameter was modelled using the behavioural data to determine what activity within the time-frequency domain overlying the sensorimotor cortex correlated with each of the different parameters. Differences in alpha (8-12Hz), low beta (13-18Hz) and high beta (19-30Hz) were found for the parameters of prior precision, sensory precision and prediction error. This study has implications for understanding how predictive coding is encoded in the brain and can help reframe disorders in which these correlates are dysfunctional to provide a new insight for the development of novel therapies.

Title: Directionally tuned signals in human EEG during step-tracking wrist movement

Authors: ***H. KAMBARA**[1], H. TANAKA[2], M. MIYAKOSHI[3], N. YOSHIMURA[4], Y. KOIKE[4], S. MAKEIG[3];
[1]Tokyo Inst. Technol., Yokohama, Japan; [2]Japan Advanced Inst. of Sci. and Technol., Nomi, Japan; [3]Univsersity of California, San Diego, La Jolla, CA; [4]Tokyo Insittue of Technol., Yokohama, Japan

Abstract: Many electrophysiology experiments in monkeys have long contributed to identifying neural activities that covary with parameters during directional arm and wrist movements. On the other hand, it remains largely unexplored the neural mechanisms of directional movements in humans, and the newly developing area of Mobile Brain/Body Imaging (MoBI) has a promise of

noninvasive recording of humans during unconstrained body movements. In this study, we report that directionally tuned neural activities during step-tracking wrist movement can be captured by high-density EEG signals during arm reaching movements
Subjects were seated on a chair with their forearm held in one of three postures (full-pronation, full-supination, or midway between the two positions) and was instructed to make step-tracking wrist movements from the neutral posture to eight different targets that required varying amounts of flexion-extension and radial-ulnar deviation. Neural activities and wrist joint kinematics were monitored in synchrony with 128 channel EEG and a motion capture.
Independent component analysis and equivalent dipole fitting of resulting brain-based independent component (IC) scalp maps were applied to the EEG data and revealed cortical current sources in visual, somatosensory, and motor cortical areas. We computed temporal correlations between trial-by-trial movement-locked event-related potentials (ERPs) of each IC. For the ERPs within same postures, all of the brain-based ICs exhibited maximal correlation for pairs of trials with same movement direction. The correlation coefficient smoothly decreased with the increasing difference of movement directions. This correlation pattern was well fitted by a Gaussian function against difference in movement directions. This finding of structured correlations indicated that the cortical ICs were tuned to the wrist movement directions. Next, we computed temporal correlations of ERPs across different forearm postures. Whereas most ICs showed no shifts with respect to the forearm postures, some ICs exhibited the shift of correlation curves, i.e., ERPs of one direction in one posture correlated maximally with those of slightly shifted direction in another posture. We found ICs exhibiting the shift in maximal correlation consistent with the shift in preferred direction of neurons representing muscle activities found in Kakei et al. (1999).
The results of this study show that the neural activities related to movement parameters, such as movement direction and muscle activities, can be captured from high density EEG recorded during unconstrained body motion.

Title: Dynamics of directional tuning and reference frames in humans: A high-density EEG study

Authors: *H. TANAKA[1], M. MIYAKOSHI[2], S. MAKEIG[2];
[1]Japan Advanced Inst. of Sci. and Technol., Ishikawa, Japan; [2]UCSD, La Jolla, CA

Abstract: Neural mechanisms controlling upper-limb reaching movements have been studied traditionally at the single-neuron level in monkey electrophysiological studies and, more recently, at the voxel level in human fMRI studies. However, the single-unit recording approach lacks a whole-brain perspective, and the fMRI approach misses sub-second neural dynamics and does not allow natural, unconstrained movements. This study exploits recent developments in EEG recording and signal processing to investigate neural computations underlying ballistic pointing movements. High-density EEG with more than 200 electrodes covering the entire scalp has near-msec temporal resolution and can be used to measure neural activities under unconstrained physical conditions, thereby resolving limitations of previous studies. We specifically asked how EEG source dynamics indexed finger movement directions (directional tuning) and posture dependence (movement reference frames) by applying representational similarity analysis. A majority of the EEG source processes studied exhibited statistically significant directional tuning in peri-movement periods, appearing before movement onset and disappearing after the movement termination. In addition, directional tuning curves shifted when the shoulder angle was rotated to perform the task within a more laterally positioned workspace, the degree of tuning curve rotation falling between that predicted by models assuming extrinsic and shoulder-based reference frames. We conclude that cortical dynamics engaged during motor control can be studied noninvasively in humans using high-density EEG and advanced signal processing, at a level matching results reported in single-cell electrophysiological studies using monkeys.

Title: Altered sensorimotor cortical oscillations in individuals with multiple sclerosis suggests a faulty internal model

Authors: *D. J. ARPIN[1,2], E. HEINRICHS-GRAHAM[2], J. E. GEHRINGER[1,2], T. W. WILSON[2], M. J. KURZ[1,2];
[1]Physical Therapy, [2]Ctr. for Magnetoencephalography, Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Multiple sclerosis (MS) is a demyelinating disease that results in impaired motor performance. However, the neurophysiological changes responsible for these motor control problems remain unknown. Potentially, these movement errors may be due to imperfections in the internal model used to make predictions of the motor output based on the task demands. Prior magnetoencephalographic (MEG) and electroencephalographic (EEG) brain imaging experiments have established that beta (15-30 Hz) oscillatory activity in the sensorimotor cortices is related to the control of movement. Recent experimental work has also shown that changes in the beta-frequency activity at movement termination, termed post-movement beta rebound (PMBR), reflects the certainty of the feedforward motor actions that were executed based on an internal model. In this study, we used MEG to evaluate the neural oscillatory activity in the sensorimotor cortices of individuals with MS (N=13; Age = 57 $\pm$ 6.5 yrs; EDSS = 5.5 $\pm$ 0.7) and healthy age-matched controls (N=13; Age = 55 $\pm$ 7.3 yrs.) during a goal-directed knee extension force task. A custom built force transducer was attached to the subject's lower leg, providing a measure of isometric knee extension force. The forces generated elevated an animated box toward the target, and the participants matched targets between 5 and 30% of their maximum force. The epochs of each trial were 10 seconds in duration (-5.0 s to +5.0 s), with the onset of the isometric force defined as 0.0 s. Each participant performed 120 trials of the target matching task while reaction time, amount of overshoot, average velocity to the target, and time to match the target were recorded. MEG was used to record the oscillatory activity of the sensorimotor cortices as the subjects performed the target matching task. The MEG data were noise corrected, coregistered to MRI, filtered, and subjected to standard artifact rejection methods. A beamformer analysis was performed for the PMBR (16-26 Hz, 4.0 to 4.8 s) following movement termination. The grand average of the beamformer images was used to find the peak voxel, and the time series of this voxel was extracted in each participant and subjected to group-level statistical analyses. Our results showed that individuals with MS had slower reaction times ($p<0.01$), a greater amount of overshoot ($p<0.01$), slower average velocity to the target ($p<0.01$), and took longer to match the target ($p<0.01$). Individuals with MS also had a weaker PMBR in the pre/postcentral gyri relative to healthy controls. The aberrant PMBR suggests that the internal model is faulty in individuals with MS and potentially responsible for their uncharacteristic motor performance.

Title: Neuromechanical changes associated with learning an isometric ankle plantarflexion target matching task

Authors: *J. GEHRINGER[1], D. J. ARPIN[1], E. HEINRICHS-GRAHAM[2], T. W. WILSON[2], M. KURZ[1];
[1]Physical Threapy, [2]Ctr. for Magnetoencephalography, Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: It is well accepted that the cortical oscillatory changes that occur prior to movement onset at the beta frequency (15-30 Hz) reflect the neural computations that are involved in planning motor actions. Moreover, a stronger beta event-related desynchronization (ERD) during the motor planning stage is associated with greater certainty that the selected motor action will meet the task demands. Still, we do not fully understand how these oscillations change as individuals learn a motor task. Nine healthy adults (Age = 23 ± 4 yrs.) practiced a discrete isometric ankle plantarflexion target matching task. The force production of the left ankle was collected with a custom-built force transducer. The generated force caused an animated a box to ascend, and the participants matched targets between 20 and 35% of their maximum force, which disappeared upon when the target was reached. The epochs of each trial were 10 seconds in duration (-5.0 s to +5.0 s), with the onset of the isometric force defined as 0.0 s. Each participant performed three 100-trial practice blocks. The cortical activity was recorded using magnetoencephalography (MEG) during the first and third blocks. Learning induced behavioral improvements were evaluated by comparing the reaction time, initial force production velocity, amount of overshoot, and amount of variability while trying to match the target between the first and third blocks. The MEG data were noise corrected, coregistered to MRI, filtered, and subjected to standard artifact rejection methods. The neural regions generating the beta ERD and time windows of interest were isolated and the data were subjected to beamformer analysis. Our results showed that the participants had behavioral improvements after practice. The reaction times were faster (P=0.017), initial force production velocity was faster (P=0.004), they had less overshoot (P=0.040), and less variability when trying to match the targets (P=0.015). These behavioral improvements paralleled the changes seen in the cortical oscillatory activity. The beta ERD ($P < 0.05$, cluster corrected) during the planning stage was stronger in the motor cortex, supplementary motor area, and frontal cortex after practice. The stronger beta ERD within these

respective areas suggest that the participants had greater certainty in selecting an isometric force that would match the prescribed targets. Altogether these results imply that changes in the strength of the beta ERD reflect the cortical changes that are associated with learning an ankle plantarflexion motor task.

Title: Improving source localization of movement-related potentials with tri-polar electroencephalography

Authors: *C. TOOLE[1], P. STEELE[3], J. DICECCO[2,4], W. BESIO[2,3];
[2]Electrical, Computer, and Biomed. Engin., [1]Univ. of Rhode Island, Kingston, RI; [3]CREmedical, Kingston, RI; [4]Naval Undersea Warfare Ctr., Middletown, RI

Abstract: Knowing where sources of activity are located in the brain can help with diagnosis. Locating the sources of electroencephalography (EEG) signals acquired on the scalp, the inverse problem, is an ill-posed problem since there are an infinite number of source configurations that can result in a particular potential map on the head surface. Therefore, additional constraints to the source space must be used to find a unique solution. Equivalent current dipole methods utilize a discrete source space in which a small number of dipoles are assumed to generate the given surface potential. Distributed source methods constrain the source space to a larger number of dipoles distributed either on the cortical surface or within the brain. Both methods have their advantages, but discrete source spaces yield an overdetermined solution while the solutions of distributed source methods are underdetermined.
In the present study, the increased spatial resolution of tri-polar EEG (tEEG) minimized the underdetermined nature of distributed source localization methods with respect to movement related potentials (MRPs). Subjects (n=5) were concurrently recorded with both conventional EEG and tri-polar concentric ring electrodes (TCREs) during periods of a visually cued, right index finger flexion task, a mouse click. Electrodes were placed on 16 of the standard 10-20 locations, including FP1, Fp2, F7, F3, Fz, F8, T7, C3, Cz, C4, T8, P7, P3, Pz, P8, and O1. Surface potentials related to index finger flexion were averaged per subject and subsequently localized using distributed source methods on the ICBM152 head model derived from a non-

linear average of MRI scans of the 152 subjects in the MNI152 database. Using the open-source data analysis application Brainstorm, a linear L2-minimum norm estimates algorithm was used to localize sources to a source space of dipoles constrained normal to the cortical surface, and subject results were normalized to Z-scores before group analysis. The locality of activated brain regions was then compared between conventional EEG and tEEG results.
Localization results obtained from tEEG appeared to be much more focal when compared to those of conventional EEG. Thus, the underdetermined nature of distributed source localization methods is decreased when used with tEEG, alleviating this drawback and producing a more accurate representation of the MRP source signal.

Abstract: Successfully performing rhythmic movements including walking synchronized to a rhythmic cue sequence, exact temporal prediction and motor execution are essential. It has been proposed that synchronous entrainment of brain activity to external pacing events may play a role in supporting temporal motor regularity. This entrainment has been suggested to optimize timing of action execution by controlling excitability in sensory cortices. In previous work (Wagner et al., 2012, 2014) we have shown that low gamma band activity in the Supplementary Motor Area (SMA, a critical motor planning node) entrains to the gait cycle during steady-state treadmill walking, suggesting a role of these oscillations in the planning of rhythmic movements. To investigate the role of cortical field oscillations in the temporal planning of gait, we performed a study in which we examined the high-density EEG dynamics of participants attempting to step in time to an auditory pacing tone sequence. After periods of steady-state walking, participants had to adapt their step length and rate to shifts in tempo of the pacing stimulus (e.g., following unforeseen shifts to a faster or slower pacing tempo) (Wagner et al., 2016). Analysis revealed that during steady-state walking, cortical field activity projecting to the scalp from one or more sources isolated in or near the SMA entrain to the rhythm of walking in both the (25-40 Hz) low gamma and (4-8 Hz) theta frequency bands, suggesting cross-frequency coupling between these rhythms. To assess this, we tested for coupling between low gamma and theta band activities by testing for coupling between all combinations of phase and amplitude in the two frequency bands. We found that during steady-state walking, ~35-Hz low-gamma band power amplitude is coupled to ~4-Hz theta phase. This coupling is maximal during stance and swing gait cycle phases, but is absent during transitions between these movement phases. We propose that this entrainment and coupling of theta and low gamma oscillations may help generate temporal predictions required for maintaining the temporally precise synchronization of gait to external pacing events.

Title: Changes associated with motor learning of TMS-evoked EEG responses

Authors: ***H. SEKIGUCHI**[1], S. TAKEUCHI[1], M. MIYAZAKI[2], K. YAMANAKA[3];
[1]Jobu Univ., Isesaki-Shi, Japan; [2]Shizuoka Univ., Hamamatsu, Japan; [3]Showa Women's Univ., Setagaya Ward, Japan

Abstract: Humans can perform accurately and quickly the intended movement with repeated training in daily living. The purpose of this study was to reveal the changes of neural network in the brain associated with motor learning by combining the electroencephalographic (EEG) recordings of the brain activity with transcranial magnetic stimulation (TMS). Eight healthy subjects (mean±S.D., 22.6±3.8 years, male n=6, female n=2) with no history of neurological disorders participated in the present study. All subjects were right-handed. Subjects were instructed to press four numeric keys on a standard computer keyboard with the fingers of their left hand (non-dominant), repeating the five-element sequence, 1-2-4-3-1, as accurately and as quickly as possible, for a period of 30 sec. One single training session consisted of 12 sets, 30-sec trials with 30-sec rest periods between trials. EEG signals were recorded using a flexible electrode cap with 16 electrodes (AFZ, F3, FZ, F4, FC1, FC2, T7, C3, CZ, C4, T8, CPZ, P3, PZ, P4, and OZ). During each rest period, TMS was applied to the scalp 6 times in inter-stimulus interval at 5 sec (72 stimulus in one session). TMS application carried out 3 times, at first session, 1 h after the first session (second session), and 1 week later (third session). Subjects trained three times per week, with each training session being comprised of 12 sets. A figure-of-eight coil was held over the right motor cortex (at the optimum scalp position to elicit motor responses in the contralateral FDI) with the induced current flowing in a postero-anterior direction, and was rotated away from the mid-line by up to 45º. The focal point was defined as the lowest threshold site giving a response specifically in the FDI muscle at rest. Stimulus intensity was at 60 % of the resting motor threshold. Performance was evaluated as the skill index (= % correct sequences / mean correct sequence time per each 30 s trial). The skill index was significantly increased with training ($P < 0.05$). We analyzed an amplitude of evoked potentials (N100 and P200), an event-related power (ERPow: the amount of change for mean power), and Phase-locking index (PLI: the extent of phase synchronization between trials). The latter two indexes are derived from a frequency analysis. There was no difference for amplitude of the evoked potentials (N100 and P200) among 3 sessions. However, the number of channels in ERPow and PLI associated with performance were increased in the frontal area of the brain in the third session. These results suggested that neural activity will be efficient in the frontal cortex with motor training.

Title: Independent preparation of “what” and “when”in the cortico-spinal pathway.

Authors: *N. HAGURA[1], Y. GOTO[2], M. MATSUMURA[2];
[1]CiNet, Suita-Shi, Japan; [2]Kyoto Univ., Kyoto, Japan

Abstract: Preparation of action requires both spatial (i.e. which action) and temporal (i.e. when to move) aspects. Here, we show that these two information are concurrently processed during the preparation period, each independently modulating the motor system. 14 subjects participated in the study. In a trial, an arrow indicating either left of right was presented on a monitor (GO signal). Subjects flexed their right wrist for the left arrow and extended for the right in a ballistic manner. In each block, the presentation ratio of left and right arrows varied (7:1, 3:1, 1:1, 1:3, 1:7), enabling the subjects to estimate which movement (flexion or extension) is more likely to be performed during that block. In each block, for half of the trials, a warning signal was presented 500ms before the GO signal. This allowed the subjects to predict the initiation timing of the movement. To evaluate the cortico-spinal excitability during motor preparation, single pulse transcranial magnetic stimulation (TMS) was applied to the left primary motor cortex 50~500ms before the GO signal, and motor evoked potentials (MEP) were measured from *flexor carpi radialis* (FCR) and *extensor carpi radialis* (ECR). Reaction time (RT) was reduced both by the information of the movement type and the movement timing, without showing any effect of interaction. This indicates that two information independently act on the motor system for efficient motor preparation. This behavioural pattern of independent information processing was similarly reflected on the MEP. Overall amplitude increased depending on the probability of the movement type (effect of movement type), but on top of that, reduction of MEP towards the GO signal was observed when the warning signal was presented (effect of movement timing). We propose that the information about movement types and movement timings are concurrently processed, possibly in different brain regions, acting on the cortico-spinal pathway from the motor cortex at different stages.

Title: The gradient level of inhibition in response preparation

Authors: *L. LABRUNA[1], C. TISCHLER[1], D. LEVITIN[2], M. J. DABIT[1], I. GREENHOUSE[1], F. LEBON[3], R. B. IVRY[1];
[1]Pshycology, UC Berkeley, Berkeley, CA; [2]McGill Univ., Montreal, QC, Canada; [3]Univ. Bourgogne Franche Comté, Dijon, France

Abstract: Cortical and subcortical inhibitory mechanisms help to sharpen the preparatory processes for a specific action, ensuring efficient performance. Relative to the selected effector, there is a gradient of inhibition such that some effectors show greater inhibition than others. This gradient could be anatomical, reflecting the distance between cortical representations of the body, functional, reflecting the history of interaction between different effectors, or a combination of factors. For example, compared to the foot, inhibition of the pinky could be greater when preparing to move the index finger either because the two fingers have neighboring cortical representations or because the two fingers are often involved in coordinated actions. In two experiments we used transcranial magnetic stimulation (TMS) to probe the state of corticospinal excitability to explore these hypotheses. In a first experiment, we compared the levels of inhibition during preparation of movements of effectors with cortical representations of variable distance relative to a probed muscle. In a second experiment, we tested professional drummers to see if they showed a different pattern of graded inhibition compared to control participants, given their history of extensive interactions between upper and lower limbs.
TMS was used to elicit motor-evoked potentials (MEPs) of the left index or left foot during a delayed response task. Each trial consisted of a fixation marker, a preparatory cue indicating the response for the forthcoming trial, and 900 ms later, an imperative signaling that the prepared response should be initiated. A single TMS pulse was applied over the right M1, either at the onset of the fixation (baseline) or before the imperative signal (delay). The results showed that MEPs were always reduced at the end of the delay period, relative to baseline, confirming the engagement of inhibitory mechanisms during motor preparation. Consistent with the anatomical hypothesis, the strength of inhibition was graded as a function of the proximity of the cortical representation of the body part involved in the prepared action to the probed muscle. The pattern of inhibition was similar in drummers and control participants, challenging the hypothesis that

the graded inhibition in different body parts is functionally related to the history of performing coordinate actions.

Title: Examining the influence of dorsolateral prefrontal cortex activity on ipsilateral primary motor cortex excitability with dual-site TMS

Authors: *M. J. BROWN, M. VESIA, C. GUNRAJ, R. CHEN;
Krembil Res. Inst., Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Objective: Frontal cortical areas interact for action planning and decision-making. The influence of the dorsolateral prefrontal cortex (DLPFC) activity on ipsilateral primary motor cortex (M1) excitability has not been systematically investigated.
Methods: Connectivity between DLPFC and M1 was examined using paired-pulse transcranial magnetic stimulation (TMS) using two coils in 12 right-handed participants (aged 21-44 years). Both right and left hemispheres were tested in separate sessions. Motor evoked potentials (MEPs) were recorded using surface electromyography from the first dorsal interosseous (FDI) and abductor pollicis brevis (ABP) muscles. The test stimulus (TS) was applied to M1 to induce MEP amplitude of ~1mV with both hands relaxed (Rest Condition) and while individuals held a 10% maximum voluntary contraction (Active condition). DLPFC was localized according to individual anatomical landmarks on MRIs along the middle frontal gyrus (BA 46). The conditioning stimulus (CS) was applied to DLPFC at stimulation intensities of 80% and 120% resting motor threshold (RMT). CS was applied before TS at inter-stimulus intervals (ISI) of 4-12, 15 and 20 ms.
Results: Despite individual variability, conditioning stimulation to the left DLPFC increased MEP amplitudes in ipsilateral M1 at two phases: an early peak between 5-8 ms and later peak at 9-11 ms. This facilitation was more prominent in the APB muscle compared to the FDI muscle. Rest condition with CS 80%RMT tended to produce greater facilitation compared to the other conditions. Interactions between right DLPFC and right M1 were more variable than the left

side.
Conclusion: These findings may provide effective parameters to evaluate DLPFC-M1 connectivity for sensorimotor actions in healthy, injured, and diseased brains.

Title: Cortical processes to predict timing of gait initiation through visual information

Authors: *K. TAKEDA[1], Y. NISHI[3], H. MANI[2], N. HASEGAWA[1], T. ISHIGAKI[3], Y. TAKAMURA[3], M. OSUMI[4], S. NOBUSAKO[4], H. MAEJIMA[2], S. MORIOKA[4], T. ASAKA[2]; [1]Grad. school of Hlth. Sci., Hokkaido Univ., Sapporo-Shi, Japan; [2]Dept. of Rehabil. Science, Fac. of Hlth. Sci., Hokkaido Univ., Sapporo-shi, Japan; [3]Dept. of Neurorehabilitation, Grad. Sch. of Hlth. Sci., [4]Neurorehabilitation Res. Ctr., Kio Univ., Kitakatsuragi-gun, Japan

Abstract: Introduction
We predict the clearance of other people spatiotemporally based on visual information to prevent collision in the crowd. As far as we know, no study has investigated the brain activities for timing control during gait initiation. The purpose of this study was to clarify the cortical processes related to timing control of gait initiation through visual information by electroencephalogram (EEG).
Methods
Thirteen healthy young adults participated in this study. Participants stood in front of a screen on which a horizontal moving target and a fixed goal were projected. They were instructed to synchronize the gait initiation when the target arrived at the goal on the screen. The participants were able to watch the target until it arrived at the goal under the control condition. On the other hand, the target vanished from 0.6 or 0.8 s before the target arrived at the goal under the vanishing condition, which was based on a previous study concerning motor preparation (Jacobs, 2008). The task consisted of 30 trials in each condition. Variable error (VE), which was the standard deviation of the temporal differences between the time when the target arrived at the goal and the initiation time of the heel-off, was calculated to assess the regularity of timing control. We measured brain activities by EEG and mainly focused on the power in the frontal region and the phase synchronization between the frontal and parietal regions in theta band (4-7Hz) during the target moving.

Results and Discussions

VE across the first 10 trials under the vanishing condition was significantly higher than that under the control condition. However, there were no significant differences between the conditions across 10 trials both of the middle and the last sessions of the 30 trials. It was suggested that the participants controlled the timing independently from the visual information in the middle and last sessions. Therefore, the first 10 trials were selected to analyze brain activities. At approximately 0.5 s prior to the arrival of the target at the goal, the power and the phase synchronization under the vanishing condition were significantly lower than those under the control condition. Furthermore, the synchronization showed significantly negative correlation with VE. We conclude that the connectivity between posterior parietal and frontal region at approximately 0.5 s before the predicted time of the motor execution is essential to control the timing of gait initiation based on visual information. Our results would be basic knowledge for prevention of collision and intervention for gait disorder, such as freezing, in the crowd.

Title: Gaze pattern differences inform hand posture to object shape during reach-to-grasp

Authors: *A. YOUSEFI[1], S. BILALOGLU[1], J. R. RIZZO[1], Y. LU[2], P. RAGHAVAN[1,2]; [1]Rehabil. Med., New York Univ. Sch. of Med., New York, NY; [2]Steinhardt Sch. of Culture, Education, and Human Develop., New York, NY

Abstract: Every day we grasp numerous objects of various shapes. Visual perception of object shape informs the planning of hand posture for an efficient grasp. A clear understanding of eye-hand coordination during adaptation of hand posture to object shape is necessary to develop appropriate treatment strategies for patients with hand function impairment. This study explores the relationship between gaze location and hand position during reaching to grasp objects of various shapes in healthy subjects. Eight neurologically intact, right-hand dominant subjects participated in the study; five were right eye-dominant and three were left eye-dominant. The

subjects sat at a table with the grasping hand palm-down in front of them, and then reached towards and grasped an object positioned at 75% of their arm length in front of them. The task was repeated seven times for nine different object shapes. The gaze vectors related to the two eyes were tracked using Eyelink2 eye tracker (SR Research Ltd, Ottawa, Ontario, Canada), and the location of the subject's head, hand and fingers were tracked by motion sensors attached to the limb segments and to the objects (6DOF Ascension sensors, Ascension Technology Corporation Shelburne, Vermont). The Cyberglove (Cyberglove system, San Jose, USA) was used to measure finger joint angles to compute hand posture. We examined the intersection of the gaze vector with the object for each eye during various phases of reach-to-grasp: upon eye opening (pre-reach), from reach onset to peak velocity (reach acceleration), from peak velocity to reach offset (reach deceleration), and grasp. The results suggest that examination of gaze patterns can inform planning strategies for control of hand shape during grasping. This information can be used as a benchmark for assessing eye-hand coordination deficits during reach-to-grasp in neurologically impaired patients such as stroke.

Title: Determination of treatment algorithms for patient subgroups for post-stroke hand function rehabilitation

Authors: ***P. RAGHAVAN**[1,2], Y. LU[3], C. BAYONA[4], S. BILALOGLU[2], A. YOUSEFI[2], A. TANG[2], V. ALURU[2], A. RANGAN[3];
[1]Rehabil. Med., New York Univ. Langone Med. Ctr., New York, NY; [2]New York Univ. Sch. of Med., New York, NY; [3]New York Univ., New York, NY; [4]New York Univ. Med. Ctr., New York, NY

Abstract: Consider a mundane task such as picking up a paper cup with coffee inside. Even this relatively simple action requires a great deal of coordination and control: one must ensure that (a) the hand posture matches the shape of the cup, (b) one doesn’t squeeze it too hard or hold it too loosely, and (c) one is able to smoothly lift it to one’s mouth. Over 85% of stroke survivors

with hemiparesis have difficulty performing these kinds of everyday tasks and – despite conventional rehabilitation – have persistent deficits in hand function that severely affect their quality of life. One of the important conclusions we have drawn from our previous experimental work is that the strategy for therapy must be targeted to the patient. That is to say, no single therapeutic strategy can be applied to all patients. This is because each patient has a unique profile of sensory and motor deficits, as well as a unique neural reserve that can be harnessed for recovery. We subject our cohort of 40 patients to a grasp and lift task under eight different learning conditions, each involving a different combination of tactile, kinesthetic and visual cues. Each patient practices the task under each of the conditions with the affected hand alone in one session, and by alternating hands in a different session. The measurements include grip and load forces, as well as several clinical tests of tactile, visual, kinesthetic and motor impairment, along with imaging data on brain lesion location and motor tract density. We will use clustering algorithms to delineate statistically significant patient subgroups which exhibit therapy-specific structure. Each of these subgroups will correspond to a 'bicluster' involving not only a specific subset of the patients, but also a specific subset of patient-traits (e.g., deficit category, clinical performance and physiological metrics). The method will pinpoint biclusters within the positively-responding patients that exhibit structure which is *not* reflected within the non-responding patients. The method can also be corrected for covariates as necessary.

Title: Plasticity in cortical control signals to muscles in pianists with overuse injury with peripheral behavioral intervention

Authors: ***S. BILALOGLU**[1], S. CHAKRABARTY[2], Y. LU[3], A. YOUSEFI[1], P. RAGHAVAN[4,1];
[1]New York Univ. Sch. of Med., New York, NY; [2]Sch. of Biomed. Sci., Univ. of Leeds, West Yorkshire, United Kingdom; [3]Humanities and Social Sci., Steinhardt Sch. of Culture, Education,

and Human Develop., New York City, NY; [4]Steinhardt Sch. of Culture, Education, and Human Develop., New York, NY

Abstract: Tension in neck muscles have been shown to be associated with overuse injury in pianists, but the relaxation of these muscles have not been found to be an effective treatment. To address this issue we examined cortical control of muscles by analyzing the EMG frequency spectrum in finger flexor and extensor muscles when 31 professional pianists with at least 10 years of experience played octaves; 20 of them were asymptomatic for overuse injury, whereas 11 were symptomatic. Subjects were tested under three postural conditions: (1) at baseline, (2) with relaxation of neck muscles (upper trapezius, UT), and (3) with activation of scapular stabilizers (lower trapezius, LT). EMG biofeedback was used to ensure that muscles were relaxed/ activated sufficiently. Bipolar surface electrodes were placed over flexor digitorum and extensor digitorum communis muscles. Electromyography (EMG) signals were pre-amplified and sampled through Spike 2 (Cambridge Electronic Design, Cambridge, England). Data was exported at 2000 Hz and imported into Matlab for data processing. EMG was filtered using bandpass filter (3-250 Hz, 5th order Butterworth) and 3 notch filters (notch at 60,120 and 180 Hz, Q factor 30, second order IIR). For each condition subjects played the C octave for 15 sec (7-8 times) with a pause of 2 seconds between each press; 3 such trials were recorded. The normalized power of the beta band (15-30 Hz) and the gamma band (30-55 Hz) in 70 ms bins before and after sound-onset were calculated. We found that asymptomatic pianists showed increased beta band power in their finger extensors (antagonists) during key press at baseline and with activation of the LT, but showed the opposite pattern with UT relaxation. The beta band power reflects the cortical inhibitory signal to the antagonist muscle. Symptomatic pianists, in contrast, showed decreased beta band power in the antagonist muscle at baseline and with UT relaxation, but a pattern more similar to asymptomatic pianists with LT activation.
These results suggest that when the UT is relaxed, cortical inhibition of the antagonist is reduced, leading to increased tension in these muscles. These data suggest that cortical inhibitory control is abnormal in symptomatic pianists relative to asymptomatic pianists, and points to a behavioral intervention that can alter the cortical control signal. We suggest that the targeted activation of scapular-stabilizing muscles rather than the relaxation of neck muscles may prevent overuse injury during skilled movement.

Title: Selective and global inhibition of interneuron circuits in human motor cortex during movement preparation

Authors: *R. HANNAH, S. TREMBLAY, J. C. ROTHWELL;
UCL Inst. of Neurol., London, United Kingdom

Abstract: Movement preparation has been suggested to be associated with a brief "global" inhibition of primary motor cortex (M1) excitability [1], affecting both task-relevant (responding) and task-irrelevant (non-responding) muscle representations. We asked whether this preparatory inhibition is global or selective for specific excitatory interneuron circuits in M1. We examined in 11 human participants how the excitability of two distinct circuits was affected at various stages during a warned reaction time task (WRTT), in which a warning cue appeared 500 ms prior to the imperative signal. A controllable pulse parameter transcranial magnetic stimulation (cTMS) device [2] was used to activate distinct interneuron circuits in M1 by changing the orientation of the induced current in the brain (posterior-anterior, PA; anterior-posterior, AP) and pulse width (30 - 120 μs). Motor evoked potentials (MEPs) were elicited in the first dorsal interosseous (FDI) muscle of the right hand using short AP (AP_{30}) and long PA (PA_{120}) pulses. Separate blocks of the WRTT were performed to evaluate AP_{30} and PA_{120} MEPs when responding with the right and left index fingers. Because the specificity of TMS pulses for distinct interneuron circuits is optimal at low intensities, participants maintained slight voluntary muscle contraction (5-10% maximum) throughout the WRTT to lower the threshold for stimulation. MEPs evoked by AP_{30} pulses had a longer latency than those evoked by PA_{120} (23.4 vs. 22.1; *t*-test, $P < 0.001$), confirming that different excitatory interneurons were recruited by the different combinations of pulse width and orientation. When responding with the right index, AP_{30} MEPs in the right FDI showed greater suppression than PA_{120} MEPs after the imperative stimulus (-31% v. -18%; Bonferroni corrected *t*-test, $P = 0.032$). In contrast, when responding with the left index, AP_{30} and PA_{120} MEPs in the right FDI were similarly suppressed after the imperative stimulus (-32% v. -31%; $P = 1.0$). The present data showed inhibition of MEPs during motor preparation in the responding muscle and in a muscle that is homologous and contralateral to the responding digit. The new result is that inhibition of the responding muscle was shown to be more selective for AP_{30}-sensitive interneurons, whereas the non-responding muscle showed a broader inhibition of both AP_{30}- and PA_{120}-sensitive inputs. These data point to partially independent forms of inhibition which may have different functional relevance and involve different neural networks.

Title: Differential effects of rTMS on motor cortex excitability, interhemispheric inhibition and performance in elderly people.

Authors: M. WISCHNEWSKI[1], G. M. KOWALSKI[1], J. FREEMAN[1], S. R. BELAGAJE[1], G. HOBBS[2], *C. M. BUETEFISCH[1];
[1]Neurol., Emory Univ., Atlanta, GA; [2]West Virginia Univ., Morgantown, WV

Abstract: There are conflicting reports on the effects of low frequency repetitive transcranial magnetic stimulation (rTMS) on primary motor cortex (M1) excitability and behavior. A comprehensive study investigating effects of rTMS on excitability of right and left M1, their interaction and relationship to performance is lacking. In a sham-controlled, randomized, double-blind study, we investigated the effects of two different rTMS interventions applied to left M1 on the excitability of each M1, interhemispheric inhibition (IHI) and hand performance. Participants were 11 healthy right handed volunteers (8 F, age = 61.6 ± 1.8 years). 1Hz rTMS at 80% and 90% of resting motor threshold (MT) and 1Hz sham stimulation at 80% MT were tested. EMG activity was recorded from the extensor carpi ulnaris muscles. Stimulation effects on M1 excitability were investigated by comparing pre- and post-intervention 1) stimulus response curve (SRC, 30-80 % maximum stimulator output) measured by a Boltzmann curve with maximum MEP (M_{MAX}), growth rate (K) and inflection point (S_{50}) as parameters; 2) Short intracortical inhibition (SICI), where a conditioning stimulus (CS) of 60% or 80% of MT preceded a test stimulus (TS) of 120% of MT by an interstimulus interval (ISI) of 2 ms; 3) IHI, where a CS to one M1 preceded a TS to the other M1 by an ISI of 10 ms. Performance was measured by the participants' accuracy on a joy stick operated pointing task where a cursor was moved to targets of different sizes at random locations as quickly as possible. An ANOVA tested the effects of stimulation on SICI, IHI and accuracy of hand performance. For SRC, the fit of a difference of curves were compared to the fit of a single curve. There was a significant effect of left M1 rTMS at intensities of 80% and 90% of MT on left but not right M1 SRC with an

increased M_{MAX}, decreased K and increased S_{50} from pre- to post-intervention. Left but not right M1 SICI was decreased after rTMS at 80%. This was not seen for rTMS of 90% MT. No clear effects of rTMS were found on IHI in either direction. There was a tendency for rTMS to affect accuracy depending on the performing hand. These preliminary findings suggest that both excitatory and inhibitory circuits are modulated differently by left M1 1Hz rTMS depending on intensity. In this population of elderly subjects, the effects of rTMS on M1 excitability seems to be limited to the stimulated M1. Further, evidence for rTMS modulation of IHI was not demonstrated. This contrasts the proposed model where 1 Hz subthreshold rTMS reduces excitability of the stimulated M1 and thereby the inhibitory effect towards the non- stimulated M1. Results are consistent with reported effects of age on motor physiology and control.

Title: Anticipatory corticospinal control of motoneurons during self-unloading of wrist muscles: comparison with usual unloading

Authors: *L. ZHANG, A. FELDMAN;
Dept. of Neuroscience, Univ. of Montreal, Montreal, QC, Canada

Abstract: When pre-loaded muscles are suddenly unloaded, the respective joint angle involuntarily moves to a new steady-state position (the unloading reflex or natural unloading). In contrast, during self-unloading produced by the subject using the contralateral hand, the joint angle remains unchanged. It has previously been shown that corticospinal influences on motoneurons of wrist muscles are maintained during natural unloading, despite changes in the joint angle and EMG activity of wrist muscles. It has also been shown that tonic corticospinal influences set the threshold position at which the wrist muscles begin to be activated. We tested the hypothesis that in contrast to natural unloading, to preserve the wrist position during self-unloading, corticospinal influences start appropriately changing the threshold position prior to

the unloading onset (anticipatory process). To test this hypothesis, we compared changes in motor-evoked potentials (MEPs) elicited by single-pulse transcranial magnetic stimulation (TMS) applied to the wrist area in motor cortex prior to natural and self-unloading. MEPs were recorded electromyographically from four wrist muscles (flexors: FCR, FCU; extensors: ECR, ECU). Results (n=12, healthy subjects) showed that shortly before self-unloading onset, MEPs in pre-loaded flexor muscles decreased in 11 subjects and MEPs in extensors increased in 7 subjects, even though the EMG levels and the wrist position before unloading remained unchanged. In contrast, before natural unloading, MEPs in all muscles were preserved. The findings suggest that in order to prevent joint motion during self-unloading, the corticospinal system initiated a change in the subthreshold facilitation of agonist motoneurons in anticipation of unloading. The EMG and kinematic patterns of behavior in natural and self-unloading are explained based on the notion of threshold position control. It is concluded that such control has the feed-forward, anticipatory nature and is mediated by the corticospinal system.

Title: Cortical coherence during movement.

Authors: *A. O'KEEFFE, N. POURATIAN;
Neurosci., UCLA Hlth. Syst., Los Angeles, CA

Abstract: Movement is thought to be governed by interactions among a hierarchy of cortical areas including primary motor cortex (M1), premotor cortex (PM) and the supplementary motor area (SMA). These cortical regions display movement related neural activity however it remains unknown how the interactions between movement cortices is regulated. We propose that coherent neural oscillations in the 12-35Hz band regulate inter-regional communication to facilitate the execution of cortically represented movement plans. Eight patients undergoing deep brain stimulation (DBS) for Parkinson's disease (PD) had local field potentials recorded from motor and premotor cortices during rest and cued movement. Spectral analyses show (1) low beta suppression within motor and premotor cortices during movement (2) that each subject demonstrates an increase in beta band coherence during movement and (3) that movement

related coherence peaks are correlated with peaks in the beta power spectra of premotor and motor cortices during movement. We have characterized the temporal and frequency dynamics of beta frequency spectral and coherence peaks in order to better understand the role for coherent neural oscillations in cued movement execution. An improved understanding of the means by which coherence in neural oscillations is facilitating movement could lead to development of minimally invasive cortical neurostimulation devices that induce interregional coherence to target akinetic symptoms in movement disorders.

Title: A comparison of widespread motor inhibition during movement preparation and stopping

Authors: *I. GREENHOUSE, L. CAO, R. B. IVRY;
Univ. of California Berkeley, Berkeley, CA

Abstract: Widespread inhibition is detectable in both task-relevant and task-irrelevant muscles during response preparation and during the stopping of initiated actions. Neuroanatomical models suggest a common basal ganglia-thalamic inhibitory pathway is engaged during these two phases of movement. Based on this, we predicted a positive correlation between the level of inhibition observed during stopping and the level of inhibition observed during response preparation.
Participants (n=11) used either the left index finger or right pinky finger to respond in a stop signal task (36% Stop trials) or a delayed response task (Go), resulting in a fully-crossed, two (response finger) by two (task) design, consisting of four distinct task conditions: L index Go, L index Stop, R pinky Go, and R pinky Stop. The four conditions were tested in separate blocks, with the imperative always preceded by a preparatory delay period. Transcranial magnetic stimulation (TMS) was applied over right primary motor cortex to elicit motor evoked potentials (MEPs) from the left first dorsal interosseous (FDI) muscle when that muscle was relevant (L index) or irrelevant (R pinky) to the tasks. MEPs were measured 800 ms into the 900 ms preparatory delay interval on a subset of trials during both tasks. On separate trials of the R pinky Stop condition, MEPs were also measured 150 ms after the imperative (Go trials) and 200 ms after the stop signal (Stop trials). We did not apply TMS after the stop signal in the L index condition because the MEPs would be elevated due to ongoing movement implementation.

The left FDI was significantly inhibited during the preparatory delay relative to an inter-trial baseline in all conditions (p's < .05) except the L index Stop condition (p = .70). The left FDI was significantly more inhibited when preparing R pinky responses than L index responses (p = .001). There was no main effect of task and no interaction. Left FDI MEPs measured during successful and failed stopping in the R pinky Stop task were suppressed relative to baseline (both p < .005) and relative to MEPs measured after the imperative on go trials (both p < .05). The level of preparatory inhibition in the R pinky Stop condition was significantly correlated with the level of inhibition during successful stopping (R = .86, p < .005) and during failed stopping (R = .71, p < .05). However, MEPs measured during the delay period were not correlated between task conditions (all p > .06). These results are consistent with the hypothesis that a shared inhibitory mechanism with a widespread effect on the motor system is engaged during the preparation of responses and during stopping.

Title: Abnormal interhemispheric interactions are present in the chronic but not in the acute or subacute post-stroke periods

Authors: *J. XU[1], M. BRANSCHEIDT[3,2], H. SCHAMBRA[4], G. LIUZZI[3], L. STEINER[3], N. KIM[1], T. KITAGO[4], A. LUFT[3], J. W. KRAKAUER[1], P. A. CELNIK[2];
[1]Neurol., [2]Dept. of Physical Med. and Rehabil., Johns Hopkins Univ., Baltimore, MD; [3]Dept. of Neurol., Univ. of Zurich, Zurich, Swaziland; [4]Dept. of Neurol., Columbia Univ., New York, NY

Abstract: The exact mechanisms of motor recovery following stroke remain poorly understood. Previously Murase et al. (2004) described in 12 chronic stroke patients the presence of persistent interhemispheric inhibition (IHI) from the healthy to the ispilesional motor cortex in the context of movement. This finding was associated with muscle strength where patients with lowest MRC have less release of IHI, hence more inhibition at movement onset. This classic study has been highly influential in the neurorehabilitation field leading to the test of many interventions geared towards rebalancing this abnormal IHI. However, to date it is unclear whether unbalanced IHI is present early after stroke, how it evolves over time, and if it has any predictive value for motor

recovery.
Here we studied over one year the evolution of movement-related interhemispheric inhibition (IHI) in patients with first-time acute onset unilateral, cortical or subcortical ischemic stroke leading to a motor deficit of the upper limb (N=22) and healthy age-matched controls (N=11). Participants were tested at 5 different time points after stroke (week 1, 4, 12, 24, and 52). At each session, participants performed a simple reaction time task, in which they made voluntary abduction movements with the index finger of their paretic hand. Paired-pulse TMS was applied at four different timings during movement preparation, with the conditioning stimulus applied to the M1 of the healthy hemisphere and the test stimulus over the lesioned hemisphere (contralateral to the paretic hand). Healthy controls always performed the task with their right hand, while the conditioning pulse was applied to the right M1 and test pulse to the left M1 (contralateral to the moving hand).
Contrary to previous believes, we found that in the acute to subacute stages (weeks 1, 4, and 12) patients showed release of pre-movement IHI similar to healthy controls ($p = 0.59$). Interestingly, the amount of release of IHI early after stroke correlated with hand strength at chronic stages (mean of week 24-52; $r = 0.78$, $p = 0.0005$). Noteworthy, in the chronic phase (weeks 24 and 52) patients have less release of IHI compared to healthy controls ($p = 0.006$), consistent with Murase et al. report. Our findings suggest that abnormal interhemispheric interactions in chronic stroke patients could be the consequence of a maladaptive process not present early after stroke. In addition, early pre-movement IHI might have predictive value for hand strength recovery.

Title: Somatotopic specificity of motor cortex plasticity in response to visuo-proprioceptive realignment

Authors: ***J. L. MIRDAMADI**[1], A. K. LYNCH[1], Y. LIU[1,2], H. J. BLOCK[1,2];
[1]Dept. of Kinesiology, [2]Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Goal-directed reaching requires integration of visual and proprioceptive information about the hand. In general, these estimates are combined and weighted in a statistically optimal manner. When we encounter a perturbation that causes a misalignment between visual and proprioceptive estimates, movements initially will be inaccurate. The brain can resolve this issue through changes in multisensory perception including weighting and realignment, or through motor adaptation. Although these processes have traditionally been studied in isolation, recent behavioral and neurophysiological studies have shown that motor adaptation influences proprioceptive realignment. Whether this link between perceptual and motor systems is reciprocal is unknown. Here, we investigate the effect of visuo-proprioceptive realignment on motor cortex (M1) excitability. Seated at a reflected rear projection touchscreen apparatus, subjects performed right hand movements to proprioceptive targets (left index finger), visual targets (white box), or both together. In one of two sessions, no misalignment was introduced. In the other session, a 70 mm misalignment was induced gradually by shifting the white box away from the left index finger. Before and after the behavioral task, single pulses of transcranial magnetic stimulation (TMS) were delivered over the hand region of M1 contralateral to the left index finger at rest. To determine whether any effects on M1 excitability are somatotopically specific, we computed input-output (IO) curves for both first dorsal interosseous (FDI) and abductor digiti minimi (ADM). Data were fitted to a Boltzmann sigmoid function. Preliminary data (n = 5) indicate that individual M1 excitability changes may be related to multisensory integration. FDI IO slope increased to a greater extent in individuals who relied more on proprioception than vision in the misaligned session, but not veridical session. According to the minimum variance model, the lower weighted (least trusted) modality is expected to realign more. Therefore, a lower weight of vision would be associated with more visual realignment and less proprioceptive realignment. These initial results are in line with our previous findings on correlations between IO slope change and realignment, and further data will clarify whether this is the case in ADM as well as FDI. Overall, the data suggest that the effect of misalignment on motor cortex excitability is a function of how individuals integrate multisensory information. This has important implications for current models of multisensory integration and motor control.

Title: Investigating the temporal aspects of action observation: evidence from soccer players

Authors: ***M. BOVE**, L. PEDULLÀ, E. GERVASONI, A. BISIO, M. BIGGIO, L. AVANZINO;
Univ. of Genoa, Genoa, Italy

Abstract: In everyday life we are constantly subjected to visual stimuli constituted by other people actions, producing a wide sequence of neural mechanisms in our brain. One of the contexts where action observation (AO) occurs is sport. A particular aspect of this phenomenon is given by the spectators' reaction following temporal errors committed by the athletes. It is now widely accepted that AO elicits an increase of the observer's corticospinal excitability and it is assumed that the perceived actions are matched to a representation of the observer's own actions depending on his/her previous motor experience. To date, the effect of an observed delayed action on the observer's motor system is still unknown. The aim of the present study was to investigate how different spatio-temporal patterns in the execution of a soccer action can affect corticospinal excitability in soccer experts (Soccer group: N=16) and in novices (Novice group: N=10). To this aim subjects were asked to watch two videos representing the same action: a correct video, where a pass was performed with the correct timing, and a delayed video, where the pass was delayed with respect to the action development. Corticospinal excitability during AO at different time points was assessed by means of transcranial magnetic stimulation for the right tibialis anterior, a muscle involved in the soccer pass movement. Considering the correct video, in the Soccer group, corticospinal excitability recorded at the moment in which the ball was passed was significantly higher than that recorded after the pass. On the contrary, in the delayed video, the Soccer group showed a significantly higher corticospinal excitability about 800 ms before the ball was passed than that recorded at the beginning or at the end of the action, i.e., when the pass was really performed. No statistically significant differences were reported for the Novice group in the different timing points for both videos. These results confirm that the observer’s motor experience strongly influences corticospinal excitability during the observation of a well known action. Further, motor experience, likely through a mechanism of temporal prediction, affects the activity of the neural system underpinning action observation inducing an increase of the corticospinal excitability when the action is expected and not when it is actually observed.

Title: The competitive effect of alternative movements with different probabilities on EEG during preparation period

Authors: *A. FUJIKAWA, Y. MATSUMOTO, T. URAKAWA, O. ARAKI;
Applied Physics, Tokyo Univ. of Sci., Tokyo, Japan

Abstract: Before a human or a monkey begins an action, neural activities relevant to preparation for the movement is observed. Neurophysiological studies in monkeys have suggested that the premotor and motor cortices simultaneously prepare for multiple movements, when multiple candidates of movements are given. Electroencephalogram (EEG) studies in humans reported that amplitude of Lateralized Readiness Potential (LRP) related to the movement preparation decreased as the number of possible movements increased (Praamstra et al. 2009). The LRP was interpreted to originate from competition among different preparation activities. Since increasing the number of the movement candidates corresponds to decreasing probability for each movement candidate, there remains a possibility that the amplitude of LRP reflects the probability for each movement, irrespective of competition. In fact, it has been reported, in Go/No-go task, that the higher the probability to move is, the larger the amplitude of LRP becomes. Moreover, the amplitude of Contingent Negative Variation (CNV) is also larger when the prior probability to move is higher. Thus, we fixed the probability of movement to one direction (80%) to determine whether EEG activity reflects the effect of competitive interaction between probable movements rather than the probability itself. We designed two conditions: (1) to move to another direction (20%), and (2) no movement (0%). Under the constant probability, we can compare the results of competitive and no competitive conditions. In this task, we first presented 1 or 2 spatial cues whose positions indicated the potential target's location(s). The thickness of lines in the spatial cue implied go probability, and subjects were asked to prepare for the movement based on prior probability. A move cue was then presented and the cue indicated whether or not participants had to move their hands to the target. When the cue indicated 'move', the cue also indicated the location of the actual target. Results showed that CNV amplitude in the competition condition was larger than that in the no competition condition at 800-900 ms after the spatial cue's onset ($p<0.05$). In contrast, there was no significant difference in LRP amplitude between the two conditions. These results indicate that the effect of competitive interaction is reflected by CNV rather than LRP during the period of movement preparation. In addition, the significant difference in CNV amplitude appeared at 300-400ms before the move cue. Thus, the

neural processing related to competition is considered to be evoked in the early stage of movement preparation.

Title: Electroencephalography based analysis of hemispheric activation asymmetry for goal- and non goal-oriented movements with virtual mirror feedback

Authors: ***M. ROHAFZA**[1], M. YAROSSI[2], E. TUNIK[3], S. ADAMOVICH[1];
[1]New Jersey Inst. of Technol., Newark, NJ; [2]Rutgers Biomed. Hlth. Sci., Newark, NJ;
[3]Northeastern Univ., Boston, MA

Abstract: Therapy for stroke often uses repetitive task practice, which is difficult to perform for patients with severe impairment. Mirror feedback (MF) therapy that uses motion of the less affected limb is potentially beneficial for recovery and can recruit the lesioned hemisphere. However, the rehabilitation outcomes vary and the neural mechanisms underlying MF are poorly understood. One contribution to the conflicting results is wide variability in the type of sensorimotor motor task that is combined with MF. We investigated the interaction of goal (target, no target) and visual feedback (veridical feedback (VF), MF) in a 2x2 factorial design. We used electroencephalography (EEG) to investigate hemispheric activation asymmetry in a timing specific manner to dissociate processes related to movement planning and execution. Eighteen healthy subjects (age: 22±3) performed fast right index finger flexion. Movements were recorded with a data glove to actuate, in real time, virtual hands shown on a display that was placed above their hands. Subjects completed four sessions with MF with a target (MG+), MF without a target (MG-), VF with a target (VG+), and VF without a target (VG-). Hemispheric asymmetry, the difference (sum squared error, SSE) in event related de-synchronization (ERD) in the beta band (15-25Hz) between motor cortices (electrodes C3 and C4), was quantified over 4s epochs at baseline (before cue presentation), planning (between cue presentation and

movement), movement execution, and at post (after movement completion). The main effect of visual feedback on asymmetry index was significant during both preparation and execution. The goal x visual feedback interaction was significant during planning only. Although there was no significant main effect of goal during planning or execution, the presence of a goal in the veridical condition was associated with increased lateralization of activity during planning. This effect may be due to inhibitory interhemispheric interactions that are in place to prevent mirror movements. In the presence of a goal, MF significantly decreased hemispheric asymmetry, compared to VF, with MG+ having the lowest asymmetry index during both planning and execution epochs. Together, these results indicate that mirror feedback may cause decreased asymmetry in sensorimotor cortices, with a distinct effect of goal on movement planning. Our study sheds light on the timing of interhemispheric interactions during MF in healthy individuals. The results will guide future investigations into these mechanisms in stroke populations and the application of mirror therapy and brain stimulation protocols to optimize therapy outcomes.

Title: The influence of cerebellar transcranial direct current stimulation on motor skill acquisition and learning in a throwing task

Authors: ***B. J. POSTON**[1], L. L. ALBUQUERQUE[1], A. K. JACKSON[1], K. M. FISCHER[1], M. A. GUADAGNOLI[1], Z. A. RILEY[2];
[1]Kinesiology and Nutr. Sci., Univ. of Nevada Las Vegas, Las Vegas, NV; [2]Indiana-University-Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Cerebellar transcranial direct current stimulation (c-tDCS) is a non-invasive brain stimulation technique that has been shown to increase motor performance in simple tasks such as planar arm movements. However, the ability of c-tDCS to enhance motor performance in a complex, goal-directed task involving whole body coordination is unknown. The purpose was to determine the influence of c-tDCS on motor skill acquisition and learning in a throwing task in young adults. The study was a double-blind, sham-controlled, between-subjects experimental design. Twenty-four young adults were allocated to either a c-tDCS group or a SHAM stimulation group. Each subject participated in a practice session followed by an experimental session, which was completed 24 hours later. In the practice session, subjects performed 10 trials

of a throwing task in a baseline testing block, followed by 6 practice blocks of 10 trials, and a post-testing block of 10 trials that was performed five minutes after the last practice block. In the retention session, subjects performed the throwing task for a single block of 10 trials. The throwing task involved accurately throwing tennis balls puts to a small target placed on a concrete wall 6 meters away from the subjects. Anodal c-tDCS or SHAM stimulation was applied during the practice blocks at a current strength of 2mA for 25 minutes. For c-TDS, the anode was place 3cm lateral to the inion overlying the cerebellar hemisphere ipsilateral to the throwing arm, whereas the cathode was placed over the ipsilateral buccinator muscle. SHAM stimulation was applied in the same manner according to established blinding procedures in which the current was ramped up and down over a period of 60 seconds. The dependent measures of interest for the throwing task were endpoint error and endpoint variance. The endpoint error was quantified as the absolute distance of the final endpoint of each throw relative to the target, whereas the endpoint variance was quantified as the sum of the variances of the *x* and *y* endpoints for each trial block. For the testing blocks, the endpoint error and endpoint variance were similar at baseline between the two groups, but were lower in the c-tDCS group compared with the SHAM group for the post-test block and the retention testing block. However, the rate of decline in endpoint error and endpoint variance was similar for the two groups during the actual practice blocks. The findings indicate that a single application of c-tDCS applied during practice of a complex throwing task increases endpoint accuracy and reduces endpoint variability in young adults when measured in retention tests performed 5 minutes and 24 hours after cessation of practice.

Abstract: Movement related cortical potentials (MRCPs) proposed as reliable and immediate indicators of cortical reorganizations in motor learning. It has been reported that decrease in amplitude and later onset of MRCPs reflect less mental effort and shorter planning time during a motor task. In this study MRCPs preceding hand movements in severe chronic stroke patients were investigated using an EEG paradigm (patients performed hand open and close for paretic and healthy hand) before and after a one-month online EEG Brain Machine Interface neurorehabilitation intervention coupled with physiotherapy. 17 severely impaired (no residual finger extension) chronic stoke patients were participated in the study. In the group of patients who received contingent feedback MRCP peak amplitude for paretic hand movements was significantly reduced over Cz and MRCP onset for paretic hand movements was significantly later over central regions in the post measurements comparing pre results. No significant changes measured in the sham-feedback group and healthy hand movements between pre-post measures. Our results suggest that our patients needed less mental effort and shorter planning time after intervention. We demonstrated for the first time significant MRCP changes after a neurorehabilitation intervention (BMI and physiotherapy) in severe chronic stroke patients.

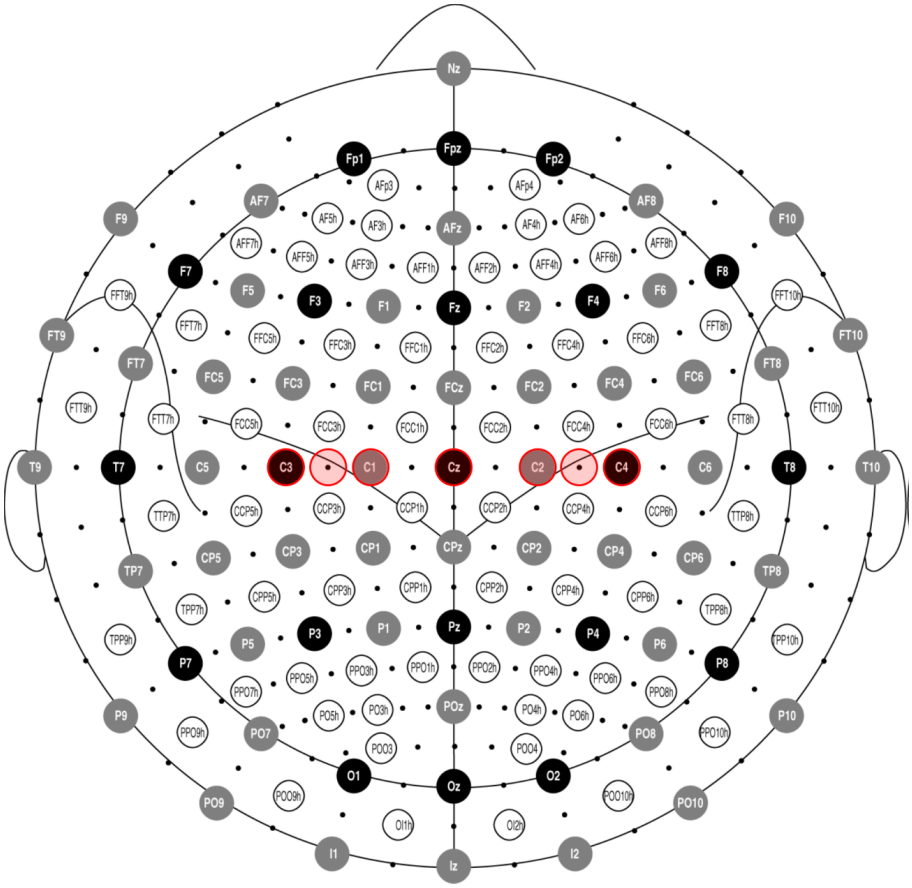
Title: Minimizing the required number of surface EEG electrodes with focused positioning

Authors: *M. B. BAYRAM[1,2], H. ARGUNSAH BAYRAM[1,2];
[1]Dept. of Med. Engin., Acibadem Univ., Istanbul, Turkey; [2]Human Performance and Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: Introduction: This study examines applying real-time PSD analysis to surface EEG signals which acquired by the minimum number of electrodes. While recording high-density EEG signals, most of the "unneeded" data are discarded in the pre-processing stage. Additionally, it is known that EEG frequency power (EEG_{FP}) of some EEG rhythms has a relationship with the voluntary motor activities, which could further state that EEG_{FP} controls the muscle contraction level: the higher the EEG_{FP}, the more the muscle contraction. The current study tested a hypothesis that, by implementing this relationship and novel feature extraction techniques, using only 7 or less electrodes would compare to 32-256 channel EEG recordings' findings. **Methods:** In Phase One, 2 healthy young (20.23 ± 1.23 years) individuals performed ~3s lasting isometric maximum voluntary contractions (MVC) of the non-dominant arm elbow flexion (EF) for 40 times, with 8s rests in between. Then, subjects were asked to repeat the procedure with their dominant arm, for 40 times. After a 10-minute rest, in Phase Two, they were asked to imagine the EF by following the same protocol. Meanwhile, 7 scalp EEG signals were recorded during the motor and imaginary tasks imaginary MVC contractions. **Results:** Our preliminary findings showed that Beta-band EEG_{FP} exhibited significant positive correlation with the EF force for both physical and imaginary contractions for the contralateral side; meanwhile for imaginary MVC, Alpha-band EEG_{FP} had also significant negative correlation. Additionally, for this preliminary study with limited number of participants, removing some of the electrodes' data caused inconsistencies within the findings. **Conclusions:** EEG_{FP} of some EEG rhythms has a direct relationship with physical and imaginary voluntary motor activities. Minimizing the number of electrodes by focusing the placement that can gather this relationship data, would lead to the faster processing. These findings may be used as a marker for a faster and more reliable Brain-Computer Interfaces, for both research and clinical.



The 10-5 electrode system has been suggested by Oostenveld et al (1). Based on this montage, Cz (as reference), C1, C2, C3, C4, C3h and C4h electrodes have been used for this study (indicated in red). (Oostenveld R, Praamstra P. The five percent electrode system for high-resolution EEG and ERP measurements. Clin Neurophysiol. 2001;112(4):713-719.)

Title: Visual perception threshold is inversely correlated with moment-to-moment changes in corticomuscular coherence during tonic isometric voluntary ankle dorsiflexion in humans

Authors: *R. MATSUYA[1], J. USHIYAMA[2,4], S. KASUGA[3], J. USHIBA[3];
[1]Keio Univ. Grad. Sch. of Sci. and Technol., Kanagawa, Japan; [2]Fac. of Envrn. and Information Studies, [3]Fac. of science and Technol., Keio Univ., Kanagawa, Japan; [4]Departiment of Rehabil. Med., Keio Univ. school of Med., Tokyo, Japan

Abstract: BACKGROUND: Oscillatory activity of the sensorimotor cortex measured by electroencephalogram (EEG) shows coherence with electromyogram (EMG) activity in a contralateral limb muscle within the 15-35 Hz frequency band (β-band) during tonic isometric voluntary contraction. Previous studies have reported that the magnitude of the corticomuscular coherence (CMC) can be changed by various factors including motor learning, attention and cognitive effort. From these findings we speculate that visuomotor feedback gain is associated to the CMC modulation caused by the learning or cognitive control. Indeed, the visuomotor feedback gain is known to be enhanced during the learning process. Recently, we reported that CMC changed from moment to moment even during tonic isometric contraction of a same motor level, and also this change affected the motor performance. Here, we aimed to investigate whether visual perception threshold is altered in association with the moment-to-moment changes in the magnitude of CMC during the serial motor task, to characterize the visuomotor feedback gain in the CMC modulation. METHODS: We recruited nine healthy participants with significant CMC between EEG and EMG measured from the tibialis anterior muscle. The participants performed tonic isometric voluntary ankle dorsiflexion and adjusted their contraction levels by reference to a cursor displayed on a monitor in front of participants. The participants were instructed to push a button by their right thumb immediately when they perceived cursor jumps. We set 10 types of cursor jumps with different jump sizes based on force SDs of each participants (i.e., 0.50, 0.75, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0 and 5.0 SD), and total 640 jumps were produced at random timings and in random orders. We divided the 640 trials into two groups (GD+ or GD-) including 200 trials depending on the magnitude of EMG β-band grouped discharge 1.5 s before timings of each jump occurrence. RESULTS: The magnitude of CMC in GD+ was significantly greater than that in GD- ($p < 0.001$). Perception thresholds calculated from the psychophysical curve between the cursor jump size and percentage of perception for each group demonstrated that the perception threshold of GD+ was significantly smaller than that of GD- ($p = 0.036$). CONCLUSION: This result suggests that the visuomotor feedback gain is upregulated with increased CMC.

Title: The mirror neuron system discriminates action exemplar: a human fMRI study

Authors: *S. FERRI, A. PLATONOV, G. A. ORBAN;
Univ. of Parma, Parma, Italy

Abstract: To understand which regions of human action observation network discriminate action's exemplars, we conducted an fMRI experiment in which the subjects, after watched videos showing a female ormale actor executing a manipulative action (grasping or pushing) toward an object (red cube or blue ball), have to perform three different 2-alternative forced choice tasks (2AFC) regarding to action, colour of the object or gender of the agent. To avoid lateralisation bias, the position of the actor was flipped in half of the blocks. 18 right-handed subjects were scanned in a single fMRI session including 8 experimental runs in which the three discrimination conditions and the fixation one were repeated twice. A fixation point was put in the centre of the screen close to the starting position of the hand. To check the steady fixation monocular eye-tracker monitored saccades for all the duration of the runs. Eye data results showed that subjects fixation well (average: 10.2 saccades per minute, SD=2.9); ANOVA confirmed that the number of saccades did not differ across conditions ($F_{3,12} = 0.3$ $p= 0.9$). The behavioural results showed the subjects performed discriminate very well in all of the presented tasks (av % of corrected responses for actions: 92%; gender: 95 %; colour: 96%; without difference between conditions $F_{3,12}= 0.5$ $p>0.3$). Conjunction analysis tests with inclusive masking revealed the regions activated more by one of the three discrimination tasks compared to the two others. Bilateral anterior intraparietal (phAIP) and left precentral sulcus (PCS) were more activated by action discrimination task (left phAIP: -42 -46 42 $t=5.8$ $p<0.05$ FEW corr; right phAIP: 36 -50 42 $t=6.3$ $p<0.03$ FEW corr; PCS: -42 -4 46 $t=5.9$ $p<0.05$ FEW corr); left middle temporal gyrus (MTG), left PGa-PGp and right fusiform gyrus (FG) were found specific for gender discrimination (MTG: -44 -68 0; $t=5.9$ FEW corr; PGa-PGp -38 -76 36 $t=6.1$ $p<0.04$ FEW corr; right FG: 28 -40 -20 $t=6.1$ $p<0.04$ FEW corr) while no specific region for colour task was found. This preliminary data highlighted the role of mirror neuron system (MNS) in discriminating between action exemplars. The activation of left MTG overlapping with extrastriate body area (EBA, Downing et al 2001) and which one in right FG cluster, set just posterior to fusiform body area (FBA, Peelen et al 2005), show that feature attention drawing to the gender improved the processing of region known to be involved to the processing of

observing body parts; this could mean that the arm and hand of actors were the cues used to discriminated between the two genders.

Title: Neural correlates of performance time on a tool-use task in chimpanzees

Authors: ***L. D. REYES**[1], S. BIANCHI[3], W. D. HOPKINS[4,5], C. C. SHERWOOD[2]; [1]Lab. for Evolutionary Neurosci., [2]Dept. of Anthrop., George Washington Univ., Washington, DC; [3]Dept. of Neurol., Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [5]Developmental and Cognitive Neurosci., Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: The manufacture and use of complex tools is a distinctive human behavior and is associated with a left-lateralized tool circuit that includes a diverse group of cortical areas. Specific white matter tracts have been associated with the tool-use circuit in humans including the superior longitudinal fasciculus (SLF), inferior fronto-occipital fasciculus (IFOF), anterior thalamic radiation (ATR), and uncinate fasciculus (UF). This study investigated the evolution of these white matter tracts in tool-use by assessing differences in white matter structure associated with performance time on a tool-use task in chimpanzees. To this end, we used diffusion tensor imaging (DTI) scans to perform tract-based spatial statistics (TBSS) of fractional anisotropy (FA) and mean diffusivity (MD) in a sample of 44 chimpanzees. The task used to measure tool-use performance consisted of a simulated termite fishing task and performance time was measured as the average time over a number of bouts (≥50). Since sex-based differences in tool-use proficiency have been observed in both wild and captive chimpanzees, we also accounted for effects of sex, age, and brain volume in the analyses. The TBSS analysis modeled the effects of an interaction between sex and tool-use by comparing the relationship between performance time on the task and both FA and MD between males and females. A linear model was also used to

assess the overall effect of tool-use on both FA and MD. Results showed a medium effect size (Pearson's $r > 0.3$) of the interaction in both FA and MD in the SLF, ATR, corticospinal tract, anterior commissure, and corpus callosum, although the results did not reach statistical significance ($p > 0.05$). The overall effect of tool-use performance time also showed a medium effect size for both FA and MD, but was not statistically significant ($r > 0.3$; $p > 0.05$). Faster performance time was associated with greater FA in the SLF and corpus callosum, and lower FA in the ATR. Faster performance time was also associated with greater MD in the ATR, IFOF, SLF, and cerebellum. Although the human circuit is left-lateralized, there was no lateralization detected with the TBSS analysis in chimpanzees, as many of the clusters appeared bilaterally. Tool-use performance time appears to have an effect on the ATR, SLF, and IFOF, tracts that have been associated with the human tool-use circuit. These results suggest that similar tracts in the chimpanzee and human brain may be involved in tool-related processing.

Title: Task-dependent changes in alpha-band power during preparation for sensory-motor action

Authors: ***Y. MATSUMOTO**, A. FUJIKAWA, T. URAKAWA, O. ARAKI;
Dept. of Applied Physics, Tokyo Univ. of Sci., Tokyo, Japan

Abstract: Previous electroencephalography (EEG) studies reported motor-preparation-related potentials and neural oscillations. The neural dynamics before movement depends on how to response to the stimulus (Shenoy et al., 2013). In the sensory-motor process, therefore, visual information such as position and shape of objects may influence the movement preparation. Actually, it has been reported that the stimulus difference, for example between position and meaning of figures, affects the brain activity for anticipation as well as behavioral and EEG data before and after the stimulus onset (Zoccatelli et al., 2010, Molin et al., 2013, Strack et al., 2013). Here, we hypothesize that the corresponding neural networks prepare for a sensory-motor action before the movement starts. The purpose of our study is to verify whether different brain areas are activated when humans prepare for movement in different sensory-motor tasks. We presented an integer (1-9, except 5) as a target cue above or below the fixation point. There were two conditions: (1) a subject should push the button (upper or lower) based on the position of

number (position-button: upper-upper & lower-lower, and vice versa), (2) which button to be pushed depends on the parity of the number (position-button: even-upper & odd-lower, and vice versa). We analyzed EEG during the delayed period after the task condition is indicated. In this study, we focus on alpha-band power during preparing the movement because it is known to be related to cortical inhibition: the power tends to decrease in task-related areas, while it tends to increases unrelated areas. As a result, the reaction time was longer in the parity condition than in the position condition. The alpha-band power around the motor area (electrode position C3) for parity discrimination was larger than that for position during 400 ms before a target cue was presented. These results show that the cortical activity around the motor area is inhibited strongly during preparing for the movement related to the parity discrimination. Accordingly, the result suggests that different neural networks have already been activated before movement onset depending on the anticipated sensory-motor process.

Title: Functional motor cortical connectivity in twins and non-related individuals

Authors: *J. E. JOSEPH, P. CHRISTOVA, A. GEORGOPOULOS;
Univ. of Minnesota, Minneapolis, MN

Abstract: Introduction: We analyzed fMRI and motor behavioral data from the Human Connectome Project (HCP; www.humanconnectome.org) to explore associations between twin pairs of participants, and between randomly matched participants. Specifically, we tested the hypothesis that neural and behavioral measures would be significantly correlated in twins but not in unrelated people. In addition, we sought to estimate the contribution of the twin status to the possible associations between twins using the coefficient of determination (r^2 x 100) as an estimate of the percent of variance explained.
Methods**:** We analyzed two groups of participants**:** twins (N = 338 participants; 169 twin pairs) and non-related participants (N = 516; 258 randomly matched pairs). Resting-state, HCP fMRI

data consisted of time series of 1200 volumes per vertex, acquired with 2x2x2 mm resolution and 720 ms repetition time. These times series were prewhitened using a (15,1,1) ARIMA model (Christova, P. et al. J. Neural Eng. 8: 046025, 2011) and their innovations cross-correlated with varying lags. For left and right motor cortices we computed all possible pairwise cross correlation functions (CCF; ~2 million CCFs/motor cortex). For each CCF we located the highest absolute CCmax and noted its value and sign. We then constructed frequency distributions of the signed CCmax (CC) for each individual motor cortex to obtain the relative frequency of occurrence of negative and positive CCs. On the average, there were 30% negative and 70% positive CCs. Across all participants, the percentage of negative CCs (overall "inhibitory drive") ranged from 8% to 46%. Finally, motor behavior was assessed by calculating age-adjusted scores for dexterity, grip strength, gait speed and endurance of each participant. Results: First, we found that the test scores for the four motor behavioral tests above were significantly correlated in twins but not for non-related participants. Second, the inhibitory drives for the left and right hemispheres, and their mean, were significantly correlated in twins [r (mean inhibition) = 0.245 (P = 0.001, N = 169); r (left) = 0.233 (P = 0.002); r (right) = 0.251 (P = 0.001)] but not in non-related participants (no significant correlations for all three measures). Conclusions: The overall inhibitory drive and the motor capacities were significantly correlated between twins but not between randomly paired unrelated participants. With respect to inhibitory drive, the percent of variance explained, based on the correlation coefficients above, amounted to an average of 6% in twins, an approximate estimate of the contribution of similar genetic makeup to functional motor cortical connectivity.

Title: Motor network dynamics when coordinating bimanual actions

Authors: *S. VISWANATHAN[1,2], R. ABDOLLAHI[2], B. A. WANG[2], S. DAUN[2,3], G. R. FINK[1,2], C. GREFKES[1,2];
[1]Dept. of Neurol., Univ. Hosp. of Cologne, Koeln, Germany; [2]Cognitive Neuroscience, Inst. of

Neurosci. and Med. (INM-3), Res. Ctr. Juelich, Juelich, Germany; [3]Heisenberg Res. Group of Computat. Biology, Dept. of Animal Physiol., Univ. of Cologne, Cologne, Germany

Abstract: Even simple hand movements involve the coordinated interactions of distributed neural populations. However, these interactions can be modulated by whether a hand is moved in isolation or in parallel with the other hand's actions. Due to the diversity of bimanual actions, the mechanisms governing network modulations in bimanual contexts remain challenging to identify. Here we assessed whether the demands of producing additional movements or of inhibiting them in a bimanual context produce dissociable effects on the network dynamics and behavioral properties of a hand's actions. FMRI and Dynamic Causal Modeling (DCM) were used to this end.

In our task, right-handed participants (*N*=23*,* mean age = 27y*)* pressed buttons synchronized with periodic visual stimuli (2.2Hz) over 28 second blocks. In each block, movements were made either with (i) the right hand; (ii) left hand; (iv) both hands together; or (iii) both hands alternating. Periodic cues induced alternating Go states (having 4 movements) and NoGo states of equal duration. With this structure, the unilateral and Alternating conditions had matched Go states requiring movements with only one hand, while the unilateral and Together conditions had matched NoGo states where all movements were halted irrespective of hand.

The unilateral and Together conditions (matched NoGo states) showed strong behavioral similarities. The mean response time (RT) for both hands decreased from the first to the fourth stimulus in both the unilateral and the Together condition. However, this RT pattern was absent in the Alternating condition. Furthermore, individual RTs in the unilateral and the Together conditions were highly correlated implicating a common mechanism. Connectivity was assessed in a bilateral cortical network consisting of M1, PMd, SMA and IPS. During unilateral movements, bilateral SMA was positively coupled to contralateral M1 and negatively coupled to ipsilateral M1. This connectivity pattern was substantially modified in both bimanual conditions. Despite the shared Go state in the Alternating condition, bilateral SMA had a positive coupling to both contra- and ipsilateral M1. This pattern was shared by the Together condition with a critical difference. Right M1 was modulated to a greater extent by left SMA in the Together condition and by left PMd in the Alternating condition.

In summary, our findings suggest that, in a bimanual context, the demand for selective inhibition modulates each hand's action to a greater extent than the added movement demands. The differential roles of SMA and PMd might be linked to these inhibitory differences in producing coordinated bimanual actions.

Title: Increased locomotor demand is associated with decreased cortical alpha power

Authors: *J. R. LUKOS[1], J. C. BRADFORD[2], D. P. FERRIS[3];
[1]Space and Naval Warfare Systems Center, Pacific, San Diego, CA; [2]U.S. Army Res. Lab., Aberdeen Proving Ground, MD; [3]Divison of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: The effect of performing simultaneous cognitive and motor tasks can affect overall task performance compared to when each task is done in isolation. However, this relationship can depend on the intensity of tasks performed. The goal of this study was to better understand the underlying neural processes associated with locomotion under variable cognitive and physical loads. We measured EEG while participants (N=18) walked on a treadmill with an empty backpack (unloaded condition) or a heavy backpack (40% body weight, loaded condition) at a 1 m/s for 1 hour. While walking, subjects also performed a visual oddball paradigm where 12% of displayed images were targets that required participants to respond with a button press. We hypothesized that there would be increased engagement in locomotor related cortical areas while walking with the heavy backpack and decreased engagement in locomotor related areas during dual tasking with the visual oddball task. To test this, we processed EEG data by removing bad channels, applying independent component analysis, and back-projecting cortical independent component weights to channel data. We tested the differences in the frequency spectrum during loaded and unloaded conditions while either walking in isolation or performing the cognitive task. We computed log power spectra for each channel using a Wilcoxon (rank-sum) test to evaluate mean power differences between conditions within a moving 3-Hz frequency window (α=0.05). We found significant differences in the low alpha frequency band (7-10 Hz) at various channels across the scalp between the loaded and unloaded conditions both when participants were performing the cognitive task and walking in isolation. Specifically, alpha power was higher for the unloaded compared to loaded conditions. However, no alpha power differences were present when comparing walking while performing the cognitive task to walking in isolation for either the loaded or unloaded conditions. We believe that the decrease in alpha power resulting from carrying a heavy load is indicative of increased cortical engagement. These preliminary results suggest that walking with a heavy load requires more cortical involvement than walking with no external load, and this involvement is unaffected by a

secondary cognitive task. Further investigation using source analysis will help to identify which cortical areas contribute to these changes.

Title: Degree of right-handedness mediates inter-hemispheric connectivity of the human motor cortex during inter-hemispheric transfer: fMRI evidence

Authors: *P. PATEL[1], M. BELLANI[2], K. RAMASESHAN[3], G. RAMBALDELLI[5], C. MARZI[6], P. BRAMBILLA[7], V. DIWADKAR[4];
[1]Sch. of Med., Wayne State Univ., Troy, MI; [2]Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy; [4]Psychiatry & Behavioral Neurosciences, [3]Wayne State Univ. Sch. of Med., Wayne State University, MI; [5]Univ. degli Studi di Verona, Verona, Italy; [6]Univ. of Verona, Verona, Italy; [7]Univ. of Milan, Milan, Italy, Italy

Abstract: Background: Approximately 90% of adults are right handed, and in these individuals, the primary motor cortex (M1) shows strong contra-lateral organization (Amunts et al., 1999). Contra-lateral organization is also a characteristic of the human visual system (Pool et al., 2014). Inter-hemispheric transfer (IT) can be probed using visuo-motor integration tasks such that visual stimulation in one hemisphere must be signaled by motor responses in the opposite hemisphere. Because the degree of handedness is related to the organization of the brain's motor system, handedness might have strong signatures in brain network connectivity during IT.
Methods: To assess IT, fMRI data were acquired using the Poffenberger paradigm (PP) in 40 healthy, right-handed subjects (3T Siemans Allegra), where handedness was established using the Edinburgh Handedness Inventory (EHI). The PP induces IT by brief tachistoscopic presentation of a visual probe to one visual hemisphere (e.g. right V1), while requiring participants to signal detection using the hand represented in the opposite hemisphere (i.e., right hand, Left M1) or the same hemisphere (i.e., left hand). Connectivity was estimated using psychophysiological interaction (PPI). PPIs were constructed by extracting time series from peak voxels. The time series was then convolved with the inter-vs-intra context of the task to indicate connectivity of the responding motor cortex. Regression analysis was conducted to determine the

relationship between degree of handedness and connectivity ($p<.05$, cluster level).
Results: For right-hand responses, a *decrease* in the degree of right-handedness predicted *increased* connectivity within LM1 (i.e. the responding M1). These effects evinced similarities, but also differences with left-hand responses. Here, decreased right-handedness predicted increased connectivity with *both* the LM1 and RM1 (i.e., responding M1).
Conclusion: These results suggest that network profiles of the motor cortices during IT (a sensorimotor context that specifically induced inter-hemispheric interactions) are strongly predicted by the degree of handedness. That decreased right-handedness (i.e., decreased lateralization) results in increased connectivity (regardless of response hand), is broadly consistent with structural MRI studies suggesting that decreased lateralization (handedness) is associated with increased thickness of callosal sub-regions (Luders et al., 2010). Assessing the generalizability of these effects (using age-matched left-handed subjects) is a focus of our continuing work.

Title: Distribution of interhemispheric structural connections between motor regions on the corpus callosum in older adults

Authors: ***J. C. STEWART**[1], J. BAIRD[1], G. PATHAK[1], S. C. CRAMER[2];
[1]Univ. of South Carolina, Columbia, SC; [2]Univ. of California, Irvine, Irvine, CA

Abstract: Many studies have shown a tendency for bilateral brain activation during movement in older adults, suggesting an increased importance of interhemispheric structural connections with age. While several methods are available to parcel the corpus callosum (CC) for

investigation of interhemispheric connections, these methods have not been validated in older adults. The purpose of this study was to determine the distribution of interhemispheric structural connections between motor regions on the CC in older adults and examine how this distribution fit within two methods of CC segmentation. Eighteen older, nondisabled adults (65 ± 9 years of age) completed a single MRI session that included diffusion tensor images (32 directions) and a T1 structural image. Previously published masks of motor cortical regions (M1, S1, PMd, PMv, SMA, preSMA) were transformed into native space and used to draw interhemispheric connections between homologous regions through the CC in FSL. Tracts were thresholded and transformed into MNI space for analysis. CC masks were drawn according to two published segmentation approaches: Hofer & Frahm (2006) and Chao et al (2009). Individual and mean tracts were compared to these callosal masks to determine whether the tract crossed the CC within the appropriate mask. Interhemispheric tracts crossed the CC in the expected pattern (from posterior to anterior: S1, M1, SMA, PMd, preSMA, PMv). Premotor connections crossed the CC in two distinct pairs: SMA/PMd, preSMA/PMv. On average, M1-M1 and S1-S1 tracts fell within the motor and sensory masks respectively, although they were at the posterior edge of the mask for one method (Hofer & Frahm) and the anterior edge for the other method (Chao). For premotor regions, the results were more variable. Using the Chao method, the average location that each tract crossed the CC fell within the premotor mask for all interhemispheric premotor tracts. Using the Hofer & Frahm method, the preSMA-preSMA and PMv-PMv tracts fell within the premotor masks but the SMA-SMA and PMd-PMd tracts did not; these tracts crossed in the motor mask and at the edge of the motor-premotor masks, respectively. Examination of individual participant data revealed a similar pattern. Interhemispheric structural connections between motor regions in this group of older adults had a similar distribution on the CC as a previous study in young adults (Fling et al, 2013). While masks drawn on the CC provide a quick assessment of the integrity of interhemispheric structural connections, further validation of these segmentation approaches is needed in older adults and clinical populations, especially for premotor connections.

Title: Cortical and network reorganization after bilateral forearm transplantation: a longitudinal case study

Authors: *C. R. HERNANDEZ-CASTILLO[1], J. DIEDRICHSEN[2], E. AGUILAR-CASTANEDA[3], M. IGLESIAS[4];
[1]Consejo Nacional De Ciencia Y Tecnología - Cátedra, Xalapa, Mexico; [2]Western Univ., London, ON, Canada; [3]Inst. Nacional de Neurologia y Neurocirugia, CDMX, Mexico; [4]Inst. Nacional de Ciencias Medicas y Nutricion, CDMX, Mexico

Abstract: Cortical reorganization after amputation is a well-known phenomenon resulting in decreased sparse cortical activity of the respective cortical territory of motor and sensory regions. In human amputees the representation of the unaffected muscles expands to cover regions previously dedicated to the missing limb. After transplantation of a new limb, the organization of the cortical representation in the sensory and motor cortices shift again, suggesting a possible reversibility mechanism. However, there is a lack of information about the reversibility of the abnormalities at the network level after transplantation and successful rehabilitation. The objective of this study was to characterize the functional connectivity changes between the cortical territory of the new hand and two intrinsic network of interest: the sensorimotor network (SMN) and the default mode network (DMN) of one patient whom received bilateral forearm transplants. The patient was a 52-year-old man who suffered a high-voltage electrical burn causing the loss of his hands. One year after the patient underwent bilateral forearm transplantation surgery. Using resting-state fMRI we identify these two networks four months after the transplantation surgery and during three consecutive years while the patient underwent physical rehabilitation. The topology of the SMN was disrupted at the first acquisition. Through the years the SMN shifted to its canonical shape. Analysis of the DMN showed no significant changes in its topology over time. Functional connectivity between the missing hand's cortical territory and the SMN increased over time. Accordingly, the correlation of resting state time series between the missing hand's territory and the DMN decreased across acquisitions. Our results show that after transplantation a new reorganization occurs at the network level, supporting the idea that extreme behavioral changes can affect not only the local rewiring but also the intrinsic network organization in neurologically healthy subjects. Overall this study provides new insight information on the complex dynamics of the brain organization.

Title: Intrinsic functional organization of the human motor cortex

Authors: *P. S. CHRISTOVA, A. P. GEORGOPOULOS;
Dept Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: Introduction: The Human Connectome Project (HCP www.humanconnectome.org) provides acquisitions of whole brain functional MRI data at high resolution and high speed. The higher resolution and short repetition time (RT) greatly enhances our ability to capture the spatial and temporal variation of brain activity and connections. This let us explore, with high anatomical accuracy and specificity, detailed interactions within a specific brain area - the motor cortex. **Method:** HCP developed protocol capable of acquiring the whole brain volume at 2x2x2 mm resolution within a repetition time of 720 ms. The resting state blood oxygenation level dependent (BOLD) time series, after proper prewhitening, were cross-correlated with varying lags. For left and right motor cortex we computed all possible pairwise crosscorrelation functions (CCF with 30 positive and negative lags) between prewhitened BOLD time series of ~2000 vertices (~2 million CCFs). For each CCF we located the highest absolute CC (|CCmax|), noted its value, sign and the lag where it occurred, and the intervertex distance. We then evaluated key spatiotemporal functions, including dependencies of the signed (|CCmax|) on intervertex distance, absolute lag on intervertex distance, and signed (|CCmax|) on absolute lag. **Results:** We found that these key functions were very robust across hemispheres and participants, indicating invariant functional interaction properties of the cortical circuitry. The frequency distribution of the signed (|CCmax|) revealed a bimodal pattern consisting of separate negative and positive CCs. We found that the percentage of negative (|CCmax|) was practically identical between the left and right motor cortex for a given participant but varied substantially among participants (range: 8.4 - 46.6%), which we term inhibitory drive. We found that the prevalence of inhibition was positively correlated with the motor dexterity and negatively correlated with the motor strength of the participant. **Conclusions:** The overall inhibitory drive is correlated with the individual's motor behavior and is the neural signature of motor capacities for a particular brain. These results are in accord with our recently advanced hypothesis that the level of motor cortical inhibitory drive is intimately related to accuracy and speed of motor performance (Mahan & Georgopoulos, Front Neural Circuits 7:92, 2013; Georgopoulos, Exp Brain Res 232:2391-2405, 2014; Georgopoulos & Carpenter, Curr Opin Neurobiol 33:34-39, 2015).

Title: A general framework for quantitatively assessing neurocomputational models with functional neuroimaging data

Authors: ***A. DALIRI**[1], J. A. TOURVILLE[2], A. NIETO-CASTANON[2], F. H. GUENTHER[2]; [1]Dept. of Speech, Language, and Hearing Sci., Boston Univ., Quincy, MA; [2]Department of Speech, Language, and Hearing Sci., Boston Univ., Boston, MA

Abstract: Advances in neuroimaging techniques such as functional magnetic resonance imaging (fMRI) have resulted in a greatly improved understanding of the neural mechanisms underlying human sensory, motor, and cognitive capabilities, leading to increasingly sophisticated neural models of these functions. Within the domain of speech production, for example, we have developed a large-scale neurocomputational model, called the Directions into Velocities of Articulators (DIVA) model, that provides a unified mechanistic account of acoustic, kinematic, and neuroimaging data on speech production. Functional neuroimaging has been a powerful means for evaluating and refining such models. To date, however, these evaluations have been almost exclusively qualitative. Quantitative evaluations of these models with functional neuroimaging is currently hampered by the absence of a general computational framework for (i) generating predicted functional activation from the models that can be directly and quantitatively compared to empirical functional neuroimaging data, and (ii) testing between different models and selecting a model that best fits empirical functional data. Here, we present a general computational framework to overcome both of these issues. We use data from a large fMRI database of speech production studies (n=116) to test between whole-brain activity patterns generated from DIVA and those generated from alternative models. Within this framework, the brain network responsible for a task is broken into a set of computational nodes, each of which is localized to an MNI stereotactic coordinate in the brain. Associated with each node is a computational load function that links the node's activity to a computation involving quantifiable measures from the task. The instantaneous neural activity at each location in the brain (e.g., each

voxel of an fMRI image) is then calculated by summing the contributions of all model nodes at that location, with each node treated as a Gaussian activity source centered at the node's location. The parameters of the Gaussians (i.e., spread and magnitude of activation) are optimized to produce the best fit to the functional data. A trust-region reflective algorithm for minimization of non-linear least squares is employed to optimize the parameters. Model comparisons are based on the overall fit level and number of free parameters of each model using the Akaike Information Criterion (AIC). The resulting computational framework can be applied to any model of a sensory, motor, or cognitive task by simply (i) assigning an MNI coordinate to each component of the model, and (ii) defining a computational load function for that component.

Title: Functional neuroimaging of position matching at the elbow

Authors: *J. M. KENZIE[1], S. E. FINDLATER[2], D. J. PITTMAN[1], B. G. GOODYEAR[2], S. P. DUKELOW[2];
[2]Clin. Neurosciences, [1]The Univ. of Calgary, Calgary, AB, Canada

Abstract: Introduction: Proprioception is our sense of the position and movement of our limbs. It allows us to know where our limbs are in space so that we can carry out coordinated movements such as reaching. Previous neuroimaging studies have identified human brain areas activated during active and passive limb motion, yet we still do not have a good understanding of the areas involved during tasks that specifically require awareness of limb position. Contralateral limb position matching tasks have been used previously to study limb position sense in healthy

and neurologically impaired humans. Here, we used functional magnetic resonance imaging (fMRI) to investigate the brain areas involved in the performance of a contralateral limb position matching task. **Methods:** Five healthy right-handed control subjects were recruited to perform a mirror-matching task at the elbow during fMRI. Subjects' arms were secured to an MRI compatible device. During the task, the experimenter moved the subject's arm (+/- 10 degrees of elbow flexion) to one of four predetermined elbow angles. After a pseudorandom delay (3-5 seconds), subjects were visually cued to mirror-match the position of the passively moved arm with the opposite arm and hold. This was repeated for 20 trials per run. Two runs were performed, testing both right and left arms. T1-weighted anatomical and BOLD-fMRI sequences were collected at 3T. We analyzed these data using a general linear model in FMRIB Software Library (FSL), and modeled group level BOLD activations for both passive and active movements. **Results:** Passive elbow movements resulted in significant BOLD activations in contralateral primary somatosensory cortex and superior parietal lobule as well as primary motor, premotor, and supplementary motor areas. These results were consistent between right and left passive arms. Active matching movements with the opposite arm resulted in significant BOLD activations bilaterally in primary somatosensory, primary motor, premotor, and supplementary motor cortices. Additionally, active matching produced BOLD activations in contralateral putamen and ipsilateral cerebellum. **Conclusions:** Our results suggest that a widespread network of sensorimotor areas are involved in processing proprioceptive information at the elbow. Passive movement primarily activated contralateral sensorimotor cortical areas. However, active position matching with the opposite arm activated these same areas bilaterally as well as subcortical and cerebellar structures. These results further our understanding of proprioceptive processing in the human brain, and the areas involved in an upper-limb position-matching task.

Title: Temporal evolution of visual and motor direction selectivity in human cortex during target representation, motor planning, and reach execution

Authors: *D. C. CAPPADOCIA[1], S. MONACO[2], Y. CHEN[1], G. BLOHM[3], J. CRAWFORD[1]; [1]Ctr. for Vision Res., York Univ., North York, ON, Canada; [2]Univ. of Trento, Trento, Italy; [3]Queen's Univ., Kingston, ON, Canada

Abstract: The human brain areas involved in reach planning have been studied extensively, but the directionally selective mechanisms for target memory, movement planning, and motor execution have not been clearly differentiated. In this study, we used an event-related fMRI design that temporally separated the major stages of memory-guided reaching and saccades into three distinct phases: target representation, motor planning, and motor execution. Subjects (N=12) fixated at midline and were shown a target to the left or right of midline. After a delay of 8 seconds (the target representation phase), subjects were instructed with an auditory cue to perform a reach or an anti-reach. This was followed by a second delay of 8 seconds (the effector-specific motor planning phase). Finally, an auditory 'go signal' prompted subjects to perform the instructed movement by reaching-to-touch a touchscreen with their right hand). Using the pro-anti instruction to differentiate visual vs. motor selectivity during movement planning, we found that only the left cuneus showed contralateral visual selectivity (selectivity based on the initial target presentation), whereas a broad constellation of left occipital (primary visual cortex, lingual gyrus & superior occipital gyrus), parietal (superior parietal occipital cortex, midposterior intraparietal sulcus, anterior intraparietal sulcus, precuneus & angular gyrus), and frontal (dorsal premotor cortex & primary motor cortex) areas showed contralateral movement selectivity (selectivity based the direction of the movement). Analysis of the time courses of these movement selective brain areas through the entire memory-planning sequence revealed early visual selectivity in most areas, followed by motor selectivity in most areas, with all areas showing a stereotypical visuomotor transition. Cross-correlation of these spatial parameters through time revealed separate functional networks for visual input, motor output, and visuomotor transformation that spanned occipital, parietal, and frontal cortex. These results demonstrate that a highly distributed occipital-parietal-frontal reach network is involved in the transformation of retrospective sensory information into prospective motor plans.

Title: Mirror symmetric movement encoding in the human motor system

Authors: *S. HAAR[1], O. DONCHIN[2], I. DINSTEIN[3];
[2]Biomed. Engin., [3]Brain and Cognitive Sci. and Psychology, [1]Ben Gurion Univ., Beer Sheva, Israel

Abstract: Cortical motor control exhibits clear lateralization whereby each hemisphere controls the motor output of the contralateral side of the body. Nevertheless, neural populations in ipsilateral motor areas are active during unilateral movements and even exhibit reliable directional selectivity during reaching movements to peripheral targets. It is unclear whether this directional selectivity is the same for ipsilateral and contralateral movements when examining different brain areas in the visuomotor hierarchy. To address this question, we measured fMRI responses in multiple visuomotor system areas of the human brain while subjects performed 'out and back' reaching movements to peripheral targets with either dominant or non-dominant hand. We trained a multivariate classification algorithm to identify movement direction according to voxel-by-voxel fMRI patterns in brain regions across the visuomotor hierarchy. The classifier was trained using a subset of trials and then tested by decoding the excluded trials. The direction of movement was successfully decoded with above-chance accuracy rates in all contralateral and ipsilateral motor areas when training and testing the classifier on trials within each condition (i.e. movement preformed with the same hand). Next we trained a classifier on movements performed with one hand and tested its accuracy when decoding movements performed with the other hand. fMRI response patterns in the visual cortex enabled above-chance decoding of movement direction (i.e. target location) across hands, demonstrating an effector-invariant representation. Response patterns in the primary motor cortex, premotor cortex and supplementary motor area enabled above-chance decoding of movement direction when flipping/mirroring the movement direction across the midline (i.e., movements to left targets was accurately decoded as movement to right targets). This suggests that motor neural populations encode/represent ipsilateral and contralateral hand movements in a mirror symmetric manner. Intermediate visuomotor regions in parietal cortex showed decoding accuracies consistent with a gradient from a visual, effector-invariant, representation in the parieto-occipital cortex to a motor, mirror symmetric, representation in the posterior-parietal cortex. These results suggest that neural populations in most of the motor system encode mirrored contralateral and ipsilateral movements, perhaps due to the equivalent join torques (dynamics) of these movements.

Title: The correlations of brain activations during self- and stimuli-triggered movements with personality traits.

Authors: *K. OMATA[1], S. ITO[2], H. OKADA[2], Y. OUCHI[1];
[1]Hamamatsu Univ. Sch. of Med., Shizuoka, Japan; [2]Hamamatsu Medicai Imaging Center, Hamamatsu Med. Photonics Fndn., Hamamatsu City, Shizuoka, Japan

Abstract: Personality is based on individual differences in cognition, emotion and behavioral patterns. The personality traits reflect individual features that govern particular patterns of behavior in various situations. Conventionally, five traits (Neuroticism, Openness, Extroversion, Agreeableness and Conscientiousness) are chief ingredients that construct individual personality. One of the battery for the traits is the NEO-Five Factor Inventory (NEO-FFI), with which we are able to score the patterns of individual personality. We hypothesized that brain activations in particular behaviors may be linked to the degrees of individual NEO-FFI scores. To investigate this, we conducted a finger-tapping task that required a behavioral change using the functional magnetic resonance imaging (fMRI) and explored an assessment of the personality traits. Twenty-three healthy volunteers participated in the fMRI study using a 3T MRI scans (Philips, Ingenia). An event-related design was employed with four conditions: voluntarily and forcibly initiation and inhibition of a continuous finger tapping. The participants were asked to start or stop finger-tapping following instructions. The fMRI data were analyzed by SPM8 using the points of the behavioral shifts as regressors in the general liner model. The personality traits of participants were assessed by the NEO-FFI. Multiple regression analysis was conducted to measure the correlations between the whole brain activity at behavioral changes and five personality scores. In the voluntary stop condition, Neuroticism scores were positively correlated with the brain activity in the bilateral putamen, the left hippocampus and the right precuneus, Positive correlations between Agreeableness score and brain activity in the left middle occipital gyrus and the right superior temporal gyrus were observed. In the forcibly start condition, the brain activations in the right middle frontal gyrus, the left precentral gyrus and the right cuneus were positively correlated with the scores of Conscientiousness. The results showed significant correlations between personality traits and activations in the particular brain regions when participants executed the finger-tapping tasks. This suggests that the variance of NEO-FFI scores

across subjects reflects personal differences in the brain responses that underpin the foundation of personality. However, further investigation is needed to determine which parts of brain subserve trait-related behaviors.

Title: Cortical activation associated with automatic control of pelvic floor muscles in women

Authors: *M. S. YANI[1], J. GORDON[1], S. P. ECKEL[2], D. J. KIRAGES[1], S. ASAVASOPON[3], J. J. KUTCH[1];
[1]Div. of Biokinesiology and Physical Therapy, [2]Div. of Biostatistics, USC, Los Angeles, CA; [3]Physical Therapy Dept., Loma Linda Univ., Loma Linda, CA

Abstract: ***Background.*** The human central nervous system automatically coactivates pelvic floor muscles with trunk and lower limb muscles. Improving our understanding of the neural centers underlying this control could improve physical therapy for pelvic floor muscle pain and dysfunction.
Objective. We have recently shown in healthy men that automatic pelvic floor muscle coactivation with gluteal muscles involves specific medial wall motor cortical regions, and we also recently discovered markers of dysfunction in these motor cortical regions in both women and men with chronic pelvic pain. Here, to link these lines of evidence, we aimed to determine if automatic pelvic floor muscle coactivation also involves motor cortical activation in healthy women.
Design. A cross-sectional study.
Methods. We used functional magnetic resonance imaging (fMRI) to measure brain activity, and electromyography (EMG) to measure muscle activity, during voluntary motor tasks involving pelvic floor muscles, gluteal muscles, and finger muscles.
Results. Using fMRI we support our hypothesis that the medial wall motor cortical regions activate in women when pelvic floor muscles automatically coactivate with gluteal muscles. These motor cortical regions strongly overlap with those we previously identified are altered in women with chronic pelvic pain. Using EMG recordings, we extend our previous findings to

provide evidence of coupled neural drive between these muscle groups.
Limitations. This cross-sectional study does not address therapeutic effects on the motor cortical regions we have identified.
Conclusions. Our findings underscore the importance of the motor cortex in automatic pelvic floor muscle control in both sexes, and now allow functional brain changes in women with chronic pelvic pain to be interpreted in the context of potential pelvic motor control dysfunction at the cortical level.

Title: Neural correlates of multisensory action predictions investigated with a custom-made passive movement device

Authors: *B. VAN KEMENADE, E. ARIKAN, K. PODRANSKI, O. STEINSTRÄTER, B. STRAUBE, T. KIRCHER;
Philipps-University Marburg, Marburg, Germany

Abstract: According to the forward model, we generate predictions about the sensory outcomes of our own actions. These predicted outcomes are then compared with the actual outcomes, and in case of a mismatch, a prediction error is generated. Previous research has only used unimodal action consequences. Since most actions lead to multisensory outcomes, we investigated the neural mechanisms of comparator processes in multisensory action predictions with a novel setup, allowing the manipulation of active and passive movements. Participants performed hand movements whilst holding the grip of a custom-made passive movement device. In active trials, participants moved the device actively, while in passive trials, their hand was moved by the device. In this way, we could disentangle action predictions from general expectations about upcoming stimuli. Active and passive hand movements were recorded by a camera and were visible to the participants on a screen. This visual feedback of their actions was displayed either

in real-time, or with a variable delay (0-417 ms). The task was to judge after each trial, comprising one hand movement, whether the visual feedback was delayed or not. In some trials, a tone was added and presented during the movement. Its onset was synchronised with movement onset using a motion detection algorithm applied to the camera images. In our analysis of the fMRI data, we parametrically modulated the regressors for each condition with the amount of delay. Preliminary results show a main effect of action in right cerebellum, in which activity correlated more positively with delay in active than in passive trials. Furthermore, we found an action*modality interaction in the right insula, indicating that activity correlated more positively in bimodal compared to unimodal active conditions and showed no effects in passive conditions. This results suggests that the cerebellum has a specific role in predicting both unimodal and bimodal action consequences. By contrast, the right insula may contribute to specific multisensory predictions concerning action outcomes. These data extend previous findings and suggest the existence of multisensory predictive mechanisms mediated by cerebellum and insula.

Title: Neural and behavioral evaluation of face and hand video stimuli

Authors: ***E. KILROY**, L. HARRISON, S. GIMBEL, S. CERMAK, L. AZIZ-ZADEH; USC, Los Angeles, CA

Abstract: To date, social and affective neuroscientific research largely relies on static images, yet people are rarely perceived in a static-state. A database that provides a spectrum of emotional and non-emotional videos is ideal for conducting a wide range of neuroscientific studies that control for processing of facial and non-facial movement. Here we present such a database: EmStim. EmStim consists of three distinct sets of video stimuli: emotional expressions (i.e., happy), non-emotional expressions (i.e., puffed-cheeks) and hand actions (i.e., cutting paper). Seven Caucasian actors (4 female; 29-39 years) were recorded making thirty-five expressions against a black background. The hands of one male and female actor were also recorded

interacting with 100 everyday objects. To enable fMRI research, all videos were edited to 3.75 seconds and controlled for low-level visual properties. Psychometeric evaluations of emotional face stimuli were collected. Additionally functional Magnetic Resonance Imaging (fMRI) study was conducted to investigate neural differences in processing the three stimulus sets during three tasks. The three stimulus sets were displayed in a pseudo-random block design consisting of 15 (5 or each type) 15-second video blocks (3 videos/block),with each block followed by 15-seconds of rest. Neurotypical child and adolescent participants observed, imitated, and mentalized to each set of videos in separate scans. Standard preprocessing and whole-brain BOLD analyses were performed. The three tasks produced significant ($p<.05$) overlapping and non-overlapping activation in the Action Observation Network (i.e., Pars opercularis). Taken together, our results suggest that EmStim is a flexible and valuable resource for social, cognitive, and affective research. Ongoing work will continue to quantify relationships among individual differences in social and motor functioning and measurements of brain function associated with the three classes of EmStim stimuli.

Title: Continuous decoding of movement from fMRI in a goal-directed manual tracking task

Authors: *D. A. BARANY[1], S. VISWANATHAN[2], S. T. GRAFTON[1];
[1]UC Santa Barbara, Santa Barbara, CA; [2]Univ. Hosp. of Cologne, Jülich, Germany

Abstract: During continuous hand movements, properties such as the position, direction, and goal of the movement are constantly changing. How does neural activity in the motor system reflect these instantaneous changes in movement? We previously developed a decoding approach to accurately reconstruct movement during a simple continuous manual tracking task from the fMRI BOLD signal across multiple sensorimotor brain regions. Here, we extend this approach to

show that multivoxel activity in these regions contains information specific to the current position and direction of the hand, independent of the visual stimulus, during a goal-directed tracking task.
Participants ($N = 20$) continuously followed one of two visual targets moving along a circular trajectory. The targets moved at different constant speeds (16 s/cycle or 12 s/cycle) and in opposite directions. In the *No Switch* condition, participants tracked one of the two targets for the entire 144 s movement block. In the *Switch* condition, participants initially followed one target while waiting for a switch cue in the opposite target. The cue signaled the participant to make a quick, straight-line movement to the opposite target, and then immediately begin to follow that target along its circular path. fMRI data were obtained on a 3T Siemans Prisma scanner with a 3x3x3 mm resolution and a 400 ms repetition time. Hand and eye positions were continuously recorded.
We used a multivoxel regression analysis to relate the time-varying conjoint activity of voxels in regions of interest to the instantaneous angular position and movement direction of each target. This regression model was then used to decode these corresponding variables on data from separate movement blocks. We found that in the *No Switch* condition, visual regions showed decoding of both targets, suggesting general representation of the stimulus position. In contrast, decoding performance in motor regions was specific to the target currently being tracked—that is, a model trained on the 16 s/cycle target positions showed accurate decoding for the 16 s/cycle movement blocks, but not for the 12 s/cycle movement blocks (and vice versa). Crucially, this specificity extended to the *Switch* condition. Models trained on one target's positions only showed accurate decoding during the time periods when that same target was currently being tracked. Together, these results show that cortical dynamics, as measured from the fMRI BOLD signal, can be used to accurately identify continuous changes in hand movement position and direction during complex visuomotor behavior.

Title: Functional MRI activity patterns in the action observation network for chronic stroke patients

Authors: *P. HEYDARI[1], S.-L. LIEW[2], H. DAMASIO[2], C. WINSTEIN[2], L. AZIZ-ZADEH[2]; [1]Brain and Creativity Inst., [2]USC, Los Angeles, CA

Abstract: The action observation network(AON) is comprised of motor regions (inferior frontal gyrus, ventral premotor cortex, and posterior parietal cortex) that are active when we make an action and when we see someone else make a similar action. Previous studies in nondisabled adults describe, during imitation (simultaneous observation and execution), regions of the brain show larger BOLD signal intensity when compared to action observation or execution. Here, we ask: in patients with stroke (described below), does AON BOLD activity follow that of nondisabled adults (highest for imitation, then execution, then observation).
In this on-going study, 13 patients with chronic, first time, left MCA stroke and mild-to-moderate UE motor impairments (Fugl-Meyer UE mean=50.3/66, range 40-63) and 13 nondisabled, age-matched subjects participated. Both groups were asked to observe, execute, and imitate left (L) and right (R) hand actions in an fMRI scanner. We investigated contrasts (observation>rest, execution>rest, imitation>rest), for various regions (Inferior Frontal Gyrus pars opercularis (IFGpo), Superior Parietal Lobule (SPL), Parietal Operculum (PO), and Precentral Gyrus (PCG)).
Analysis indicated, in patients with stroke, BOLD percent signal change for the L/nonparetic hand was highest for imitation bilaterally in IFGpo, PCG, SPL, and PO, followed by execution, then observation. BOLD percent signal change for R/paretic hand was highest for execution bilaterally in the same ROIs, however, percent signal was highest during for execution, followed by observation and finally imitation for R ROIs but execution followed by imitation and finally observation for L (ipsilesional) ROIs.In nondisabled adults, percent signal change for the L hand was highest for imitation in the L PCG. In these adults, percent signal change for the R hand was highest for imitation, followed by execution, and lastly observation for all bilateral ROIs: IFGpo, PCG, SPL, and PO.
Our preliminary analyses suggest that AON regions are engaged during action imitation, execution, and observation of UE actions in individuals with motor deficits due to stroke. Patients with stroke showed a higher ipsilesional (L) BOLD percent signal change for execution, then imitation, and lastly observation involving the R (paretic) hand. Engagement of these regions may suggest recruitment of AON is highest for the less skilled hand to perform such movements (paretic in the stroke group). Alternatively, this may be due to task difficulty. Further research is required to determine such a distinction. This information may be useful in understanding poststroke rehabilitation methods using imitation.

Abstract: The field of therapeutic bioelectronics uses electronic devices that interface with the nervous system to treat a rapidly expanding list of diseases and disorders. Next-generation treatment strategies rely heavily on neural recording methods to trigger and shape the parameters of therapeutic stimulation by providing detailed feedback about neural dynamics in real time. Wired systems for neural recording create problems for chronic, everyday use; therefore a fully wireless implantable system is desired. However, emerging wireless approaches based on electromagnetics struggle to power and communicate with implanted devices at sizes below the millimeter scale while maintaining power levels within established safety limits. We have previously shown that both theoretically and experimentally, ultrasound is an attractive alternative for powering and communicating with sub-millimeter scale implanted devices at biologically compatible power levels. Recently, we designed and built neural dust, a wireless, batteryless, and scalable ultrasonic backscatter system. Robust, in-house fabrication flow and custom application specific integrated circuits (ASICs) enabled miniaturization of both the motes and the interrogator. We implanted neural dust motes in rats to demonstrate high-fidelity wireless recording of neural activity *in-vivo*. We are currently working towards chronic implantation of neural dust motes. These data demonstrate the potential for ultrasound-based neural interface systems to play a central role in expanding the potential of future bioelectronics-based therapies.

Title: Reducing power consumption of dbs device using platinum-iridium coating

Authors: *A. PETROSSIANS;
Ophthalmology, USC, Los Angeles, CA

Abstract: Reliable and efficient neuromodulation devices are needed for numerous clinical neuromodulation therapies. Deep brain stimulation (DBS) therapy is a technique for treatment of movement disorders. A DBS device includes a battery powered implantable pulse generator (IPG) which is implanted underneath the clavicle and sends electrical signals through one or two extension leads to one or two linear electrode arrays that are implanted deep into the brain. Continuous electrical stimulation of deep brain structures can decrease the symptoms of movement disorders such as Parkinson's disease and essential tremor. DBS therapy is expanding to a multitude of neurological disorders. Electrodes are the interfaces that transfer the electrical signals from these devices to neural tissue. An improved electrode material will have a significant impact on the capabilities of the devices and the effectiveness of treatment by enabling more efficient charge delivery and thus longer battery life. In addition, better electrode materials will allow the use of microfabricated electrodes for chronic stimulation at higher charge density and will reduce stimulus artifact and increasing signal to noise ratio, thus improving detection of important biomarkers needed for closed loop stimulation strategies. In this study, the electrochemical impedance values, measured using some commercial implantable pulse generators, showed that current was increased during voltage pulsing. As a result, lower voltage is needed to provide the same amount of desired current amplitude for the coated electrodes. The lower voltage requirements for an implant will lead to reduced power consumption. The impedance values were collected on the coated and uncoated DBS leads using voltage pulses (3V, 80μs). The impedance measurement results showed that the mean impedance value of the uncoated leads was reduced from 241ohm to 166ohm. The electrical testing results showed that the DBS leads modified with platinum-iridium require 31% less power. Thus, implant battery life can be extended by using more efficient electrodes. In this investigation, comparison of platinum-iridium coated DBS electrodes vs uncoated electrodes showed that the power consumption of the DBS device was significantly reduced, leading to longer battery life of the device.

Title: Soft, mechanically brain-like composite materials improve the long-term, electrical characteristics of the neural interface

Authors: ***A. SRIDHARAN**, V. VOZIYANOV, J. MUTHUSWAMY;
Arizona State Univ., Tempe, AZ

Abstract: Quality of neuronal signals recorded at the neural interface rapidly deteriorates after different durations of implantation time. In addition to abiotic material degradation factors, the mechanical mismatch between the implant and brain tissue has been hypothesized to exacerbate the inflammatory response impairing the electrode-neuron interface, leading to signal loss. In our recent studies, we have shown that soft, mechanically-compliant substrates cause lower strain and strain rates at the interface. The main objective of this study is to assess whether soft, brain-like composite materials improve the long-term, electrical and functional performance of the neural interface. Tungsten or platinum/iridium microwire arrays coated with a novel soft, brain-like silicone and carbon nanotube (CNT) composite were implanted in the somatosensory cortex of rats. For tungsten electrodes, electrical impedance characteristics and noise levels were stable (n=9 electrodes) compared to uncoated controls (n=6 electrodes) over long-term implantation conditions. 75% (12 of 16) of soft-coated platinum/iridium (Pt/Ir) electrodes in a microwire array implanted for 5 months in a rat model showed similar stability in noise levels and impedance at 1 kHz. Increased noise levels in 4 of 16 soft-coated Pt/Ir electrodes correspond to increased impedances by 5 months. Analysis of spontaneous neural activity showed significantly larger peak-to-peak amplitudes of isolated units for soft-coated, tungsten electrodes (60-150 μV) compared to controls (<60μV). Similar trends in peak-to-peak amplitudes for spontaneous units are seen for soft-coated Pt/Ir electrodes (80-100 μV). Soft-coated Pt/Ir electrodes implanted over 5 months in the barrel-cortex region also showed single unit response upwards of 200 μV in amplitude to mechanical stimulation of whiskers at 1 Hz and 2 Hz. Single and multi-unit responses to whisker stimulation showed a peak response at 40 msec post-stimulus with a

duration of ~100 msec. In contrast, SNRs obtained during spontaneous or passive periods of activity showed a mixed response across the 16 channel array over implantation time with 50% of electrodes increasing in SNR (>+0.5dB) at 5 months and 30% decreasing (-0.5dB) in SNR. Future studies will focus on improving the stability of neural signals using various metrics. This study demonstrates that brain-like, soft neural interfaces can potentially improve chronic, long-term electrical impedance and neural recordings.

Title: The influence of different impedance values in neuronal recording: a correlational study in marmoset.

Authors: *B. B. GARCIA[1], J. H. SATO[1], M. F. P. ARAÚJO[1], H. S. G. PEREIRA[1,2,3];
[1]Edmond and Lily Safra Intl. Inst. of Neuroscience,Neuroengineering Program, Santos Dumont Inst., Macaiba, Brazil; [2]State Univ. of Rio Grande do Norte, Mossoró, Brazil; [3]Anita Garibaldi Ctr. for Hlth. Educ. and Res., Macaíba, Brazil

Abstract: Several features influence the quality of the neuronal signal recorded from chronically implanted electrodes. Besides the intrinsic factors of the neural tissue, extrinsic factors may also affect the accuracy of the recordings. Among those, impedance is of major importance. In this study, we investigated whether the pre-implant impedance of tungsten wire electrodes was correlated with the number of units recorded by each electrode. Sixty-four microeletrodes(two arrays of 32 electrodes) were manufactured using tungsten microwires covered by an inert material surface (TEFLON), with a sharp extremity (45 degrees). Microwires of two different diameters (100 and 50 μm) were used. The former was primarily used for stimulation and recording of subthalamic nucleus (STN) and the latter for neuronal recordings of several brain

areas: motor primary cortex (M1), putamen (Put), globus pallidus internus (GPi), globus pallidus externus (GPe), ventrolateral nucleus (VL) and ventroposterior lateral nucleus (VPL) of thalamus. The impedance of each microeletrode was measured before the arrays were implanted in a male marmoset (350g). The pre-implant values of impedance varied from 50 to 860 kΩ. Two weeks after the implant, local field potentials (LFPs) and single- and multi-unit activity were recorded from the arrays while the animal was freely moving inside a plexiglass box. All procedures were approved by the Institution's Ethics Committe for Animal Use (protocol 03/2015). The neuronal data was sorted offline (Offline Sorter, Plexon, USA). A total of 54 units were recorded from the two arrays. A Pearson test was used to measure the correlation between the number of recorded units in each electrode and its pre-implant impedance. A very small correlation value (0.02; p=0.867) was obtained. These results indicate that the quality of the signal in each channel (number of units) was not significantly correlated to their impedance. Therefore, impedance variations ranging from 50 to 860 kΩ do not seem to influence the number of single and multi-unit signals recorded from chronically implanted electrodes.

Title: Functional evaluation of a superoxide dismutase mimic coating for chronically implanted neural electrodes

Authors: *X. S. ZHENG, X. T. CUI;
Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Recent advancement in brain-machine interface (BMI) has shown promise in enabling functional restoration of individuals with limb loss. Often a metal electrode array is chronically implanted into the brain region of interest, and neural signals can be recorded and decoded to control an external prosthesis. However, due to the brain’s foreign body response, microglia near the electrode site become activated and secrete pro-inflammatory cytokines, recruiting additional macrophages, and produce cytotoxic factors such as reactive oxygen species (ROS). The presence of ROS around the implant promotes neuronal death thereby degrading neural signal

quality overtime. Superoxide dismutase (SOD) can remove superoxide (a form of ROS) through dismutation by converting superoxide to molecular oxygen and hydrogen peroxide. However due to its low stability and poor bioavailability SOD has been unsuccessful in treating neurological diseases induced by oxidative stress. SOD mimics (SODm) have shown to be neuroprotective in *in vitro* and *in vivo* models of disease influenced by oxidative stress such as Alzheimer's disease and stroke. When immobilized onto the surface of neural electrodes, SODm may reduce neuronal death around the implant. Here we evaluate the acute and chronic performance of electrodes coated with immobilizable SODm (iSODm) in adult rats. 16-channel linear silicon probes with or without iSODm coating were implanted in the motor cortex of adult male rats for up to 3 months. In acute evaluations, animals were sacrificed 1 week after electrode implantation, and immunohistochemistry was performed to compare neuronal survival around the implant. In chronic evaluations, weekly impedance was measured, and neurophysiological recordings of spontaneous motor activity were acquired while the animals were freely moving. At endpoint, all animals were sacrificed and immunohistochemistry was performed. Significantly greater neuron density in every 50 μm zone between (0 μm -- 250 μm) around the coated implants were observed after 1 week of electrode implantation. Chronically, the iSODm coating showed great promise in allowing electrodes to record high quality single units throughout the 3-month period with endpoint signal to noise ratio up to 7.91, and up to 50% in single unit yield. These results indicate the iSODm coating's efficacy in promoting neuronal health around neural electrodes and have the potential to benefit chronic neural recording for BMI or basic neuroscience research.

Title: Neural and vascular morphological changes after chronic electrode implantation

Authors: *Y.-R. GAO[1], M. YE[1], D.-H. KIM[1], A. LOZZI[1], A. BORETSKY[1], C. G. WELLE[1,2], D. X. HAMMER[1];
[1]DBP/OSEL/CDRH, US Food and Drug Admin., Silver Spring, MD; [2]Departments of Neurosurg. and Bioengineering, Univ. of Colorado Denver, Aurora, CO

Abstract: Neuroprosthetic devices that interface with the nervous system provide control signals for prosthetic or robotic assistive devices to restore movement capabilities to patients with paralysis or amputation. Although implanted electrodes that provide this interface perform well for a certain period of time, eventually the number of neurons that can be detected declines, and device performance suffers. Factors involved in this loss of function may include biological changes to neural tissue or electrode material degradation. One important but understudied component of the tissue response is tissue perfusion through the cerebral vascular system. Robust vascular perfusion is critical to normal brain function and may provide an important biomarker of device failure. Therefore, chronic tracking of neurovascular dynamics may provide insight into the long-term performance of implanted electrodes. We conducted a longitudinal study using two-photon laser scanning microscopy (TPLSM) and optical coherence tomography (OCT) imaging in the same mouse (Thy1-eGFP) at similar time points to monitor the neural and vascular morphological changes associated with electrode implantation. Animals were prepared for long-term imaging with craniotomy and window implantation under which one, two, or four-shank Michigan microelectrodes were inserted. Vascular changes monitored by OCT were assessed for both surface and intracortical vessels. Neuronal dynamics were measured with TPLSM and analyzed separately in the dendritic tuft, apical dendrites, and soma. The responses to implanted electrodes varied significantly across animals. Electrode implantation leads to vessel dilation and flow decrease during the first few days, new vessel growth in superficial layers of cortex, followed by relative stabilization of the deeper capillary network, as compared with pre-implantation baseline. Some animals experienced traumatic mechanical damage characterized by flow drop-out and dendritic bisection/retraction. The achievable TPLSM and OCT penetration depth decreased over time more rapidly at the region nearest the electrode, as compared to the control region. In summary, we were able to monitor neurovascular changes after electrode implantation up to 4 months to evaluate cortical damage on cellular and capillary spatial resolution scales. We observed key changes to both cerebral vessels and neurons that may contribute to future methods for evaluating the safety and performance of brain implantation devices.

Title: Evaluation of neural cell adhesion molecule L1 coating for improved chronic recordings

Authors: *P. CODY[1], N. SNYDER[6], J. DU[7], R. TIEN[1], J. WILLIAMS[2], S. SUWAY[3], J. ORELLANA[8], Y. INOUE[4], T. KOZAI[1], C. LEGENAUR[5], A. SCHWARTZ[5], X. CUI[1]; [1]Bioengineering, [2]Systems Neurosci. Inst., [3]Ctr. for Neurosciences, [4]Systems Neurosci., [5]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [6]Interphase Materials, Pittsburgh, PA; [7]Shenzhen Inst. of Advanced Technology, Chinese Acad. of Sci., Shenzhen, China; [8]Ctr. for Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Neural probes are used in brain-machine interface based prosthetics to restore movement to paralyzed individuals. Intracortical neural electrodes provide the greatest spatiotemporal resolution compared to other recording approaches to enable optimal decoding of neural activity for prosthetic control. Inflammatory brain responses including glial scarring and neural degeneration degrade and limit the longevity of recordings thereby severely hindering the clinical potential of neural probes. Our lab has demonstrated that the neural cell adhesion protein, L1, may be covalently conjugated to silicon and parylene based neural probe surfaces to reduce inflammatory glial activation, improve neuron survival and enhance neurite outgrowth throughout a chronic period in a rat model as verified with quantitative histological measures. Chronic electrophysiological recordings from L1 coated and uncoated parylene-C insulated Utah arrays were compared in male Rhesus monkeys and rats up to 72 and 12 months respectively. Each monkey was implanted in the motor cortex with both a coated and uncoated 96 channel Utah array while each rat was implanted in the primary monocular visual cortex with either a coated or uncoated 4x4 Utah array. Coated monkey arrays exhibit significantly greater number of units than uncoated. For rats, a repeatable and established visual stimulation paradigm was used to compare evoked activity between array treatments. In addition to a battery of histological analyses, laser capture micro-dissection to assay RNA expression changes in the immediate micro vicinity of the probe is developed, and combined with immunohistochemical staining, to better elucidate the mechanism of L1's benefits. Recording performance from rat implants is quantified with single-unit yield (percent of electrode sites recording single-units), single-unit signal-to-noise amplitude ratios, and multi-unit signal-to-noise firing rate ratios. Understanding the effect and mechanism by which L1 improves neural probe performance will inform approaches to better realize the full clinical potential of neural prosthetics for treating paralysis.

Title: Dexamethasone retrodialysis attenuates microglial response to implanted probes *In vivo*

Authors: ***T. D. KOZAI**[1,2,3,6], A. S. JAQUINS-GERSTL[4], A. L. VAZQUEZ[5], A. C. MICHAEL[4], X. CUI[1];
[1]Bioengineering, [2]Ctr. for the Neural Basis of Cognition, [3]McGowan Inst. for Regenerative Med., [4]Chem., [5]Radiology, Univ. of Pittsburgh, Pittsburgh, PA; [6]Neurotech Ctr., Univ. of Pittsburgh Brain Inst., Pittsburgh, PA

Abstract: Intracortical neural probes enable researchers to measure electrical and chemical signals in the brain. However, penetration injury from probe insertion into living brain tissue leads to an inflammatory tissue response. In turn, microglia are activated, which leads to encapsulation of the probe and release of pro-inflammatory cytokines. This inflammatory tissue response alters the electrical and chemical microenvironment surrounding the implanted probe, which in turn interfere with signal acquisition. Intervention strategies like neurocamouflage L1CAM coatings have shown great promise in both rodent & primate models. Dexamethasone (Dex), a potent anti-inflammatory steroid, can be used to prevent and diminish tissue disruptions caused by probe implantation. Herein, we report retrodialysis administration of dexamethasone under in vivo two-photon microscopy to observe real-time microglial reaction to the implanted probe. Probes under artificial cerebrospinal fluid (aCSF) perfusion with or without Dex were implanted into the cortex of transgenic mice that express GFP in microglia and imaged for 6 h.

Acute morphological changes in microglia were evident around the microdialysis probe. The radius of microglia activation was 177.1 μm with aCSF control compared to 93.0 μm with Dex perfusion. Dexamethasone had a profound effect on the microglia morphology and reduced the acute activation of these cells.
Our data also showed that Dex can cause large differences in microglial morphology that were not necessarily captured by traditional microglia activation metrics. While most microglia cells generally had processes that were radially projected, in some instances the microglia around Dex eluting probes had retracted most of their processes in a near amoeboid morphology and were generally wrapped around nearby BBB structures. Beyond the role of Dex as an anti-inflammatory drug, glucocorticoids have important roles regulating metabolic, arousal, attention, cardiovascular, and homeostatic functions. The Dex related changes in metabolism may contribute to the thickening of processes and increased apical processes compared to ramified microglia, although this remains to be studied. Previously we showed loss of perfusion and evidence of ischemia around the implants. When vascular injury during probe insertion is limited, Dex may be neuroprotective due to its anti-inflammatory effect. In contrast, if key vascular structures are damaged during probe insertion, delivery of oxygen and nutrients (and removal of neurotoxic waste products) may be reduced, and Dex might exacerbate local ischemia due its associated changes in cellular metabolic rate.

Title: Elucidating the role of macrophage lineage in the FBR to chronically implanted microelectrode arrays

Authors: ***B. VELAGAPUDI**, M. B. CHRISTENSEN, P. A. TRESCO;
The Univ. of Utah, Salt Lake City, UT

Abstract: Neural electrodes have the ability to help patients suffering from CNS diseases and injuries by recording electrophysiological activity of populations of neurons. However, microelectrode arrays have not achieved widespread clinical implementation. This is due to

device inconsistency and unreliability, which are largely attributed to the foreign body response (FBR). Previously, our lab has shown that the FBR is a cell-mediated neuroinflammatory reaction associated with activated microglia and/or macrophages. However, it is unclear how each cell population contributes to the FBR due to the fact that yolk-sac derived microglia are indistinguishable from bone marrow derived macrophages using traditional immunohistochemical markers. To address this issue, our group utilized transgenic mice carrying CX3CR1 (GFP labeled microglia and macrophages) and HOXB8 (Td-Tomato labelled bone marrow derived macrophages). Transgenic mice (N = 18) were implanted with Michigan-style microelectrodesand sacrificed following an indwelling period of 8 weeks. Next, all animals were transcardially perfused and immunohistological analysis of brain tissue sections and explanted microelectrodes was performed. The transgenically labelled cells colocalized with IBA-1 immunoreacitvity indicating that CX3CR1-GFP and HOXB8-Td Tomato were reliable labels for macrophages and microglia. We observed both transgenically labeled cells in non-implanted hemispheres, with non-bone marrow derived cells constituting the vast majority of the labeled population. Surrounding implant sites, we observed a dramatic increase in the incidence of bone marrow derived macrophages at the implant interface that co-localized with CD68, indicating that bone marrow derived macrophages are the primary activated cell type involved in the FBR. Retrieved electrodes also showed CD68+ and HOXB8+ cells at the surface. The FBR showed a labeling pattern that was consistent with observations made in other species. The results suggest that the M1 macrophages may have a different developmental origin than M2 macrophages.

Title: Extracellular matrix coatings minimize the FBR to high density microelectrode arrays

Authors: ***M. POLEI**, P. A. TRESCO;
Bioengineering, Univ. of Utah, Salt Lake City, UT

Abstract: Utah Electrode arrays (UEAs) record single unit neuronal activity inconsistently due in part to neural tissue loss associated with implantation coupled with the foreign body response (FBR), which exacerbates the initial iatrogenic injury. Moreover, we have shown that the extent

of tissue loss, blood-brain barrier leakiness and astrogliosis is inversely correlated with single unit recording performance in rats. Recently, we have demonstrated the utility of the FDA-approved neurosurgical hemostat Avitene™, a xenogeneic extracellular matrix (ECM) material, to limit neural tissue loss and improve neuronal tissue integration following the implantation of UEAs in the rodent motor cortex. Emerging evidence suggests that cell-type and tissue-specific ECM can modulate the activation state of macrophages, which we hypothesize will lead to further improvements in biocompatibility and recording. In the search for such ECM coatings, we investigated the hemostatic and immunomodulatory potential of a variety of cell-type specific ECMs using *in vitro* assays. ECM was collected from primary astrocytes, fibroblasts, mesenchymal stem cells (MSC) and glial restricted precursors (GRP), suspended in 0.25M acetic acid and dehydration adsorbed onto the walls of 1.5mL vials. Citrated rat whole blood was collected and added to tubes. Calcium was added to initiate coagulation and the tubes inverted every 15 seconds until a stable clot formed, as indicated by the ability to fully invert tube. Time to clot formation was recorded and normalized to uncoated control vials. Additionally, primary microglia and macrophages were isolated from post-natal day 1.5 rat pups and either cultured on ECM-coated or uncoated substrates under conditions of serum activation. The morphology of the microglia and macrophages were quantified as amoeboid (activated), migratory or stellate (resting) and compared statistically. All ECMs studied showed the ability to accelerate coagulation of rat blood. Morphometric studies of brain-resident microglial and macrophage activation showed that astrocyte-derived and GRP, but not Avitene™, MSC or fibroblast ECM coatings showed enhanced potential to down-regulate the activation state of microglia and macrophages. These results suggest that a cell-type and tissue specific ECM shows enhanced immunomodulatory potential *in vitro*. We hypothesize that such coatings may be a useful for reducing the FBR to UEAs and other devices chronically implanted in the CNS.

Abstract: This paper presents a new brain-computer interface for living rat through deep brain stimulation with Carbon Nano-tube (C N T) coated micro-electrodes. Stimulation is used to reward and train the rat in order to make it move in desired directions. Surgery is performed on a rat's brain to put micro-electrodes in M F B and S1BF areas (in left and right hemispheres). We used four bipolar implanted micro-electrodes which are C N T coated by drop coating method. C N T suspension is obtained by solvents: (CH3)2CO, CH2Cl2 and (CH2)4O. Then micro-electrodes are coated and dried at 80 °C. They are tested in -v i t r o- to enhance the accuracy of experiments. Some of C N Ts are separated form electrode. But experiments showed that there is not serious problem for this phenomenon. On the other hand, in in -v i v o- experiments, the exact locations of electrodes are tested by removing the brain. Electrical stimulation of rat is done through an isolated portable signal generator circuit (as slave) which is carried by the rat. It has a RF receiver for communication with computer and a micro-controller for signal generation. Stimulation electrodes are connected to micro-controller so that the resistant is about 100 KΩ in A C S F. Slave system is connected wireless to a computer (as master) so that an operator is able to control it. A graphic user interface is designed for ease of operation. The remote control system is implemented and tested on rat. The stimulation of both hemispheres (M F B and S1BF areas) is done simultaneously and non-simultaneously. The whole system is examined in three-day period and it showed that the brain-computer interface for rat using C N T coated micro-electrodes is the effective in practice.

Title: How to get PEDOT on your neural electrodes: reliable, functionalized and homogenously coated

Authors: *L. ASPLUND, C. BOEHLER, F. OBERUEBER, S. HEIZMANN, C. KLEBER, R. HASSARATI, A. SCHOPF;
Univ. of Freiburg, Freiburg, Germany

Abstract: With the introduction of PEDOT coatings to the field of neural interfaces new perspectives have opened up. PEDOT electrochemically grown onto electrodes results in substantially lowered impedance and elevated charge injection capacity. Furthermore, biofunctionalization of PEDOT is relatively easy, both in terms of its surface modification and as a drug delivery system. For this reason PEDOT, as neural electrode, has during recent years taken the step from the hands of electrochemists to more biologically oriented research facilities. A challenge in this development is to establish coating processes for the large variety of devices of interest with an outcome that can be trusted over months of implantation. Probe surveillance in situ is rarely possible wherefore reliability is of the utmost importance. We here report on the various aspects that determine the quality of electrodeposited PEDOT. The impact of the deposition process on delamination failure, dissolution, delivery functionality and overall film quality were investigated. Prevention strategies targeting the most common failure modes were established. PEDOT was grown on a variety of common probe systems, from flexible to silicon shafts and microwires, and characterized with a broad range of techniques. Their properties for recording and stimulation were analysed considering both short and long term use. The choice of deposition parameters greatly influenced the outcome even when films appeared equal in high resolution microscopy. By an optimized process, increased homogeneity of both the bulk and the surface coverage could be achieved as well as improved electrochemical stability. By introducing an additional platinum electroplating process step reliability could be accomplished for a larger variety of substrate materials. Furthermore, by adhesion promotion layers, PEDOT could be stably anchored over at least 600 million bi-phasic pulses. These qualities also substantially influenced the drug delivery functionality of the films. In summary, we show here the importance of making the right process choices for ensuring a high quality PEDOT electrode. Substrate material was found to have strong impact on the outcome but, by introducing additional process steps, even challenging substrates could be reliably coated.

Title: Signal quality changes and histological tissue reactions during long-term micro-electrocorticographic recordings

Authors: *C. A. GKOGKIDIS[1,4], X. WANG[1,4], M. GIERTHMUEHLEN[1], S. DOOSTKAM[2], M. SCHUETTLER[6], J. RICKERT[6], J. HABERSTROH[3], T. STIEGLITZ[4], W. BURGARD[5], T. BALL[1];

Abstract: Great efforts are currently being made to develop implantable devices for clinical applications. Micro-electrocorticography (µECoG) is a promising candidate technology to acquire signals from the cerebral cortical surface due to its high spatial and temporal resolution and low invasiveness. However, little is known about the long-term characteristics of chronic µECoG recordings and tissue reactions caused by the implants, albeit this topic is of fundamental importance for long-term application in humans. To address these topics, we developed an ovine model for the testing of µECoG devices. 4 animals were implanted subdurally with electrodes on either the somatosensory or auditory and motor cortex for durations between 162 and 575 days and µECoG recordings were carried out throughout this time period. Peripheral sensory and auditory stimulation were used to elicit either somatosensory- or auditory-evoked potentials (SEPs & AEPs) and their frequency-resolved SNR was calculated. Post-explantation cortical tissue samples were extracted and examined with histopathological staining methods to detect pathological tissue reactions. In the present study, we demonstrate that SEPs and AEPs are suitable to monitor long-term signal stability of chronic µECoG recordings. Analysis of changes

of signal, noise, and SNR characteristics over several months revealed systematic changes, especially a steady decrease in both signal and noise amplitudes. SEPs and AEPs were reliably measured in the first months followed by a decline in amplitude. A significant SNR decline was observed for SEPs and a similar tendency also for AEPs. Post mortem histology revealed astro- and microgliosis and meningeal thickening by a factor of approx. 2-3, in the area beneath the implanted electrode. We propose that this substantial meningeal thickening might be the main reason for signal decline, since electron microscopy and electrochemical assessment of the electrode contacts revealed no differences between pre- and post-implantation characteristics. In summary, the present work provides data to characterize long-term signal quality of µECoG recordings combined with histological analysis important on the way to clinical applications. We are currently extending our approach to simultaneous neural recordings from motor cortex and motion capture to study movement-related information as needed for neuronal motor prostheses controlled by µECoG-based implants.

Title: *In vivo* 2-photon imaging of neural implants: surface modification with L1CAM camouflages devices from microglial encapsulation

Authors: ***J. R. ELES**, T. D. Y. KOZAI, N. R. SNYDER, C. F. LAGENAUR, A. VAZQUEZ, X. T. CUI;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Implantable brain electrodes are versatile tools in neuroscience research, brain mapping, and brain-machine interfaces for paralysis and limb loss victims. Their long-term efficacy, however, is limited by microglial and astrocytic scarring and neurodegeneration around the implant that that rapidly degrades the electrical characteristics of the recorded signal. Our group has previously demonstrated in rodents and primates that coating neural probes with a

neuron-specific adhesion protein L1CAM can "camouflage" the probe as non-foreign, which reduces glial scarring and neuronal death.
The current study uses in vivo 2-photon imaging to explore the dynamics of the L1CAM coating in real time. We implanted 5 L1CAM coated and 5 uncoated silicon Michigan Arrays in the cortex of 10 mice with fluorescently-labeled microglia (GFP) for at least 6 hours. Immediately after implantation, microglia within 150 µm of either L1CAM coated or control electrode arrays extended processes toward the implants. Despite similar patterns of extension, there was significantly less process encapsulation of the L1CAM coated probe's surface (Fig1). Further, microglia within 50µm of the L1CAM coated implant were significantly less reactive.
These results highlight the effectiveness of surface modifications on neural implants to influence the early host-tissue response. This demonstrates that, while microglia extend processes as a first response to implantation trauma, their phenotype is modulated by direct contact with bioactive surfaces. These results ultimately demonstrate the acute mechanisms of L1CAM coating, which has shown promising longevity in 2.5 year primate studies.

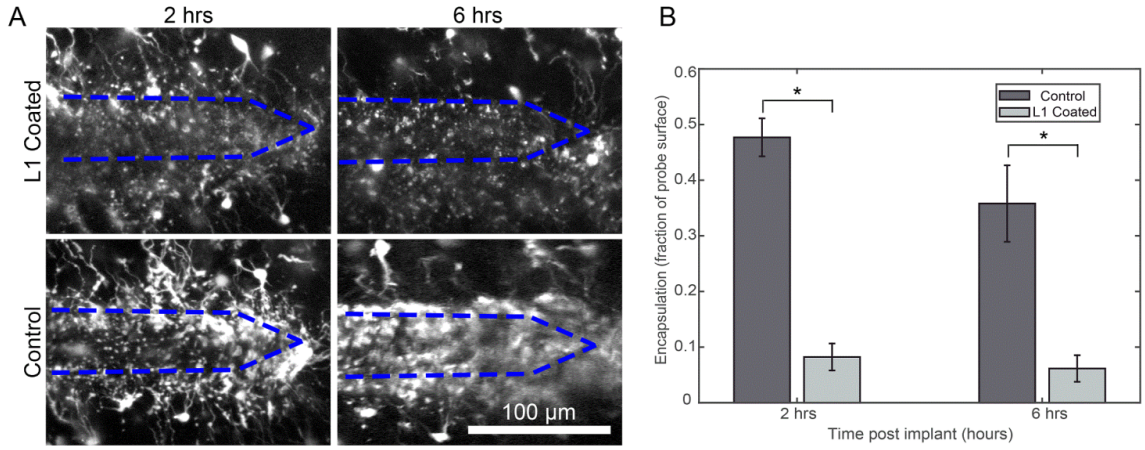

Figure 1: L1CAM coating reduces microglial encapsulation at 2 and 6hrs post implant. A) Two-photon microscopy of L1CAM coated (top) and uncoated (bottom) electrode arrays (outlined in blue) implanted in transgenic mice enable real-time imaging of microglial response to implant. B) Threshold-based quantification of microglial reveals significant reduction of encapsulation on L1CAM coated probes (Mean +- SEM; $p < 0.05$).

Title: Multicolor genetically-encoded calcium-sensitive bioluminescent reporters of neural activity for brain-machine interfaces

Authors: *M. A. PENDER[1], K. LIN[1], A. BARES[1], E. DING[1], M. G. KAPLITT[2], C. B. SCHAFFER[1], N. NISHIMURA[1];
[1]Nancy E. and Peter C. Meinig Sch. of Biomed. Engin., Cornell Univ., Ithaca, NY; [2]Brain and Spine Center, Weill Cornell Med. Col., Ithaca, NY

Abstract: Next-generation brain machine interfaces (BMIs) for applications such as prosthetics require the ability to map activity of neural networks over large areas, should maintain the sensitivity and resolution to detect firing of a single neuron, and must be durable. Current BMIs based on implanted electrodes can record activity from individual neurons, but cannot accurately record more than a few neurons per electrode, and degrade over time. Our approach measures neural activity by light emission from calcium-sensitive bioluminescent proteins known as fluorescent protein-aequorins (FP-Aeqs). We “barcode” neurons using a gene-therapy viral vector approach to express assortments of different color FP-Aeqs. In FP-Aeqs, aequorin acts as a calcium-sensitive donor for bioluminescence resonant energy transfer (BRET) to an acceptor connected by a flexible linker. To expand FP-Aeq’s emission spectrum, we modify and/or swap the FP, engineer mutations/truncations in the linker, and modify known interactive regions (Fig. 1a b). Selected constructs are packaged into adeno-associated viral (AAV) vectors and co-injected into rodent barrel cortex. At least three weeks after injection, multiphoton microscopy is used to directly excited FP-Aeq, confirming that a mix of AAV vectors stochastically produced different barcodes in individual neurons (Fig. 1c). Then, the cofactor required for the bioluminescent reaction, coelenterazine, is micro-injected through a craniotomy into the rodent brain. Using photomultiplier tubes, we detected spectrally separated bioluminescent emission from an anesthetized mouse in response to whisker stimulation (Fig. 1d e). Trajectories of intensity at different wavelengths showed different states before, during, and after whisker stimulation (Fig. 1f). Calcium-sensitive bioluminescence enables recording of neural activity from rodent cortex. Color-coding increases the complexity of the information relative to single-color reporters. This tool could provide a long-term, robust BMI for patients to enable control of prosthetic devices.

Title: Plasticity in the excitability of neurons surrounding implanted neuroprostheses

Authors: *J. W. SALATINO[1,2], D. R. MONCREASE[3], E. K. PURCELL[1,2,4];
[1]Biomed. Engin., [2]Neurosci., [3]Chem. Engin. and Material Sci., [4]Electrical and Computer Engin., Michigan State Univ., East Lansing, MI

Abstract: Implanted microelectrode arrays in the brain ("neuroprostheses") provide a unique opportunity for studying and treating neurological injury and disease by directly recording or modulating neuronal activity. However, suboptimal integration with the brain has been reported, where loss of neuronal density and glial encapsulation plague long-term devices (Biran 2005). However, evidence of a direct correspondence of these observations to functional outcomes

remains incomplete. Here, we investigate the hypothesis that alterations in the excitability of neurons surrounding implanted devices contribute to variable signal quality, where the functional properties of the affected neurons are modified as a function of distance and time from the site of insertion. Initial evidence for these effects was collected from non-functional, single shank microelectrode arrays (Neuronexus) implanted in the primary motor cortex of adult female Sprague-Dawley rats (Charles River) for predetermined timepoints (3 days, 1 week, 4 weeks), where brains were fixed with paraformaldehyde, sectioned, stained using immunohistochemistry, imaged with an Olympus Fluoview 1000 Confocal Microscope, and analyzed using a custom-modified MATLAB script adapted from (Kozai 2014). Antibodies against voltage-gated sodium and potassium channels were chosen to study fluctuations in the expression of ion channels in neurons identified by NeuN labeling. We observed initially increased ion channel expression (potentially indicating hyperexcitability) during early time points (3 days, 1 week), followed by a subsequent reduction in channel expression (a possible indicator of hypoexcitability) at the chronic time point (4 weeks) within the recordable radius of the device-interface (Henze 2000). These results were coupled with observations of shifts in the relative expression of markers of inhibitory and excitatory neurotransmission surrounding the device, where long-term time points were associated with increased inhibitory marker expression. Combined, these results support the hypothesis that local shifts in the excitability of neurons may contribute to the reported instability in recording quality over time, which may inform new strategies for improving the long-term performance necessary for clinical and research applications. Future work will correlate our findings with the quality of recordings collected from functional devices. ***References:*** **R. Biran et. al / Experimental neurology, 195(1) (2005) 115-126; D.A. Physics, U.S. Food and Drug Admin., Silver Spring, MD; [2]Univ. of Maryland, College Park, MD; [3]Electrical and Computer Engin., [4]Dept. of Bioengineering, Univ. of Utah, Salt Lake City, UT; [5]Departments of Neurosurg. and Bioengineering, Univ. of Colorado, Denver, CO

Abstract: Reliable coupling of electrodes to the nervous system dictates chronic implant performance and the success of neuroprosthetic devices. Closed-loop neuroprosthetic systems can utilize implanted electrodes to record motor signals used for prosthetic control and deliver electrical stimulation to create sensory perception. The relative ease of access and simple circuitry in the peripheral nerves make them an attractive interface site for advanced neuroprostheses. Using a rat sciatic nerve model, this study aims to evaluate and compare the chronic recording and stimulation performance of microelectrode arrays with very low impedance electrodes to that of commercially available arrays.
Utah arrays (UA) were purchased from Blackrock Microsystems and modified Utah arrays (mUA) were provided by Dr. Loren Rieth. mUAs boast a very low impedance tip metallization based on IrOx, with median impedance < 10 kΩ and standard deviations of < 4kΩ (saline). Encapsulation for mUAs incorporates atomic layer deposited alumina underneath 6 μm Parylene-C. Arrays were implanted into the rat sciatic nerve and EMG arrays into the gastrocnemius and tibialis anterior muscles for 12 weeks, and tissue harvested for histology following study termination. Connector mounts were 3D printed to house Omnetics connectors attached to the electrodes for recording and stimulation. Two cranial screws were implanted over the somatosensory cortex to record stimulation-induced somatosensory evoked potentials (SSEP). Weekly broadband impedance measurements were recorded followed by electrophysiology to study recording performance. Two channels in each array were selected for studying stimulation stability. Stimulation evoked SSEPs and muscle activation was recorded weekly. Walking track tests were used to assess functional changes associated with long term implantation.
No differences in the recording capability of the UA and mUA, as measured by the number of channels with neural activity, were observed. Session-to-session variability in evoking SSEP was observed during stimulation of the nerve. Functional tests indicated nerve recovery around 2 weeks post-implantation. The arrays implanted into the nerve showed electrical and mechanical compatibility and did not impede recovery of function. However, chronic application of these devices may be impacted by session-to-session variability, which warrants further investigation.

Abstract: After paralysis, attempted movement is known to activate primary motor (M1) and somatosensory (S1) cortex, although the latter is less well studied. Most previous work has been conducted with functional magnetic resonance imaging (FMRI) or magnetoencephalography (MEG). However, recent clinical brain-computer interface (BCI) trials, which have shown promise for improving function for people with paralysis, offer an opportunity to study human motor control at a single unit level. Here we investigated M1 and S1 activity using intracortical recordings while a person with tetraplegia attempted to perform movements of his arm and hand. Under an Investigational Device Exception, pre-surgical functional neuroimaging (PSFN) was used to implant two 88-channel microelectrode arrays in M1, one in shoulder, one in elbow/finger representation. Two 32-channel arrays were implanted in finger areas of S1. Intracortical data were collected 4, 8, and 12 months after implantation while a 28-year old male with a C5 motor/C6 sensory ASIA-B SCI attempted to move his right arm and hand along with videos of single-joint movements. Shoulder, elbow, and wrist movements could be overtly performed, while finger movements were covertly attempted. Modulated units were identified as those with significant changes in firing rate distribution during movement compared to rest ($p<0.05$, two-sample Kolmogorov-Smirnov test).We found that of all recorded units, over half displayed significant modulation during at least one movement (see Table 1). The medial motor array was dominated by shoulder-related units as in PSFN, while units on the other arrays were responsive to a number of different movements. This is particularly surprising on the sensory arrays, which were targeted to finger-related areas based on PSFN. We show that even after chronic tetraplegia, both M1 and S1 units respond to attempted movements, both covert and

overt. In general, units were broadly responsive to multiple movements. Further investigation is needed to examine specific movement parameters (speed, position, etc.) to determine if additional insight regarding unit behavior can be gained. Additionally, future work should examine the activation of S1 during sensory imagery as well as motor imagery.

	Motor Medial	**Motor Lateral**	**Sensory Medial**	**Sensory Lateral**

Title: Encoding of intended grasp force in primary motor cortex during brain-computer interface controlled robotic arm use

Authors: *J. E. DOWNEY[1], J. WEISS[2], A. B. SCHWARTZ[3], R. GAUNT[2], J. L. COLLINGER[2];
[1]Dept. of Bioengineering, [2]Physical Med. & Rehabil., [3]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Brain-computer interfaces (BCIs) for neuroprosthetic arm control are being developed as assistive devices for people with tetraplegia. Often signals from primary motor cortex (M1) are used to decode endpoint velocity, but M1 is also known to encode force. For BCI-controlled grasping, it is important to be able to modulate force in order to grasp objects of varying weights and fragility. We sought to determine if we could decode a BCI user's representation of grasp force during attempted grasping of virtual objects.

Under an Investigational Device Exemption, a 28 year-old male participant with chronic C5 motor and C6 sensory AIS B spinal cord injury was implanted with two microelectrode arrays in M1 and two microelectrode arrays in S1. Neural data was recorded while the participant watched a virtual prosthetic arm grasp a spherical object. Trials started with an auditory cue naming a graspable object (marshmallow, tomato, can of soup) chosen to span the range of possible grasp force representations. After a 2 s planning period he attempted to grasp with "the minimum force required to grasp and lift the cued object". He then attempted to hold the object with the appropriate amount of force for 2 s before being cued to release it. The virtual arm automatically grasped and released the object regardless of the participant's actions. To determine whether the intended grasp force was encoded in the recorded neural activity, each channel's firing rate was averaged over a 1 s sliding window (0.2 s step size). Each window was used to train and test a naïve-Bayes classifier using leave-one-out cross validation to create a time series of classification accuracy.

Classification accuracy of the 3 objects using firing rates in M1 peaked at 88% for the 1 s window starting 0.2 ms in to the 2 s hold time, and remained above 85% for the rest of the hold time. The accuracy did not diverge from chance level until the participant began attempting to grasp the object. When the object was released, the classification accuracy fell to 62% at the end of the trial. Classification accuracy using S1 firing rates followed a similar trend, but increased

later than M1 accuracy by approximately 0.5 s and peaked at only 67%.
This study shows that graspable objects requiring a variety of forces (the participant reported relative force ratings of 1, 2, and 4) can be well classified from M1 and, to a lesser extent, S1, in a BCI user with tetraplegia. Future work will integrate this decoded information into closed-loop BCI arm control to attempt to improve the users' ability to grasp and manipulate a variety of objects.
We thank Paul Marasco and Zachary Thumser for insightful discussion regarding study design and data interpretation.

Abstract: The parietal cortex is centrally involved in sensorimotor transformations for motor outputs such as reaches and grasps. We have shown in studies of both human subjects and non-human primates (NHP) that trajectory signals of intended limb movements can be extracted from population activity in posterior parietal cortex (PPC) and used for BMI applications in which cursors or robotic limbs are controlled by the recorded neural signals. Additional signals can also be extracted from the PPC that represent higher-level or more abstract intent. Of particular interest to brain-machine interfaces is the finding from prior animal electrophysiology recordings and human brain imaging data that representations of intended movements in both the ipsilateral

and contralateral limb are found within a single hemisphere. The bilateral nature of these signals indicates a higher-level element of activity, an idea affirmed by other similarly abstract characteristics of neuronal activity such as coding of sequences of movements and the encoding of the goals of a movement. In a recent and ongoing study of a human tetraplegic subject with PPC implants we have been able to decode both trajectory and goal signals, indicating the cognitive approach to BMIs is applicable to human subjects. Here we investigate the nature of the bimanual representation in the posterior parietal cortex using intracortical electrophysiological data recorded from a human with tetraplegia. As further evidence that the posterior parietal cortex encodes high-level bimanual activity, we have identified neurons in presumed human analogues of the anterior intraparietal area and Brodmann's area 5 whose firing rates modulate during planning and execution of motor imagery of both contralateral and ipsilateral limbs. Furthermore, bimanual representations are evident across both single-unit firing rates and population-level local fields. The involvement of the parietal cortex in bimanual movement planning confirms an important characteristic of this versatile brain area, and points toward applications in neural prosthetics whereby implants in a single hemisphere could be used to provide bilateral control of neural prostheses.

Title: Detection of phonemes, short words and phrases from single units and 12-20 Hz frequency Beta band data during overt and covert speech recorded chronically from a speaking human.

Authors: *P. R. KENNEDY[1], C. R. GAMBRELL, 30096[2], N. SHIH[2];
[1]Neural Prosthetics, Neural Signals Inc, Duluth, GA; [2]Neural Signals Inc., Duluth, GA

Abstract: Recording from a speaking human allows comparison between overt and covert speech with a view to developing a speech prosthetic for locked-in subjects (mute and paralyzed, but intelligent and awake). Four Neurotrophic Electrodes were implanted into the articulatory motor area of PRK's dominant hemisphere on June 21st 2014. Amplifiers and transmitters, powered by inductive coils, were added in October 2014. Overt and covert speech was assessed during production of 39 phonemes, 290 short words and six phrases.

The recognition of *covert* speech onset is obviously important. During *overt* speech, this is achieved by using the 12-20 Hz Beta peaks that are detected at the onset and offset of phonemes (Sarmah and Kennedy 2013) and at inflection points during the vocalizations. Extrapolating from *overt* speech results to *covert* speech, we expect that the presence of Beta peaks during *covert* speech implies speech onset, inflection points and offset. The presence of these Beta peaks indicates that the peaks can provide a means to determine what is being covertly vocalized. The data indicate that by comparing the pattern of beta peaks during overt and covert vocalizations, a 'look up' table of phrases can be developed. For example, the phrases, HELLO WORLD and WHICH PRIVATE FIRM, show differences between their beta peaks due to (1) their different lengths and (2) the inter-peak intervals of the inflection. The data indicate that this is true for both overt and covert speech. These findings demonstrate that distinct phrases, of differing lengths and inter-peak intervals, can be distinguished on the basis of their beta peaks.
Beta peaks also provide a trigger for initiating decoding of single units. There are 10 trials within each session for all phonemes and phrases for overt, covert and control periods. There is an operator triggered Event Marker available to indicate approximate Speech Onset, and in the case of *overt* speech, the Event Marker is archived along with the Recorded Speech and the Single Unit data. With *covert* speech only the Event Marker and Single Unit data are available so the Beta peak is used to decide on decoding onset. Analysis of the Single Unit activity is achieved by examining bursts that follow the Beta peak. In *overt* speech the Beta peak is found to occur at speech onset. So if a phoneme or part of a phrase is determined by *overt* speech to endure for say 30 ms, the analysis for c*overt* speech begins at the Beta peak and only 30 ms is analyzed. Thus the Beta peaks are used to determine the amount and timing of data to be analyzed. We focused on four phonemes and found that the Unipho software program (written by Chad Gambrell) indicates an 80% phoneme detection rate that occurs within 200 ms.

Title: Towards a multi-state click decoder in intracortical brain computer interfaces

Authors: *J. G. CIANCIBELLO[1], M. VILELA[1], T. HOSMAN[1], J. SAAB[1,2,4], D. LESENFANTS[1,2,4], D. M. BRANDMAN[3,2], B. FRANCO[5], L. R. HOCHBERG[1,2,4,5,6], J. D. SIMERAL[1,2,4,5];

Abstract: *Background*: Intracortical brain-computer interfaces (iBCI) are being developed to enhance communication and independence for individuals with motor impairments. Assisted with the BrainGate2 BCI system, individuals with quadriplegia and locked-in syndrome have previously used their intracortical neural activity to control a computer cursor (Hochberg et al., 2006; Simeral et al., 2011). As cursor velocities increase, distinguishing a click from cursor movement must occur on a faster time scale. Here we present a new click decoding strategy aimed to enhance on-screen keyboard typing performance. We hypothesize that discrete characterization of cursor motion could improve the ability to distinguish click from ongoing movement. *Methods*: BrainGate2 participant T9 (52-year-old male with amyotrophic lateral sclerosis) had two 96-channel microelectrode arrays (Blackrock Microsystems, Salt Lake City, UT) inserted into the dominant motor cortex. Non-causal spike rates and spike power from 20-ms bins were extracted during center-out-and-back radial-8 training and testing blocks (5 sessions). The participant was instructed to imagine moving his dominant hand to control the computer cursor and closing his hand to click. Data was used to build a Kalman filter and multi-class LDA (MCLDA) classifier with unique labels for eight cursor directions (0-44°, 45-89° 90-134°, etc.) and click. The MCLDA makes a classification decision based on a maximum likelihood estimate of the click class vs. all cursor movement classes. Point-and-click control was tested on a set of 14 center-out-and-back radial-8 task blocks and one QWERTY-typing block, during which the participant copied sentences. *Results*: T9 was able to point-and-click with a hit rate of 96.4% ± 4.3 during the center-out-and-back radial-8 test blocks. In the QWERTY block T9 copied sentences using the QWERTY on-screen keyboard at a rate of 21 correct characters per minute with 94% accuracy. *Conclusion*: The MCLDA is a new approach enhancing click decoding with increased cursor velocities by separating the high dimensional neural data with respect to cursor direction. Future sessions will compare performance from gold-standard state decoding methods (binary LDA) and MCLDA approaches. Developing a reliable click signal is essential for effective long-term BCI use that can improve the quality of life for individuals with severe motor impairments.

For Brain Sci., Brown Univ., Providence, RI

Abstract: Hundreds of thousands of people live with loss of motor function due to spinal cord injury (SCI) and could benefit from a neuroprosthetic that restores arm movements. Functional Electrical Stimulation (FES) is a method of delivering current to nerves and muscles to produce movement, and has been shown capable of restoring independence to people with spinal cord injuries, enabling activities such as eating, writing, and grooming. Intracortical brain computer

interfaces (iBCIs) have been proposed as a promising command interface for FES systems. Neural activity recorded via penetrating microelectrode arrays has been shown to be related to reaching kinematics in able-bodied primates and humans with paralysis, and iBCIs have been used to infer complex movement intentions (10+ degrees of freedom) for controlling robots. iBCIs rely on precise recordings of microvolt sized signals, but FES generates relatively larger electric fields in the paralyzed limbs. Electrical artifacts during stimulation could interfere with accurate neural recordings and limit the usefulness of iBCIs for control of FES prostheses. The goal of this work is to characterize the artifacts recorded by intracortical microelectrode arrays during functional electrical stimulation in a human, and to propose ways to mitigate those artifacts for real-time iBCI control of FES. BrainGate participant T8, who has C4 SCI, received two 96-channel intracortical microelectrode arrays placed in the motor cortex. Additionally, he had 24 intramuscular stimulating electrodes and four anodes placed in the right arm for restoring movement of the paralyzed limb. We also applied temporary surface patch electrodes to stimulate a subset of the same muscles. Stimulation artifacts were present in the neural recordings during both surface and intramuscular stimulation. However, surface stimulation artifacts were on average 175x larger than baseline neural signals while intramuscular stimulation artifacts were only 3-4x larger. Typical artifact durations were 0.5 milliseconds in length and the waveforms were highly consistent across electrodes within each array (184/192 with >90% correlation). The FES artifacts increased the iBCI computed neural feature values and reduced our ability to predict intended movements. These results demonstrate that implanted FES produces substantially smaller stimulation artifacts than surface stimulation, and that the artifacts are brief and consistent, allowing a FES-iBCI to adapt during real time neural control.

Title: Idle state detection from motor cortical activity in a person with tetraplegia using an intracortical brain-computer interface

Authors: *D. LESENFANTS[1,4,2], J. SAAB[1,4,2], T. HOSMAN[1], M. VILELA[1], B. JAROSIEWICZ[3,4,2], B. FRANCO[5], S. S. CASH[5,7], E. N. ESKANDAR[6], J. D. SIMERAL[4,1,5,2], J. P. DONOGHUE[3,1,2,8], L. R. HOCHBERG[4,1,5,7,2];

Abstract: *Background*: Brain-computer interfaces based on intracortical recordings (iBCI) have recently allowed two participants with tetraplegia to control a commercial Android tablet (Nuyujukian et al., SfN2015). Two outstanding issues are the inability for the participants to turn the system on/off without the assistance of a caregiver, and unintended cursor actions during idle periods. Detecting the "idle state" from neural activity could address these issues by informing the system of the user's intention (or lack of intention) to control an assistive device. The system can then automatically transition between responding to volitional neural control and idling. Here, we report the ability to distinguish motor cortical activity in task-related blocks from idle intertask periods in an individual with tetraplegia using an iBCI.
Methods: The participant in this study (T9) is a 52-year-old man in the BrainGate2 trial with amyotrophic lateral sclerosis. During research sessions, neural signals were recorded from two 96-channel microelectrode arrays (Blackrock Microsystems, Salt Lake City, UT) placed in his dominant motor cortex. Multi-unit spike rates and power in the spike band were extracted in 20ms bins for each channel during neural control in a center-out-and-back task, and during intertask rest periods. Three sessions (A to C) were used for the following offline data analysis. Features from session A were used to train a linear discriminant analysis (LDA) classifier, then applied to an independent dataset from session B in order to evaluate the effect of two parameters on classification performance: length of the classifier's sliding window (T, ranging from 0.1 to 5sec), and number of features (F, ranging from 10 to 250). Optimal T and F were selected based on the area under session B's Receiver Operating Characteristic (ROC) curve, and then tested in session C.
Results: The optimal set of parameters (with an area under the ROC curve of 0.83) was

determined to be 3 sec of neural history combined with 100 features (35 spike rate and 65 spike power features). Linear classification could distinguish idle intertask from cursor control/task periods with a positive predictive value of 81.5% and a negative predictive value of 95.9%. *Conclusion*: This study illustrates the ability to detect idle state periods from intracortical neural recordings with high accuracy in an individual with tetraplegia. Using idle state detection online could prevent undesirable cursor movements during idle periods and allow users to turn the system on and off without the assistance of a caregiver.

Title: Adaptive threshold for point-and-click applications using intracortical brain computer interface

Authors: *M. VILELA[1], J. CIANCIBELLO[1], T. HOSMAN[1], J. SAAB[1,4,2], D. LESENFANTS[1,4,2], B. FRANCO[5], B. JAROSIEWICZ[3,4,2], J. SIMERAL[1,4,5,2], L. R. HOCHBERG[4,1,5,6,2];

Abstract: Background: The development of intracortical Brain-Computer Interfaces (iBCI) aims to help people with locked-in syndromes to communicate and interact more completely with their environment. One of the potential applications of this technology is the full control of a computer, where the system enables the user to move the cursor and click on desired areas of the computer screen. To this end, the iBCI system needs to decode the continuous desired motion in parallel with the discrete desired clicks from the user's neural activities. The decoding of the discrete click states is often performed by a classifier, which in turn thresholds a continuous state signal to distinguish between the click and non-click classes. Here we present an algorithm that takes the state signal from a classifier and constantly updates its threshold to detect desired clicks. Methods: The proposed algorithm detects desired click by identifying when the state signal crosses its threshold. The threshold is updated from a collection of state signal points that were classified as non-click. Specifically, the algorithm recomputes the statistics of the local distribution of non-click data points in real-time, then treats clicks as outliers of this distribution. To increases responsiveness in classification, the threshold is exponentially decreased when Δ consecutive positive derivatives are detected. The parameter Δ is updated as the average time of events with consecutive positive derivatives in the non-click data points. Results: The algorithm was tested online with BrainGate2 clinical trial participant (T9) who has two 96-channel microelectrode arrays in the dominant premotor gyrus (Blackrock Microsystems). A Kalman filter was used for directional control while the log ratio of likelihoods from a multiclass linear discriminant classifier was used as state signal. After the calibration blocks, participant T9 was able to use a virtual QWERTY keyboard to copy sentences for 4 blocks, each lasting 10 minutes. These 4 blocks averaged a 17.7 correct selections per minute with overall 90% accuracy. Offline analysis of the same data using the third dimension of the Kalman filter as state signal shown similar results. Conclusion: The adaptive threshold algorithm is a versatile tool that works in conjunction with two different click decoders. Moreover, because the threshold is constantly updated, the algorithm is able to adjust to non-stationarities and short transients in the state signal and correctly detect clicks. This scenario is particularly important for long recordings where an initial fixed threshold becomes inefficient as the state signal changes its range.

Hosp., Boston, MA; [18]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Previous work in non-human primates has suggested that neural activity in the motor cortex is correlated with movement speed independently of direction (i.e., the equation $f = a + B \cdot V + c||V||$ describes neural activity more accurately than $f = a + B \cdot V$, where f is the firing rate of a neuron, V is a hand velocity vector, and a, B and c are model coefficients). Here, we interpreted this direction-independent activity to represent the magnitude of a feedback control vector instead of movement speed (so that V now represents a feedback control vector instead of velocity). Using this interpretation, we analyzed neural activity from motor cortex while three participants in the BrainGate2 pilot clinical trial controlled a computer cursor using a brain-computer interface. We found that direction-independent, "control vector magnitude" information was strongly encoded in threshold-crossing rates and high-frequency spectral power. Including ||V|| in the tuning model increased the average variance explained by 33%, 85%, or 202% depending on the participant. Since ||V|| is linearly independent from V, neural tuning to ||V|| is not leveraged by linear velocity decoders. We present a new decoding architecture that can explicitly decode the encoded signal ||V|| and then combine it with the magnitude information also present in V that is decoded by a standard, linear velocity decoder (Kalman

filter). The new "magnitude" decoder substantially increases the signal-to-noise ratio of decoded movement speeds offline relative to a standard Kalman filter (31%, 36%, or 152% average increase depending on the participant). Online performance tests of the magnitude decoder in one participant show that it can increase the user's ability to hold still on top of a target (the cursor stays twice as close to the target center) with no sacrifice in the time taken to reach the target.

Abstract: Objectives: Brain Computer Interfaces (BCIs) are being designed to allow individuals with tetraplegia to control assistive communication and environmental control devices. A core component of BCI technology is the decoder that translates neural information into command signals for such devices. We developed a nonlinear, non-parametric decoding algorithm that we call the Gaussian-process discriminative Kalman filter (GPDKF). In contrast to many other non-parametric filtering approaches, GPDKF yields a closed-form solution with interpretable parameters and provides a principled approach to dealing with signal noise and non-stationarities. We then incorporated this decoder into a closed-loop asynchronously updating system (CLAUS) that re-computes parameters online based on the most recent neural data. We validated this decoding approach during closed-loop intracortical BCI use by a person with tetraplegia.
Methods: A research participant (T9) with amyotrophic lateral sclerosis received two 96-channel multielectrode arrays that were placed in the dominant precentral gyrus as part of the BrainGate2 pilot clinical trial. The participant performed BCI-enabled computer cursor tasks with the GPDKF-CLAUS system, including center-out and random target acquisition tasks.
Results: Starting with null filter parameters, T9 developed unassisted cursor control -- allowing for target acquisition in a center-out task -- within 2.5 minutes. Standard Fitts regression parameters were comparable to previously published results. Offline analyses suggested that the GPDKF was more robust to non-stationary signal behavior than a Kalman filter.
Conclusions: The GPDKF-CLAUS decoder is a novel approach to neural decoding that removes linear assumptions of neural behavior. It provides principled methods for addressing signal non-stationarities in iBCI, and preliminary findings suggest that neural control quality is at least comparable to published controls.

Abstract: Intracortical brain-computer interfaces (iBCI) have been used by people with tetraplegia to control computer cursors, assistive robotics, and prosthetics limbs. In this study, we examined how neural encoding of direction varies when a user alternates between controlling an on-screen cursor versus a robotic arm, and whether contextual differences in control based on the effector exist. We hypothesized that combining training data from both cursor and robotic arm tasks will allow for a neural decoding filter that would effectively control either effector. A major focus of this study was to elucidate whether neural firing patterns are contextually altered by control of a "virtual" cursor versus a physical robotic arm.
As part of the BrainGate2 pilot clinical trial, a participant (see prior abstracts) was asked to control either a cursor or robotic arm. We used a two-dimensional paradigm in which the participant had to guide either a computer cursor or robotic arm over a series of targets displayed on a computer screen, and dwell over the target for a period of 500ms. In the first set of research sessions, eight uniformly sized targets were arranged in a radial configuration. In subsequent sessions, variable sized targets were placed at randomly determined locations. Both devices used the same control scheme with matching effector speeds. We calibrated multiple filters in three

open-loop calibration scenarios in which the participant observed either, i) only cursor movement, ii) only robotic arm movement, or iii) simultaneous cursor and robotic arm movement. After obtaining the baseline performance for each filter using the modality under which it was trained, we had the participant control the effector using a filter trained with data from the opposite modality (i.e. cursor control using a filter trained on robotic arm movement). We found contextual alterations in neural firing patterns occur in relation to the end modality being controlled. However, a static neural decoding filter trained on both cursor and robotic arm blocks could provide accurate control of either effector. In the random target acquisition tasks, the participant was able to reach the target with an average time of 4.4 seconds while controlling a cursor, compared to 5.5 seconds while controlling the robotic arm. Accuracy of target acquisition was 95% in cursor control compared to 97% in robotic arm control.
Although contextual differences exist in neural firing patterns based on the modality being controlled, these disparities can be overcome using a filter trained on data that includes control of both effectors.

Title: Retrospectively supervised point-and-click decoder calibration during practical use of an intracortical brain-computer interface

Authors: *B. JAROSIEWICZ[1,4,2], A. A. SARMA[3,4,2], J. SAAB[3,4,2], B. FRANCO[5], L. R. HOCHBERG[4,3,5,6,2];

Abstract: Brain-computer interfaces (BCIs) aim to help restore independence to people with severe motor disabilities by allowing them to control a cursor on a computer screen or other effectors with neural activity. However, physiological and/or recording-related nonstationarities in neural signals can limit long-term decoding stability. High-quality neural control can be restored using decoder calibration routines in which the user is asked to move the cursor to prescribed targets so that neural activity patterns can be mapped to movement intention. However, it would be time-consuming and impractical to require users to pause use of the BCI to perform decoder recalibration routines whenever neural control degrades. We recently demonstrated computational methods that can recalibrate a decoder using data acquired during practical point-and-click control of the BCI by retrospectively inferring that the person's movement intention at each moment had been directly toward the next self-selected target. These methods were limited to directional control of the cursor. Here, we extend this principle to allow the *click* decoder to also be recalibrated using data acquired during practical BCI use. In this study, the click decoder was a simple 2-state LDA classifier running in parallel with the kinematic decoder; however, these methods can be applied to any click decoding algorithm that turns a continuous signal (such as click log-likelihood, velocity or position in the click dimension, etc.) into a binary signal (click vs. non-click). We retrospectively labeled neural data patterns as corresponding to "click" during all time bins in which the decoded click log-likelihood had been above the click threshold that was used during real-time neural control. The periods that our kinematic decoder's retrospective target inference heuristics determined to be intended cursor movement periods were retrospectively labeled as "non-click". Once these neural activity patterns were labeled, the click decoder was calibrated using standard LDA classifier training methods. Combined with real-time bias correction and baseline rate tracking during pauses in neural control, these retrospective labeling methods enabled a BrainGate participant with ALS (T9) to type whatever he wished across 11 research sessions spanning 29 days, maintaining high-performance point-and-click control without ever needing to interrupt keyboard use for explicit calibration tasks. By eliminating the need for daily calibration tasks with prescribed targets, this approach advances the potential clinical utility of intracortical BCIs for individuals with severe motor disability.

Abstract: Background: Intracortical brain-computer interfaces (iBCIs) have emerged as a promising assistive technology for restoring hand grasping in individuals with tetraplegia. To date, most iBCIs intended for human use have utilized only kinematic information from the motor cortex. However, during natural hand grasping, the motor cortex encodes a combination of kinematic and kinetic information. Previous studies in non-human primates have investigated the feasibility of utilizing kinetic neural information, identified during executed force production, as control signals for iBCIs. Here, we further elucidate how force-related information is represented in the motor cortex in an individual with chronic tetraplegia. Specifically, we characterize the

extent of neural modulation that occurs during observed, imagined, and attempted forces. **Methods:** Participant T8 of the BrainGate2 Clinical Trial (55-year-old male, C4-level spinal cord injury) was asked to observe, imagine, and attempt producing four discrete force levels with the dominant hand. Full broadband neural recordings were obtained from two 96-channel microelectrode arrays (Blackrock Microsystems, Salt Lake City, UT) in the dominant precentral gyrus. We characterized the modulation of two time-varying features (spike firing rates, high frequency spike powers) during force production. These features were also used as inputs to a linear discriminant analysis (LDA) classifier, to discriminate the observed, imagined, and attempted force levels offline. **Results & Conclusions:** The number of neural features tuned to force production, as well as offline discrimination performance, was greatest during attempted force, and least pronounced when force production was observed. Additionally, tuned features exhibited various temporal profiles, with some tuned to the preparatory phase of force production, others tuned to active force production, and still others tuned to both phases. These results suggest that force-related information is retained in motor cortex in individuals with tetraplegia, and that it is feasible to incorporate cortical activity during attempted force production into iBCIs that restore hand grasping function.

Abstract: Brain Machine Interface (BMI) has been actively researched and is gradually being applied in clinical scene to restore human disability. Compare to movement-assist-BMI, further improvement is still expected for verbal-communication-assist-BMI. Single unit recording is one of the most promising modality, for its high temporal resolution and high specificity in encoding neural functions. Our objective in this study was to evaluate the use of spike frequency and power spectrum obtained from human face motor cortex(FM cortex) while articulating Japanese alphabet. We recorded neuronal activities from subjects with refractory epilepsy, who underwent intracranial electrode placement for the purpose of detecting the epileptic foci. For the subjects whose FM cortex was included in potentially peri-epileptogenic zone, an electrode consisting of 6 microneedle combined with 3 macroelectrodes was used to cover the FM cortex. The protocols were reviewed and approved by the institutional ethical committee of the University of Tokyo Hospital. The task was to pronounce a single Japanese alphabet displayed on a monitor, which was pseudo-randomly presented. Neuronal activity was simultaneously recorded from macroelectrodes and microneedles (Cerebus, Black Rock). A standard expectation maximization clustering was performed to obtain single unit activities (Offline Sorter, Plexon). Local field potentials (LFPs) were band pass filtered for 6 different frequency band (Delta, Theta, Alpha, Beta, Low Gamma, High Gamma), and Hilbert transformed to obtain its power spectrum respectively. Feature vector from single unit activities was produced by optimizing the bin of spike frequency. The power spectrum was also averaged across time to produce its feature vector. We constructed multiclass classifier using SLR (Sparse Logistic Regression) or SVM (Support Vector Machine), and the performance was evaluated respectively. Binominal test revealed that the decoding accuracy of vowels were significantly over chance level ($P<0.05$), and best when feature vector consisted of spike frequency alone. Though LFP power spectrum alone was not able to meet the significance level, combination of LFP power spectrum and spike frequency reached significance level. This tendency remained as the number of decoding alphabet ranged from 2 through15. Our results suggest that optimization and further investigation for feature production from FM cortex recordings could be effective in developing verbal-communication assist BMI.

Title: Learning mechanisms in the posterior parietal cortex: A brain-machine interface study with a tetraplegic human

Authors: *S. SAKELLARIDI[1], V. N. CHRISTOPOULOS[2], T. AFLALO[2], K. W. PEJSA[2], E. R. ROSARIO[3], D. OUELLETTE[3], N. POURATIAN[4], R. A. ANDERSEN[2];

Abstract: One of the central questions in neuroscience is how the brain learns new tasks. Previous studies have considered two potential mechanisms: *i*) neural activity modulated by learning is independent of the structure and the normal activity of the neurons (*individual-neuron* learning) and ii) neurons use the existing network structures and the activity modulation is biased by these structures (*intrinsic-variable* learning). Here, we aim to dissociate these two hypotheses by recording neuronal activity from a tetraplegic subject (C3-C4 lesion 6 years post injury) implanted with a 96 channel microelectrode array in the anterior intraparietal (AIP) cortex. We conducted brain-machine interface (BMI) experiments, where the subject controlled a computer cursor by center-out wrist movements to two peripheral stimuli (S1, S2) by modulating the activity of one neuron (the trained neuron). The preferred direction of the trained neuron was towards the location S1. In a first block of trials (BMI-pro), the subject had to increase the activity of the neuron to move to S1, and suppress the activity to move to S2. In a second block of trials (BMI-anti), we enforced an opposite stimulus-response rule, such as the firing rate should be lower for S1 and higher for S2. This rule forces the trained neuron to flip its preferred stimulus location tuning between the BMI-pro and the BMI-anti trials. To dissociate between the two hypotheses, we recorded activity from an ensemble of "untrained" neurons. Untrained neurons are not involved in the control, but they are part of the pre-existing structure that plans the movements. If the trained neuron modulates its activity independently from the pre-existing structure, the untrained neurons will not flip their preferred stimulus (*individual-neuron* learning). However, if the subject learns a new strategy to modulate the activity of the trained neuron after introducing the opposite stimulus-response rule, the untrained neurons will also flip their preferred stimulus location (*intrinsic-variable* learning). Preliminary results are in favor of intrinsic-variable learning. We also explored whether a preferred learning mechanism varies with the task complexity i.e., is individual-neuron learning pursued when the task becomes more cognitively complex to solve? To address this question, the subject had to control the activity of two trained neurons according to the imposed stimulus-response rules. Preliminary results are also in favor of the intrinsic-variable learning. Overall, humans learn to volitionally control single-neuron activity in AIP by preferentially exploring and exploiting their natural movement repertoire.

Title: Closed-loop control of a sensorized virtual prosthetic hand by a human subject after amputation

Authors: ***D. T. KLUGER**, D. M. PAGE, S. M. WENDELKEN, T. S. DAVIS, D. T. HUTCHINSON, C. DUNCAN, D. J. WARREN, G. A. CLARK;
Bioengineering, Univ. of Utah, Salt Lake City, UT

Abstract: The limited availability, high cost, and lack of sensors for most commercially available high-degree-of-freedom prosthetic hands hinder research of neuromuscular interfaces for prosthetic hands. Using a virtual prosthetic hand (VPH) within a virtual reality environment (VRE) helps overcome these barriers. We have developed methods to give an amputee bi-directional, closed-loop control of a VPH in real time via implanted neuromuscular interfaces. This implementation of a sensorized VPH within a VRE supports the use of our bidirectional control algorithms for next-generation prosthetic hands.
We recorded from two 96-channel Utah Slanted Electrode Arrays (USEA; Blackrock Microsystems) implanted in residual arm nerves, and from an intramuscular 32-channel EMG assembly (Ripple, LLC) in the amputated left arm of a human subject. A motor-calibration phase captured EMG and neural recordings in response to visual movement cues of a VPH. Selected signals were weighted and combined using a Kalman filter to decode intended movements. We calibrated sensory feedback by stimulating each of the 192 USEA electrodes, and asked the subject to report the nature of evoked sensations. Electrodes that evoked proprioceptive and tactile stimuli were mapped to corresponding sensors on the VPH. The VPH wrist and digits in the MuJoCo VRE (Roboti LLC) moved in response to decoded intended movements. VPH sensor activity mediated the delivery of USEA stimulation. Motion tracking of the subject's residual limb moved the VPH through virtual space.
Motor decodes granted our subject simultaneous and independent control of up to 8 degrees of freedom, while USEA stimulation evoked 110 cutaneous and proprioceptive percepts spanning the missing hand. Our subject successfully performed literature-validated Action-Research Arm

Test (ARAT) tasks and other functionality assessment tasks modeled in MuJoCo in closed-loop. The subject identified whether a large, small, or no cylinder was placed in the VPH 26/38 times ($p < 0.001$, binomial test) without visual, audio, or other somatosensory cues.
This work demonstrates that a combined EMG/peripheral nerve interface can provide bidirectional control of a prosthetic hand. The subject's performance of virtual functionality assessment tasks further shows that a VRE can be used to assess neuromuscular-interface-mediated bidirectional closed-loop prosthetic hand control. These tests were completed in a virtual space without an expensive commercially-available physical prosthesis, which presently lack sensory output. Results encourage the development of our control and feedback algorithms for similar sensorized physical prostheses.

Abstract: Peripheral nerves provide a promising source for neuroprosthetic control, given their functional selectivity and relative ease of accessibility. However, current interface methods, such as intrafascicular electrodes, are limited in a clinical setting either by low signal amplitude or interface instability. Here, we address some of these issues by extracting neuroprosthetic control signals from Regenerative Peripheral Nerve Interfaces (RPNI) implanted within a person with a transradial amputation.

RPNIs are constructed by suturing a small graft of devascularized, denervated muscle to the residual end of a severed nerve. The graft then revascularizes, regenerates and becomes reinnervated by the transected nerve. Overall, RPNIs act as stable bioamplifiers for efferent action potentials and produce recordable electromyography (EMG) signals, making them a viable source for neuroprosthetic control. Here, the subject was implanted with 3 RPNIs, one on each of the median, ulnar, and dorsal radial sensory nerve, for the treatment of symptomatic neuromas. Due to the distal location of the subject's amputation, only the median and ulnar RPNIs contained motor information.

Using percutaneous fine-wire bipolar electrodes, we were able to record a 300-400μVp-p EMG signal from the median RPNI with a signal-to-noise ratio (SNR) of 24.2 during thumb flexion and a 100-120μVp-p EMG signal from the ulnar RPNI with a SNR of 5.84 during finger abduction. In addition to the two RPNIs, we recorded EMG from residual muscles: the flexor digitorum superficialis (FDS) with a 100-120μVp-p signal and a SNR of 6.30, and the flexor pollicis longus (FPL) with ~1mVp-p signal and a SNR of 47.8. The FDS signal correlated with middle finger flexion, while the FPL signal correlated with thumb flexion.

Using these signals, we successfully predicted the subject's attempted movements in real-time. A Naïve Bayes classifier was able to classify movements as either thumb, middle, or little flexion in a 100-trial session with 100% accuracy using temporal features of the EMG waveform within 100-500Hz. These predicted movements were further used to control a Touch Bionics iLimb prosthetic hand placed in front of the subject. In addition, using the same classifier offline, we were able to classify pinch grasp, thumb opposition, thumb/little opposition, or finger adduction movements with 96.4% accuracy.

For future work, nerves can be surgically subdivided into individual fascicles to construct multiple RPNIs to increase the number of degrees of freedom. In general, we have demonstrated that RPNIs may produce a sufficient signal amplitude to control hand level prosthetics in a clinical setting.

Title: Intersegmental coordination of bipedally standing rat

Authors: *Y. SATO[1], T. FUNATO[1], D. YANAGIHARA[2], Y. SATO[3], S. FUJIKI[2], S. AOI[4], K. TSUCHIYA[4];
[1]The Univ. of Electro-Communications, Chofu-Shi, Japan; [2]The Univ. of Tokyo, Meguro-Ku, Japan; [3]Teikyo Heisei Univ., Nakano-Ku, Japan; [4]Kyoto Univ., Kyoto-Shi, Japan

Abstract: Human and animal use redundant joints and muscles for maintain their posture under various environments. These joints and muscles do not move independently, but certain coordination structure among motors is considered to exist. The study of coordination is important because it potentially affects the functionality of motor control. For example, coordinated motion was reported to decrease by cerebellar ataxia (Bakker et al., 2006) and this was reported to cause inability in maintaining posture (Kung et al., 2009). Another important point of the coordination is that it can be qualitatively evaluated from the measured motion. Pinter et al. (2008) examined principal component analysis (PCA) for the measured joint motion of human standing and showed that the motion is composed of two coordination patterns. They, in addition, quantitatively showed that these patterns were correlated with the motion of center of mass (COM) and its reaction.
These characteristic of coordination expects us that quantitative evaluation of coordination will reveal the functionality of motor control and its dysfunction due to ataxia. However, how such a coordination and ataxia is connected is not still uncovered. In order to approach this question, animal with ataxia is effective. In our previous studies, we have succeeded to enable the measurement of bipedally standing motion of rat and it enables detailed investigation to the change of motion due to ataxia.
In this study, in order to investigate the coordination structure of rats, bipedally standing motion of an intact rat was measured for 300 seconds. We measured each joint positions using motion capture system and extracted intersegmental coordination of bipedally standing motion using singular value decomposition (SVD). The cumulative contribution ratio showed 2 coordinative motions were dominant, especially 1st coordination accounted for about 60 percent of all the motion. Then, these coordinations were compared with the motion of COM and trunk motion. As a result, 2 coordinations were highly correlated with COM and trunk motion, respectively. Therefore, this study shows bipedally standing motion of rat is composed of two coordinated motions; motion for COM control as principal importance and trunk motion as supplemental motion.

Title: Effects of visual feedback training using center of gravity along with center of pressure for static postural balance

Authors: *H. MANI[1], K. TAKEDA[2], N. HASEGAWA[2], Y. SATO[2], S. TANAKA[2], Y. SUDA[2], H. MAEJIMA[1], T. ASAKA[1];
[1]Fac. of Hlth. Sciences, Dept. of Rehabil. Sci., [2]Grad. Sch. of Hlth. Sci., Hokkaido Univ., Sapporo-Shi, Japan

Abstract: Introduction
Visual feedback training indicated by a center of feet pressure (COP) in standing has been applied commonly for postural balance. The different displacement between the COP and the center of gravity (COG), the projection of the body's center of mass (COM), is more sensitive to detect the postural stability compared to the COP alone. Our previous study showed that the COP fluctuated closely and evenly around the COM in athletes with excellent postural stability. We investigated thus the effects of visual feedback training using the COG along with the COP on static postural balance.
Methods
Twenty three healthy young adults participated in this study. The participants were divisible into COP group and COG+COP group randomly. A 3D motion analysis system and a force plate were used to calculate the COM in the sagittal plane and the COP in the horizontal plane, respectively. COG in the horizontal plane is given by the force plate signals. In the training session, the participants of COP group received the real-time COP on a screen, and were required to keep the COP within the 2 standard deviations (SD) of the COP fluctuation, which was measured on a rigid surface before the training, on a form pad placed on the force plate in the anterior-posterior (AP) direction. The participants of COG+COP group received the real-time

COG in addition to COP, and were required to keep the COG within the 2 SD as well as evenly the relative displacements between COG and COP on the form pad in the AP direction. The participants performed the trial for 40 s, and the training consisted of 12 trials. In the test sessions pre-training and post-training, the participants were required to stand on the form pad as steady as possible for 60 s. The average of COP and COM displacements, COP and COM velocities, and the distance between COP and COM displacements (the COP- COM distance) in the AP direction were calculated to assess postural stability. Then, the mean absolute value of the COP- COM distance (|COP- COM|) and the absolute value of the mean COP- COM distance (COP- COM) were calculated.

Results and discussion

After the training, the mean of the COM velocity in the COG+COP group was significantly slower than that in the COP group. In addition, the mean of the COP- COM in the COG+COP group was significantly shorter than that in the COP group. Furthermore, there was a significant correlation between the COG velocity and the COP- COM. The slower COM velocity would be caused by that the COP fluctuated around the COM more evenly in the COG+COP group compared to the COP group. We conclude that the novel feedback training using the COG along with COP is more effective to improve static postural balance than that by the COP only.

Title: Task performance during a modified Sørensen test in subjects with and without chronic low back pain

Authors: *J. S. THOMAS, R. D. KAYA, R. L. PUTHOFF, M. E. APPLEGATE, S. T. LEITKAM, D. W. RUSS;
Ohio Univ., Athens, OH

Abstract: Time to task failure (TTF) on the Sørensen test, which requires individuals to maintain the unsupported trunk in a horizontal position, predicts first-time episodes of low back pain (LBP) as well as the development of chronic LBP. However, TTF on the Sørensen test may be influenced by anthropometric characteristics (i.e. trunk mass, trunk muscle mass, trunk length) and strength of the trunk extensor muscles. Thus, we examined TTF in both healthy

controls and subjects with chronic LBP performing 1) a standard Sørensen test, and 2) a modified test that accounted for anthropometric and trunk extensor strength differences. Fifteen subjects aged 18-45 years participated in the study (8 LBP; 7 HC). The tests were performed during separate sessions separated by at least 72 hrs. In each session, subjects were positioned prone with the iliac crest aligned with the edge of the table, the pelvis securely strapped to the table, and the ankles secured using a T-bar with an embedded single DOF load cell. The trunk rested on a platform connected to a counterbalancing weight stack through a pulley system. A 6-DOF load cell fixed between the floor and the platform was used to assess trunk forces and moments. Subjects performed four maximal voluntary contractions (MVC) of the trunk extensors, with visual feedback of the extensor moment to encourage maximal effort. For the standard Sørensen test, only the weight of the platform was accounted for with the counterweight system. For the modified test, the counterweight load was set such that the participant had to elicit 30% of maximal trunk extensor moment effort to maintain the horizontal position. During both test conditions, the subject received visual feedback on trunk position from a potentiometer mounted on the platform to maintain the target trunk position. Task failure occurred when the subject could no longer maintain the target position (± 1 degree) for more than 3 seconds. The data were analyzed with a mixed model ANOVA. TTF in the control group (139 ± 13.9 seconds) was longer than in the LBP group (93 ± 13.0 seconds; $p<0.05$). Collapsed across groups, TTF in the modified test (166 ± 16.9 seconds) was longer compared to the standard Sørensen test (66 ± 6.6 seconds; $p<0.05$). Baseline vertical forces at the trunk (441± 50.1 N for control versus 460 ± 52.9 N for LBP) and hip (491 ± 56.1 N for control versus 437 ± 51.6 N for LBP) did not differ between groups. However, baseline trunk extensor moments were significantly lower in subjects with LBP than in controls (20.5 ± 5.8 versus 40.7 ± 6.26 Nm, respectively; $p<0.05$). These data suggest that differences in performance on the Sørensen could be accounted for by an inability to generate trunk extensor moment.

Title: A new biomechanical interpretation of the ankle and hip strategies in balance control during human standing

Authors: *S. SASAGAWA[1], A. IMURA[2], K. NAKAZAWA[3];
[1]Dept. of Human Sciences, Kanagawa Univ., Yokohama, Kanagawa, Japan; [2]Dept. of Human Sciences, Kanagawa Univ., Yokohama, Japan; [3]Dept. of Life Sciences, Grad. Sch. of Arts and Sciences, The Univ. of Tokyo, Tokyo, Japan

Abstract: Depending on behavioral (kinematic) context, postural responses of standing humans have been classified into two distinct strategies; i.e., the ankle and hip strategies. During quiet, unperturbed stance on a firm surface, human body behaves as a single-link inverted pendulum rotating around the ankle joint (ankle strategy). When large perturbations are imposed or when participants stand on an unstable surface, multiple coordination patterns between the ankle and hip joints are observed (hip strategy). In contrast to such conventional formulation, several researchers have shown a co-existence of the ankle and hip strategies even during quiet standing. In addition to this, Suzuki et al. (2015) have theoretically revealed that a consistent reciprocal relationship between the ankle and hip angular accelerations (i.e., hip strategy) always emerges as a mechanical consequence of passive body dynamics, regardless of joint torque patterns of the two joints. The purpose of this study was to formulate a new biomechanical interpretation of the ankle and hip strategies in balance control during human standing. Eight healthy young participants were instructed to stand quietly on a firm surface. Three-dimensional Cartesian coordinates of reflective markers attached to the ankle, hip, and shoulder joints were measured with an optical motion capture system. As expected from the theoretical consideration mentioned above, a consistent reciprocal relationship between the ankle and hip joint angular accelerations in the amplitude ratio approximately 1:3 was observed across participants. On the other hand, the coordination patterns of the ankle and hip joint torques showed relatively large variation across participants. Our results indicate that multiple joint torque patterns, which (partially) represent active neural control of the participants, result in a single stereotypical kinematic pattern due to the human body structure (length, mass, moment of inertia, and so on). We suggest that the relative contribution of the ankle and hip joint torque; i.e., amplitude ratio of the ankle and hip joint torque fluctuations, can be an alternative, meaningful index for evaluating postural control strategies during quiet standing.

Title: Use of the Cleveland Clinic-Postural Stability Index to characterize postural instability in Parkinson's disease

Authors: *S. J. OZINGA, M. M. KOOP, S. M. LINDER, T. DEY, J. L. ALBERTS; Biomed. Engineering/ ND20, Cleveland Clin., Cleveland, OH

Abstract: Background: Postural instability is a hallmark of Parkinson's disease (PD). Objective metrics to characterize postural stability are necessary for the development of treatment algorithms to aid in the management of declines in balance. The aim of this project was to validate a mobile device platform and resultant three-dimensional balance metric that characterizes postural stability. **Methods:** An iPad/iPhone mobile Application was developed, in which biomechanical data from the embedded accelerometer and gyroscope were automatically processed to characterize movement of the center of mass in the medial-lateral, anterior-posterior, and trunk rotation directions. Twenty-seven mild to moderate individuals with PD and 27 age-matched controls completed balance tasks in which the support surface, stance, and vision were altered. A postural stability metric quantifying the amplitude (peak-to-peak; P2P) of sway acceleration in each movement direction was compared between the PD and control groups. The P2P value in each direction for each individual with PD across all trials was expressed as a normalized value of the control data in order to identify individuals with PD with severe postural instability (percentile value of postural instability greater than 95^{th} percentile of controls). Lastly, the normalized P2P data in all three directions were then combined to create a balance metric, Cleveland Clinic-Postural Stability Index (CC-PSI), to quantify postural instability across all movement directions. **Results:** Patients with PD showed significantly greater postural instability compared to the control group across all balance conditions shown by the CC-PSI metric ($p<0.01$ for all tests). Additionally, within the PD group, postural instability increased across all sway directions as sensorimotor integration became more challenging as the difficulty of the postural stability task increased. **Conclusions:** Overall, the CC-PSI, which can be rapidly derived using a mobile device, provides an unbiased and systematic metric for the quantification of postural stability in PD patients. The ease of data acquisition and processing make the CC-PSI ideally suited to better understand specific postural stability declines in PD patients and assisting in its treatment.

Title: Development of a directional intervention protocol based-evidence for individuals with chronic low back pain

Authors: *A. F. CARVALHO[1,2], A. H. NOWOTNY[2,1], M. R. OLIVEIRA[2,1], L. A. STURION[2,1], N. A. SHIRABE[1], C. E. CARVALHO[1], F. K. S. BERALDO[1], F. K. S. BERALDO[1], L. C. L. CARVALHO[1], A. W. GIL[1], R. A. DA SILVA JR[2,1];

Abstract: Low back pain is one of the most musculoskeletal disorders in the world, with higher rate of incidence and prevalence. From some guideline evidences, the acute back pain may recover spontaneously, while subacute and chronic pain needs specific care. Actually, there is no directional intervention standardized protocol in physical therapy for better management in low back pain. The purpose of this work was to develop a directional protocol of intervention for individuals with chronic low back pain. Methods: Based on a model of evaluation and intervention, individuals between 18 and 80 years, both genders, with unknown mechanical chronic low back pain were recruited voluntarily. Participants performed four assessment steps: (1) clinical history; (2) Questionnaires: pain (VAS), disability (Roland Morris), psychosomatic (fears and beliefs: FABQ); (3) functional tests (sit and rise, walking 15 meters time, back time endurance); and (4) postural balance control (on a force platform). After baseline assessment, the participants were allocated to a specific therapy protocol related to flags colors: red (acute palliative care), orange (electrotherapy + stretching), yellow (manual therapy + manipulation) green (postural control + stabilization exercises + strengthening), and white (education). Back management was performed for 60 minutes (1-week) including into 15 minutes of education + home exercises, for a total of 12 weeks. Results: A total of 32 participants (mean age 40 ± 11 years) participated, but only 13 completed to 12 weeks. 92% of the sample started in the orange flag intervention while 8% in yellow. At the end of 6 weeks, 100% of the sample was into green protocol. A significant improvement after intervention (P <0.05) were found for: pain (-55% reduction), disability (-25% on score), fears and beliefs associated with the work (- 27% on score). A significant improvement (P < 0 .05) were also found for sit and rise functional test (14%), back endurance (44% of increase), as well as for postural control paramters (in mean 20% stability increase). In conclusion, the directional intervention protocol evidence-based in

physical therapy would be effective and used on clinical practice for chronic low back pain management.

Title: Neuromuscular pattern of trunk during one-leg balance stance in individuals with and without chronic low back pain

Authors: *R. A. DA SILVA JR[1], A. F. CARVALHO[2], A. H. NOWOTNY[2], M. R. OLIVEIRA[2], L. A. STURION[2], N. SHIRABE[2], P. E. DE SOUZA[2], R. S. DA SILVA[2], K. P. FERNANDES[2], E. R. VIEIRA[3];

Abstract: The prevalence of chronic low back pain (CLBP) is higher in adults and is often associated with poor neuromuscular postural control. The purpose of this study was to compare the neuromuscular pattern of trunk in individuals with and without CLBP during a one-leg stance. Twenty volunteers, paired by sex, being 10 with CLBP (mean age 33 yrs) and 10 without nonspecific CLBP (mean age 30 yrs) participated in the study. The participants performed three 30-second trials of a one-leg stance on a force platform, while surface electromyography (EMG) measurement were obtained bilaterally on back (multifidus at L5, iliocostalis lumburum at L3), rectus abdominis and biceps femoris (hip extensor) muscles. The EMG amplitude analysis was processed by the RMS (250ms window) and normalized by the peak of activation of muscles during the balance task. Simultaneously, the centre of pressure parameters from force platform were also computed for the balance assessment. Overall, participants with CLBP presented significantly poorer balance by centre of pressure parameters ($P < 0.05$) than participants without CLBP (Effect Size: ES $d = 1.44$). Significant poorer neuromuscular activation of trunk ($P < 0.05$) was reported for CLBP (in mean range across muscles of 49% to 89%) than those without

CLBP (in mean range of 59% to 91%), especially for the back muscles investigated (multifidus: ES d = 1.0; and iliocostalis: ES d = 1.6). Not significant differences between groups were reported for activation of rectus abdominis (without CLBP = 91% vs. with CLBP = 89%) and of biceps femoris (without CLBP = 82% vs. with CLBP = 75%).The findings indicate that CLBP affects the neuromuscular postural control of trunk, especially in back muscles for the balance during one-leg stance.

Title: A novel characterization of human balance control during standing with visual sensory deprivation

Authors: *W. BOEHM, K. NICHOLS, K. GRUBEN;
Univ. of Wisconsin Madison, Madison, WI

Abstract: Human standing requires complex neuromuscular coordination involving integration of sensory feedback to inform the body's control strategy. The resultant control must meet the physical constraints that define balanced standing, that is, zero average translational and rotational whole-body acceleration. To study how humans meet these criteria, we examined the force at the end-effector of the body's control, the feet, during quiet unaided standing. The force of the ground on the feet (F) is the only force on the body that can be altered to keep the body upright. The sagittal-plane F was measured during unaided standing with eyes open (EO) and eyes closed (EC) to examine how neuromuscular control of balance varied with the removal of visual information. Study participants (n=11, aged 18-53 years, 5 female) stood unaided with a plate measuring 3-dimentional force under each foot for 10 5-second duration trials in each condition presented in random order. The variability and mean speed of center of pressure (CP) displacement and the coordination between CP and F direction (θ_F) were analyzed for each leg, as well as both legs combined. Standing yielded distinct coordination patterns between the EO and EC trials. The intersection point (IP) height of F vectors that result from systematic CP

versus θ_F variation in the 3.4-7.7Hz range was significantly higher with eyes closed (p=0.001 for each leg, p=0.0008 for combined legs). With eyes closed, the average combined IP increased 7.5% of body height above the average IP height of 27% body height with eyes open. CP variability and mean speed were not significantly different between the EO and EC standing conditions (p=0.5 & p=0.41, respectively). These results suggest that humans modify their neuromuscular balance strategy when faced with visual sensory deprivation. The raised IP seen with visual impairment reflects a change in coordination that would increase whole-body angular stiffness at an energetic cost. It is interesting that the CP variability and mean speed, conventional measures of standing behavior, were not different between the two conditions. The IP may characterize the ability to adapt to balance challenges such as visual deprivation, and may be useful for better understanding the disordered mechanism in those with impaired balance.

Title: 12 weeks of balance and mobility training with or without simultaneous cognitive training improves reaction time but does not improve posture in healthy older adults

Authors: *D. A. JEHU[1], N. PAQUET[2], Y. LAJOIE[1];
[1]Human Kinetics, Univ. of Ottawa, Ottawa, ON, Canada; [2]Rehabil. Sci., Univ. of Ottawa, University of Ottawa, ON, Canada

Abstract: Falls are a major issue for older adults, and may be caused by an impaired interaction of postural and cognitive functioning. An extensive amount of research has been devoted to improving dynamic balance via balance training; however mixed findings exist as to whether balance training improves postural control. The purpose of study was to determine whether balance and mobility training (BMT) or balance and mobility plus cognitive training (BMT+C) would reduce postural sway and reaction time and maintain these improvements after a 12-week follow-up in healthy older adults. Participants were allocated the BMT (n=15; age: 70.2 ± 3.2), BMT+C (n=14; age: 68.7 ± 5.5), or the control group (n=13; age: 66.7 ± 4.2). The BMT involved training one-on-one, 3 times per week for 12 weeks on a balance obstacle course while completing manual tasks. The BMT+C involved training one-on-one, 3 times per week for 12

weeks on a balance obstacle course while completing manual and cognitive tasks. During the testing sessions, participants stood on a force plate for 30 s in feet-apart and semi-tandem positions while completing simple reaction time and choice reaction time tasks at baseline, at the 12-week post-training, and at the 12-week follow-up. They were instructed to stand as still as possible while verbally responding as fast as possible to the stimuli. No group differences in center of pressure (COP) Area, COP Velocity, or Sample Entropy of the COP displacement in the medial-lateral or anterior-posterior directions were shown after the training or 12-week follow-up. The BMT and BMT+C showed faster reaction times after training and maintained these improvements at the 12-week follow-up compared to the control group. No differences in postural sway or RT emerged between the BMT and BMT+C groups. Both training groups improved reaction time after the interventions and sustained these improvements over time, but showed no reduction in postural. These results suggest that multi-task balance and mobility training improves attention demand in healthy older adults.

Title: Different leaning effects of dynamic postural control by visual or auditory feedback training

Authors: *N. HASEGAWA[1,3], M. SAKUMA[4], S. TANAKA[1], Y. SATO[1], K. TAKEDA[1], H. MANI[2], H. MAEJIMA[2], T. ASAKA[2];
[1]Grad. school of Hlth. Sci., [2]Dept. of Rehabil. Science, Fac. of Hlth. Sci., Hokkaido Univ., Sapporo-Shi, Hokkaido, Japan; [3]Sapporo Yamanoue Hosp., Sapporo-shi, Japan; [4]Natl. Hosp. Organization East Saitama Natl. Hosp., Hasuda-shi, Japan

Abstract: Introduction
Feedback training using sensory information such as visual, auditory or somatic senses is commonly applied to improve postural balance. Most of the previous studies concerning the feedback postural training have reported the effects of static postural control by visual feedback training. However, the differences of learning effects between visual feedback training and the other sensory feedback training are unclear. Therefore, the purpose of this study was to investigate the different learning effects by auditory feedback training compared to visual feedback training for dynamic postural control.

Methods

Eighteen healthy young adults participated in this study. The subjects were randomly separated into a visual (n = 9) or auditory group (n = 9). In test sessions, the subject was required to stand on a force plate in front of a screen, and bring his/her center of pressure (COP) by voluntary body's sway in line with the hidden target, which moved a sine-wave pattern, in the anterior-posterior (AP) direction. The target became visible on the screen in connection with a beep sound only when the target reached to the inflection points of the sine-wave. In a training session, the subject was asked to bring the COP in line with the hidden target using a visual circle on the screen, which changed in the diameter of circle according to the distance between the COP and the target, for 30 s in the visual group. In the auditory group, the subject was asked to bring the COP in line with the hidden target using a sound, which changed in the tone according to the distance between the COP and the target, for 30 s. The subject performed 40 trials on the same day. The test sessions consisted of 4 times when the time before the training (pre-test), after 20 trials (mid-test), after all trials (post-test), and 48 hours after the training (retention). The average and the standard deviation of the distances from the COP to the target (D_{ave} and D_{sd}) were calculated each trial. Two-way mixed-design ANOVA was used with factors *Group* (Visual and Auditory) and *Test session* (Pre, Mid, Post and Retention) in the indices.

Results and discussion

D_{ave} and D_{sd} showed significant reduction during the training session in each group. However, D_{sd} of the auditory group showed significant reduction compared to that of the visual group in the retention test although D_{sd} in the post test showed no significant difference between the groups. These results supported the previous study that demonstrated the different effects of motor learning of hands between visual and auditory feedback trainings. We conclude that auditory feedback training is superior to visual feedback training to learn dynamic postural control.

Title: The effect of mental fatigue on postural stability

Authors: *A. MORRIS, A. CHRISTIE;
Human Physiol., Univ. of Oregon, Eugene, OR

Abstract: Proper allocation of attentional resources is required for maintaining postural stability. Research indicates that fewer attentional resources are available for balance control when individuals engage in a dual task paradigm involving concurrent performance of a cognitive task. However, these effects have not been studied under conditions of mental fatigue. To determine if mental fatigue has an effect on postural stability, center of pressure (COP) displacement in response to standing platform perturbations was recorded at the beginning and end of 20 minutes of the psychomotor vigilance task (PVT). The PVT is a sustained attention task that induces mental fatigue, as indicated by increases in reaction time to visual stimuli. Six young, healthy individuals (23.5 + 3.7 years; 5 F) participated in the study. Reaction time during PVT was significantly longer in the last 5 minutes of the task compared to the first five minutes ($p= 0.03$; $d= 0.73$), indicating mental fatigue. Center of pressure displacement in the anterior-posterior direction was significantly larger at the end of the mental fatigue task compared to the beginning of the task ($p= 0.03$; $d= 0.76$). The increase in center of pressure displacement in response to an unexpected postural perturbation suggests that mental fatigue has the functional consequence of compromising postural stability.

Title: Standing postural control while stepping over randomly moving virtual obstacles

Authors: *H. IDA[1], S. MOHAPATRA[2], A. S. ARUIN[3];
[1]Jobu Univ., Isesaki, Japan; [2]Sch. of Physical Therapy and Rehabil. Sci., Univ. of Montana, Missoula, MT; [3]Dept. of Physical Therapy, Univ. of Illinois at Chicago, Chicago, IL

Abstract: The purpose of this study was to investigate early (EPAs), anticipatory (APAs), and compensatory (CPAs) postural adjustments during control of vertical posture while stepping over a virtual obstacle. Ten healthy adults were asked to stand upright and avoid contact with an approaching virtual obstacle by lifting their left leg while maintaining their balance. This

approaching obstacle was projected virtually by a head mount display. Experiments involved virtual tasks in two different conditions: (1) steady obstacle heights (10, 20 and 30 cm) and (2) unsteady up-and-down (hopping-like) obstacle heights (up to 10, 20, and 30 cm). Surface electromyography (EMG) signals were recorded bilaterally from the tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF), biceps femoris (BF), rectus abdominis (RA), erector spinae (ES), and external oblique (EO) muscles. The EMG signals from the supporting (right) side were then integrated from -550 to -150 ms (EPAs), -150 to +50 ms (APAs), and +50 to +250 ms (CPAs) in relation to the moment of the initiation of the left ankle elevation (T0). Similar time windows were used for the analysis of the integrated EMG signals from the muscles on the lifting (left) side.
Two-way ANOVAs (obstacle movement × obstacle height) for the EPAs showed a significant main effect of obstacle movement for the ES muscle ($p = 0.019$) on the supporting side and MG muscle ($p = 0.047$) on the lifting side. For the APAs, a significant main effect of obstacle movement was found in the EMG signal of RA muscle ($p = 0.040$) on the supporting side. Subsequently for the CPAs, there were significant interactions between obstacle movement and obstacle height in BF muscle ($p = 0.044$) on the supporting side and in the muscles of MG ($p = 0.011$), BF ($p = 0.004$), and EO ($p = 0.003$) on the lifting side. The results indicate that the various characteristics of obstacle movement (steady or unsteady) could influence the preparatory phase (EPAs and APAs) of postural control. This phenomenon later becomes more evident during the reactive phase (CPAs) of postural control. This outcome suggests that the CNS uses early, anticipatory, and compensatory postural adjustments to maintain control of posture while stepping over virtual obstacles.

Title: Intermittent muscle activities occur according to joint state during human quiet standing

Authors: *H. TANABE[1], K. FUJII[2,3], M. KOUZAKI[4];
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Nagoya Univ., Nagoya, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan; [4]Kyoto Univ., Kyoto, Japan

Abstract: INTRODUCTION: The neural-muscular-skeletal causality of maintaining upright posture is not yet fully understood experimentally because postural control tasks are aperiodic and non-stationary. Intermittent processes of the postural control mechanism play an important role in stabilization dynamics in the vicinity of the equilibrium. Thus, we focus on the intermittent system of the postural feedback loop to visualize the causality among neural intermittent motor command triggering, muscle activities, and skeletal fluctuations. The aim of this study was to investigate the direct relationship between joint fluctuation, muscle activity and torque output.
METHODS: Eight healthy males were instructed to stand quietly on a force platform for 120 sec. Joint motions data was obtained using a 3D optical motion capture system. We also recorded surface Electromyography (EMG) over six leg muscles. We computed joint angles and torques of the ankle, knee, and hip in the sagittal plane. We also determined phasic on/off (activation/deactivation) switching of muscle activity from EMG data by using two low-pass filters, each of which represents phasic and tonic components of muscle activations.
We then divided the time history of a state point in the phase planes of each joint into on and off periods for each muscle to visualize the phasic kinetic-kinematic relationship. Each on/off area was fit into a Gaussian distribution for every muscle's on/off-period, and we plotted their centers for all trials. We did the same procedure in the torque planes.
RESULTS: Most muscles activated when the state point was located in the anatomically opposite area in the phase plane and deactivated when it was in the anatomical action direction. In addition, phasic muscle activation and deactivation were associated with torque generations in the anatomical action direction.
DISCUSSION: We experimentally visualized the causality among joint oscillations, phasic muscle activities, and torque output during quiet standing. Extracting phasic components of muscle activities allowed us to observe the direct causality, which has long been difficult to demonstrate because joint fluctuations are aperiodic and muscle activities are small and contain many frequency components during quiet standing without any disturbances. Our results will comprise fundamental knowledge of postural control closed-loop mechanisms and will be useful for evaluating balancing skills in future analysis. In conclusion, our results suggest that phasic muscle activities occur depending on the joint state in the phase space, leading to joint actuation via torque generation along with anatomical action direction.

Title: Learning postural control with continuous visual feedback in healthy young adults and chronic stroke survivors

Authors: *L. PELLEGRINO[1], P. GIANNONI[1], L. MARINELLI[2], M. CASADIO[1];
[1]Dept. Informatics, Bioengineering, Robotics and Systems Engin., [2]Dept. of Neuroscience, Rehabilitation, Ophthalmology, Genetics, Maternal and Child Hlth., Univ. of Genoa, Ge, Italy

Abstract: Visual feedback is largely used in rehabilitation to improve the control of standing or sitting posture and to train shifting weight by moving the entire body or just the trunk. Postural control deficits are common in stroke survivors and often the rehabilitation programs include balance training based on the continuous feedback of a cursor on a computer screen controlled by the position of the Center of Pressure (CoP). The goal of this study is to test if subjects are able to transfer the control of their CoP from a training protocol based on continuous visual feedback to performance without visual feedback and to directions and displacement amplitudes different from those experienced during training. We addressed the following questions: (i) if and to what extent it is possible to learn the proposed task, independently from age and/or disease, (ii) if and to what extent a population of chronic stroke survivors can learn the proposed task. To answer the first question we enrolled eleven healthy young adults (7 Female; 22±1.12 years), and to answer the second question eleven chronic stroke survivors (6 Female; 59±12 years). The subjects seated on a stool positioned on top of a custom-built force platform. The stool had a support for the feet and it was positioned on top of a force platform. The estimated CoP positions were mapped to the coordinates of a cursor on a computer monitor, placed 2 meters away from the platform at eye level. When the subject's trunk was in the upright posture, the cursor was at the center of the screen. Subjects had to reach targets by shifting their CoP. During training, the targets were presented in three different directions (0, 135 and 270 degree) at 8 cm from the center and continuous visual feedback of the cursor was provided. Then, we tested if subjects in absence of visual feedback were able to reach the same targets as well as targets in different directions (45, 90, 180, 225 and 315 degree) and with two different displacement amplitudes in the trained directions (5 and 11 cm, respectively). Healthy subjects and stroke survivors -as expected - had different performance levels, however with training both groups improved duration, smoothness and accuracy of cursor movement trajectories. In absence of visual feedback, the performance of both groups was worse with respect to the level reached at the end of training. However, while healthy subjects partially transferred the learned abilities to the no visual feedback condition most stroke survivor did not. This result suggests that a postural training based exclusively on continuous visual feedback could provide limited benefits for stroke survivors.

Title: Increased postural threat influences the conscious perception of voluntary leaning

Authors: *T. W. CLEWORTH[1], T. INGLIS[1,2,3], M. G. CARPENTER[1,2,3];
[1]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Intl. Collaboration On Repair Discoveries, Vancouver, BC, Canada; [3]Djavad Mowafaghian Ctr. for Brain Hlth., Vancouver, BC, Canada

Abstract: BACKGROUND AND AIM: Threat-related postural changes, such as decreased amplitude of sway [1,2], occur in conjunction with significant increases in vestibular and proprioceptive gain [3,4]. Recently, this increased sensory gain with threat has been thought to compensate for decreased postural sway, which leads to a discrepancy between perceived and actual sway during quiet stance [5]. The impact these changes in perceived sway have on more voluntary, large amplitude postural movements is currently unknown. Therefore, the aim of this study was to examine how changes in threat influence conscious perceptions of voluntary leaning to different degrees of maximum voluntary lean.
METHODS: Eight young healthy adults, fitted with kinematic markers placed on the right side of the body, stood with eyes open on a forceplate mounted to a hydraulic lift placed at two heights (0.8m and 3.2m). Subjects first stood in the high condition and leaned as far forward as possible, rotating only at the ankle joint, to establish a performance-based limit of stability (maximum lean). Then, at each height, subjects voluntarily swayed to a target (10% to 100%, in increments of 10%, of maximum lean) displayed visually on a screen in front of them as Center of Pressure (COP) or whole body angular displacement. Once the target was reached, subjects reported the amount of perceived lean (as a percent of maximum lean). Psycho-social questionnaires were used to record balance confidence, fear and anxiety. Physiological arousal was recorded from electrodermal activity of the hand (EDA).
RESULTS: Threat significantly increased EDA, fear and anxiety, and decreased balance confidence ($p<0.05$). Subjects were able to voluntary lean to all target positions, based on COP and angular displacement feedback, at both heights equally. However, the amount of perceived lean was greater at High versus Low heights, particularly for targets between 30% and 100% maximum lean.
CONCLUSIONS: When subjects are asked to lean to a target in a threatened state, they perceived themselves to be at a further proportion of maximum lean. These results could be

explained by a fear related increase in sensory gain, and/or a decrease in perceived limit of stability. Discrepancies between actual, and perceived, postural abilities may be an important contributor to increased fall risk in fearful individuals.

Title: Postural control as a function of sloped support surfaces

Authors: *A. DUTT-MAZUMDER;
Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC

Abstract: This investigation examined the effects of slope of the surface of support (35°, 30º, 20º, 10º Facing Down, 0° Flat and 10º, 20°, 25° Facing Up) and postural orientation on the margins of postural stability in quiet standing of young adults. The findings showed that the center of pressure - CoP (displacement, area and length) had least motion at the baseline (0° Flat) platform condition that progressively increased as a function of platform angle in both facing up and down directions. The virtual time to contact (VTC) dynamics revealed that the temporal margins to the functional stability boundary were progressively smaller and the VTC time series also more regular (SampEn - Sample Entropy) as slope angle increased. Surface slope induces a restricted stability region with lower dimension VTC dynamics that is further constrained when postural orientation is facing down the slope. Thus, the study shows preliminary evidence of VTC being used as a promising tool to study spatio-temporal control for a postural system across sloped surface.

Title: Influence of task-related and person-related variables on the impaired anticipatory postural adjustments of people with low back pain: insight into heterogeneous results across studies

Authors: *J. V. JACOBS[1], J. R. HITT[2], S. M. HENRY[3];
[1]Ctr. for Physical Ergonomics, Liberty Mutual Res. Inst. for Safety, Hopkinton, MA; [2]Univ. of Vermont, Burlington, VT; [3]Univ. of Vermont Med. Ctr., Burlington, VT

Abstract: Although some studies on the anticipatory postural adjustment (APA) demonstrate the APA is delayed in subjects with low back pain (LBP), other studies have not replicated this finding. Inter-study differences in task-related and person-related factors may account for these differential findings in the literature. Thus, the association of such factors with APA onset latencies must be determined in people with LBP. This study evaluated 13 subjects with LBP and 13 subjects without LBP during seated, rapid arm flexion in self-initiated and cued movement conditions. We evaluated (a) APA onset latencies of the erector spinae, internal oblique, and external oblique muscles relative to deltoid muscle onset with surface electromyography, (b) velocity of arm movement with passive-marker motion capture, and (c) pre-movement cortical negativity with electroencephalography. Task- and person-related factors of movement condition, movement velocity, cortical function, numeric pain ratings, pain-related fear of movement (Fear Avoidance Beliefs Questionnaire; FABQ), and disability level (Modified Oswestry Questionnaire) were therefore evaluated for association with LBP-related changes in APA onset latencies. Results demonstrated a significant group-by-condition interaction, such that APA onset at the external oblique muscle exhibited greater delay for the subjects with LBP compared to the subjects without LBP in the cued condition than in the self-initiated condition. A group main effect demonstrated larger cortical pre-movement negativity for the group with LBP, but also significantly slower arm-raise velocities. When applying arm-raise velocity as a covariate, the interaction effect on the APA latency of the external oblique muscle remained significant, but the group main effect on cortical pre-movement negativity did not. Correlation analysis demonstrated significant correlations of the external oblique muscle's APA latency with Oswestry and FABQ scores in both the self-initiated and cued conditions. These results demonstrate that delayed APAs with LBP can be influenced by the task-related factor of cueing as well as person-related factors of pain-related disability and fear of activity. Differences in pre-movement cortical function appear related to modulating the arm-raise velocity, but delayed

APAs remained evident in the group with LBP independent of differences in arm-raise velocity. These results highlight the importance of subject-sample characteristics and task condition when comparing across studies of postural coordination with LBP.

Title: Smartphone-based assessment of changes in postural stability in neurological patients after a therapeutic exercise intervention

Authors: ***B. L. TRACY**[1], A. A. SCHMID[2], D. M. MILLER[3], K. E. TIMROTH[3], B. E. HOLLAND[3], L. R. JANKOWSKI[3], M. F. FRITZ[3];
[1]Hlth. & Exerc Sci., [2]Occup. Therapy, [3]Hlth. and Exercise Sci., Colorado State Univ., Fort Collins, CO

Abstract: Accurate measures of postural stability provide information on functionally important feature of neuromuscular output in health and disease. Force platforms are accurate and commonly used, but they are expensive, require trained personnel, and are not portable. The modern smartphone, however, contains very sensitive triaxial accelerometers. Apps can log the acceleration values at up to 100Hz, thus the smartphone can serve as a portable, easily used movement sensor in settings outside the laboratory. The purpose was to validate the iPod Touch ($200) against a force platform ($10k) to assess changes in postural stability in neurological patients (stroke, peripheral neuropathy) after an individualized, rehabilitative yoga intervention. Stroke survivors and peripheral neuropathy patients (N=24, 52-92 yrs) were tested before and after eight weeks of supervised yoga. Standing postural stability was measured with the eyes open and closed. Foot stance width was set at 10% of height. The iPod was fixed to a strap just lateral to the greater femoral trochanter. During the 60s trials, the center-of-pressure (COP) underneath the feet and the acceleration at the hip were simultaneously recorded. The two streams of data were time-aligned with a small tap. The standard deviation (SD) of the COP in

A/P and M/L directions and the SD of the acceleration in the corresponding X and Z axis of the iPod was measured to indicate the average variability in the signal. The average of two trials was taken for each visual condition. Change scores were computed for the SD value from pre- to post-training. Correlations were computed between the change values from the two devices for both directions and visual conditions. The change scores were distributed around zero. The change values from the force platform and the iPod were consistently positively correlated. In the M/L direction, the R-squared value was 0.753 for eyes open and 0.538 for eyes closed. In the A/P direction, the R-squared was 0.77 for eyes open and 0.847 for eyes closed. For the total sway values (summed M/L and A/P), the R-squared value was 0.882 for the eyes open condition and 0.781 for eyes closed. When values for eyes open and eyes closed were pooled, the R-squared for the total sway was 0.860. Small changes in postural sway after intervention in neurological patients can be detected reasonably accurately with inexpensive, portable, user-friendly, smartphone technology. These devices may thus provide a suitably sensitive quantitative tool for balance measurement in clinical settings and remote community locations.

Abstract: Botulinum neurotoxin A (BoNT/A) consists of heavy (Hc) and light (Lc) chains linked by a disulfide bond. Hc targets gangliosides whose proximity to motor nerve terminal active zones facilitates BoNT/A endocytosis by the vesicle membrane recycling process. Lc is a Zn-endoprotease, which acts intracellularly to specifically cleave the SNARE complex protein SNAP-25, and thereby suppress excitation-secretion coupling and produce flaccid muscle paralysis. While in vitro inhibitors of the Lc endoprotease exist, none facilitate functional

recovery for muscles paralyzed in vivo. This is attributed to failure of Lc inhibitors to gain access to the nerve terminal cytosol. To translate in vitro Lc inhibition into therapeutic efficacy, we are investigating fusion proteins (FP) consisting of Hc linked to an inhibitory cargo against Lc. As a proof of concept we examined delivery of GFP into nerve tissue by a FP consisting of Hc linked to GFP. First, we confirmed that the GFP cargo is delivered into the cytosol of cultured NG108-15 cells. Next, delivery of the GFP into motor nerve terminals of mouse Triangularis sterni nerve muscle preparations (NMPs) was examined. NMPs were incubated for 90 min in physiologic solution containing 8-10 µg of FP. Induction of FP endocytosis was induced by depolarization with 40 mM KCl or 5-Hz supramaximal nerve stimulation for 90 min. NMPs were washed and stained with rhodamine-conjugated α-bungarotoxin for 30 min to visualize endplates prior to visualization of neuromuscular junctions (NMJs) using confocal microscopy. Analysis of 25-µm thick optical sections indicated GFP uptake in response to both KCl depolarization and nerve stimulation. Pretreatment of stimulated (5 Hz, 90 min) NMPs with 6.7 pM BoNT/A also accumulated GFP within nerve terminals upon subsequent injection with FP. To determine if GFP is delivered in BoNT/A-paralyzed muscles in vivo, we first injected a mouse hind limb with 3 µl 6.7 pM BoNT/A. The EDL muscle of the injected hind limb was paralyzed within 24-36 hrs. The paralyzed limb was then injected with 10 µl of ~1 mg FP/ml on each of three consecutive days. Mice were then sacrificed, and EDLs were harvested and examined with confocal microscopy. Our observations demonstrate that this novel cargo delivery platform can deliver GFP to control and BoNT/A-poisoned motor nerve terminals. We are now examining various BoNT/A Lc inhibitory cargos for therapeutic efficacy in mice poisoned with this potent neurotoxin.

Title: Botulinum neurotoxin type A-cleaved SNAP25 is confined to primary motor neurons and expressed on the plasma membrane following intramuscular toxin injection

Authors: ***R. S. BROIDE**, J. FRANCIS, B. B. CAI;
Biol. Sci., Allergan PLC, Irvine, CA

Abstract: Botulinum neurotoxin type A (BoNT/A) is used clinically for a growing number of therapeutic and cosmetic indications. The present study was performed to assess the potential for neuronal transport and transcytosis of BoNT/A (onabotulinumtoxinA) following peripheral administration. In this study, the expression of BoNT/A-cleaved substrate ($SNAP25_{197}$) was characterized in a rat motor neuron pathway following toxin intramuscular injections at relatively low (3 U/kg) and high (10 & 30 U/kg) doses. Using a highly selective anti-$SNAP25_{197}$ antibody in combination with quantitative, high-resolution 3D imaging, we performed a systematic evaluation to determine whether $SNAP25_{197}$ is confined to the primary motor neurons (MN), or is also found in neighboring cells and/or nerve fibers within the spinal cord (SC). The results demonstrated that $SNAP25_{197}$-IR staining is co-localized with biomarkers for MNs, but is not co-localized with markers for neighboring neurons, nerve fibers or glial cells. Additionally, we found that a high dose of BoNT/A (30 U/kg), but not a lower dose (3 U/kg), resulted in spread of toxin activity to distal muscles, giving rise to sporadic $SNAP25_{197}$ signal in the muscles and associated SC regions without evidence for transcytotic (cell to cell) migration. Despite the spread in $SNAP25_{197}$-IR staining, functional effects, as measured by the Digit Abduction Score assay were not detected in the distal muscles. These results suggest that BoNT/A efficacy is confined to the primary MNs and that any evidence of distal activity is the result of limited systemic spread of the toxin at high doses and not through transcytosis within the SC. Lastly, we discovered that at the higher doses of BoNT/A, $SNAP25_{197}$-IR staining was expressed throughout the MN and was highly co-localized with synaptic markers on the plasma membrane, persisting for at least 6-days following toxin treatment. These final data support previous studies suggesting that $SNAP25_{197}$ acts as a dominant-negative SNARE protein within the affected MNs.

Title: Pharmacological modulators of presynaptic calcium concentration reverse botulinum neurotoxin-induced silencing of synapses *In vitro* and delay paralysis in *Ex vivo* muscle preparations

Authors: *A. B. BRADFORD, P. H. BESKE, J. B. MACHAMER, T. M. RUSSO, P. M. MCNUTT;
US Army Med. Res. Inst. of Chem. Def, Gunpowder, MD

Abstract: Botulinum neurotoxins (BoNTs) are potent paralytics that cause respiratory arrest through blockade of cholinergic neurotransmission. There are currently no effective treatments to counteract toxin function within the nerve terminal. We have previously characterized 3,4-diaminopyridine (3,4-DAP) as a potential treatment to delay paralysis from multiple BoNT serotypes (BoNT/A, /B and /E) or to assist recovery from partial paralysis. These studies suggested that rescue of neuromuscular transmission in intoxicated nerve:muscle preparations by 3,4-DAP acts through increase release probability. Based on these findings, we hypothesized that increasing presynaptic calcium concentration ($[Ca^{2+}]_i$) enhances presynaptic release of neurotransmitter in intoxicated motor neurons by increasing release probability. To test this hypothesis and to identify potential therapeutic interventions, we performed a primary screen in synaptically-active neuron cultures of candidate drugs that have previously been shown to enhance presynaptic $[Ca^{2+}]_i$ through diverse mechanisms. We identified several compounds that restored spontaneous synaptic activity in cultures intoxicated with BoNT/A. Lead candidates were then tested in an *ex vivo* model of botulism using phrenic nerve-hemidiaphragm (PND) muscle preparations. A subset of these drugs transiently enhanced evoked muscle twitch in paralyzing tissues, delaying but not preventing full-paralysis. Co-administration with 3,4-DAP resulted in additive or synergistic effects on muscle twitch amplitudes, suggesting multiple sources of increased $[Ca^{2+}]_i$ can combine for added effect. Evoked end plate potentials (EPPs) and spontaneous miniature EPPs (mEPPs) were characterized for some of these drugs in PNDs, confirming their mechanism of action involves enhanced presynaptic release probabilities. Collectively, these experiments show the potential of presynaptic therapeutic intervention, indicate that increased $[Ca^{2+}]_i$ delays and temporarily reverses BoNT-induced paralysis, and identify several drugs that offer potential clinical utility in botulism patients.

Title: 3,4-DAP reverses botulinum-induced muscle paralysis by increasing neurotransmitter release probability at unintoxicated release sites

Authors: *J. MACHAMER, A. BRADFORD, T. RUSSO, P. MCNUTT;
US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Botulinum neurotoxins (BoNTs) are a potent family of protein-based toxins that inhibit neurotransmission by cleaving and inactivating soluble NSF attachment protein receptor (SNARE) proteins, causing progressive muscle paralysis and death by asphyxiation. There is currently no treatment to accelerate the recovery of neuromuscular function in patients exposed to BoNT. While administration of aminopyridines such as 3,4-DAP have been proposed to reverse symptoms of BoNT paralysis, their mechanism of action is unclear and diverse studies have resulted in mixed conclusions about their efficacy. Here, we use *ex vivo* mouse hemidiaphragm preparations to rigorously evaluate the effects of 3,4-DAP treatment on BoNT intoxication of neuromuscular junctions. Application of 3,4-DAP enhanced the force of muscle contraction and prolonged the time-to-full paralysis in hemidiaphragms intoxicated with human pathogenic BoNT serotypes A, B, or E. Potentiation of contraction strength was inversely proportional to the extent of paralysis, with near-complete loss of contraction enhancement in fully paralyzed preparations. To more precisely evaluate the effects of 3,4-DAP treatment on synaptic function, we recorded evoked postsynaptic endplate potentials in unintoxicated and intoxicated hemidiaphragm muscle cells in the presence or absence of 3,4-DAP. These results indicated that 3,4-DAP works by enhancing release probability at intact (e.g., non-intoxicated) release sites, and therefore the reduced effect size of 3,4-DAP at late stages of disease are the consequence of the decreasing availability of intact release sites. Based on these findings, we modeled the effects of 3,4-DAP on the probability of exceeding threshold neurotransmitter release as the number of intact release sites decreases, representing the progressive intoxication of a single nerve terminal. Collectively, these studies identify the probability of release at intact release sites as a potential therapeutic target for treatment of botulism and identify disease states that are likely to be amenable to 3,4-DAP treatment.

Title: Conditioning at the neuromuscular junction: Elucidating the eliciting conditions

Authors: *M. M. STRAIN, J. D. TURTLE, Y.-J. HUANG, J. W. GRAU;
Dept. of Psychology, Texas A&M Univ. Dept. of Psychology, College Station, TX

Abstract: Research shows that the spinal cord is capable of learning without brain input (Grau, 2014, *Neurobiol Learn Mem*). In these studies, rats with a spinal cord transection were given shock to the tibialis anterior [TA] muscle whenever the hindleg was extended. Rats trained in this manner exhibit a progressive increase in flexion duration. The spinal cord was shown to be necessary for learning this response (Crown, 2002, *Physiol Behav*). However, recent work shows that the spinal cord is not necessary for the maintenance of the memory. Indeed, rats given instrumental training prior to receiving a sciatic transection or intrathecal lidocaine were able to perform the instrumental response. EMG and immunohistochemical evidence indicates that the memory is maintained within the neuromuscular junction (NMJ) (Hoy, 2011, *TAMU library*). Further research has show that the isolated NMJ is capable of Hebbian LTD (Dan, 1992, *Science*). Here we explore the role of the NMJ in learning and maintaining the instrumental response. We began by determining whether learning could be induced at the NMJ by substituting spinal cord input with stimulation of the peroneal nerve. In Experiment 1, rats received a spinal cord and sciatic nerve transection. Twenty-four hours later, rats were prepared for instrumental learning and stimulation of the peroneal nerve. Groups received contingent simulation with either paired stimulation of the nerve and TA or stimulation to the TA or nerve alone. Only rats in the paired condition exhibited an increase in leg flexion. For Experiment 2, we examined whether the response is necessary for learning or if pairing muscle and nerve stimulation was sufficient. Twenty-four hours after the spinal cord and sciatic transection, rats received stimulation to the peroneal nerve that was either paired or explicitly unpaired with TA stimulation. Results indicate that pairing nerve stimulation with TA activation causes a lasting (30 min) increase in flexion. In Experiment 3, we manipulated the timing of the stimulations. Rats were set up as explained above, however instead of simultaneous pairings of the nerve and TA, they received TA stimulation immediately followed by nerve stimulation or nerve stimulation followed by TA stimulation. We found TA activation prior to nerve stimulation produced the largest increase in leg flexion. These studies indicate that the NMJ is sensitive to temporal relations between stimuli and undergoes a form of plasticity. This may have

implications for therapies that rely upon electrical stimulation of muscles to foster locomotor recovery or prevent spasticity. Future studies will examine the underlying mechanisms responsible for NMJ plasticity.

Title: Ighmbp2 deficiency corresponds to protein translation changes and leads to differentiation defects in motoneurons

Authors: *V. SURREY[1], M. MORADI[1], B. DOMBERT[1], H. VYAS[2], C. WINKLER[2], U. FISCHER[3], S. JABLONKA[1];
[1]Inst. for Clin. Neurobio., Univ. Hosp. Wuerzburg, Wuerzburg, Germany; [2]Dept. of Biol. Sci., Natl. Univ. of Singapore, Singapore, Singapore; [3]Dept. of Biochem., Univ. Wuerzburg, Würzburg, Germany

Abstract: Spinal muscular atrophy with respiratory distress type 1 (SMARD1) is a monogenic motoneuron disorder caused by mutations in the IGHMBP2 gene encoding for a ribsosome associated ATPase/Helicase. Despite detailed knowledge about underlying genetic alterations, the cellular mechanisms leading to this disease are not well understood. In the neuromuscular degeneration *(Nmd2J)* mouse, which is the mouse model for the juvenile form of SMARD1, similar pathological features such as diaphragmatic palsy and skeletal muscle atrophy as displayed in SMARD1 patients are observed. Ex vivo studies of *Nmd2J* mice revealed that motor axon loss precedes atrophy of the gastrocnemius muscle and does not correlate with neurotransmission failures at the motor endplate. The already described independently occurring myogenic abnormalities in diaphragm and heart of the *Nmd2J* mouse raised the question whether spinal motoneuron degeneration develops cell autonomously. In order to address this question we performed in vivo studies from Ighmbp2 deficient zebrafish embryos, and in vitro studies from Ighmbp2 deficient mouse embryos. In both animal models a markedly enhanced axonal branching in primary motoneurons had been observed. A time lapse imaging study via fluorescence recovery after photobleaching (FRAP) visualized a local translation delay of β-actin mRNA in growth cones and cell bodies from enriched Ighmbp2 deficient mouse motoneurons,

although the amount of β-actin mRNA showed no aberration. All together these data suggest that motoneuron pathology under Ighmbp2 deficiency occurred cell autonomously in association to local protein translation mechanisms.

Title: Effects of tamoxifen on single muscle fiber function and protein expression after spinal cord injury

Authors: I. K. SALGADO VILLANUEVA[1], A. E. RODRIGUEZ[1], A. I. TORRADO[1], M. E. SANTIAGO[1], W. R. FRONTERA[2], *J. D. MIRANDA[1];

Abstract: Spinal cord injury (SCI) is associated with skeletal muscle atrophy and dysfunction. Efforts to treat SCI have focused almost exclusively on restoring nerve communication with little attention to muscle deterioration. The timeline of event leading to muscle changes must be understood in order to develop effective interventions in the acute phase of SCI. Therefore, the purpose of this study was to determine when changes in muscle fiber contractility and biochemical composition start to occur after SCI. We measured the contractile properties of permeabilized single muscle fibers from rat tibialis muscle at 2 and 7 days post-injury (DPI). Female rats were injured at the T10 level with the NYU impactor. SCI resulted in changes in the maximum shortening velocity of single muscle fibers at 7 DPI but no changes were observed at 2

DPI. The expression of type 2B myosin heavy chain was also decreased by 7 DPI. Available treatments for muscle dysfunction have not been shown to be practical nor effective in acute SCI. Tamoxifen (TAM), an FDA approved for the treatment of cancer, is a selective estrogen receptor modulator (SERM) that interacts with estrogen receptors. We treated rats with TAM immediately after SCI and analyzed the expression profile of the contractile protein of soleus, myosin heavy chain-1A (MHC-1A), and the transcription factor associated with satellite cell proliferation in skeletal muscle, Pax-7. Western Blot analysis demonstrated that SCI reduced the amount of MHC-1A in the soleus muscle at 28 DPI and this change returned to basal levels if the injured rats were treated with TAM. Moreover, TAM increased the expression of Pax-7 at 28 DPI in the soleus muscle of rats with SCI. Together, these data suggest that damage to hindlimb skeletal muscles start to show-up within the first week after SCI and a pharmacological agent like TAM may be effective in maintaining the contractile properties of skeletal muscle fibers after trauma.

Title: Association of small ankyrin 1 with sarcolipin

Authors: *A. LABUZA, P. F. DESMOND, J. MURIEL, M. L. MARKWARDT, M. A. RIZZO, R. J. BLOCH;
Physiol., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Small Ankyrin 1 (sAnk1) is a ~20kDa transmembrane (TM) protein that binds to the cytoskeletal protein, obscurin, and stabilizes the network sarcoplasmic reticulum (nSR) in skeletal muscle. We have recently shown that sAnk1 binds to the sarco(endo)plasmic reticulum Ca^{2+}-ATPase 1 (SERCA1) and regulates its activity (Desmond, 2015). Here, we show that sAnk1 binds to a second regulator of SERCA1, sarcolipin (SLN). Antibodies to sAnk1 co-immunoprecipitate (co-IP) with SLN in COS7 cells transfected to express both proteins, as well

as from isolated SR membranes. An anisotropy-based FRET method (AFRET) also demonstrated the close association of sAnk1 with SLN. Close association was further demonstrated by the use of half-Venus constructs of sAnk1 and SLN. The C-terminal portion of Venus was fused to SLN while the N-terminal portion was fused to sAnk1. Independently, neither show fluorescence, but when co-expressed these two constructs were fluorescent, indicating reconstitution of Venus. We now propose to test the possibility that a three-way complex exists containing sAnk1, SLN, and SERCA1, by using the two half-venus constructs and a cerulean form of SERCA in AFRET assays. The likelihood that a 3-way complex forms is suggested by the fact that antibodies to SERCA1 co-IP more sAnk1 from transfected COS7 cells when SLN is present than when it is absent. We anticipate that AFRET will confirm this.
In preliminary studies, we also show sAnk1, SLN, and SERCA are all expressed within the brain, suggesting that SERCA activity may be regulated similarly in neurons as in muscle. These results have significant implications for the development of therapeutic approaches to treat a variety of diseases linked to calcium misregulation such as muscular dystrophies and neuropathies.

Title: Oxidative stress and reduced gsh:gssg ratio in ryr1-related myopathies.

Authors: ***M. S. RAZAQYAR**, J. WITHERSPOON, J. ELLIOTT, I. ARVESON, K. MEILLEUR;
NINR, Bethesda, MD

Abstract: RYR1-Related Myopathies (RYR1-RM) are a group of disorders that are caused by mutations in the skeletal muscle ryanodine receptor gene *RYR1*. Mutations in *RYR1* hamper RyR1's ability to regulate calcium and cause either RYR1-RM or Malignant Hyperthermia. RYR1-RM comprise the most common group of congenital onset myopathies, affecting over 1/90,000 people in the United States. It is also the second most common group of muscle diseases in childhood. Individuals present with symptoms of generalized hypotonia, muscle weakness, delayed motor milestones, fatigability, and, in severe cases ophthalmoplegia, scoliosis, and respiratory failure. RyR1 calcium dysregulation leads to oxidative stress, impaired

excitation-contraction coupling, and characteristic skeletal muscle fiber type predominance. A recent study by Dowling *et al.* (2012) conducted in a zebrafish model of RYR1-RM and human myotubes implicated mitochondrial oxidative stress as an important pathophysiological mechanism in RYR1-RM. Durham et al. (2008) also showed reduced levels of an endogenous antioxidant, GSH, in a mouse model of RYR1-RM. GSH counteracts oxidative stress by being oxidized into glutathione disulfide (GSSG). Both groups separately showed that N-acetylcysteine (NAC), a precursor of GSH, reduced oxidative stress in all three preclinical models. Because preclinical models of RYR1-RM have shown increased mitochondrial oxidative stress and decreased GSH, we hypothesized that the GSH:GSSG ratio would be decreased in RYR1-RM patients compared to healthy controls.Whole blood was collected from 27 fasting patients (14 adults, 13 children), immediately mixed with agents for preservation of thiols, centrifuged, and frozen. Analysis to determine plasma GSH:GSSG ratios was performed at Emory as previously described (Jones et al. 2009). The mean GSH:GSSG ratio for the 27 patients was 13.2 ($\pm$ 5.84) with an adult mean of 14.3 ($\pm$ 5.05) and a pediatric mean of 12.1 ($\pm$ 6.61). The difference in ratio of GSH:GSSG between adult and children was not significant. The previously reported mean for healthy adults was 21.3 $\pm$ (10.5). There was a significant difference in mean GSH:GSSG ratio between RYR1-RM adults and healthy adults (p=0.016). This is the first report of GSH:GSSG ratios being reduced in patients with RYR1-RM, suggesting increased oxidative stress in this population. Mutations in *RYR1* hamper RyR1's ability to regulate calcium leading to mitochondrial oxidative stress, among other comorbidities. We are conducting a double blind, placebo-controlled trial in RYR1-RM patients to determine NAC's effectiveness in reduction of oxidative stress and alleviation of associated symptoms.

Title: Functional analysis of $Na_v1.4$ mutation in a case presenting with Schwartz-Jampel features, myotonic discharges, and herculean development

Authors: X. XIONG[1], D. H. FELDMAN[1], T. L. KLASSEN[2], C. G. SANCHEZ ACOSTA[3], L. PLAZA-BENHUMEA[4], R. MASELLI[1], *C. LOSSIN[5];

Abstract: Schwartz-Jampel syndrome (SJS) is an autosomal recessive skeletal dysplasia characterized by varying degrees of myotonia and chondrodysplasia linked to mutations in the heparin sulfate proteoglycan perlecan gene, *HSPG2*. The details of the underlying molecular pathophysiology of this syndrome are poorly understood. We report on a case with SJS-like features including myotonic discharges in EMG and herculean musculature; both parents were asymptomatic. Whole-exome sequencing revealed no relevant genetic alterations in HSPG2, but it did identify a variant in the skeletal muscle voltage-gated sodium channel $Na_v1.4$ gene, *SCN4A*, which has well-established ties to myotonic disorders. The associated amino acid substitution falls into a highly conserved region of $Na_v1.4$, which is predicted (SIFT) to have significant impact on the function of the channel. To obtain a better understanding of the mutant channel's biophysical abnormalities, we conducted whole-cell voltage clamping and found subtle changes in the voltage dependence of in-/activation and fast inactivation recovery. Slow inactivation was affected as well, in that the mutant tended to require shorter, less depolarizing pulses to enter slow inactivation, and longer hyperpolarization to recover from the same. Preliminary analysis suggests a net loss-of-function, which is in agreement with the recessive pattern of transmission of this pedigree, but it constitutes a challenge when it comes to explaining the myotonic component of the disorder. Furthermore, the absence of genetic alteration in *HSPG2* and the lack of an obvious connection between $Na_v1.4$ dysfunction and chondrodysplasia opens the possibility of another, so-far unknown contributing factor, pointing to genetic heterogeneity in SJS.

Title: Chronic inflammatory demyelinating polyneuropathy weakness is associated with reduced muscle mass and motor unit loss

Authors: *K. GILMORE[1], K. KIMPINSKI[2], T. DOHERTY[3], C. RICE[4];
[2]Dept. of Clin. Neurolog. Sci., [3]Dept. of Physical Med. and Rehabil., [1]The Univ. of Western Ontario, London, ON, Canada; [4]Sch. of Kinesiology, Dept. of Anat. & Cell Biol., The Univ. of Western Ontario, London, London, ON, Canada

Abstract: Introduction: Chronic inflammatory demyelinating polyneuropathy (CIDP) is an acquired neuropathy of immunological origin. It is characterized, usually, by symmetrical weakness in proximal and distal muscles that progresses for greater than 2 months. Evidence indicates that disease-related post-synaptic damage and muscle fiber atrophy lead to neuromuscular junction remodeling and impaired neuromuscular transmission (Deschenes et al. 2011). Increased understanding of the functional limitations and pathophysiology of CIDP are of particular interest due to the treatable nature of the disease. We sought to compare dorsiflexion strength, motor unit (MU) numbers of the tibialis anterior (TA) and TA cross sectional area (CSA) in CIDP (n=6) with age (64 ±15) and sex matched controls (n=6).
Methods: The TA was selected due to its known involvement in CIDP and its high-degree of accessibility for needle EMG. In an isometric dynamometer, dorsiflexion strength with twitch interpolation to assess voluntary activation was recorded. Surface and concentric needle electromyographic (EMG) signals were collected from the TA . To estimate the number of MUs in the TA the decomposition enhanced spike-triggered averaging technique was applied (Stalberg and Sonoo, 1994). This required subjects to contract isometrically at 25% of their maximal voluntary strength for a series of 30s contractions until at least 20 suitable MU trains were acquired. MRIs were acquired via serial axial planes in a 3.0 Telsa magnet. Proton density images for anatomical measures were acquired using a 2D FLASH sequence with the following parameters: 1,500 ms repetition time (TR), 14 ms echo time (TE), 256×192 matrix, 243×325 mm field of view, 30 slices, 5-mm slice thickness with slice separation of 2 mm. OsiriX (v 7.0, 32 bit) MR imaging software was used to measure maximal TA muscle CSA.
Results: CIDP patients were ~50% weaker than controls despite near maximal voluntary activation (~98%) of the dorsiflexors. The estimated number of functioning MUs in the TA was ~45% fewer in CIDP patients. MRI results indicated that CIDP patients had ~55% less TA muscle area compared to controls. From these preliminary results, those with CIDP have significantly less dorsiflexion strength likely due to fewer numbers of MUs innervating the TA and substantially lower TA muscle mass as reflected by smaller muscle CSA compared with controls.
Conclusions: Dorsiflexion muscle weakness in CIDP patients appears multifactorial and is due to loss of MUs, which may be directly related to muscle atrophy of the TA.

Title: Biophysical and structural properties that contribute to the special biomechanics of the octopus arm

Authors: *L. ZULLO[1], F. MAIOLE[2], S. M. FOSSATI[3], N. NESHER[4], B. HOCHNER[5]; [1]Inst. Italiano Di Tecnologia, NSYN, Genova, Italy; [2]Univ. of Genova and Inst. Italiano di Tecnologia, NSYN, Genova, Italy; [3]NSYN, Inst. Italiano di Tecnologia, Genova, Italy; [4]Sch. of Marine Sci., The Ruppin Academic Ctr., Michmoret, Israel; [5]Dept. Neurobiology, Silberman Inst. of Life Sci., The Hebrew Univ., Jerusalem, Israel

Abstract: The *Octopus vulgaris* arm is a highly flexible structure with a virtually unlimited number of degrees of freedom. The arm's extraordinary motor capabilities are achieved despite the absence of a rigid skeleton and a composition of mainly incompressible muscle tissues. In this study we aim at elucidating the structural and biophysical properties that contribute to the special biomechanical properties of the octopus arm musculature and their neuromuscular control. Especially we want to investigate a new hypothesis whereby in the octopus the muscle and collagen tissue close interactions contribute to create stiffening not only due to the antagonistic action of the different muscle groups, but also due to "particles jamming" possibly resulting from stiffening-induced increase in friction between arm's muscle cells and connective tissue. In order to do so we analyzed passive and active force/velocity relationship in both isometric and isotonic activation of arm musculature segments. For this we use a Dual-Mode Lever Arm System on in-vitro preparations. We found that each muscle type might differently contribute to the arm stiffening and that their coordinated action might be the key element for the formation of jamming forces in the arm. We then asked how the neuromuscular system is organized to control this special biomechanics. We performed a confocal microscopy investigation of muscles by using specific staining markers for presynaptic nerve terminals and postsynaptic acetylcholine (ACh) receptors. We found that ACh receptors are concentrated in a signal 'eye shaped' invagination (≈5X20μm) along the cell longitudinal axis. Motor neurons terminals were also localized in a single spot in close opposition with the ACh receptors. Although these results suggest a direct neural control of each muscle cells, it is still possible that a system of gap junctions between the muscle cells serves to control and coordinate the basal level of muscle responsiveness. As the presence of Innexins (the main constituents of

invertebrate gap junctions) might be a good indicator for gap junction-like structure, we cloned part of the octopus innexin gene and evaluated its expression at the level of various tissues. Real Time PCR analysis revealed that innexin is differentially expressed in tissues such as muscle, brain and skin. Next, we will perform in-situ hybridizations to determine its tissue distribution. Taken together these findings have an important relevance in the understanding coordination control mechanisms and biomechanics of this muscle hydrostatic limb.

Title: Light-activation of channelrhodopsin-2 expressed in chick embryo hindlimb muscle mimics neural activation of muscle

Authors: ***J. R. WHITAKER**[1], S. FROMHERZ[2], P. R. PATRYLO[1], A. A. SHARP[3]; [1]Physiol., Southern Illinois Univ. Carbondale, Carbondale, IL; [2]Biol., Saginaw Valley State Univ., University Center, MI; [3]Anat., Southern Illinois Univ. Sch. of Med., Carbondale, IL

Abstract: Numerous studies have shown that proper neuronal and muscle activity is required for normal development of central motor circuitry as well as peripheral structures such as the neuromuscular junction. The elucidation of how each component of this complex system contributes to the normal process of development is generally hampered by the non-selective nature of pharmacological agents. Accordingly, our goal was to directly and non-invasively control excitation of select groups of muscle fibers in a living chick embryo in order to better understand the role of muscle activity in neuromuscular development. Previously, we developed an optogenetic approach that allowed persistent heterologous expression of a fusion protein consisting of a channelrhodopsin-2 variant (ChIEF) and the fluorescent reporter tdTomato (Tom) in neural tissue of living chick embryos (Sharp & Fromherz 2011). In order to drive expression of ChIEF-Tom in muscle tissue, we replaced the CAG (chicken β-actin) promoter upstream of the ChIEF-Tom coding region in our original expression plasmid with the muscle-specific, myosin light chain promoter (Wang et al. 2011). Electroporation was used to deliver plasmid DNA encoding ChIEF-Tom to hindlimb muscle precursor cells in the somites of embryonic day

(E) 3 chick embryos. Following electroporation, fluorescence of the Tomato reporter was detected in muscle fibers of embryos between E6 and E18. Histological examination of chick hindlimbs revealed muscle fiber specific expression of ChIEF localized to the plasma membrane and distinguishable from immunohistochemically-labeled myosin heavy chain in the cytoplasm. To test for functionality, the hindlimbs of chick embryos were carefully exposed *in ovo* on E9 or E10 and light from a blue LED was directed onto hindlimb muscles showing ChIEF expression. Light-evoked movements were quantified using video-microscopy and kinematic analysis. Light-activation of ChIEF resulted in hindlimb movements corresponding with the muscles that showed ChIEF expression. Muscle contraction persisted for the duration of light exposure (seconds) without decrement. Both the rate and magnitude of evoked movements were directly related to changes in light intensity and duration. Bursts of short duration (5-10 ms) light pulses could be used to imitate neuronal activation of muscle. For example, adjustment of pulse frequency and duration altered movement amplitude and rate and both fused and unfused tetanus could be obtained. Our findings indicate that light-activation of ChIEF expressed in chick hindlimb muscle can be used to better understand the role of muscle activity in neuromuscular development.

Title: Development of a separation method of neural component from spastic resistance

Authors: *K. TAKEDA[1], S. MIZUNO[2], H. MAEDA[2], K. OHNO[1], A. ORAND[1], G. TANINO[1], H. MIYASAKA[1], S. SONODA[2];
[1]Nanakuri Inst, Fujita Hlth. Univ., Tsu, Mie, Japan; [2]Dept. of Rehabil. Med. II, Sch. of Medicine, Fujita Hlth. Univ., Tsu, Mie, Japan

Abstract: Spasticity is involuntary muscle tone which causes resistance to motion. Quantification of increased joint resistance by the abnormal neural activity during passive rotation is important in stroke rehabilitation. Clinical evaluation of spasticity is usually performed by modified Ashworth scale (MAS) which is an ordinal scale that assesses the resistance during passive joint movement by the examiner. Recent studies, including ours, developed some devices which quantitatively measure the resistance torque during manually or

motor-driven passive movement because the MAS has been criticized for their low reproducibility. Although the quantitative measurement of resistance torque is meaningful, the observed torque includes not only neural but also non-neural components. Therefore, in the present study, we propose a new method to divide the resistance torque into neural component and viscoelasticity. A custom made device, electromotor installed ankle-foot orthosis, was used to rotate an ankle joint of stroke patients with spasticity. The resistance torque (plantar flexion torque), angle, and surface electromyography (sEMG) of the gastrocnemius (GC) and tibialis anterior (TA) muscles were simultaneously measured at 1 kHz sampling from 20 degrees of plantar flexion to over 10 degrees of dorsiflexion. We measured the resistance torque at two different angular velocity; approximately 5 deg/s (low velocity) and 90 deg/s (high velocity). The sEMG signals were rectified and integrated via a time window of 400 ms. For the resistance torque at the low velocity condition, a three-piece linear regression was applied to evaluate the coefficients of elastic element which depend on the muscle length (joint angle). The elastic element is common by the resistance torque of low velocity and high velocity conditions. Viscous component, which depends on the angular velocity, and neural components based on the sEMG signals of GC and TA with time delay were separated by using a system identification approach from the elasticity subtracted resistance torque at the high velocity condition. Then, the plantar flexion torque of ankle joint which formed by passive rotation could be divided into elastic, viscous, GC neural, and TA neural components with less residual error.

Title: Wireless innervation of neurons using electromagnetic fields in craw

Authors: *B. KUTER[1], E. C. GUSTAFSON[3], E. P. WIERTELAK, 55105[2];
[2]Neurosci. Studies, [1]Macalester Col., Saint Paul, MN; [3]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Transcranial magnetic stimulation (TMS) has been shown effective in the treatment of a variety of post-stroke movement disorders. That TMS has this effect may indicate some underlying neuronal mechanism that can be modulated by TMS' electromagnetic fields (EMF). As an initial approach to examining such a possibility, the effect of TMS was examined by

exposing standard crawfish electrophysiology preparations to varying strengths of EMFs generated by a dual metal-plate array. The crawfish were prepared by dissecting off their tails, and exposing their superficial flexor. This muscle was then probed with a microelectrode, and placed between the two EMF-generating plates. The inserted microelectrode then recorded the resting membrane potentials of the muscle. Signals ranging from 2.0 MHz to 5.0 MHz were tested, in increments of 0.5 MHz with exposure and resting times of 35 seconds. When the mean difference between each frequency on and off levels were compared, the application of EMF at all strengths produced significant effects on The results indicated that unknown neuronal mechanisms were being affected by the EMFs. There was an optimal frequency range present in the tested frequencies around 4.5 MHz. Future research in this laboratory will focus on examination of effects in this range. Elucidation of the underlying mechanism for this effect of EMF could help shed light on the processes involved in EMF-exposure, and in the further future lead to methodology on reliably controlling a cell's resting membrane potential wirelessly.

Abstract: We have successfully created an *in vitro* 3D bioactuator using rat spinal cord tissue and C2C12 skeletal muscle cells. This is a major step towards enabling the fabrication of biological machines capable of sensing, processing the input, and exerting a force upon the surrounding environment. Whereas, previous studies have successfully created neuromuscular junctions in static 2D cultures (Das *et al, Biomaterials* 2010), here we show dynamic activation of culture muscle strips due to neuronal input on a recently developed 3D platform (Cvetkovic *et al*, *PNAS* 2014, Raman *et al*, *PNAS* 2016, Chan *et a*l, *Scientific Reports* 2012). Skeletal muscle

strips were created on a 3D printed flexible skeleton in order to engineer a muscle actuator. Spinal cord sections taken from the postnatal day 3-5 rat pups were then placed onto the muscle strip and allowed to grow in a 50/50 mixed spinal cord and muscle differentiation medium. The spinal cord tissue adhered well to the muscle strip and sent out substantial extensions into the surrounding myotube bundles. Using immunohistochemistry, we examined the efficacy of neurite outgrowths from the spinal cord and subsequent innervation into the muscle strips, leading to neuromuscular junction formation. We also examined functionality of the 3D engineered biological machine using glutamate stimulation to specifically excite neurons of the spinal cord and patch-clamp electrophysiology to demonstrate robust electrical activity and health in the nascent biological machine. This system realizes the goal of creating a functional, biomimetic machine with neuronal input that is capable of movement through the normal physiological mechanisms of the neuromuscular junction. This achievement advances us along toward the eventual goal of realizing a forward-engineered, autonomous integrated cellular machine and system with a host of applications for tissue engineering, drug testing, and a better *in vitro* model for studying development of nervous and musculoskeletal systems.

Title: The effect of an 8 week CrossFit type exercise program on inflammatory injury and balance

Authors: *G. S. BAINS[1], E. LOHMAN[1], L. BERK[1], N. DAHER[1], R. CHETTIAR[1], O. AMBODE[1], B. MIRANDA[1], R. SINGH[1], F. NUGENT[2];
[1]Allied Health/Physical Therapy, Loma Linda Univ., Loma Linda, CA; [2]Southern Utah Univ., Cedar City, UT

Abstract: CrossFit type exercises (CFE) are a combination of resistance and aerobic training which involve constantly varied intensity and functional movements. High sensitivity C Reactive Protein (hs-CRP) is a known inflammatory biomarker. To our knowledge, there have been no published studies showing the relationship of CrossFit exercises on balance improvement and on hs-CRP modulation. **PURPOSE:** To evaluate the effect of 8 weeks of CFE on inflammation through acute hs-CRP modulation and balance parameter measurements compared to a no

exercise control group. **METHODS:** Sixteen adult subjects were randomly assigned to a CFE group (25.7 ± 2.2 years, n=9) or a control group (25.6 ± 3.1 years, n=7). Previously, all subjects were exercising at a low level of intensity for a minimum of 6 weeks and were not trained in CFE. The CFE gradually increased in intensity weeks 1 to 4, and then increased to a very heavy intensity weeks 4 to 8. High sensitivity CRP concentrations were drawn at baseline and 48 hours post exercise at the end of weeks 1,4,8, and 9. Additionally, vertical jump height and balance testing (limits of stability) were assessed at baseline and at 48 hours post exercise at week 8. **RESULTS:** There was no significant change in hs-CRP concentrations over time within each group. For hs-CRP concentrations for the CFE group, there was a significant change ($p=.04$) from baseline to week 1 (23.1%), a borderline significant change ($p=.07$) from week 1 to week 9 (21.1%), and no significant change ($p=.73$) from baseline to week 9 (1.4%). Additionally, from baseline to week 8, vertical jump height, reaction time, and movement velocity each significantly increased ($p<.05$) in the CFE group by 13.2%, 21.2%, and 30.7% respectively. There was no significant change in hs-CRP, vertical jump height, reaction time, and movement velocity in the control group. **CONCLUSION:** We suggest, after completing 8 weeks of CFE program, subjects were observed to have a reduced inflammatory response as assessed by hs-CRP. Although we continuously increased exercise intensity throughout the study, hs-CRP concentrations did not significantly change from baseline to week 9. However, we suggest that the CFE group was able to gradually acclimate to the CFE program. Therefore, this modulation in inflammatory response could be suggestive of the resultant acclimation that translates for an improvement in vertical height jump level and faster reaction time and movement velocity in mainstream CrossFit athletes. CFE is an effective training program in maintaining a minimal non-significant inflammatory response as assessed by hs-CRP 48 hours post exercise. Further research is suggested to expand these encouraging findings.

Title: Intermittent leg cycling sprints induce fatigue-related suppression of human soleus Hoffmann reflexes

Authors: *G. E. PEARCEY[1], S. NOBLE[1], B. MUNRO[2], J. L. BISHOP[2], E. ZEHR[1]; [1]Rehabil. Neurosci. Lab., Univ. of Victoria, Victoria, BC, Canada; [2]Exploration Team, Nike Sport Res. Lab., Beaverton, OR

Abstract: Intermittent sprints (IS) are known to induce neuromuscular fatigue that can be attributed to a combination of central and peripheral mechanisms. Furthermore, fatigue due to tetanic stimulation of the triceps surae induces suppression of the soleus Hoffmann (H-) reflex, as does non-fatiguing arm and/or leg cycling. However, it is unknown whether cycling IS alter the excitability of the soleus 1a monosynaptic reflex. Thus, the purpose of this experiment was to determine if fatiguing IS alter the excitability of the soleus H-reflex. 13 healthy young participants performed 7 x 10 s sprints interleaved with 3 min unloaded cycling on a Monark ergometer. Sprints were braked with 9% mechanical loading and participants were instructed to cycle all-out for the 10s duration. H-reflex and M-waves of the right soleus were evoked by stimulation of the tibial nerve at the popliteal fossa. M-H recruitment curves were recorded pre- and post-session at rest. H-reflexes corresponding to ~90% maximal H-reflex amplitude were evoked during unloaded cycling just prior to the first IS, after each sprint and then 5 and 10 minutes after sprint 7. Results indicated that there was significant fatigue throughout the IS protocol, since the average power output was reduced by 6.2 ± 2.29% ($p = 0.036$) by sprint 3 and remained reduced by up to 14.2 ± 2.52% ($p = 0.001$) during sprint 7. Following sprints 1 through 7, H-reflex amplitudes were suppressed by 22.5 - 30.5% ($p < 0.01$), and remained suppressed by 21.7 ± 2.52% ($p = 0.001$) 5 min following sprint 7. Pre- to post-protocol comparisons of resting M-H recruitment curves revealed that there was an increase in the minimum current required to evoke an H-reflex (threshold) and a decrease in the maximal H-reflex amplitude. These data suggest that IS induce significant fatigue that results in reduced power output, and the fatiguing effects of IS result in decreased excitability of the human lumbar spinal cord.

Abstract: In female mammals, the lower urogenital tract is essential for excretory and reproductive functions including micturition, defecation, sexual intercourse and crossing of fetuses during deliveries. Pelvic and perineal striated muscles play important roles in the physiology of the lower urogenital tract. In micturition, the pelvic muscles participate in urine storage, whereas the perineal muscles participate in voiding of urine. We reported that that blocking the activity of perineal muscle bulbospongiosus (Bsm), ischiocavernosus (Iscm) and pelvic muscle as the pubococcygeus (Pcm) causes changes in micturition similar that multiparous female rabbits. So a model of damage was done to the nerves of the pelvic and perineal muscles. Virgin female chinchilla rabbits 10 to 12 months old were used in the study. Cystometrograms were recorded simultaneously with electromyograms and intraurethral pressure, with and without denervation and/or crushing of Bsm was evaluated. Pcm electromyographic activity was recorded as control. After denervation of Bsm the urodynamic parameters showed decrease in voiding volume and increased in residual volume. In intraurethral pressure, decreased the maximum pressure and threshold pressure. When the nerve of Bsm was crushed, the threshold pressure and the maximum pressure decreased and the voiding duration increased. The intraurethral pressure decreased and the intraurethral threshold increased. Electromyographic records shown activity of Bsm during the expulsion and activity of Pcm during urine storage. Bsm activity disappeared after denervation, and after crushing, the activity showed diminished and disorganized. The results suggest that the Bsm contributes to the regulation of urine expulsion, and if its innervation is damaged during delivery, could be affect its function.

Title: Identifying the function of tyramine in the mouse uterus

Authors: M. AGRE, B. OBAYOMI, L. TOWNLEY, *D. P. BALUCH;
Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: Pregnancy and the birthing process are natural events but still little is known about the signaling mechanism(s) that induce contractions. Globally, premature labor occurs in 12% of all pregnancies resulting in 15 million babies born preterm. Even though the cause of preterm labor can vary, understanding the signaling pathway that regulates muscle contraction could provide additional treatment options to stop premature labor. The uterus is composed of smooth muscle and in conjunction with the associated nerve fibers, forms a plexus which covers the muscle fibers. The plexus has swollen areas called varicosities that contain neurotransmitters. Within the uterine tissue, the smooth muscle receives opposing inputs from the sympathetic and parasympathetic parts of the ANS. Smooth muscle can be stimulated or modulated by many sources such as neurotransmitters (i.e. norepinephrine), hormones (i.e. epinephrine) and chemicals (i.e. nitrous oxide). In this study we are researching an alternative modulator of smooth muscle activity, a monoamine produced in the catecholamine biosynthesis pathway called tyramine. During catecholamine biosynthesis, dopamine, tyramine, octopamine, and norepinephrine are all derived from the tyrosine precursor. Tyramine is known to be associated with peripheral vasoconstriction, increased cardiac output, increased respiration, elevated blood glucose and release of norepinephrine. Our research has found tyramine and its specific receptor TAAR1 to be localized at the uterine neuromuscular junction in relation to muscular contraction. This project is focused on distinguishing the synchronous and alternating signaling pathways, between the epinephrine and octopamine pathways, which regulate muscle contraction.

Title: New measurement system of human arm stiffness for clinical evaluation

Authors: *T. YUKAKO[1], K. IGARASHI[1], S. KATSURA[1], F. NAKAI[2], C. YAMADA[2], Y. ITAGUCHI[3], H. YOSHIZAWA[4], K. FUKUZAWA[2];

Abstract: The present study reports a new robotic-measurement system of arm stiffness for clinical evaluation. Quantitative evaluation using robotic devices has advantages to implement efficient rehabilitation programs. To assess sensorimotor abilities of upper limb, arm stiffness is considered as one of integrative indices. Arm stiffness is defined as an end-point force of an arm generated in response to an applied displacement. Arm stiffness at a certain position can be represented as an ellipsoid. It helps us to understand musculoskeletal condition of an arm including muscle rigidity and abnormal reflex.Conventional systems for arm stiffness measurement required a parallel-link-driven manipulandum consisting of rotational motors, the size of which was too large to install in clinical settings. They used a force sensor to measure arm stiffness, which could deteriorate measurement accuracy. A gantry robot developed in our laboratory was composed of three linear-direct-drive motors, which reduced the size of the device and realized high-accuracy of measurement due to exclusion of coordinate transformation. Further, the robotic device can measure arm stiffness in three dimensions, which might be useful in clinical situations.We estimated stiffness ellipsoid based on measured arm stiffness using the robotic device. Six students participated in the experiment (four males and two females, from 21 to 25 years old). Their upper and lower arms were hanged to eliminate gravity effects. They gripped a vertical handle attached to the device during the measurement. Perturbations were applied to the participants' arm through the handle in 26 directions (one trial). The amplitude of perturbations were 8mm and lasted 850ms with a 150ms ramp. We used force and position data for 150ms from the onset of perturbation to estimate arm stiffness. Arm stiffness was measured three times at one location and at five different locations in total. The time for one trial took about 100s. A stiffness ellipsoid was calculated by multiplying the stiffness matrix and the unit sphere. Stiffness matrix was derived using a least mean square method. The results showed that major axes of the ellipsoids were oriented to the shoulder of the participants, which is the prominent property of arm stiffness. We observed the same range of stiffness values compared to the previous studies, which validated our measurement system. In

addition, the variance of the measurement was small (about 63 % in SD of stiffness matrices). The equivalent stiffness values and small variance in measurement suggested that one trial is adequate for daily use of our system in clinical settings.

Title: Rat whiskers are used in airflow sensing

Authors: ***Y. S. YU**[1], M. M. GRAFF[1], C. S. BRESEE[2], Y. B. MAN[1], M. J. Z. HARTMANN[1,3]; [1]Dept. of Mechanical Engineering, Northwestern Univ., Northwestern Univ. Dept. of Mechanical Engin., Evanston, IL; [2]Northwestern Univ. Interdepartmental Neurosci. Program, Evanston, IL; [3]Northwestern Univ. Dept. of Biomed. Engin., Evanston, IL

Abstract: Mechanisms for flow sensing and anemotaxis are well studied in arthropods, and in some aquatic and flying mammals. Remarkably, however, no study to date has yet investigated the sensory cues used by terrestrial mammals for anemotaxis. The present work is the first to investigate the cues that allow terrestrial mammals to detect and localize airflow.Two lines of evidence suggest that rat vibrissae can be used for flow sensing. First, the mechanical response of a rat vibrissa to airflow contains information about both flow direction and magnitude(*1*). Second, a common neural drive of whisking and sniffing(*2*) confers a degree of temporal precision that could align anemotaxic information with odorant information during olfactory search. We therefore tested the hypothesis that the vibrissae contribute significantly to the ability of rats to localize airflow. In this study, five rats trained on a five-alternative forced-choice airflow localization task exhibited significant performance decrements after vibrissal removal. In contrast, vibrissal removal did not disrupt performance of control animals trained to localize a

light source. Importantly, the performance decrement of individual rats was correlated with their airspeed threshold for successful localization; animals that found the task more challenging relied more on the vibrissae for localization cues. Following vibrissal removal rats deviated more from the straight-line path to the air source, choosing sources further from the correct location. Results demonstrate that the rodent vibrissal-trigeminal system, which has a well-established role in tactile detection and texture discrimination, also contributes significantly to anemotaxis. This discovery provides a link between the vibrissotrigeminal system and olfactory search, and offers a behavioral rationale for the coupling between oscillatory neural circuits that drive sniffing and whisking. In the field of ethology, our results enable comparisons of flow sensing behaviors in terrestrial mammals, arthropods, and pinnipeds, and could inform analysis of foraging behavior.

Abstract: Rats use active, rhythmic movements of their mystacial vibrissae (whiskers) to tactually explore the environment. Recent work has suggested that rats can change tactile sensing resolution by modifying the "spread" or the "spacing" of the whiskers. Spread is defined as the angular distance between the rostral- and caudal-most whiskers on one side of the face, while spacing is defined as the distance between adjacent whiskers. In the present work, we quantified aspects of the mystacial pad anatomy that underlie the rat's ability to change spacing and spread. We focused on the geometry of the whisker follicles and the intrinsic muscles that connect two adjacent follicles within a row. We sectioned four complete mystacial pads, performed three-dimensional reconstructions of all follicles, and identified the attachment points of the intrinsic muscles around the follicles. Results showed that all whiskers emerge from the mystacial pad at approximately equal angles relative to the skin. Follicle length and spacing, as well as muscle attachment points, all vary in proportion to each other across the array. Simulations based on these measurements suggest that if each intrinsic muscle were to receive the same rate of activation from lower motor neurons, all whiskers would rotate approximately through the same angle. In other words, a motor command sent to any lower motor neuron projecting to an intrinsic muscle could be in a common rate code. Thus the geometry of the pad ensures an invariance at the level of lower motor neurons, leaving changes in sensing resolution under voluntary control at more central levels.

Title: The effect of social stress on the dopaminergic pathway of the escape circuit in zebrafish

Authors: *K. CLEMENTS[1], T. MILLER[1], E. JI[2], F. ISSA[1,2];
[1]Biol., East Carolina Univ., Greenville, NC; [2]Physiol., UCLA, Los Angeles, CA

Abstract: The occurrence of a chronic stressor causes an elongated state of physiological changes, affecting both peripheral and central body systems in a detrimental manner to the health of the organism. One approach to test the effects of a chronic stress is to induce a social hierarchy. Zebrafish form social hierarchies that consist of either socially dominant or subordinate fish. We have observed that once a social hierarchy has been established, behavior patterns between males reflect their social standing; social dominants display aggressive behaviors (attacks), while socially subordinates display submissive behaviors (retreats). The objective of this project is to determine the effects of chronic stress on dopaminergic neurotransmission and its effects on the highly characterized Mauthner escape circuit. When startled, zebrafish produce a stereotyped escape response that is mediated by auditory activation of the Mauthner command neurons which innervate spinal motor neurons. We tested the effects of social stress on the Mauthner escape response by recording the far-field potentials of fish escape to auditory pulses of increasing intensity (70-105 decibels). We observed that socially subordinate fish have a lower threshold for producing an escape when compared to both dominant and communal fish. These results suggest that a chronic state of stress on the subordinates influences the underlying neural signaling responsible for this escape behavior. To better understand the neural bases of social status-dependent change in Mauthner sensitivity, we tested whether social stress affects the dopaminergic system. Through application of the dopamine precursor, L-DOPA, we have found that the dopaminergic system is socially regulated. We have also applied dopamine receptor agonists and antagonists. We observed that chronic stress may be affecting the presence of dopamine 1 (D1) receptor in submissive animals, causing a sensitization in production of escape response. Gaining a better understanding of how chronic social stress influences the dopaminergic pathway will facilitate the advancement of new treatments of disorders that disrupt natural dopaminergic function.

Title: Social status-dependent molecular regulation of dopaminergic pathways in the brain of zebrafish (danio rerio)

Authors: *T. H. MILLER[1], K. CLEMENTS[1], E. JI[3], F. ISSA[2];
[1]Biol., [2]East Carolina Univ., Greenville, NC; [3]Univ. of California, Los Angeles, CA

Abstract: In zebrafish (*Danio rerio*), social interactions between adult males consist of a series of aggressive encounters that ultimately lead to the formation of stable hierarchies of either socially dominant or subordinate animals. Although it has been shown that social status leads to neurophysiological changes in brain structure and function, our understanding of how identified brain circuits are modulated by social status in vertebrate model systems is limited. Preliminary results have shown that there is a social-status dependent effect on the sensitivity of the C-start escape response. We hypothesize that the activation pattern of the Mauthner neural circuit, that mediates the C-start escape response in zebrafish, is likely affected by social experience through the regulation of the dopaminergic system. The focus of this study is to determine how social experience affects the regulation of the expression on genes in the dopaminergic pathway in the zebrafish brain, and how this may relate to the Mauthner neural circuit. Our results indicate that the brain-wide dopaminergic system is modulated on a transcriptional level, with social status-dependent regulation of dopamine supply and receptor expression. We show that although there were no significant differences in the expression of tyrosine hydroxylase (th), dopa decarboxylase (ddc) and vesicular monoamine transporter (vmat) in dominant and subordinate animals, we found that whole brain expression of dopamine active transporter (dat) was significantly up-regulated in dominant animals compared to subordinates. In addition, drd1b receptor expression was down-regulated in dominants compared to subordinates. Finally, the hypothalamic and hindbrain sub-regions also display social status-dependent transcriptional modulation of the dopaminergic system. To fine tune our examination of the dopaminergic system relative to the Mauthner Neural circuit, we plan to examine expression of dopaminergic genes in the Mauthner Command neurons and specific regions of the hypothalamic nuclei known to project to the spinal cord. Our findings suggest that there is a social-status dependent regulation of the dopaminergic system via modulation of pre- and post- dopaminergic synaptic pathways.

Title: Trade-offs between speed and variability in responses to looming visual stimuli

Authors: *K. D. BHATTACHARYYA[1], D. L. MCLEAN[2], M. A. MACIVER[2];
[1]Biomed. Engin., [2]Northwestern Univ., Evanston, IL

Abstract: Predation of mobile animals by other mobile animals, in which the biological arms race between predator and prey can led to increasing morphological and neural complexity, may have been the central mechanism for the Cambrian radiation. Two of the weapons prey have for survival in predatory encounters are 1) reducing the predictability of their escape maneuver and 2) increasing the speed of their escape maneuver. However, high accelerations and velocities are subject to biomechanical constraints and working at the limit of biomechanical capacity may vitiate variability. Consequently, animals may need to trade-off speed and variability in escape behaviors - implying that behavioral urgency plays a role in the variability of an escape maneuver. A time-sensitive aversive stimulus, like the looming stimulus, which is the rapid expansion of an image creating an impression of an approaching object or predator, can be used to interrogate the impact of behavioral urgency by tuning the rate of approach or image expansion. We investigated whether the variability of the escape trajectory was inversely related to the rate of expansion or approach of the looming stimulus by studying the angle of escape in the looming-evoked responses of larval zebrafish. In a free swimming assay, we found that variability in the angle of escape does indeed increase with a more gradual expansion of the looming object. Additionally, in a partially-restrained preparation, we performed calcium imaging of the Mauthner cell, a command neuron known to be involved in escape turns, with simultaneous high-speed imaging of body kinematics during escape responses to looming stimuli. We discovered that rapidly approaching stimuli are more likely to activate the Mauthner cell. The kinematics of escape responses mediated by Mauthner cell activity were more stereotyped than Mauthner cell inactive responses that are more common with slowly looming stimuli. The results provide insight into a fundamental question in ethology of how animals produce variable or flexible behavior to fixed stimuli.

Title: The visual system of the northern elephant seal

Authors: *E. C. TURNER, E. K. SAWYER, J. H. KAAS;
Vanderbilt Univ., Nashville, TN

Abstract: Northern elephant seals (*Mirounga angustirostris*) are part of a diverse clade of carnivorous animals known as pinnipeds (seals, sea lions, and walruses). Pinnipeds are notable for their large, ape-sized brains, yet little is known about the central nervous system of these federally protected animals. The northern elephant seal spends most of its life at sea, but surfaces briefly on land each year to breed and birth; this unique coastal niche may be reflected in specific evolutionary adaptations to their sensory systems. Here we report on select parts of the visual pathway (optic nerve, lateral geniculate nucleus, and primary visual cortex) of the nervous system of the northern elephant seal. Using stains for Nissl, cytochrome oxidase, and vesicular glutamate transporters in one elephant seal pup and the external anatomy of the brain of a second pup, we investigated the cytoarchitecture of the lateral geniculate nucleus and primary visual cortex. Similar to in rodents and primates, we find that these markers are useful for the identification of architectonic borders. We find that the lateral geniculate nucleus has distinct layers similar to that of closely related species. Primary visual cortex is located within the most posterior end of the highly gyrified cortex, and extends far anterior along the dorsal surface and medial wall. Toluidine blue was used to visualize myelinated axons in the optic nerve of the northern elephant seal, and we found two distinct classes of myelinated fibers, those with thick myelin sheaths (9%) and those with thin myelin sheaths (91%). Axons with thick myelin sheaths tended to be larger in diameter and clustered near each other in one small section on the edge of the optic nerve, while the rest of the optic nerve contained a more consistent distribution of many thinly myelinated axons mixed with fewer thickly myelinated axons. The results may be useful for other comparative studies related to the evolution of large brains.

Title: Predation behavior is based on background thermoregulation in a pit-viper Gloydius brevicaudus

Authors: *Q. CHEN[1], Y. TANG[2];
[1]Chengdu Inst. of Biology, Chinese Acad. of Sci., Sichuan, China; [2]Chengdu Inst. of Biology, Chinese Acad. of Sci., Chengdu, China

Abstract: Predators with excellent vision are able to distinguish even very small optical differences between target and background. For pit-vipers, the thermal sense is believed to complement vision and provide a substitute imaging system in dark environments. For example, the thermal sense would image a scene consisting of a living mouse in a cold cave as a bright spot on a dark background, projected onto the topographic map of the midbrain tectum. This raises the question of how the thermal imaging system would perform if background temperatures were variable across different portions of the scene. In order to find out we investigated prey capture under such circumstances in the short tailed pit viper, *Gloydius brevicaudus*. Snakes used in this study were tested in a modified predation cage in which the background temperature was maintained at 33℃(normal) on one side of the cage and 40℃ (heated) on the opposite side using a feedback controller. Each of twenty four short-tailed pit vipers was tested on five predation trials. Snakes successfully captured prey on 78 of 120 trials. In the successful trails, snake preferred to strike prey on the normal side (26℃) rather than the warmer side (33℃). Nevertheless testing revealed no orientation bias when they snakes chose between a 26℃and 40℃background temperature difference. In conclusion, the infrared system cannot be viewed as a simple thermal sensor, because increasing the intensity of background radiation does not necessarily mask the target signal. Furthermore the infrared imaging system functions analogously to how the visual system can identify a grey target against a black background as well as a white background as shown by the effect of varying the background temperature from 26℃to 33℃to 40℃. Thus this behavioral research suggests that the pit viper infrared system can accomplish a 'brightness constancy' computation reflecting the difference between the target and the background which is analogous to they way the visual system computes the luminance difference between the target and the background.

Title: A three-dimensional stereotaxic mri brain atlas of house crows (corvus splendens)

Authors: *S. SEN[1], S. PAUL[1], P. RAGHUNATHAN[1], S. S. KUMARAN[2], S. IYENGAR[1]; [1]Systems Neurosci., Natl. Brain Res. Ctr., Gurgaon, India; [2]All India Inst. of Med. Sci., delhi, India

Abstract: The cognitive abilities of the Corvidae family of birds are comparable to those of higher mammals. Higher brain functions such as tool-use, logical deduction, long-term facial memory and the use of working memory which these birds exhibit are almost at par with those of apes and chimpanzees. Amongst corvids, crows are especially proficient at these tasks and fast emerging as a potential model to study these complex cognitive behaviors. Currently, there is an increasing interest in understanding the neural basis of higher cognitive functions across different species using non-invasive neuroimaging modalities such as functional Magnetic Resonance Imaging (fMRI) and Positron Emission Tomography (PET). MRI-based anatomical brain atlases are used as the standard reference space in neuroimaging studies. In order to decrease the variability between various brain structures or functions and to compare across different experimental animals of the same species, individual MR images are normalized to the brain atlas space. Since there was no such atlas available as a reference for the crow brain, for the first time, we have constructed a three dimensional (3D) MRI brain atlas of the Indian house crow (*Corvus splendens*) using high resolution iso-voxel structural MR images of their brain.The brain atlas encompasses an MRI brain template and a parcellation map delineating major avian brain areas such as the striatum, different areas of the pallium and brainstem. Our brain atlas provides a standard reference space for neuroimaging-based studies and would be useful for marking stereotaxic locations of brain regions at any given head-angle. It would also be valuable for various surgical procedures such as injecting neuroanatomical tracers or pharmacological agents into the brain, electrophysiological recordings as well as brain tissue sectioning. This 3D brain atlas of the house crow will be made freely available on our institutional website.

Title: Regressive evolution of the hagfish visual system: blind but hopeful monsters

Authors: *W. T. ALLISON;
Univ. of Alberta, Edmonton, AB, Canada

Abstract: We study the Pacific Hagfish in an evo-devo framework, with special attention to the first appearance of the vertebrate eye over evolutionary time. Other cyclostomes (lampreys) and all jawed vertebrates share the familiar camera-style eye. The last common ancestor of lamprey and vertebrates also had a photoreceptive pineal gland. Thus the Hagfish, oft-reported to lack a pineal, eyes and vision, are positioned perfectly to understand the appearance of the vertebrate eye over evolutionary time. The eyes of adult hagfish are quite small and buried under a layer of epidermis, leading credible sources to suggest hagfish lack vision altogether and their eyes are pineal-like in several characters.

Here we revisit the rarely-examined Pacific Hagfish (*Eptatretus stoutii*), with special attention to the smallest (≈youngest) individuals we can acquire, and applying contemporary histology methods to reveal novel compelling arguments that hagfish possess almost all features of a vertebrate eye; this codifies hagfish eyes as functional, though degenerating during ontogeny. Young hagfish possess a camera-like cup-shaped eye, though we have yet to observe a classical vertebrate lens. We found the ocular media to be broadly transmissive to light from the UV to red portions of the spectrum (340-700 nm). We used a panel of 22 antibodies to perform immunohistochemistry on hagfish eye cryosections. Three independent opsin antibodies all reveal robust photoreceptors at the outer nuclear layer and indistinguishable from vertebrates. Hagfish photoreceptor outer-segments are aligned into an apparent RPE homolog containing engulfed photoreceptor outer segments detected by both electron microscopy and opsin IHC. Importantly, young hagfish retinas have three recognizable nuclear layers separated by synapses as detected by multiple stains and antibodies. Thus, several data sets all independently demonstrate that young hagfish have eyes that are not pineal-like, but have organization at the tissue- and molecular-level shared with lampreys and all jawed vertebrates. Therefore the retina of Pacific Hagfish degenerates with ontogeny and adult tissues have been mis-interpreted to implicate that the eyes of hagfish never develop and never evolved. Further, examination of young hagfish brain reveals a pineal gland, based on specific and polarized opsin IHC labelling at a ventricle wall in the dorsal midline. This serves as a final argument against the need for

hagfish eyes to exclusively serve a pineal-like function. In sum, here we discover and detail hagfish eyes and vision, revising our understanding of the early vertebrate eye evolution.

Title: Modulation of locomotor behaviors by a dopaminergic population in the zebrafish hypothalamus

Authors: *J. P. BARRIOS[1], A. D. MCPHERSON[3], S. ANJEWIERDEN[2], J. B. NEWTON[2], S. J. LUKS-MORGAN[1], R. I. DORSKY[1], A. D. DOUGLASS[1];

Abstract: Dopamine (DA) is a key modulator of locomotor networks in multiple contextsIn vertebrates, DA modulates locomotor behaviors at multiple sites, including the spinal cord and the basal ganglia of vertebrates. DA shifts these networks between distinct functional states that optimize sensorimotor processing to best deal with dynamic environmental challenges. A major challenge in neuroscience is to understand the flexibility of sensorimotor circuits imparted by neuromodulators like DA. In this work, we have shown that a specific population of DA neurons in the zebrafish is involved in the generation of locomotor behaviors and we are now investigating the circuit level mechanisms by which this occurs. This DA population is genetically defined by expression of tyrosine hydroxylase-2 (TH2) and is specifically expressed in the hypothalamus. We have shown that ablation of these neurons reduces the frequency of spontaneous locomotor behaviors and optogenetic stimulation increases that frequency. We are currently using a combination of *in-vivo* imaging, ablation, and optogenetic approaches tTo elucidate the circuitry involved inanatomical and functional basis of this locomotor effect., Wwe have begun to rigorously characterize the behaviors evoked by optogenetic stimulation of *th2*+ neurons. Stimulation can evoke both startle and routine swim behaviors, depending on stimulation light intensity. Furthermore, we are using projection-tracing techniques to identify anatomical targets of *th2*+ neurons. We are also using in-vivo two-photon calcium imaging to correlate the activity of *th2*+ neurons with specific spontaneous locomotor behaviors in a head-

fixed, tail-free preparation. Our dataOptogenetic stimulation show that *th2*+ neuron activity of *th2* neurons is sufficient to lower audiomotor startle threshold, further suggesting a role of these neurons in the modulation of startle behavior. We are currently investigating the role of DA from this population in prepulse inhibition of the startle response using chemogenetic ablation and a *th2* knockout zebrafish. Understanding the role of this hypothalamic DA population in the modulation of sensorimotor circuitry in the zebrafish will provide key insights into the flexibility of neural circuits and the implications of that flexibility for behavior.

Title: Lesions of the telencephalon and the application of a dopamine D1 receptor antagonist result in similar modifications of the acoustic startle response in goldfish.

Authors: *A. N. OPALKA[1,2], N. FISCHER[1], R. F. WALDECK[1,2];
[1]Biol., [2]Neurosci. Program, The Univ. of Scranton, Scranton, PA

Abstract: Normally goldfish make a quick, complete turn away from a vibratory stimulus known as a startle response, which is mediated by the Mauthner cell (M-cell) and connected to motor neurons in the spinal cord. Previous studies have shown that full ablation of the telencephalon significantly decreased the likelihood of a complete startle response in goldfish (Collins & Waldeck, 2006). However, the precise identification of the location within the telencephalon is not known nor the projection to the M-cell in the brainstem. Different regions of the telencephalon were lesioned, and fish were then tested for the resultant behavior to determine the specific location of cells related to modification of the startle response. In a second set of experiments, a dopamine D1 subtype receptor antagonist (SCH23390) was applied to determine dopamine involvement in this modified startle response. Acoustic startle responses were tested and recorded for three consecutive pre- and post-testing days in both sets of experiments. In one set of fish, different areas of the telencephalon were lesioned and then tested for changes in startle response. In a second set of fish, no surgery was performed, but fish were immersed in SCH23390 solution on the fourth day followed by post-testing after immersion for three consecutive days. Behavior analysis was carried out using Logger Pro 3.9 to determine mean-startle angle (MSA). In regards to the location, MSA differs between medial and lateral

telencephalon lobe lesions. Right- and left-medial lesions decrease MSA while right- and left-lateral lesions have less effect. In regards to a possible dopaminergic projection from the telencephalon, statistical analysis revealed significant differences in the MSA between control and antagonist groups. Fish immersed in the D1 antagonist showed similar turning modifications as those fish following lesions of the telencephalon. Future directions hope to show the neuroanatomical projections from the telencephalon to the brain stem.

Title: From drug discovery to neural mechanisms of nicotine-induced motor behavior in zebrafish

Authors: *H. SCHNEIDER;
Dept. of Biol., Depauw Univ., Greencastle, IN

Abstract: New pharmacotherapeutics for smoking cessation therapy can be identified using zebrafish neurobehavioral assays. Gaining a better understanding of the action of newly discovered chemicals involves the recording of neural network activity in the brain. The goal of this project is to develop chemical treatment schedules that can be used in both nicotine-response assays of freely swimming larval zebrafish and electrophysiological or imaging experiments of embedded or suspended larval zebrafish. Translating experiments on freely swimming zebrafish larvae to fixated or suspended individual larva required certain adjustments of nicotine dosage and application method. Agarose embedding did not seem to change the overall response of larval zebrafish to nicotine, but delayed an increase in locomotor activity by 10 to 20 min compared to the immediate onset in freely swimming larvae. Using lower concentrations, allowed for repeated nicotine applications that alternated with embryo water rinses. High nicotine concentrations have caused irreversible changes in locomotor activity. Focal application of chemicals directly onto the head region reduced the delay that occurs when drugs are applied to the water for transdermal delivery. In recording experiments, focal application onto the head or injections into the brain could minimize adverse effects of chemicals and reduce behavioral changes due to irritant properties of chemicals that could be associated with transdermal

delivery. Developing methods for nicotine-response assays in embedded or suspended larval zebrafish represents the first step towards measuring nicotine-induced neuroadaptations of larval brain activity using methods such as calcium-imaging.

Title: Processing of sensory input by pyramidal neurons in the electrosensory lateral line lobe of the weakly electric fish Apteronotus albifrons

Authors: *D. MARTINEZ, M. CHACRON;
Fac. of Medicine, Dept. of Physiol., McGill Univ., Montreal, QC, Canada

Abstract: One of the main goals of neuroscience is to understand how neuronal activity represents different features of sensory input. Studies have shown that the basic building blocks of the brain are common across vertebrates and that higher cognitive abilities result from more complex connectivity patterns. A comparative approach between species is thus likely to uncover general strategies used by the brain to encode sensory input.
Weakly electric fishes are a diverse group composed of many genera. In particular, species within the *Apteronotidae* genus produce a quasi-sinusoidal electric field through the electric organ discharge (EOD). These fish can detect EOD perturbations caused by prey and/or conspecifics through an array of peripheral receptors that then synapse onto pyramidal neurons within the electrosensory lateral line lobe (ELL). Within the *Apteronotidae* genus, species *Apteronotus albifrons* and *Apteronotus leptorhynchus* are closely related. Indeed, both species have very similar body morphology and almost identical brain anatomy (Maler, 2009). Yet, at the same time, both species display important differences in EOD properties as well as in the structure of electrocommunication signals (Kolodziejski, J et al, 2007). On the one hand, one might expect that both *A. leptorhynchus* and *A. albifrons* use similar coding strategies because of their nearly identical brain anatomy. On the other hand, recent studies have shown large heterogeneities in the physiology of neurons with identical morphology. To answer this, we

recorded the spiking responses of pyramidal neurons within the ELL of *A. albifrons* both in the absence and in the presence of electrosensory stimuli. Our stimuli consisted of both natural (sinusoidal) as well as artificial (noise) stimuli in which we varied first and second-order attributes. A comparison between our results and those obtained previously in *A. leptorhynchus* revealed surprising similarity between ELL pyramidal neural responses to similar stimuli. Our results strongly suggest that both *A. albifrons* and *A. leptorhynchus* employ similar coding strategies and that previously observed differences between communication signals and behaviors are used to distinguish between and con and hetero-specifics.

Title: Dance complexity related to the volume of a sensorimotor region in manakins

Authors: *W. HELMHOUT[1], G. PANO[1], W. R. LINDSAY[2], L. B. DAY[1];
[1]Biol., Univ. of Mississippi, University, MS; [2]Goteborg Univ., Goteborg, Sweden

Abstract: Manakins are a family of birds the males of which use acrobatic, non-vocal display behaviors to attract females to mate. Across the manakin family (Pipridae), species perform displays of varying complexities with variation in the number and type of display sites, acrobatic postures, and number of mechanical sounds. Females of at least one species, select males on the basis of 10s of ms differences in performance of certain male display elements suggesting strong sexual selection. Our lab recently showed a positive relationship between display complexity and brain weight, brain volume, and relative cerebellar volume in manakins suggesting specializations of motor regions might be contributing to species differences in overall brain size. The arcopallium (AP), is another brain region likely to be specialized for complex displays. AP has both motor and limbic functions, and in oscines (songbirds), a specialized portion of the AP, the robust nucleus of the arcopallium (RA), is known to function in song production of vocal courtship displays. Manakins are suboscines that do not appear to have vocal learning or an RA. However, the AP has been shown to be larger in golden-collared manakin males that perform displays, than in females that do not. In addition, the AP in golden-collared manakins contains many androgen receptors, similar to those found in the RA of songbirds; a trait not seen in other

suboscines that do not have complex display. Thus, the AP in manakins is capable of responding to testosterone (T), and because display in manakins in known to be activated by T, the AP could play a role in the courtship behaviors of manakins. Another area, the Nucleus Taeniae (Tn) of the AP, could also be implicated in display complexity. Tn has been shown to have high concentrations of androgen receptors, and though once considered part of AP, it is exclusively limbic and may have distinct function from AP. We compared AP, Tn, and nucleus rotundus (Rt) volume of 12 different manakin species and the closely related ochre-bellied flycatcher; species were chosen for their varying display complexities. The volume of Rt, a visual thalamic nucleus, was used as a control. Marginal means from a general linear model and mean residuals from a least squares regression analysis were used as size adjusted volumes. Adjusted volumes were regressed on complexity using phylogenetic generalized least squares to adjust for relatedness. We found a significant positive relationship between AP volume and display complexity of the manakins' non-vocal courtship behaviors, but no relationship between Tn or Rt and display complexity.

Title: Olfactory navigation in realistic odor landscapes: modeling and simulation of odor localization and path-following strategies in mice

Authors: *J. HENGENIUS[1], N. URBAN[2], B. ERMENTROUT[3];
[2]Dept. of Neurobio., [3]Dept. of Mathematics, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Navigation via chemical gradients is vital for survival and reproduction in motile organisms, but airflow at the spatial scales of animal navigation is dominated by turbulence. The resulting spatiotemporal fluctuations in odor concentrations prevent animals from relying on direct estimation of local odor gradients for directional cues. Despite these fluctuations, animals are observed using robust strategies to localize odor sources in turbulent environments. We consider possible olfactory navigation strategies in mice, an organism widely used in behavioral and neurobiological study of olfaction. Despite a wealth of information about mouse olfaction, the properties turbulent odor environments and their effects on navigation strategies are poorly

understood. Our approach was two-pronged. First, we measured the statistical properties of experimental odor environments using photo-ionization detection (PID) of the odorant methyl salicylate and light sheet imaging of advected particulates. Second, we characterized rule-based navigation algorithms and their performance in simulated odor landscapes of varying complexity. Measured odors exhibited decreasing mean and increasing coefficient of variation with increasing distance from the source, suggesting mice might use sniff concentration and/or sniff-to-sniff fluctuations in concentration to determine their position relative to a source. We therefore evaluated several model classes: (1) binaral, concentration comparison between nostrils, (2) casting, lateral head movement while sampling concentration, (3) intermittency, evaluating time intervals between odor detection events, and (4) hybrid strategies. All models were simulated in spatial arenas containing odorant point sources or trails, with odor environments of varying levels of realism ranging from noise-free static distributions to turbulent landscapes. All four strategies increased mouse dwell times in high concentration regions of the arena relative to random walks, though only binaral and casting models displayed dynamics qualitatively similar to observed mouse behavior. Interestingly, we found that near-source dwell times were increased by odorant noise in the in binaral and hybrid models, suggesting that animals may exploit turbulence to improve odor localization. Additionally, low-pass filtering (via simulated neuronal computation) improved the concentration signal-to-noise ratio in extremely intermittent odor landscapes. These findings provide insight into the role of turbulent flow in olfactory navigation - not only as a source of noise but as a property that improves localization.

Title: Bidirectional manipulation of mTOR signaling reveals complicated contribution to sensory learning

Authors: *S. AHMADIANTEHRANI[1], S. E. LONDON[2];
[2]Psychology, Inst. for Mind and Biol., [1]Univ. of Chicago, Chicago, IL

Abstract: The mechanistic target of rapamycin (mTOR) serine/threonine kinase is a nexus in a complex signaling cascade that regulates protein translation in neurons. Disruption of mTOR signaling is implicated in neurodevelopmental and psychiatric disorders, and is routinely demonstrated to affect learning and memory. We previously reported that in juvenile zebra finch songbirds, mTOR signaling is required for tutor song memorization, the sensory learning foundation of learned vocal communication. In adults, sensory song learning is used for individual recognition, essential for establishing and maintaining mate bonds and navigating the colony community. Both tutor song memorization in juveniles and adult song recognition learning require processing within the auditory cortex. Here, we asked if mTOR signaling is also implicated in adult song recognition learning. We verified that major components of the mTOR cascade are present and phosphorylated in the adult auditory cortex after hearing song. We employed an established paradigm of song recognition learning to assess if mTOR activation is modulated: all birds hear 3hr of "training" song playbacks one day, then either no song (Trained-silence), the same song (Trained-familiar), or a different song (Trained-novel) 24hr later. We measured phosphorylation of the ribosomal protein S6 (pS6), which depends on mTOR activity, as a readout for cascade activation. In unmanipulated birds, we see maximal levels of pS6 in the auditory cortex of birds that hear novel song, low levels in Trained-silence, and intermediate levels in Trained-familiar group. This pattern recapitulates the profile of zenk (zif268, egr-1, ngfi-a, krox24) induction. As zenk is a molecular marker for active learning processes, these data support the conclusion that mTOR signaling contributes to adult song recognition learning. Manipulation of mTOR to decouple song experience from signaling, however, revealed unexpected results. We hypothesized that both constitutive activation and inhibition of mTOR signaling during the training experience would disrupt learning and memory events and transform the molecular signature for familiar song into one that mirrored that of novel song. However, when mTOR was constitutively activated, we found pS6 levels equivalent to that in unmanipulated birds; inhibition decreased pS6 levels to those of Trained-silence birds. In combination with control experiments, these results lead us to suggest the relationships between mTOR and learning and memory may be different in juvenile and adult brain, and reconsider the mechanisms by which learning of ethologically-relevant vocal signals may occur.

Title: An efficient and flexible gene manipulation strategy in zebra finch brain

Authors: *S. E. LONDON[1,2], S. AHMADIANTEHRANI[3];
[1]Dept of Psychology, [2]Inst. for Mind and Biol., [3]Dept of Psychology, Inst. for Mind and Biol., Univ. of Chicago, Chicago, IL

Abstract: The connections between genes, brain, and behavior are fundamental to our understanding of neurobiological processes. Songbird models meaningfully contribute to many fields as the system has great strengths due to its developmental biology, quantifiable behavioral characterization, defined neural circuits for cognition and behavior, sequenced genome, and strong parallels to human speech acquisition. However, likely because of immune system properties, gene delivery strategies commonplace in other systems have been more difficult to implement in songbird brain. We were motivated to develop a reliable, efficient, and flexible strategy to manipulate the genome in brain cells of the songbird in service of directly testing gene-brain-behavior relationships. We therefore adapted in vivo electroporation procedures for use in the early Posthatch zebra finch chick. Briefly, plasmid constructs are infused into the lateral ventricles of Posthatch day 3 (P3) chicks. Paddles placed on the head deliver square voltage pulses that permit plasmids to enter cells along the ventricle. Neuroanatomical specificity is obtained via careful paddle positioning. We use a transposase, also expressed off of a plasmid construct and co-electroporated with the transgene plasmid(s), to integrate transgenes into the genome. We optimized the voltage, duration, and frequency of the pulsing; transposase type; paddle placement; and the age of electroporation. We achieve a high level of survivability (>95%) and efficiency (>60% of ventricular cells express transgenes), stable expression through P50, and neuroanatomical specificity - a large majority (~75%) of transgene-expressing cells were concentrated in the targeted brain region, the auditory cortex. The procedure is effective with multiple constructs co-electroporated. This strategy is therefore appropriate for gene delivery experiments that test circuit and behavioral hypotheses using a variety of manipulations, including gene overexpression or interference including CRISPR editing, inducible technologies, optogenetic or DREADD cellular control, and cell type-specific expression.

Title: Epigenetics of learning in zebra finch

Authors: *D. CONDLIFFE[1], J. GEORGE[1], C. BARTON[1,2], A. LEITAO[2], M. GAHR[2], P. HURD[1], D. CLAYTON[1];
[1]Sch. of Biol. and Chem. Sci., Queen Mary Univ. of London, London, United Kingdom; [2]Max Planck Inst., Institute for Ornithology, Germany

Abstract: Songbirds like the zebra finch (Taeniopygia guttata) communicate through learned vocalizations (songs). In the ascending auditory pathway, neurophysiological discrimination of learned vocalizations is most evident in portions of the caudomedial pallium (the "auditory lobule," AL). Initial exposures to a novel song trigger robust transcriptional changes in the AL, in particular causing a sharp increase in transcription of the EGR1 gene. However, this response habituates when the same song is repeated, suggesting acquisition of a learned memory. As EGR1 encodes a DNA-binding protein, we hypothesized that the EGR1 protein binds to gene targets that are involved in memory formation. Moreover, as EGR1 binding is sensitive to DNA methylation within its binding site, we hypothesized that changes in DNA methylation at EGR1 target sites contribute to the process of habituation. To test these hypotheses, Chromatin Immunoprecipitation for EGR1 was first combined with next-generation sequencing (ChIP-seq) to compare the ALs of adult male zebra finches in two conditions: 1) isolation overnight in silence; 2) hearing a novel song recording. The resulting data identified binding sites of EGR1 throughout the genome and provided evidence for shifts in binding at the time when novel song memories are being formed. In ongoing work, Reduced Representation Bisulfite Sequencing (RRBS) is being performed to identify changes in DNA methylation that may be linked to habituation. This is the first time EGR1 binding has been mapped in zebra finch and the first time DNA methylation has been investigated during song learning in the zebra finch.

Title: CREB-mediated interplay of genes and environment in the postnatal song learning in songbirds

Authors: *K. ABE, D. WATANABE;
Kyoto Univ., Kyoto, Japan

Abstract: The development of behavioural traits in animals is influenced both by intrinsic and extrinsic factors. Vocal communication in humans and songbirds is one of the most prominent of such behaviours. The development of this ability, especially, requires social learning, that is, learning influenced by social interaction, education, or imitation, which enables the cultural transmission of information between generations. Previously, we have generated transgenic songbirds expressing enhanced or suppressed activity of CREB transcription factor. This parctical method to manipulate the genome of songbirds enables us to explore the molecular interdependence between intrinsic and extrinsic factors that influence song acquisition. Here we investigated the relationship between different learning situations and gene expression patterns during the postnatal development of vocal skills in zebra finches (*Taeniopygia guttata*). We found that inadequate song "tutoring" during development reduces the phosphorylation of CREB (c-AMP responsive element binding protein), alters the expression of genes containing CREB-binding elements, and reduces the quality of acquired songs. Transgenic manipulation to suppress CREB activity in zebra finches reduced song quality and auditory memory formation without affecting basal hearing ability or the acoustic quality of calls. Furthermore, although transgenic finches expressing constitutively active CREB were just as apt as wildtype finches to learn songs from a live tutor, in the absence of a live tutor these transgenic finches showed comparatively enhanced song acquisition, suggesting that the augmented CREB activity compensated for the lack of social input. Thus, different forms of transgenic CREB affected song acquisition, depending on the social condition. Our results provide an insight into the molecular mechanisms that determine how social influences affect the postnatal development of learned behaviours.

Abstract: Vocal learning is a rare trait found in at least five mammalian and three independently evolved avian lineages. This trait is crucial for speech in humans, and can be attributed to specialized sensorimotor vocal circuits in the forebrain that possess unique connections compared to their adjacent brain areas. One hypothesis for evolution of vocal learning in vocal learning species are genetic differences that control and maintain the connections of forebrain vocal-motor pathways to brainstem vocal motor neurons. Transcriptome-scale gene expression studies indicate that the human laryngeal motor cortex (LMC), which controls the motor aspects of speech and song, is similar to the robust nucleus of the arcopallium (RA), the song production nucleus of songbirds. More than 55 genes contribute to their shared specialization, including genes that are enriched functionally for axon guidance, with downregulation of *SLIT1* being one of the most specialized. The *SLIT* family of genes acts through receptors of the *ROBO* family and controls commissural axon guidance, cell proliferation, and dendritic branching, among many other similar functions. To test the hypothesis that *SLIT1* gene expression specialization could be responsible for contributing to the specialized connection and thus production of learned vocalizations, we used an adeno-associated virus (AAV1) driven by a Super Core Promoter (SCP) to overexpress the human *SLIT1* gene bilaterally in RA of adult male zebra finches. We found that overexpression of human *SLIT1* caused birds (n = 14) to produce songs with reduced matches to their original song. These changes in song motif were characterized by decreases in overall song similarity of motifs, song accuracy, and song sequential match that reflect changes in temporal structure of songs, due to the birds having reduced stereotyped motif structure. In addition, we observed changes in song acoustic features including higher entropy and goodness of pitch. We did not observe these effects in control (n = 6) birds that received injections of an AAV virus expressing the reporter gene, green fluorescent protein (GFP) in RA. Ongoing experiments are examining the connectivity of the RA song nucleus in the *SLIT1* manipulated birds. Our results suggest that maintained differential downregulation of *SLIT1* in RA of adult birds is at least important to maintaining production of normal songs.

Title: A comprehensive profiling of differential gene expression specializations in the song system of a vocal learning songbird, Taeniopygia guttata.

Authors: *G. GEDMAN[1], A. PFENNING[2], J.-N. AUDET[3], J. PALPENT[1], E. D. JARVIS[1,4]; [1]Duke Univ., Durham, NC; [2]Computat. Biol., Carnegie Mellon Univ., Pittsburgh, PA; [3]Biol., McGill Univ., Montreal, QC, Canada; [4]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Vocal learning is a rare and complex behavior seen in three to four independent lineages of birds and mammals, including in humans, which we use for speech and song. Among these avian lineages, the songbird has been the best studied. Their vocal learning circuit consists of an anterior forebrain pathway (AFP) containing pallial LMAN and striatal Area X nuclei involved in song learning, and the posterior forebrain pathway (PFP) containing pallial nuclei HVC and RA involved in song production. Analogous brain regions have been proposed for human speech, and recent transcriptomic analysis using microarrays suggests further convergence at the level of gene expression for the RA and Area X song nuclei to the human laryngeal motor cortex (LMC) and anterior striatal speech area respectively. HVC and LMAN did not exhibit significant convergence in gene specializations to speech regions in the human brain. These lack of molecular parallels may be attributed to not having profiled the surrounding cell populations, limited genes on microarrays, the computational tools used, or that parallels don't exist. Here, in an attempt to gain a more comprehensive view of the gene expression specializations necessary for vocal learning brain regions, we conducted RNA-seq transcriptome experiments of all four major song nuclei and the surrounding cell populations of the zebra finch. Brain regions were microdissected and RNA was sequenced using Illumina paired-end sequencing. We found that all nuclei exhibited more genes downregulated relative to their surround, suggesting that song nuclei develop with fewer of their respective pallial/striatal genes. Only 20 genes were similarly specialized in all song system nuclei, involved in a range of biological processes, including axon guidance, calcium signaling, and angiogenesis. LMAN had the lowest amount (233) of specialized genes, enriched for long-range projection development. HVC had the most (1172) specialized genes, enriched in cell signaling and nervous system development. Area X also had a large set of genes (946) specialized, enriched in neurogenesis and developmental functions. RA had an intermediate number (513) of specialized genes, enriched in angiogenesis and projection formation. Of the 55 genes found to be convergent

between songbird RA and human LMC in microarray experiments, 21 emerged in our RNA-seq dataset, including the axon guidance gene SLIT1. We plan to use these data in future comparisons to human cell type specific expression data to elucidate vocal learning analogs between humans and songbirds.

Title: Transcriptome profiling of the vocal nuclei in zebra finches (T. guttata) reveals molecular specializations of neural circuits for the production of learned song

Authors: *S. FRIEDRICH, P. V. LOVELL, C. V. MELLO;
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Vocal learning is a behavioral trait that enables animals to acquire vocalizations through imitation. This rare trait is prevalent in songbirds and is subserved by a set of interconnected brain nuclei that control and coordinate vocal and respiratory organs. The connectivity and physiology of these vocal control nuclei have been extensively studied in songbirds, and in particular in zebra finches (*T. guttata*). In contrast, even though there has been some progress in examining gene expression profiles of vocal nuclei, our understanding of their molecular organization and specializations is still limited. Previous efforts using cDNA (Lovell et al., 2008) and short oligo microarrays (Hilliard et al., 2012; Hara et al., 2012; Whitney et al., 2015; Pfenning et al., 2015) have identified differentially expressed transcripts in several zebra finch vocal nuclei, including HVC, RA, and nXIIts of the direct vocal motor pathway, and striatal area X within the anterior pathway for vocal plasticity. However, these reports were mainly focused on identifying differentially expressed transcripts that are convergently shared with other avian vocal learning groups (i.e. parrots and hummingbirds) and with humans. Here we report a detailed and extensive transcriptome profiling analysis of these vocal nuclei in zebra

finches, based on a reanalysis of publically available microarray data from the Mello, Jarvis, and White labs. Our efforts include a comprehensive genome-based curation and annotation of oligo arrays from the Jarvis lab, the identification of possible transcript variants that may explain some of the expression profiling variability, and the definition of reliable significance cut-off based on the use of confirmatory in situ hybridization data derived from the ZEBrA online database (www.zebrafinchatlas.org). Bioinformatics analyses reveal evidence for the differential regulation of numerous genes that are involved in neuronal excitability and plasticity (e.g. ion channels, transmitters, neuromodulators, and their receptors), as well as circuit connectivity (e.g. axon guidance cues). These findings provide novel insights into molecular specializations of vocal control circuits in finches, identify candidate pathways related to patterns of connections between vocal nuclei, and point to candidate target genes for further mechanistic and regulatory studies.

Title: Comparative transcriptomics of vocal nuclei of Anna's hummingbirds and zebra finches reveal convergent and group-specific molecular features of vocal learning circuits in hummingbirds and songbirds

Authors: *P. V. LOVELL, M. WIRTHLIN, C. V. MELLO;
Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: Vocal learning is a rare behavioral trait that enables animals to acquire their vocal repertoires though imitation, providing a substrate for speech and language development in humans. Among birds, recent phylogenomics studies have helped establish that vocal learning evolved independently at least twice, namely in hummingbirds and in songbirds/parrots (the latter now being considered sister taxa with the trait likely originating in a common ancestor). Identifying features of the vocal learning circuitry that may have evolved convergently across these avian vocal learner groups offers unique opportunities for identifying fundamental requirements and principles associated with this trait. With this goal in mind, we have analyzed the transcriptomes of key vocal nuclei that are present in the Anna's hummingbird, a known

vocal learner, in comparison with analogous nuclei in zebra finches, a songbird species and a model organism for vocal learning research. We focused on identifying transcripts that are differentially expressed in the three primary nuclei of the direct vocal control pathway, namely HVC, RA, and nXIIts (data for the latter two nuclei were made publically available by the Jarvis lab). Because samples from the Anna's hummingbird were cross-hybridized to oligo-based (Pfenning et al., 2014) and cDNA-based microarrays (Lovell et al. 2008) that were specifically developed for zebra finches, several preparatory steps had to be applied, including a careful curation of oligo and EST sequences in the context of cross-alignments to the Anna's hummingbird genome, and an analysis of splice variants contributing to array signal variability. Our analysis has revealed several hundred transcripts that are significantly up- or down-regulated in all three nuclei compared to adjacent brain tissues. Intriguingly, while a subset of these transcripts appear to be unique to the Anna's vocal control system, and thus may reflect properties unique to vocal learner hummingbirds, other subsets were shared with zebra finches and may reflect more broadly required features of vocal learning systems. Of interest, both shared and unique subsets include genes involved in several aspects of neuronal structure and physiology, including ion channels, neurotransmitter receptors, modulators of synaptic structure and function, and modulators of long-distance connectivity. Together, these findings shed light on possible constraints on the evolution of avian vocal learning circuits that may reflect fundamental requirements of vocal learning systems. They also identify genes that represent choice candidate targets for mechanistic studies involving gene manipulation.

Title: Identification of candidate gene regulatory sequence elements associated with the emergence of vocal learning in songbirds

Authors: *M. WIRTHLIN, P. V. LOVELL, C. V. MELLO;
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: How does a novel behavior evolve at the level of the genome? The occurrence of novel genes, as well as mutations in protein-coding sequences that alter gene function, have been demonstrated in the genomes of vocal learning songbirds compared to vocal non-learner outgroups (Wirthlin et al, 2014). However, such events are rare, and do not sufficiently explain the emergence of specialized brain nuclei for the acquisition and production of learned vocal behavior. In contrast, the anatomical, molecular, and physiological properties of these specialized nuclei have been linked to drastic changes in the expression of pre-existing genes. These changes in gene expression are thought to be the result of changes in cis-regulatory elements associated with these genes. However, identifying the critical regulatory sequences underlying the expression of genes in specific brain regions remains a fundamental challenge in neurogenomics. In order to identify the changes in regulatory sequence that may be associated with the emergence of vocal learning circuits, we developed a pipeline for comparative brain-expressed gene promoter analysis. We used multiple expressed sequence databases to annotate transcriptional start sites in the reference genome of a model vocal learning species, the zebra finch. We next identified transcription factor binding site motifs that are enriched in the promoters of genes selectively expressed in vocal control nuclei, which are present only in vocal learning species - these were considered candidate vocal learning regulatory motifs. We then identified orthologous promoters in additional high quality avian genomes, and determined which candidate motifs were enriched only in orthologous promoters in songbirds, versus those that had preadapted in non-learner lineages. We discuss the most promising regulatory motifs identified and their putative target gene networks in the context of their known biological functions, and highlight examples of genes that could subserve the known molecular and physiological properties of brain nuclei critical for learned vocal behavior. These analyses provide a framework for understanding how shifts in gene regulatory sequence composition could lead to the emergence of vocal learning circuits. They also provide a general roadmap for integrating knowledge from genomics, gene expression analysis, neuroanatomy, physiology, and phylogenetics to provide novel insights into the evolution of behavior.

Title: An update and new applications of the zebra finch expression brain atlas (www.zebrafinchatlas.org)

Authors: *C. V. MELLO, P. V. LOVELL;
Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: The Zebra finch Expression Brain Atlas (ZEBrA; www.zebrafinchatlas.org) is a publicly accessible online resource for investigating the brain distribution of genes involved in the physiology, development, and maintenance of functional circuits in the brain of songbirds. It consists of a comprehensive in situ hybridization database representing the expression patterns for a large set of transcripts in brain of adult male zebra finches (*T. guttata*), a representative songbird species. Its major features include: (1) The In situ database - a collection of high-resolution (0.46 μm/pixel) digital images presented along with annotated drawings from a reference Histological Atlas. ZEBrA currently houses more than 2,000 images (>100 GB) corresponding to ~500 brain expressed genes, including markers of all major nuclei that comprise the song system. (2) A reference Histological Atlas Browser - A set of 18 annotated drawings prepared in registration with Nissl- and Myelin-stained images of sagittal brain sections derived from the Karten/Mitra atlas. (3) A Gene Family Search Tool - A feature that facilitates searches for genes based on their membership in specific gene families. (4) A Neuroanatomical Marker Search Tool - A search engine that allows users to retrieve a list of genes that are markers of a given structure, or of multiple structures. Recent applications of ZEBrA include: (1) utilizing the comprehensive in situ database to validate and establish cut-off criteria for transcriptomics experiments utilizing laser capture microdissections and microarrays; (2) performing quantitative analysis of regional gene expression patterns to identify molecular signatures of specific brain areas in zebra finches; (3) obtaining evidence of heterogeneity of cellular patterns of gene expression as a basis for cellular phenotyping within vocal control nuclei; (4) utilizing the ZEBrA platform and its embedded features as a resource that can be adopted by individual labs for cataloguing, storing, and accessing high resolution brain gene expression data.

Title: Egg laying male has androgynous song system

Authors: *J. A. HOWELL, N. WEBB, R. PEREZ, A. HRIBAR, L. DAY;
Univ. of Mississippi, University, MS

Abstract: Zebra finch sexes differ in plumage, song nuclei, and behavior. The effects of sex chromosome genes, autosomal genes, and hormones to sexual differentiation are not completely understood. Unusual birds that have both male and female traits help us understand sexual differentiation. A "chimera" in our aviary had male plumage and a male partner, laid eggs, and produced viable offspring. Using mate preference tests we found that the chimera and its lineage were less preferred as mates than controls, suggesting differences making them unattractive to other birds in the aviary. Males of the chimeric lineage also had greater same-sex mate preferences than control males; chimeric lineage and control females did not differ. Sampling blood, eggs, gonads, sexually dimorphic feathers and skin, beaks, and hearts, all chimeric tissues have ZW female chromosomes. Thus, only the plumage of the chimera suggested any abnormalities. To compare the song system of the chimera to males and females, brain tissue of the chimera, male partner, and a female control was cut at 30 μm, and every third slice was mounted for Nissl staining. We measured volume, cell number, and cell size of three sexually dimorphic song nuclei. The proportions for male to female were consistent with other studies. Our chimera is between the two. For instance, male:female ratio for RA is ~5.74. Our male:female RA ratio is 4.81 and male:chimera RA ratio is 1.30. For LMAN, the male:female ratio is 5.10 and male:chimera ratio is 1.83. HVC could not be seen in the female due to errors in coverslipping, but the male:female HVC ratio is ~6.20. Our male:chimera HVC ratio is 1.74. Area X is prominent in male zebra finches but does not appear in females. However, we have identified a putative X in our chimera. We will use other X markers to verify this. In HVC, RA, and LMAN, the cell number and relative volume tended to be doubled in the male compared to the chimera, but quadrupled in the male compared to the female. Cell soma size was similar for the male and chimera for HVC. For LMAN, soma size ratios were 1.73 for male:chimera and 1.43 for male:female. Other males and females will be measured to determine where the chimera is in the standard male/female range for these measures. These results suggest that although the chimera had a full female genotype, it had a partially masculinized song system. We will be analyzing video recordings of the chimera and its mate to find out if the chimera produced song and to observe nesting and mating behaviors. Other studies with a similar chimeric bird, with male plumage and a female reproductive system, had a fully female song system suggesting multiple pathways for some shared phenotypic traits.

Title: Expression of lipoprotein receptor-related proteins (LRPs) in brain of zebra finches: possible links to VSVg-pseudotyped viral infectivity

Authors: *T. VELHO[1,2], P. V. LOVELL[3], M. WIRTHLIN[3], C. LOIS[1], C. V. MELLO[3]; [1]Biol. and Bioengineering Dept., CALTECH, Pasadena, CA; [2]Brain Inst., Federal Univ. of Rio Grande do Norte, Natal, Brazil; [3]Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Low-density lipoprotein receptor (LDLR) is thought to be the primary receptor through which viral particles pseudotype with the vesicular stomatitis virus glycoprotein (VSVg) gain entry into cells. The lipoprotein receptor-related proteins (LRPs) appear to function as alternate, secondary receptors for the same VSVg. Intriguingly, VSVg-pseudotyped lentiviral infectivity in songbirds, such as the zebra finch, appears to be much less efficient when compared to mammals, as reflected in a smaller percent of infected cells upon lentiviral injections into different tissues, including the brain. To investigate whether the empirical species differences in infectivity levels are due to biological differences in receptor expression, we set out to examine the zebra finch orthologs of LDLR and LRPs to determine their expression levels in the brain. Intriguingly, comparative genomics analysis indicates that the zebra finch LDLR is highly divergent and truncated compared to orthologs in both chicken and mammals, and is possibly pseudogenized. We have also identified at least 10 distinct LRP genes in the zebra finch genome, which in constrast with LDLR show a high degree of sequence conservation when compared to mammalian orthologs. Of these, we have successfully examined the brain expression of 8 genes by in situ hybridization, and found convincing evidence for brain expression for 6 finch LRPs, with varying levels or degrees of cellular and regional specificity. In particular, LRP1 nad LRP8 show robust brain expression, and the relative distribution of labels cells suggest the possibility that their expression may be restricted to specific cell types. Studies are currently underway to assess whether distinct cell types in the songbird brain (e.g. GABAergic vs Glutamatergic) express unique combinations of LRPs, and to further address the possibilitiy that one or more LRP may be critical for mediating VSVg-dependent viral infectivity in finch brain tissue.

Title: Robust male-specific expression of the UTS2B gene emerges early in the development of a zebra finch forebrain vocal control nucleus

Authors: *Z. W. BELL, J. M. GEORGE, D. F. CLAYTON;
Sch. of Biol. and Chem. Sci., Queen Mary, Univ. of London, London, United Kingdom

Abstract: The UTS2B gene encodes an octapeptide, which is highly expressed in the spinal cord and brainstem of mammals, with functional studies focusing mainly on vasoregulation. Unexpectedly, several transcriptomic analyses have suggested that UTS2B is expressed in or around parts of the songbird brain involved in vocal communication and perception. The objective here was to use *in situ* hybridization to localize the expression of UTS2B in the zebra finch brain. As in mammals, the mRNA was detected in brainstem nuclei. However, it was also detected in cells scattered throughout the forebrain, with a striking concentration of cells specifically within the song control nucleus HVC. Concentrated expression in HVC was observed only in males, and was already evident at 15 days post-hatch, well before the functional maturation and sexual differentiation of the song control circuit. The expression showed no noticeable *diel* changes or activity dependence. HVC is a key part of the telencephalic song control circuit, which is unique to oscine songbirds. Thus evolution of the song control circuit may be linked to genomic changes that expanded the expression of UTS2B into the forebrain, especially into HVC. While the functional significance of this remains unknown, it suggests a potentially broader role for UTS2B in the evolution and control of complex behaviours.

Title: Reelin signaling in the basal ganglia: striatal, pallidal, or both?

Authors: *E. FRALEY[1], P. E. PHELPS[2], S. A. WHITE[2];
[1]UCLA, Santa Monica, CA; [2]UCLA, Los Angeles, CA

Abstract: The aim of this investigation is to determine how Reelin signaling influences basal ganglia function, with a focus on vocal communication. Like human speech, birdsong is a learned vocal behavior. We previously established that, like the human speech-related transcription factor FoxP2, members of the Reelin-signaling pathway are also regulated by singing behavior. This behavioral driven regulation is particular to the striato-pallidal song nucleus, area X. Reelin signals through high affinity receptors appolipoprotein receptor 2 (Apoer2) and very-low density lipoprotein receptor (Vldlr) to initiate phosphorylation of the intracellular signaling molecule Disabled-1 (Dab1). Reelin signaling has established roles in regulating neuronal migration and modulating dendritic morphology and plasticity. To dissect which cells express what components of the Reelin-signaling pathway, we drew from our cross-species investigation of the murine basal ganglia. In mice, we identified cells in the globus pallidus that express Dab1 and cells in the anterior striatum that express Reelin. We then hypothesized that pallidal cells in zebra finch area X would also be Dab1 positive. Indeed, using co-immunostaining and tracing techniques we have now identified Dab1 positive cells in area X that are pallidal. Additionally, the wide expression of Vldlr includes both striatal and pallidal cells in area X. We thus conclude that Reelin signaling is likely to not only influence cortico-striatal synapses, but also the striato-pallidal synapses; thereby impacting output of area X to the downstream thalamic nucleus in the zebra finch song control circuit. Activity-dependent enhancement of dendritic morphology of subsets of cells in both striatum and pallidum may thus be mediated by Reelin signaling. This phenomenon may not be exclusive to the zebra finch, and we suggest a striato-pallidal Reelin signaling mechanism exists in the mouse; although vocal regulation of gene expression changes in this species has yet to be determined.

Title: FoxP2 overexpression coupled with auditory deprivation in adult zebra finches disrupts molecular microcircuitry in a song-dedicated basal ganglia nucleus

Authors: *N. F. DAY[1], Z. D. BURKETT[1], A. T. HILLIARD[2], X. XIAO[1], S. A. WHITE[1]; [1]Integrative Biol. & Physiol., Univ. of California Los Angeles, Los Angeles, CA; [2]Dept. of Biol., Stanford Univ., Palo Alto, CA

Abstract: Human mutations in the FOXP2 transcription factor result in language disorders and altered basal ganglia structure. The neural underpinnings of speech learning can be investigated in songbirds because, like speech, birdsong is learned through social interactions, relies on auditory feedback and cortico-basal ganglia circuitry, and compensates for experimentally-induced errors. In the songbird brain, most FoxP2-enriched areas (e.g. cortex, thalamus) show a static expression level, whereas Area X (a song-dedicated basal ganglia nucleus), shows dynamic regulation: *FoxP2* mRNA and protein decrease when juvenile and adult males sing, after which songs are more variable. This 'on-line' regulation during singing is critical for song learning, but the role of FoxP2 in the active maintenance of a learned vocal motor skill is poorly understood. What is known includes that auditory feedback is crucial for the learning and the maintenance of song and speech, because deafness in adulthood causes both to deteriorate. In songbirds, hearing and FoxP2 are linked: The more a bird hears itself practice, the lower its Area X FoxP2 levels; no such correlation is observed in deaf birds.

To investigate the post-developmental role of FoxP2 in adult zebra finches, we used an adeno-associated virus (AAV) to constitutively augment levels of FoxP2 in Area X to test whether song maintenance and gene networks in the mature organism are altered. Birds were injected with either GFP- or FoxP2-overexpressing AAV constructs; a subset of each group were then deafened. We examined the syntactical and phonological changes that accompany auditory deprivation following FoxP2 (or GFP) overexpression. We then performed RNAseq on tissue punches of Area X from these same birds and conducted Weighted Gene Co-Expression Analysis (WGCNA). Gene networks were correlated to song behaviors to determine suites of genes that are regulated by singing, auditory state, or overexpression of two FoxP2 isoforms. These analyses provide clarification of FoxP2 targets within the basal ganglia. They also reveal changes to the 'molecular microcircuitry' of Area X that occur when behavior-driven cycles of

FoxP2 are interrupted by overexpression and/or after prolonged auditory deprivation. Elucidation of these molecular events will launch novel investigations into genes or regulatory pathways that are critical for the ongoing maintenance of a procedurally-learned task that underlies human speech and language.

Title: FoxP2 isoform-specific overexpression in juvenile zebra finches alters transcriptional networks underlying learned vocalization.

Authors: *Z. D. BURKETT[1,2], N. F. DAY[1], A. T. HILLIARD[4], J. B. HESTON[3,1], X. XIAO[1,2], S. A. WHITE[1,2,3];

Abstract: The transcription factor FoxP2 is necessary for proper development of learned vocalizations in humans and songbirds. In the zebra finch, FoxP2 is dynamically downregulated in the basal ganglia song control nucleus Area X during vocal practice in juvenile and adult birds. When this behavioral downregulation is blocked during vocal learning by knockdown or overexpression of FoxP2, adult vocalizations are similarly poor. This suggests that behavior-linked cycling of the molecule is critical for learning. In addition to the 'full-length' isoform, a truncated version of FoxP2 that is capable of dimerizing but incapable of binding to DNA exists in both humans and zebra finches. This isoform perhaps functions as a post-translational regulator of other FoxP2 isoforms, though its role in vocal learning has been uninvestigated. Using viral vectors, we overexpressed the full-length or truncated isoforms of FoxP2 in Area X during vocal learning. We observed alterations to the birds' vocal phenotypes specific to the overexpressed isoform. The data replicate our prior findings for the full length FoxP2, provide

new insight regarding the truncated isoform, and indicate that the dynamic regulation of each isoform contributes uniquely to vocal learning and variability. We then performed RNA-sequencing and weighted gene coexpression network analysis on Area X micropunches from these animals to understand how dysregulation of these isoforms and their concurrent changes in vocal behavior are reflected in the transcriptome.

Title: Attenuated expression of contactin associated protein-like 2 in a primary motor nucleus of the song system impairs vocal imitation

Authors: *S. A. WHITE[1], Q. CHEN[2], Y. MAI[2], M. C. CONDRO[2], S. C. PANAITOF[3]; [1]Integrative Biol. & Physiol., Univ. of California Los Angeles, Los Angeles, CA; [2]Univ. of California, Los Angeles, CA; [3]Univ. of Nebraska, Kearney, CA

Abstract: Human mutations in contactin associated protein-like 2 (CNTNAP2) are associated with cortical dysplasia-focal epilepsy, autism spectrum disorder, and specific language impairment. Across these diffusely debilitating disorders, deficits in speech and language are a common theme. Songbirds are useful models for the study of human speech disorders due to the significant similarities between the learning of song and speech. The laryngeal motor cortex, a language control region in the human brain shares striking genetic and anatomical similarities with the robust nucleus of the arcopallium (RA), the primary vocal control nucleus in songbird cortex. These include shared gene expression profiles and direct cortical projections onto the motor neurons that control the muscles of phonation. In the zebra finch (*Taeniopygia guttata*), song learning and the underlying neural circuitry are sexually dimorphic; males, but not females, learn their courtship songs using an interconnected set of song-dedicated brain regions. Within RA, Cntnap2 expression becomes sexually dimorphic during the sensorimotor phase of song learning: Males retain high levels whereas expression declines in females. Interestingly, the

divergence in expression appears due to the shorter isoform of this neurexin-like protein. To begin to assess the role of Cntnap2 specifically in vocal learning, here, we developed RNAi constructs to attenuate levels of both long and short zebra finch Cntnap2 isoforms. After confirming the knockdown effect in a human cell line and in primary cultures of zebra finch telencephalon, we stereotaxically injected an adeno-associated virus (AAV) bearing the RNAi constructs in vivo into RA at the onset of sensorimotor learning. Pupils who received the targeting RNAi failed to accurately imitate their tutor's song, omitting a higher percentage of syllables compared with siblings who received a non-targeting construct. The targeting RNAi did not interfere with the pupil's ability to modify its own song over the course of sensorimotor learning. Sholl analysis revealed that attenuation of Cntnap2 altered dendritic morphology of RA neurons, providing a possible mechanism underlying the vocal deficits. These results suggest that among Cntnap2's many functions within the nervous system, its expression within the cortical vocal control region alone is critical for accurate vocal imitation.

Title: Accumulation of singing experience regulates the critical period of vocal plasticity during birdsong active learning

Authors: *S. HAYASE, M. KOBAYASHI, E. OHGUSHI, K. WADA;
Hokkaido Univ., Sapporo/Hokkaido, Japan

Abstract: Motor learning processes, such as human language acquisition or birdsong learning, require repeated and voluntary practice during a critical period in ontogeny. During these motor learning processes, it remains unclear how the critical period is regulated. Past studies shed light on the effect of "passive" experience, *i.e.* reception of sensory stimuli, on the regulation of critical periods in sensory systems. To reveal the contribution of "active" motor experience for the critical period of motor learning, we focused on songbirds, which possess an analogous vocal system to human and learn a song in juvenile stage. In the song system of songbirds, a number of neuroplasticity-related genes are induced by singing behavior. *Arc*, a neuroplasticity-related IEG,

was strongly induced by singing in juveniles than adults in pallial nuclei RA in the song system; an analogous region to motor cortex layer V in mammals. This suggests a potential effect of singing experience-dependent and brain region-specific motor-driven genes on the regulation of the critical period of vocal learning. Then, we inhibited the singing behavior of juveniles until maturity to suppress singing-driven IEGs induction and examine the effects on vocal development. The singing-inhibited birds produced highly plastic vocal patterns at adult stage, while the dendritic spine density in RA projection neurons showed juvenile-like values, indicating that the accumulation of singing-experience, not aging, is crucial for regulation of vocal plasticity. To elucidate the molecular mechanisms underlying such accumulation of singing-experience in the vocal system, we performed RNA-seq and co-expression analysis in RA on a genome-wide scale. As a result, a total of 126 motor-driven genes were regulated by the accumulation of singing-experience, including epigenetic regulators. These genes were strongly induced by singing in RA of juveniles and singing-inhibited birds but not in freely singing adults. In addition, the vocal learning ability of singing-inhibited birds was preserved. These results suggest that a set of motor-driven IEGs engages as a count accumulator of voluntary singing experience to coordinate the critical period of vocal learning.

Title: Vocal combinatorial behavior in rats

Authors: ***T. RIEDE**, C. HERNANDEZ, M. SABIN, H. BORGARD;
Midwestern Univ., Glendale, AZ

Abstract: The coordination between breathing and laryngeal motor control is critical for normal vocal production, including ultrasonic vocal behavior in laboratory rats. Features of fundamental frequency of ultrasonic calls depend on specific activity patterns of intrinsic laryngeal muscles and muscles contributing to the build- up of subglottal pressure. Rats concatenate different call types of their 50-kHz repertoire into single utterances, i.e. calls are produce in short succession during the same breathing cycle. We now describe how rats also combine and recombine 22-kHz and 50-kHz calls into single composite calls. Twentytwo-kHz and 50-kHz ultrasonic calls are well-characterized different call types, yet they are sometimes concatenated into one breath and are part of the same call. The 22-50 composite calls were found in males during the initial

encounter with a female. The finding demonstrates the existence of a flexible laryngeal-respiratory coordination in rats. Combining two calls either into a single breath or into two subsequent breathing cycles has consequences for vocal activity and possibly the function of vocal signals.

Title: Male mice emit ultrasonic vocalizations during agonistic interactions

Authors: D. T. SANGIAMO, M. R. WARREN, X. ZHONG, *J. P. NEUNUEBEL; Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: In the animal kingdom, innate social behaviors play a crucial role in survival and reproduction. For example, agonistic behaviors between two males such as fighting and chasing shape the formation of hierarchies, which allows the dominant male to access food, territory, and females (Dewsbury, 1982). In mice, agonistic behaviors are accompanied by ultrasonic vocalizations (USVs) (Gourbal et al., 2004) although some reports suggest that USVs are only produced during reproductive behaviors (Whitney et al., 1973). Conflicting evidence as well as limitations in the ability to determine which mice are vocalizing in a social context makes the relationship between aggressive behavior and USVs unclear. To address this problem, a microphone-array based system was used to triangulate the location of USVs from groups of freely interacting mice (6 groups of 2 males and 2 females; 12-21 weeks old B6.CAST-Cdh23Ahl+/Kjn) and assign the vocalizations to specific animals. A total of 108,213 vocalizations were detected with 37.4% assigned to specific mice. Males produced 81.6% of the assigned vocalizations and 18.4% were emitted by females. To examine the relationship between aggressive behavior and USVs, a machine based-learning program was used to determine when males were chasing and fighting each other (Kabra et al., 2012). There were 411 fights detected (mean duration = 3.44 seconds; SEM = 0.13). In every experiment, each male chased the other male (n = 723; mean duration = 1.06 seconds; SEM = 0.03). The male vocalization rate was examined before, during, and after fights and chases. For fights, the vocalization rates were significantly different between each of the three periods (mean vocalization rate before = 1.32 Hz; SEM = 0.11; during = 1.77; SEM = 0.10; after = 0.74; SEM = 0.09; 1-way ANOVA, $F_{2,1230}$= 27.0, $p < 10^{-11}$). Male mice vocalized at a higher rate during fights than before or after fighting

(Tukey-Kramer; before, $p < 0.005$; after, $p < 10^{-9}$). In addition, males vocalized at a higher rate before fights than after them (Tukey-Kramer; $p < 10^{-4}$). Male vocalizations were observed before, during, and after chases (mean vocalization rate before = 1.19 Hz; SEM = 0.08; during = 0.99; SEM = 0.07; after = 1.15; SEM = 0.08); however, there were no significant differences between the periods (1-way ANOVA; $F_{2,2166} = 2.0$; $p = 0.13$). These results show that male mice vocalize during their agonistic interactions in competitive living conditions. In the future, our work will focus on classifying more aggressive behaviors and looking at whether specific types of vocalizations co-occur with specific aggressive behaviors.

Title: Sex differences in the acoustic structure of mouse ultrasonic vocalizations

Authors: M. S. SPURRIER[1], *E. ROTH[2], M. R. WARREN[1], J. P. NEUNUEBEL[1];
[1]Dept Psychological and Brain Sci., [2]Dept Neurobiol, Univ. of Delaware, Newark, DE

Abstract: During social interactions, mice produce ultrasonic vocalizations (USVs) (Sales, 1972). These vocalizations are primarily attributed to males when they interact with a female (Whitney et al., 1973; Warburton et al., 1989), although evidence shows that vocalizations are emitted when two female mice interact (Maggio and Whitney, 1985; Moles et al., 2007). Recently, work from Neunuebel et al. (2015) indicated that male and female mice housed in large, mixed sex groups vocally interact during courtship; however, it is unknown if female mice vocalize in the presence of males during dyadic interactions. This gap in knowledge exists because prior research was unable to identify which mouse was vocalizing during social interactions. To overcome this challenge, we used an 8-channel microphone-array based system to record vocalizations and behavior from freely interacting dyads of male and female mice for 30 minutes (9-21 weeks old B6.CAST-Cdh23Ahl+/Kjn mice). Thirty minutes prior to the start of the recording session, non-invasive lavage and cytological assessment of vaginal cells were performed. Sexually experienced female mice in estrus were randomly paired with novel, yet sexually experienced male mice. A total of 41,436 vocalizations were detected (median = 5,390; IQR = 1,459-5,710) with 41.8% assigned to specific mice. For the assigned vocalizations, 85.1% were male and 14.8% were female. Although both sexes vocalized, male mice vocalized

significantly more than females (median male count = 1,966; IQR = 575-2,141; median female count = 294; IQR = 71-372; Mann-Whitney U-test, $z = 3.0$, $p < 0.005$). Next, we investigated potential sex differences in vocal production by calculating the duration, bandwidth, and pitch of the vocalizations. When comparing the duration of male and female vocalizations, no difference was detected (median male = 17.4 msec; IQR = 12.9-27.5; median female = 18.1; IQR = 13.2-27.3; Mann-Whitney U-test, $z = -1.6$, $p = 0.11$). In contrast, the bandwidth of vocalizations was significantly larger for males than females (median male = 10.1 kHz; IQR = 6.8-14.8; median female = 7.5; IQR = 5.7-10.9; Mann-Whitney U-test, $z = 20.0$, $p < 10^{-88}$). This resulted from male mice vocalizing at considerably higher frequencies than females (median male = 79.1 kHz; IQR = 71.6-83.8; median female = 75.6; IQR = 69.1-83.2; Mann-Whitney U-test, $z = 9.2$, $p < 10^{-19}$), since there was no difference between low frequencies (median male = 65.6 kHz; IQR = 60.9-72.6; median female = 65.8; IQR = 60.1-73.2; Mann-Whitney U-test, $z = -1.5$, $p = 0.14$). These results reveal sex differences in the acoustic structure of vocalizations recorded when pairs of male and female mice socially interacted.

Title: Direct quantification of a social communication deficit in a mouse model of autism

Authors: ***M. R. WARREN**, J. P. NEUNUEBEL;
Univ. of Delaware, Newark, DE

Abstract: Autism is a behaviorally defined disorder characterized by social impairments and vocal deficits. A number of mouse models of autism exist that exhibit these symptoms (Bader et al., 2011; Tania et al., 2013), but a comprehensive understanding of the impairments has been hampered by the inability to localize vocalizations to a particular mouse as animals freely interact in complex, dynamic social contexts. To address this, a sound source localization system was used to simultaneously record video and audio from groups (2 males and 2 females, 8-12 weeks of age) of mouse models of autism (Cacna1c<tm2ltl>/J, n=6), as well as their wild-type littermates (n=5) over a period of five hours. Social interactions were quantified by calculating the total duration each animal spent near another animal over 20 minute intervals. We showed that male Cacna1c mice spent significantly less time interacting with their male counterparts as

compared to their wild-type littermates (2-way ANOVA, $F_{1,14} = 3.2$, $p<10^{-3}$). Moreover, for both groups the interactions significantly decreased over time ($F_{1,14} = 25.2$, $p < 10^{-3}$). When two females interacted, no differences in time (2-way ANOVA, $F_{1,14} = 0.7$, $p = 0.74$) or genotype ($F_{1,14} = 3.0$, $p = 0.09$) were observed between the Cacna1c and wild-type mice. To assess the interplay between social behavior and vocalizations, we analyzed the vocal activity of two mice while they were socially interacting. We discovered that the vocal activity was considerably lower in the Cacna1c mice than in wild-type animals. For both the Cacna1c and wild-type animals, the vocal activity decreased over time (2-way ANOVA, $F_{1,14} = 5.2$, $p < 0.03$; $F_{1,14} = 7.6$, $p < 10^{-10}$). The vocal activity of the females during their interactions was significantly lower in the Cacna1c mice compared to wild-type mice (2-way ANOVA, $F_{1,14} = 9.3$, $p < 0.003$); however, there was no difference over time ($F_{1,14} = 0.6$, $p = 0.88$). To investigate potential deficits in vocal exchanges for both males and females, we compared the number of social interactions where both animals vocalized. There were notable differences between Cacna1c and wild-type mice (males; $\chi^2 = 83.5$; $p < 10^{-10}$; females; $\chi^2 = 29.6$; $p < 10^{-7}$). For the male mice, wild-type animals jointly vocalized in 23.9% of the social interactions compared to 16.2% for Cacna1c mice. Cacna1c and wild-type females jointly vocalized in 2.8% and 5.4% of their interactions, respectively. By tracking the vocal behavior of individual mice as they interacted, we revealed a striking communication deficit in a mouse model of autism.

Title: Dopaminergic mechanisms of vocal communication in prairie voles

Authors: ***M. L. GUSTISON**[1], N. NEVÁREZ[1], M. SEHRSWEENEY[2], M. WYBRECHT[1], I. K. WOHL[1], E. E. WRIGHT[1], B. J. ARAGONA[1];
[1]Psychology, [2]Ecology and Evolutionary Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: The two distinct families of dopamine (DA) receptor systems within the nucleus accumbens (NAc) shell, the D1- and D2-like receptor systems, differentially mediate the formation of pair bonds in prairie voles. Specifically, activation of D2-like receptors facilitates pair bond formation whereas D1-like activation prevents this behavior. Functionally, however, it

remains unclear how activation in these different receptor systems influence the complex social behaviors important for social bonding. One of the key ways that humans and other mammals engage in social interaction is through vocal communication. In prairie voles, for instance, adult male virgins show a robust increase in the frequency and complexity of ultrasonic vocalizations (USVs) when exposed to novel females, especially if they are in estrous. Here, our objective was to determine whether D2-like activation (i.e. the receptors that promote pair bond formation) promote the production of USVs in male prairie voles when exposed to a novel female, whereas D1-like activation (the receptors that prevent pair bond formation) reduce USV production upon exposure to a female. Specifically, we peripherally administered either a D1-like agonist (SKF 38393) or a D2-like agonist (quinpirole) and quantified changes in USVs upon being exposed to a female. Remarkably, we found that males treated with the D2-like agonist showed both higher rates of USVs, as well as showed a significantly larger repertoire of USV types, compared to males given the D1-like agonist. This is especially significant because, in a separate group of animals, we show that call repertoire size during the first several minutes of exposure to a novel female predicted how strongly the pair eventually bonded and showed associated neuroplasticity within the DA system within the NAc shell. Moreover, follow up choice experiments suggest that females prefer males that have been treated with the D2-like agonist, potentially indicating that adult USVs function to attract mates and that this is mediated in a DA receptor specific manner. Our results strongly suggest that USVs serve to advertise the ability/motivation to form a long-term social bond, making this behavior a key signal in the facilitation of partner choice.

Title: Temporal dynamics of locus coeruleus activity during courtship in male mice

Authors: D. ECKMEIER, *S. D. SHEA;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Noradrenaline released by the brain stem nucleus locus coeruleus (LC) plays a central role in regulating brain state. Specifically, elevated LC firing is associated with enhanced

arousal, attention, neuronal plasticity and memory. Brain levels of noradrenaline increase during investigation of novel stimuli, in response to pain, during stress, and during social interaction. In the context of reproductive behavior, these surges appear essential for recognition of partners on consecutive encounters. In awake animals, LC neurons exhibit a bimodal firing pattern composed of an arousal-dependent baseline firing rate punctuated by brief bursts in response to stimuli. Whether and how the temporal structure of activity during courtship is distinct from that exhibited during non-social activities are not known. Moreover, while LC was classically thought to respond to novel and arousing stimuli, more recent data show that its firing is more closely locked to initiation of behavior in operant tasks. Whether this temporal relationship to behavior is maintained for social interaction is also not known. We therefore investigated the temporal structure of LC activity and its relationship to interactive behavioral events during courtship in awake male mice. We recorded single unit and multiunit activity using a head-mounted drive with movable 16 channel microwire bundles. We recorded from adult (>3 months) C57/BL6 males during courtship and non-social activities. In addition, we documented behavior with infrared video and ultrasound audio. Preliminary qualitative inspection of the data shows that LC firing is dynamic during courtship of a receptive female partner (e.g. chasing behavior and vocalization). These are the first reported recordings from LC neurons in awake behaving mice freely engaging in social behavior.

Title: Alterations in USV and cortical structure in KOR-1 KO mice

Authors: B. VILJETIC[1], M. ANSONOFF[1], S. WIJERANTE[1], M. PINTAR[2], M.-R. RASIN[2], *J. E. PINTAR[2];
[1]Neurosci. and Cell Biol., [2]Dept Neurosci & Cell Biol, Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: We have analyzed ultrasonic vocalization patterns exhibited by KOR-1 KO mice both as neonates and as young adults. We have found that the number of vocalizations in KOR-1 KO mice are significantly reduced at both stages in different behavioral contexts. Moreover, the

types of vocalizations are also significantly altered in neonates. We have also begun to determine whether any alterations in brain circuitry occur in KO-1 KO mice that potentially could be related to altered behavior. In these initial studies, we have examined cortical organization in 129S6 WT and 129S6 KOR-1 KO as well as compared the 129S6 WT pattern to that of C57Bl6/J mice. Cortical layer organization was assessed using the upper and lower layer markers CDP and TLE4, respectively, while gliogenesis was assessed using APC. Several significant results have arisen from the analysis to date. First, there is a significant decrease in the ratio of upper and lower layer neuronal markers in KOR-1 KO mice compared to isogenic 129S6 WT mice. Second, this change appears to primarily result from a decrease in the number of CDP neurons. Third, there is a dramatic decrease in the ratio of upper to lower layer markers in C57Bl6/J WT mice compared to 129S6 mice. Fourth, the distribution of CDP neurons is restricted to most upper cortical layers in C57WT mice compared to 129S6. Fifth, the extent of glia presence is similar in all three genotypes examined. Together, these data provide the first evidence that neuronal organization within the neocortex is altered not only between distinct mouse strains but also in KOR-1 KO mice.

Title: Movement and electric analysis of freely swimming pulse type weakly electric fish

Authors: ***R. D. PINTO**, A. C. FREIRES DE OLIVEIRA, R. T. GUARIENTO, L. O. B. ALMEIDA, I. H. Z. DE STEFANI, M. R. GONÇALVES;
Inst. Fisica De Sao Carlos - Univ. Sao Paulo, Sao Carlos, Brazil

Abstract: Weakly electric fish are unique model systems in neuroethology because they allow experimentalists to non-invasively record spatio-temporal electric patterns of pulses used by the central nervous system in electrocommunication and electrolocation [1]. Pulse-type electric fish present stereotyped pulses but are able to dynamically alter their inter pulse intervals (IPIs)

according to different behavioral contexts such as aggression, hiding, mating, as well as when stimulated with different artificial distributions of IPIs [2] as if they were comming from conspecifics.
Here we address how the behavior of fish performing a dominance contest is reflected by electrical patterns and movement, simultaneously recorded. We are specially interested in a behavior in which only one of the fish intermittently replace its pulses by a continuous pattern known as chirp [4]
Our experiments consist in recording simultaneously two video cameras and a 12 electrode array assembled in a big tank (1x0.5x0.5)m, where two *Gymnotus carapo* specimens, previously unknown to each other, are allowed to freely swim and interact.
A dedicated computer algorithm was applied to detect the timing and discriminate fish pulses [3] and another algorithm was applied to infer the 3D position of the fish from the camera's recording.
After the contest, we report the statistics of IPIs of both dominant and submissive fish and correlate them to their movements. We also show that it is possible to extract the position of fish from the electrode array time series. We found that chirping usually occurs either when fish are close to each other or the submissive fish is approached by the dominant. The chirping fish also usually retreats immediately after the chirp.

Title: Dynamics of electrical behavior of Gymnotus carapo electric fish during dominance contest

Authors: *R. TUMA GUARIENTO[1], T. S. MOSQUEIRO[2], P. MATIAS[3], V. CESARINO[3], L. O. B. ALMEIDA[3], R. D. PINTO[3];

Abstract: Weakly electric fishes detect a self-generated electric field to detect objects in the environment [1] and to communicate to conspecifics [2]. *Gymnotus carapo* is a pulse-type electric fish that shows a strong non-sex biased dominance relationship [3], which makes this species an interesting model for studying dominance establishment [4]. Recent studies dwelled on how information is electrically communicated during the dominance contest [5]. We hypothesize that electrical behavior has an important role in dominance determination, since fish express very different electrical patterns during and after the dominance contest. Understanding the dynamics of such process can bring new insights of the neuroethology of these animals: how a pulse train mediated interaction can lead to behavioral changes. In this study we analyzed quantitatively how the electrical behavior changes over time using a state-of-art method of pulse-sorting the signals from two freely swimming fish.
One of the main submissive cues is called chirp, when an animal emits a high frequency noise instead of pulses [3]. We detected these regions by using supervised learning, trained with manually selected chirp and non chirp segments. In addition we are also able to detect and sort the emitter of each pulse [6].
During the beginning the contest, we found that both fishes present transitory frequency increases. However, after a few minutes, one of them, the future dominant, establishes a higher average pulse frequency, while the other, the future submissive, begins to chirp and emits pulses with intervals 10 times larger than if it was alone. The number of chirps and offs is proportional to how submissive the fish is, i.e., how likely it was to run away during the contest.

Title: Non-invasive inference of neuronal refractory time in pulse type weakly electric fish communication

Authors: *A. S. RIOS, R. T. GUARIENTO, L. O. B. ALMEIDA, I. H. Z. DE STEFANI, R. D. PINTO;
Dept. of Physics and Interdisciplinary Sci., Univ. of Sao Paulo, Sao Carlos, Brazil

Abstract: Electrolocalization and electrocommunication are complex tasks performed by the nervous system of weakly electric fish [1]. Pulse type fish process information from a myriad of electric field sensors disposed over their skin to sense self- and conspecific- stereotyped electric pulses, called electric organ discharges (EOD). These remarkable animals are able to change the complexity of their spatio-temporal electric patterns according to different stimuli [2]. In their central nervous system, the sensorial information reach a population of neurons (spherical cells) dedicated to fire when a pulse is detected, and they seem to be preferentially tuned to self generated pulses [3]. Here, we address the role of such refractory time in electrocommunication. In principle, a long refractory time poses a blind period after a self EOD in which no pulses from other conspecifics can be detected. We show that using some tools from Information Theory we were able to access such refractory times noninvasively. Our experiment consists in recording long time series from a 12 electrode array assembled in a big tank (1x0.5x0.5)m where two *Gymnotus carapo* specimens are allowed to freely swim and interact [2]. A dedicated computer algorithm was applied to detect the timing (time stamp) and discriminate fish pulses [4]. We compute the Transfer Entropy (TE) and the Average Mutual Information (AMI) to infer the amount of information that one fish's EOD time stamps express about the other fish's EODs time stamps [2,5] in several time windows. We chose one of the fish as the response fish and, for each value of a response refractory time parameter (*Tr*), we re-sample the stimuli fish EODs by removing all those EODs that occurred during *Tr* after a pulse in the response. Then we compute TE and AMI for the re-sampled series. We found peaks of both TE and AMI in the same windows along the series for values of *Tr* that are compatible with the refractory time of the spherical cells measured *in vitro*. Our result is an independent evidence that such refractory times must be considered in communication analysis.

Title: Specification of male versus female acoustic communication behaviors in *Drosophila* virilis

Authors: *C. A. BAKER, X.-J. GUAN, M. MURTHY;
Neurosci., Princeton Univ., Princeton, NJ

Abstract: Many animals, including insects, engage in acoustic duetting, a complex behavior in which males and females control the timing of their courtship songs relative to each other. However, the mechanisms underlying duetting remain largely unknown. Our lab has recently developed *Drosophila virilis* as a model for studying acoustic duetting. Male and female *D. virilis* produce spectrotemporally distinct songs via wing vibration; males coordinate their songs with females based on auditory feedback, while females rely largely on tactile feedback to time their songs (LaRue et al 2015, *eLife* 4:e07277). These differences raise the question of how the underlying circuits produce these sexually dimorphic behaviors. Here we test whether the *fruitless* gene, which plays a critical role in directing male-specific courtship behaviors in other insects, contributes to sex differences in *D. virilis* courtship.
In *Drosophila melanogaster*, only males sing during courtship. Particular *fruitless* transcripts are sex-specifically spliced, leading to the production of FruM protein in male *D. melanogaster* neurons. The presence of the Transfomer protein in females prevents FruM expression by

directing female splicing of the sex-specific transcripts. When female *D. melanogaster* are forced to express FruM, they court wild-type females and sing (Demir & Dickson 2005, *Cell* 121:785-794), albeit with an aberrant song (Clyne & Miesenboch 2008, *Cell* 133:354-363).
To test whether *fruitless* also contributes to *D. virilis* courtship behaviors, we used CRISPR-Cas9 to remove the Transformer binding sites from the *fruitless* gene, thus forcing production of the male-specific FruM protein in both sexes. We recorded song and associated courtship behaviors in high throughput and used single-fly PCR to determine which flies carried our designed mutation.
We confirmed that FruM transcripts were made in mutant female brains. Unlike *D. melanogaster*, FruM-expressing *D. virilis* females did not court wild-type females. *D. virilis* FruM females duetted with males but produced altered song parameters. Mutant females were also less receptive and less fertile, despite vigorous courting by males. Finally, *D. virilis* FruM females engaged in aggressive interactions seen in wild-type male-male, but not male-female, pairings. Our results reveal that *fruitless* is indeed involved in sex-specific behaviors in *D. virilis*, but its role in this duetting species may be different from that in *D. melanogaster.* Further experiments will test this prediction, as well as generate tools to label and activate/silence *fruitless*-expressing neurons in *D. virilis* to dissect the role these neurons play in acoustic duetting.

Title: A circuit screen for song production neurons in *Drosophila melanogaster*

Authors: *A. HAMMONS[1,2], D. PACHECO[2], M. MURTHY[2];
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ

Abstract: The courtship song production circuit in the fruit fly *Drosophila melanogaster* provides an excellent animal model for studying the decision-making and motor pattern generation that are important for mate selection in a number of species. With the small and genetically tractable nervous system of *Drosophila*, identification of the specific neurons involved in courtship song production allows interrogation of the principles underlying the transformation of complex patterns in the nervous system to a motor output. Though some neural classes in the song pathway have been identified (von Philipsborn et al. Shirangi et al.), there are

likely many more neurons in these circuits. Moreover, the functional properties and connectivity of identified neuronal classes remains uncharacterized. To uncover additional components of the neural circuit underlying song production, we performed a neural activation screen for ventral nerve cord (VNC) neurons that drive song production in headless males by expressing the temperature-sensitive ion channel TrpA1 in subsets of neurons (labeled by the Janelia GAL4 collection). We identified seven GAL4 lines capable of song production when artificially activated. An intersectional approach where TrpA1 was restricted to neurons expressing either the *fruitless* or *doublesex* gene revealed that five of these GAL4 lines contain VNC song production neurons that do not express either of these two genes. Chronic inactivation (using tetanus toxin light-chain (TNT), a genetically encoded protein that blocks synaptic transmission) of these candidate neurons during a courtship pair assay that measures both male and female movement while also recording song, allowed us to characterize these neurons' effect on song patterning and female responses to song. Ongoing experiments using *in vivo* calcium imaging of song circuit neurons in the VNC combined with optogenetic activation of P1 song command neurons will determine whether or not these newly identified neurons form an interconnected song circuit with those neurons previously identified.

Title: Characterizing neural activity in the song motor circuit of *Drosophila*

Authors: *D. A. PACHECO PINEDO, M. MURTHY;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: *Drosophila melanogaster* exhibit a robust and complex courtship ritual, during which males chase females and produce a courtship song by unilateral wing vibration. This acoustic signal is arranged in bouts that consist of two syllables: sine and pulse. Drosophila singing is actively patterned in response to sensory feedback from the female (Coen et al. 2014). Recent mapping of the neural centers underlying song production have identified clusters of neurons located in the brain and the ventral nerve cord (von Philipsborn et al; Shirangi et al.). Despite the characterization of some components of the song circuit, we still don't fully understand how this patterned behavior is generated and how sensory cues are integrated to modulate song features. This is partially because many neurons of the song motor circuit remain to be mapped and none of these neurons have been functionally characterized. In order to have a singing-related activity map with a fine anatomical resolution, we have developed an assay that combines stimulation of different stages of the song circuit, monitoring of neural activity throughout the entire nervous system, along with a readout of fictive singing in a fixed fly. The Gal4-UAS binary system was used to express a red-shifted channel rhodopsin (ReachR) in specific components of the song circuit. A second and orthogonal binary system, LexA-LexAop, was used to independently express a genetically encoded calcium indicator (GCAMP6s) broadly. We developed a whole brain and nerve cord 3D-imaging pipeline that automatically segments regions of interest and maps them to reference brain coordinates for systematic anatomical comparison across flies. As fly dissections prevent recordings of song production directly, we extra-cellularly recorded from the motor neurons that drive the wing muscles, providing a fictive readout of singing. We present data on the neural dynamics and functional connectivity that underlie song production and patterning in *Drosophila*.

Title: Social consequences of interruptions during marmoset conversations

Authors: *C. TOARMINO[1], C. T. MILLER[2];
[1]Univ. of California San Diego, San Diego, CA; [2]Neuroscience/Psychology, UCSD, La Jolla, CA

Abstract: Social living is an integral feature of primate societies. As such, social rules emerge that regulate individual and group behaviors. The ability of group members to recognize and follow these rules is critical to their survival and reproductive success, and violations to these rules may have a significant behavioral impact. Common marmosets, like other primates, follow rules during social and communicative interactions. However, it is unknown how violations to these rules impact the communicative exchange and the social treatment of the violator. Here, we examined the social consequences of interruptions during their natural conversations called antiphonal calling. We used a novel, multi-speaker interactive playback design with two 'Virtual Monkeys' (VMs) that simulated individual marmosets to test how interruptions impacted the dynamics of the conversation. One VM was denoted VM-Norm, as it produced normal responses to subjects' vocalizations, and the other was denoted VM-Int, as it occasionally interrupted subjects' own phee calls. Two types of phee calls were produced by the VMs: 1) antiphonal phee calls were broadcast in response to subjects' vocalizations, and 2) when subjects were vocally inactive for a period of time, one VM was selected to broadcast a spontaneous phee call to attempt to engage the subject in communication. This design afforded subjects the opportunity to learn about the individual behaviors of each VM and make decisions about whether or not to interact with those VMs based on that information. We recorded subjects' responses to each VM's different phee call types. We found that subjects were significantly less likely and slower to respond to an interruption from VM-Int than an antiphonal call from VM-Int or VM-Norm. Interruptions effectively ended the vocal exchange between subjects and VM-Int for that bout of calling. However, interruptions had no effect on subjects' decisions to respond to either VM when the VM initiated the vocal exchange (*i.e.,* a VM's spontaneous call). We repeated this experiment with familiar and non-familiar stimuli, different age groups, and an increased rate of interrupting and found that these results persist regardless of these conditions. We are currently examining how interacting with the same interrupter over multiple days influences subjects' decisions in conversations.

Title: Primate frontal cortex neurons predict the outcome of natural conversations

Authors: *V. JOVANOVIC[1], S. NUMMELA[1], L. DE LA MOTHE[2], C. T. MILLER[1];
[1]UCSD, San Diego, CA; [2]Dept. of Psychology, Tennessee State Univ., Nashville, TN

Abstract: Communication is an inherently interactive process that weaves the fabric of society together for both human and nonhuman primates alike. Yet much of what is known about the neural basis of communication in our simian cousins has been limited to studies of static signals. To investigate the properties of the primate brain during active social signaling, we recorded the activity of frontal cortex neurons as freely-moving marmosets engaged in natural conversations. The responses of all neurons (n=258) to vocalization stimuli were compared in two behavioral contexts during conversations with a Virtual Marmoset (VM): when subjects produced a response following hearing a vocalization stimulus (Antiphonal) and when no response occurred (Independent). Across three subjects, PCA indicated that the greatest source of variance in firing rate was explained by these two behavioral contexts. Furthermore, we observed that frontal cortex activity could reliably predict whether a conspecific's vocalization would elicit a vocal response with 92% accuracy. In fact, correct classification was not stimulus-driven, as neural activity preceding the stimulus could still reliably predict the behavioral outcome. This finding was surprising for at least the following two reasons. First, this population of neurons did not exhibit robust changes in firing rate to vocalization stimuli. Second, the PCA analysis included all neurons, not just those that were modulated by the conversational behavior. These data suggest that the state of the brain prior to hearing a conspecific vocalization determines whether marmosets will produce a response and engage in a conversation. The close coupling between brain state and behavioral context is further evidenced by analyses of extended conversations, as brain and behavior exhibit a near perfect correlation. These data suggest that active social signaling may have a profound effect on the neuronal processes and lend unique insight into facets of the primate social brain.

Title: Asymmetry in vocal communication in marmosets - influence of social context and gender differences

Authors: *J. SHARMA[1], R. LANDMAN[2], J. HYMAN[3], L. BRATTAIN[4], K. JOHNSON[4], T. QUATIERI[4], K. SRINIVASAN[3], A. WISLER[4], G. FENG[5], M. SUR[6], R. DESIMONE[3]; [1]Picower Inst. For Learning & Memory, MIT and MGH, Cambridge, MA; [2]Broad Inst. and McGovern Inst., Cambridge, MA; [3]McGovern Inst. of Brain Res., Cambridge, MA; [4]Lincoln Labs, MIT, Lexington, MA; [5]McGovern Inst. of Brain Res. and Broad Inst., Cambridge, MA; [6]Picower Inst. for Learning and Memory and Simons Ctr. for Social Brain, Cambridge, MA

Abstract: Common marmosets are highly gregarious animals and use a rich vocal repertoire while communicating with conspecifics during social interactions. Recent studies indicate that they take turns in uttering calls (anti-phonal calling). There is also evidence that these exchanges are modulated by social context and specific calls are used to locate a group member when out of visual contact, when under threat or to show anxiety. To study these vocal/social interactions in a naturalistic home-cage environment, we developed a wireless lightweight flexible neck collar, equipped with a micro-electro-mechanical system (MEMS) acoustic microphone, a non-acoustic contact microphone for detecting caller vocal-fold vibration, and a Bluetooth module for wireless data transmission. The initial testing was done on marmoset dyads and spectral analysis of their calls was performed to identify individual caller. Approximately 80% of calls could be attributed to an individual based on relative sound pressure alone. The remaining 20% were attributed with addition of data from the contact microphone. Cross-correlation between audio channel and vibrational signal allows identification of most likely caller. We examined vocal interactions between dyads within the home-cage environment. We find that antiphonal calling occurs not only for ‘phee’-calls, but also for other calls such as ‘trill’, and even while in visual contact. We selectively removed one member of a dyadic pair (male or a female) from the home cage for short periods, while within or without visual contact. Analysis shows that there is directionality in these interactions - when the female is out of the home cage but within view, there is an increase in temporal coherence, where one animal calls at a lag of about 0.5 sec after his/her partner. An asymmetry between dyads is also found when one animal is taken out of the room, but within audible range. When the female is taken out, dyads ‘phee’-call back and forth, but when the male is taken out, there is no ‘phee’-calling. The first 'phee'-call is typically uttered by the animal that is outside. Directionality in vocal interactions may be thus be associated with the sex of the animal, social context, dominance and relatedness. Further research is underway on multiple dyads to confim and to explore neural underpinnings and behavioral consequences of this asymmetry.

Title: A framework for studying the neuronal basis of interactive social behavior

Authors: ***K. HAROUSH**[1], Z. WILLIAMS[2];
[1]Neurosurg., [2]Harvard Med. Sch., Boston, MA

Abstract: Social interactions are a fundamental part of many animal societies, and are increasingly more elaborated and sophisticated in humans and non-human primates. A key aspect of successful social interchange is the ability of individuals to cooperatively interact in order to reach mutually favorable goals such as obtaining and sharing food, defending from predators and building social bonds that benefit future generations. In human societies, cooperation further plays a central role in many interpersonal, economic and political decisions. At the same time, many mental health disorders are characterized by shared substantial deficits in social interactions. Therefore, our ability to understand and treat these various disorders depends on our ability to crack the neuronal coding of basic elements of social interactions in healthy individuals. However, the single neuronal basis, network computations and causal underpinnings of social interactions is largely unknown. A main challenge remains decomposing this complex behavior into a biological problem that could be quantitatively studied. We propose a framework for studying social interactive behavior by using game-theory driven principles. This formal framework allows disentangling neuronal signals that relate to the multiple aspects of social interactions, such as predicting another individual's intentions, weighing previous experiences with others and assessing possible personal profit.

Title: Understanding language genetics: establishing bats as a mammalian model of vocal learning

Authors: P. RODENAS-CUADRADO[1], J. MENGEDE[1], M. YARTSEV[2], U. FIRZLAFF[3], *S. VERNES[1,4];
[1]Max Planck Inst. For Psycholinguistics, Nijmegen, Netherlands; [2]Helen Wills Neurosci. Inst., Berkeley, CA; [3]Lehrstuhl für Zoologie, Freising-Weihenstephan, Germany; [4]Donders Ctr. for Cognitive Neuroimaging, Nijmegen, Netherlands

Abstract: The capacity for speech and language is a fundamental trait of humankind, and is of intense interest across diverse fields including linguistics, anthropology, neurobiology, cognitive neuroscience and molecular and evolutionary biology. Although humans are the only extant species with language, animal models have begun to reveal the biological bases of language relevant traits like vocal learning. Vocal learning, the ability to acquire and reproduce sounds through vocal imitation is essential for the acquisition of spoken language and is an extremely rare ability, found only in humans and a handful of other species (some birds, bats, elephants, whales and seals). To date, the only neuro-genetic studies on vocal learning have been performed in songbirds. Although these studies have given important insights into how genes may contribute to vocal learning, a comparative approach with other species will be vital in order to obtain a complete picture on how vocal learning is genetically encoded.
To this end, we are establishing bats as a molecular model system for the study of vocal learning. Bats are able to employ an astonishingly complex vocal repertoire for conveying social information and there is evidence across multiple bat species for vocal learning. As mammals, they are evolutionarily distant from songbirds and thus provide an ideal comparison for findings from avian systems. We present a range of work including gene knockdown studies, brain expression analysis, immediate early gene staining and transcriptomics, aimed at establishing bats as a viable molecular model for the study of vocal learning. Taken together these studies will ultimately advance our knowledge about the molecular encoding of vocal learning in the mammalian brain. Moreover this work will be highly complementary to work in avian models. Given the evolutionary distance between bats (mammalia) and songbirds (aves) this presents a unique opportunity to compare how vocal learning has evolved across these very different species. Integrating our findings in bats with songbird data and clinical studies in humans will

provide fundamental insights into the genetic underpinnings of vocal learning and ultimately shed light on how human spoken language may have evolved.

Title: Changes in EEG approximate entropy reflect auditory processing and functional complexity in frogs

Authors: ***G. FANG**, Y. LIU, Y. TANG;
Chengdu Inst. of Biology, CAS, Sichuan, China

Abstract: Brain systems engage in what are generally considered to be among the most complex forms of information processing. In the present study, we investigated the functional complexity of anuran auditory processing using the approximate entropy (ApEn) protocol for electroencephalogram (EEG) recordings from the forebrain and midbrain while male and female music frogs (*Babina daunchina*) listened to acoustic stimuli whose biological significance varied. The stimuli used were synthesized white noise (reflecting a novel signal), conspecific male advertisement calls with either high or low sexual attractiveness (reflecting sexual selection) and silence (reflecting a baseline). The results showed that 1) ApEn evoked by conspecific calls exceeded ApEn evoked by synthesized white noise in the left mesencephalon indicating this structure plays a critical role in processing acoustic signals with biological significance; 2) ApEn in the mesencephalon was significantly higher than for the telencephalon, consistent with the fact that the anuran midbrain contains a large well-organized auditory nucleus (torus semicircularis) while the forebrain does not; 3) for females ApEn in the mesencephalon was significantly different than that of males, suggesting that males and females process biological stimuli related to mate choice differently.

Title: Call initiation in African clawed frogs

Authors: *A. YAMAGUCHI;
Biol., Univ. of Utah, Salt Lake City, UT

Abstract: The most salient product of brain activity is behavior. Understanding the neural mechanisms underlying behavior presents a formidable challenge requiring a well-chosen model system. Vocalizations of the African clawed frog *Xenopus laevis* are an exceptionally well suited model system for this objective for the following reasons. First, a simplified mechanism of vocal production (independent of respiratory musculature) allows straightforward interpretations of neuronal activity with respect to behavior. Second, neural mechanisms of calling can be studied *in vitro*: application of serotonin (5-HT) to an isolated male brains readily elicits fictive advertisement calls. Using this "singing brain in a dish" preparation, we have identified and characterized the basic building blocks of *Xenopus* vocal circuits to date. Although we have been successful in identifying the neurons that are involved in rhythm generations, we have very little understanding of initiation of this vocal circuitry in the brainstem. The goal of the present study is to identify a population of neurons that mediate call initiation. Using local field potential (LFP) recordings, we discovered a population of neurons in the regions medial to the anterior laryngeal motor nucleus (n.IX-X) that show stereotyped activities prior to call initiation. The activity recorded in these regions are rhythmic (~ 35Hz) and precede the beginning of calls by ~100 msec. This activity are blocked by antagonists for synaptic transmission (50uM APV, 10uM DNQX, 10uM bicuculline, and 1uM strychnine), indicating that it is not derived from electrically-coupled pacemaker neurons . It also is not mediated by vocal motor neurons because when all the laryngeal motoneurons are silenced by retrograde loading of QX-314, an intracellular Na+ channel blocker, via the laryngeal motor axons, rhythmic activity can still be elicited by serotonin application. Thus, we conclude that there is a population of synaptically connected interneurons medial to the anterior n.IX-X that play a role in call initiation in response to 5-HT in the *Xenopus* brainstem. At a molecular level, we have previously shown that call initiation is mediated by 5-HT_{2C} receptors, which are expressed in rostral raphe nucleus. Because of the proximity of the LFP recording site and the rostral raphe nucleus, we suggest that a

population of interneurons in the rostral raphe nucleus generate oscillatory rhythms in response to 5-HT and activate the vocal pattern generator in the brainstem.

Title: Innate lymphoid cells: novel mediators of gut-brain immune regulation?

Authors: *N. C. DERECKI[1], G. ALEMAN-MUENCH[2], P. SOROOSH[2], H. BANIE[2], J. KARRAS[2], L. CHANG[2], M. HESSE[2], T. LOVENBERG[1], A. BHATTACHARYA[1]; [1]Neurosci., [2]Immunol., Janssen Res. and Develop., San Diego, CA

Abstract: Recent clinical data strongly suggests that mood disorders of the central nervous system (CNS), including major depressive disorder (MDD) are associated with increased levels of peripheral chronic inflammation. Along these lines, comorbidity between Inflammatory Bowel Disease (IBD) and MDD have been documented in epidemiological studies. The precise cellular and molecular mechanisms, however, that underlie these connections between peripheral gut inflammation and CNS dysfunction have remained elusive. To probe the hypothesis that players involved in gut inflammation may be linked with concomitant neuroinflammation, we examined CNS tissues in parallel with intestinal tissues in the innate immune anti-CD40 mouse model of IBD. Flow cytometric examination of peripheral tissues (colon and blood) in parallel with CNS tissues (meningeal lymphatics and brain) revealed a robust, synchronous response by meningeal macrophages and CNS microglia to induction of intestinal pathology. In addition, infiltration of brain by significant numbers of peripheral monocytes and granulocytes was observed. Finally, an unexpectedly prominent population of several subtypes of innate lymphoid cells (ILC) were revealed to be present in meningeal tissues; moreover, these cells were dynamically regulated as a result of peripheral anti-CD40-induced inflammation. Phenotypic characterization of these meningeal ILC revealed them to exhibit basic properties consistent with ILC in other tissues but significantly different (from gut and lung ILC) in terms of levels of receptor and transcription factor expression. In line with work examining the effects of IL-23, IL-25, and IL-33 on ILC, we saw robust local CNS expansion following peripheral administration of these cytokines. Interestingly, parenchymal microglia and myeloid cells in the meningeal spaces were also significantly different in terms of activation phenotype and cytokine production in $RAG2^{-/-}$ mice—which lack T and B cells—and $RAG2^{-/-}$Common $\gamma C^{-/-}$ mice—

which lack T and B cells and ILC, suggesting a key role for ILC in immune regulation of the CNS. These findings reveal a novel network of immune cells that may be involved in both homeostatic regulation of peri-CNS areas and locally-mediated dysregulation of these same areas during peripheral inflammation.

Title: Cholinergic signalling in forebrain regulates peripheral inflammation

Authors: ***V. A. PAVLOV**[1,2], K. R. LEHNER[2], H. A. SILVERMAN[3,2], M. ADDORISIO[3], T. TSAAVA[3], M. OCHANI[3], W. HANES[3], P. S. OLOFSSON[3], S. S. CHAVAN[3], N. M. NATHANSON[5], Y. Institute, The Univ. of Western Ontario, London, ON, Canada

Abstract: The brain regulation of physiological functions is integral to survival**.** Relatively little is known about the brain neuronal regulation of immune function and inflammation. Brain cholinergic signals have been implicated in controlling peripheral inflammation (Nat Rev Endocrinol, 2012, 8:743), but specific insight into the role of the inherently complex system of neurons releasing acetylcholine and cholinergic receptors in the brain is lacking. The basal forebrain cholinergic system is a major neuromodulatory system in the brain. Here, by using neuron- and receptor-specific genetic and pharmacological approaches, we studied the role of forebrain cholinergic signalling in the regulation of peripheral inflammation and the mediating role of the M1 muscarinic acetylcholine receptor (M1 mAChR). Selective elimination of

acetylcholine release in the forebrain by genetic Cre/loxP ablation of the vesicular acetylcholine transporter (a protein required for synaptic acetylcholine release) and interruption in vagus nerve activity abolished the suppression of serum TNF by the centrally-acting cholinergic drug galantamine in murine endotoxemia. Optogenetic stimulation of basal forebrain medial septum cholinergic neurons, a major source of brain cholinergic input to areas with abundant M1 mAChR localization, reduced serum TNF in endotoxemic mice, as compared to sham stimulation ($P<0.04$). Activation of acetylcholine action on the brain M1 mAChR by using intracerebroventricular administration of the selective positive allosteric modulator benzyl quinolone carboxylic acid (BQCA) also suppressed serum TNF levels ($P<0.02$). In addition, peripheral administration of the centrally-acting BQCA suppressed serum TNF and improved survival in lethal murine endotoxemia and polymicrobial sepsis and these effects were abolished in M1 mAChR KO mice. These findings provide novel insights into the role of forebrain cholinergic signalling in the regulation of innate immune responses and inflammation and are of interest for developing new brain-based treatments for conditions characterized by excessive pro-inflammatory cytokine levels and inflammation.

Title: Antibody efflux from cerebrospinal fluid to systemic circulation

Authors: ***J. NESTOR**, C. KOWAL, B. VOLPE, B. DIAMOND;
Ctr. for Autoimmune and Musculoskeletal Dis., Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: Neuropsychiatric Systemic Lupus Erythematosus (NPSLE) is a disorder seen frequently in Systemic Lupus Erythematosus (SLE) patients, which covers a wide range of symptoms such as stroke, cognitive dysfunction and depression. Our lab believes that some of these symptoms are mediated by autoreactive antibodies, which have cross-reactivity to both dsDNA and the NMDA receptor. We have previously shown that these antibodies can cause

damage in the brain parenchyma, when different agents are used to disrupt the blood brain barrier (BBB). In depth studies have been completed looking at the events causing breaches in the BBB, but until recently with the discovery of antibody transportation through the "glymphatic system" and perivascular spaces, the mechanisms determining antibody efflux from the CNS have remained elusive. This study addressed the flow of antibodies from the CSF into either the brain parenchyma or back into systemic circulation. Our model involves injection of antibody and control proteins directly into the lateral ventricle of mice and measuring corresponding protein levels in both brain parenchyma and serum. Our study suggests an IgG-specific transport mechanism mediated by FcRn, whereas the efflux of other antibody classes and non-immunoglobulin proteins appeared to be unaffected by the presence of the FcRn receptor. Understanding the movement of antibodies from the CSF into different areas of the brain can help us understand the different presentations associated with NPSLE and other antibody-mediated neuropsychiatric disorders. The efflux of antibodies from the CSF back into circulation will also be important in the development, design and dosing of new antibody-based treatments that are being used to target various neurological disorders.

Title: The involvement of the brain's choroid plexus in stress response

Authors: *A. KERTSER, K. BARUCH, M. SCHWARTZ;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Severely stressful conditions can trigger an inflammatory response within the brain, yet the underlying mechanism and the implications of this response to post traumatic pathologies are not fully understood. Recently, we identified the brain's choroid plexus (CP) as an active immunological interface between the brain and the circulation, which can support the recruitment of "healing" immune cells to the central nervous system (CNS) following injury. Accordingly, we hypothesized that post traumatic complications associated with cognitive impairments, might involve CP dysfunction as a gateway for leukocyte trafficking. We found that CP gateway activity can be induced in an epithelial NFκB-dependent mechanism, which could be experimentally suppressed, using endogenous inhibitors. Addressing this signaling pathway in a mouse model, we found that glucocorticoids can directly affect CP gateway activity

and may lead to reduced CNS immunosurveillance following severe traumatic stress. Together, these findings extend our understanding of signals which regulate CP gateway activity, and may point to novel therapeutic targets in treating CNS pathologies.

Title: Investigating neuroimmune function throughout pregnancy and the postpartum period.

Authors: *M. L. SHERER[1], C. K. POSILLICO[2], J. M. SCHWARZ[2];
[1]Psychology, [2]Univ. of Delaware, Newark, DE

Abstract: It is well known that the maternal immune system changes dramatically during pregnancy in order to prevent the developing fetus from being attacked by the maternal immune system. The reduced activity of many peripheral immune cells combined with an increased production of anti-inflammatory cytokines provides an immune environment very different from a non-pregnant female. As an example, many women who suffer from autoimmune disorders actually find relief from the severity of their symptoms while pregnant due to these changes in immune function. However, these peripheral immune alterations leave the mom at a greater risk for diseases normally mitigated by an inflammatory response. Despite this evidence, no one has examined whether changes in neuroimmune function also occur during pregnancy and the postpartum period. It is well known that changes in immune function are often linked to the onset of certain mental health disorders, including depression. Thus, we hypothesize that changes in immune function that are associated with pregnancy and the postpartum period may increase the risk of postpartum depression following birth. Previous studies in our lab have found significant changes in inflammatory molecules within both the prefrontal cortex and the hippocampus of postpartum rats. In the current study, we investigated the impact of an immune challenge (LPS) during various time points throughout pregnancy and postpartum period on the expression of immune molecules in the brain with future experiments examining how these changes in immune function may influence mood and anxiety during pregnancy and the postpartum period.

Title: Three-dimensional mapping of neural-immune interactions in the spleen of naïve mice.

Authors: E. HAMMOND, I. BRUST-MASCHER, E. N. MILLER, *C. REARDON;
SVM:Anatomy, Physiol. and Cell Biol., UC Davis, Davis, CA

Abstract: Background: The neuro-inflammatory reflex is an important physiologic mechanism for regulating systemic inflammation during both homeostasis and inflammatory diseases. It has previously been shown that the neuro-inflammatory reflex requires interaction between the splenic nerve and choline acetyltransferase (ChAT) expressing T cells. Although it has been suggested that the tyrosine hydroxylase (TH) expressing sympathetic nerves of the spleen communicate with $ChAT^+$ immune cells via synapse formation, alternative mechanisms have not been eliminated.
Objective: To elucidate the nature of the interaction between the sympathetic nerves of the spleen and $ChAT^+$ immune cells.
Methods: Spleens from naïve ChAT-GFP mice were optically clarified using the CLARITY technique and subjected to immunostaining using anti-GFP and anti-TH antibodies, followed by detection with Alexafluor-488 and -546 labelled secondary antibodies. Volumes of tissues (3x3x1.5mm) were acquired using two-photon microscopy. ChAT-GFP^+ splenocytes and TH^+ neurons in the imaged 3D volume were identified and modelled allowing distance between immune cells and neurons to be calculated using Imaris image analysis software. Analysis of B- or T-cells intimately associated with TH^+ neurons was performed in tissue sections using super-resolution Stimulated Emission Depletion (STED) microscopy
Results: In spleens from naïve ChAT-GFP mice we found the vast majority of ChAT-GFP^+ cells were not closely associated with TH+ sympathetic neurons. In calculating the distance to GFP^+ cells to nearest TH^+ neuron, approximately 1% of ChAT-GFP expressing cells were within 5µm of TH^+ nerve fibers. Analysis of closely juxtaposed TH^+ neurons and ChAT-GFP^+ or ChAT-GFP- B-cells or T-cells revealed no difference in the surface area of the 3D contact occurring between neurons and these immune cells.
Conclusions: Our data suggest that the vast majority of ChAT-GFP^+ splenocytes are not intimately associated with sympathetic nerves, and that ChAT-GFP^+ immune cells do not appear to make unique synapse like structures with neurons. These data suggest the existence of an alternative mechanism of neuro-immune communiation.

Title: Increased oxytocin immunoreactivity in male and female germ-free Swiss-Webster mice.

Authors: ***N. V. PETERS**[1], M. J. PAUL[3], B. CHASSAING[2], J. DUNN[1], A. T. GEWIRTZ[2], G. J. DE VRIES[1];
[1]Neurosci. Inst., [2]Ctr. for Inflammation, Immunity and Infection, Georgia State Univ., Atlanta, GA; [3]Psychology, Univ. at Buffalo, Buffalo, NY

Abstract: The microbiota is the collection of microorganisms that inhabit our bodies, including the gut. Both gut microbiota and the neuropeptides oxytocin (OXT) and vasopressin (AVP) are implicated in anxiety-related and social behavior. Our lab has previously found that AVP-immunoreactivity is increased in suprachiasmatic nucleus (SCN) projection sites in juvenile mice raised under germ-free (GF) conditions, with those effects persisting into adulthood in females only. Here, we tested whether OXT immunoreactivity was similarly affected in juveniles, and if recolonization of GF mice at weaning with a complex microbial community from conventionally housed (CC) mice may reverse these effects. We compared OXT immunoreactivity in juvenile (postnatal day 21: P21) and adult (P63) male and female GF or CC Swiss-Webster mice, or born GF and re-colonized with microbiota at 3 weeks of age (RE). Similar to AVP-immunoreactivity, juvenile GF male and female mice show increased OXT-immunoreactivity in the paraventricular nucleus of the hypothalamus and supraoptic nucleus, whereas there is no difference in the bed nucleus of the stria terminalis or the anterior hypothalamus. These results suggest that gut microbiota affect AVP neuropeptide systems in an age-dependent manner and OXT, at least in juveniles, and raises the possibility that AVP and OXT contribute to the gut-brain axis regulation of anxiety-related and social behaviors.

Abstract: The loss of appetite during sickness is a common and often debilitating phenomenon. Although pro-inflammatory cytokines are recognized as mediators of these effects, their mechanism and sites of action remain poorly understood. Here we show that interleukin 18, previously shown to have anorexigenic effects, acts on neurons of the Bed Nucleus of the Stria Terminalis to reduce food intake via the interleukin 18 receptors. Different cell types in the periphery produce Interleukin 18 while centrally it is present in microglia, ependymal cells and neurons of the medial habenula. The two subunits of the interleukin 18 receptor, - α and - β, are densely expressed in the anterodorsal division of the Bed Nucleus of the Stria Terminalis. We demonstrated that local injection of recombinant interleukin 18, 50 ng/ml, in the anterodorsal division of the Bed Nucleus of the Stria Terminalis, significantly reduced both c-fos activation and food intake for at least 6 hours. Electrophysiological experiments carried out in brain slices containing the Bed Nucleus of the Stria Terminalis demonstrated that the aforementioned dose of interleukin 18 strongly reduced the excitatory input on specific subtype of the Bed Nucleus of the Stria Terminalis type III neurons through a presynaptic mechanism. Interleukin 18 was ineffective in brain slices containing the Bed Nucleus of the Stria Terminalis from interleukin 18 KO mice. Interestingly, type III neurons sensitive to interleukin 18 were located in a restricted area of the Bed Nucleus of the Stria Terminalis defined as the juxtacapsular Bed Nucleus of the Stria Terminalis, which contains neurons projecting to the Lateral Hypothalamus. These results identify a site and a mode of action for interleukin 18 that indicates possible targets for the treatment of cachexia or other eating disorders.

Title: Vagus nerve stimulation decreases activation of select $CD4^+$ T cell populations and NK cells in mice

Authors: ***J. ESTELIUS**[1,2], K. CHEMIN[1,2], E. LE MAÎTRE[1,2], J. LAMPA[1,2];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Rheumatology Unit, Karolinska Univ. Hosp., Stockholm, Sweden

Abstract: Activation of the cholinergic anti-inflammatory pathway (CAP), the efferent branch of the inflammatory reflex, through electrical vagus nerve stimulation (VNS) is known to decrease an inflammatory response via $ChAT^+$ T-cells in the spleen. However, the full extent of the relationship between VNS and the immune system requires further investigation. To elucidate changes in the immune response to endotoxaemia induced by stimulation of the vagus nerve, male C57BL/6 mice underwent VNS or sham surgery after i.p. injection of lipopolysaccharides (LPS). This was followed by organ collection and cell preparation 6h post-surgery. Flow cytometric analysis revealed that VNS significantly reduced the expression of the early activation marker CD69 on $CD4^+$ T-cells in spleen and blood ($t(4)=-3.3$, $p<0.05$ and $t(4)=-4.0$, $p<0.05$ respectively). Further analysis of the $CD4^+$ T-cell compartment demonstrated significant CD69 reduction in both naïve ($CD44^{low}$, $CD62L^{high}$) ($t(4)=-3.3$, $p<0.05$, and $t(4)=-4.2$, $p<0.05$, spleen and blood respectively) and memory ($CD44^{high}$, $CD62L^{low}$) ($t(4)=-3.7$, $p<0.05$, spleen) T-cells after VNS. Interestingly, $CD335^+$ NK cells also showed a significant reduction in CD69 up-regulation with VNS ($t(5)=-3.4$, $p<0.05$), without effects on cell numbers. Conversely, $FoxP3^+$ regulatory $CD4^+$ T-cells as well as B-cells remained unaffected by VNS regarding both cell numbers and CD69 expression. Collectively, our data indicate that immune suppression through VNS selectively affects early endotoxaemia-induced activation in both spleen and blood, as measured by inhibition of CD69 up-regulation, in $CD4^+$T-cells of both naïve and memory

phenotype, as well as in NK-cells. No effect was observed in either regulatory $CD4^+$ T-cells or B-cells. These findings are in line with general immunosuppressive effects on T-cell subsets. Moreover, we detected a previously unknown VNS mediated suppression of NK-cell activation, which will increase our understanding of neuro-immune regulation pathways and may contribute to the development of novel immunomodulatory therapeutic strategies in chronic inflammatory diseases.

Title: Delayed contribution of hematopoietically-derived central nervous system macrophages in mixed chimeric mice utilizing the myeloablative compound Busulfan

Authors: M. I. ROCHA, K. B. PRUNER, J. M. KURTZ, *T. D. WILLIAMS;
Biol., Emmanuel Col., Boston, MA

Abstract: Several lines of evidence suggest there is minimal recruitment of peripheral monocytes to central nervous system (CNS) macrophage population in the absence of disease. Therefore, CNS inflammation may actively recruit peripheral immune cells in the response to disease. However, turnover of hematopoietically-derived immune cell precursors may also influence contribution to the CNS over time in non-disease states. To study this contribution, we established mixed syngeneic chimeric mice utilizing the myeloablative drug Busulfan followed by a hematopoietic stem cell transplant (HSCT) of GFP^+ donor cells into C57BL/6 recipient mice (n=30). Recipient mice were administered Busulfan (30mg/kg body weight) 7, 5, and 3 days prior to HSCT, followed by transplantation of $20*10^6$ bone marrow cells from C57BL/6-Tg(UBC-GFP) donor mice. Blood chimerism levels were analyzed through flow cytometry and yielded greater than 90% donor-derived monocytes by 1 week post-HSCT. Beginning at 8 weeks post-HSCT, approximately 2-3% of CNS macrophages were $CD11b^+$ $CD45^{mid}$ GFP^+. Supporting immunofluorescence evidence of CNS donor-derived macrophages was observed by Iba-1^+GFP^+ non-ramified cells in the choroid plexus as well as Iba-1^+GFP^+ ramified cells in the brain parenchyma. To further study how increased HSC proliferation affects donor cell contribution to CNS macrophage populations, chimeric mice (n=5; 45 weeks post-HSCT) were treated with an

additional Busulfan administration (25mg/kg body weight on two separate days). Following this partial myeloblation stress, we observed consistent high levels (>90%) of peripheral blood monocyte chimerism and no change in $CD11b^{+}CD45^{mid}GFP^{+}$ CNS cells at 8 weeks, however at 13 weeks (n=2), an increase to ~6% $CD11b^{+}CD45^{mid}GFP^{+}$ CNS cells was observed. Taken together, these data suggest the establishment of peripheral chimerism needs to occur prior to any significant contribution of hematopoietically-derived precursor cells to the CNS macrophage population.

Title: Molecular mechanisms of csf hypersecretion in intraventricular hemorrhage-associated hydrocephalus.

Authors: *J. K. KARIMY[1,2], D. B. KURLAND[1], B. CARUSILLO[1], J. ZHANG[3], V. GERZANICH[1], J. SIMARD[1], K. T. KAHLE[2];
[1]Neurosurg., Univ. of Maryland Baltimore, Baltimore, MD; [2]Neurosurg., Yale, New Haven, CT; [3]MRC Protein Phosphorylation and Ubiquitylation Unit, Univ. of Dundee, Dundee, United Kingdom

Abstract: Intraventricular hemorrhage (IVH), is the accumulation of blood within the ventricles, and is associated with high morbidity and mortality via IVH-associated hydrocephalus (IVHH). IVHH distorts the surrounding brain tissue, resulting in cognitive and motor impairments, or death. IVHH is attributed to impaired CSF reabsorption at the arachnoid granulations; however, the contribution of CSF hypersecretion is unknown. NKCC1 is regulated by SPAK via phosphorylation, and is critical to the formation of CSF. A novel method to measure the rate of CSF secretion was used to study the role of the SPAK-NKCC1 pathway in IVHH. IVH resulted in ventriculomegaly, due to a 3-fold increase in CSF secretion, determined to be due to SPAK-mediated phosphorylation of NKCC1. Methods to inhibit phosphorylation of NKCC1 significantly attenuated the hypersecretion of CSF and ventriculomegaly associated with IVHH.

These results provide evidence that the SPAK-NKCC1 pathway drives the pathogenesis of IVHH and is a potential therapeutic target.

Abstract: Bone marrow stromal cells (BMSCs), a major type of mesenchymal stromal cells, produce long-lasting attenuation of pain hypersensitivity after tissue or nerve injury. This effect involves BMSC's ability to induce an anti-inflammatory phenotype, represented by increased anti-inflammatory cytokine production and alternatively activated monocytes/macrophages population. We further studied the effect of BMSC on NF-κB and the regulatory T cells (Tregs), the two upstream events that are important for cytokine regulation and monocyte polarization. In Sprague Dawley rats with a ligation injury of the masseter tendon (TL), BMSCs (1.5M/rat) were infused i.v. at 1 w post-TL. At 1 w, but not 8 w after BMSC infusion, western blot and immunostaining showed that p65 of NF-κB was significantly increased in the rostral ventromedial medulla (RVM), a key structure in endogenous pain modulation that has been shown to be involved in BMSC-produced pain relief. P65 exhibited predominant neuronal localization in the RVM with scattered distribution in glial cells, as shown by double immunofluorescence with NeuN, GFAP and CD11b. At 7 d post-BMSC infusion when there was

clear antihyperalgesia, BAY 11-7082 (0.5 pmol/0.5μl), an inhibitor of NF-κB signaling, was injected into the RVM. Compared to vehicle-injected rats, BAY 11-7082 attenuated BMSC-produced antihyperalgesia, as indicated by a significant increase in mechanical sensitivity to von Frey filament probing. These results suggest that NF-κB transcriptional activation contributes to BMSC-produced pain relief. The $CD4^+CD25^+Foxp3^+$regulatory T cells (Tregs) have been shown to induce alternative activation of monocytes/macrophages and TGF-β induces $CD4^+$ $CD25^+Foxp3^+$Tregs from native $CD4^+$ T cells. The NF-κB activity is likely down-stream to these signaling events. Our RT-PCR results showed that TGF-β expression in primary BMSCs that produced pain relief was 2-fold higher than 20-passage BMSCs that did not produce pain relief in rats, consistent with a role of TGF-β in inducing Tregs for BMSC-induced antihyperalgesia. Flow cytometry was performed on peripheral blood cells after removing red blood cells from C57B mice with triple labeling and appropriate isotope controls. Compared to naïve mice, the frequency of $CD4^+CD25^+Foxp3^+$Tregs among the $CD4^+$ population was decreased in mice with injury of the infraorbital nerve, but increased to above the naïve level in the nerve-injured mice at 8 w after receiving BMSC. Taken together, these results suggest a scenario that BMSC-secreted mediators induce Tregs, followed by subsequent activation of anti-inflammatory phenotype in the host, leading to long lasting pain relief.

Abstract: In vertebrates, the immune and nervous systems have co-evolved complex and complementary mechanisms to detect danger and protect tissue from damage. This functional integration includes bidirectional communication between the two systems that can become maladaptive in disease situations. We have found that lung nociceptor neurons mediate a feedforward inflammatory loop during allergic inflammation by both sensing and responding to type 2 inflammatory cytokines and by fueling immune cells influx through local neuropeptide release (Talbot et al, Neuron 2015). The cellular mechanisms that engage airway nociceptors to initiate this cascade remain, however to be identified. Calcium imaging and electrophysiological recording reveal that nodose ganglion neurons from allergen (ovalbumin) sensitized mice respond with activation to the allergen when it is complexed with immunoglobulin subtype E (IgE), a response absent in FcεR1α knockout mice. Stimulated nociceptors in turn locally release Substance P (SP) which act on lung goblet cells to trigger mucus secretion, mucin imbalance (Muc5AC/Muc5B) and accumulation. During allergic inflammation, the ablation of TRPV1+ sensory neurons or silencing with QX-314, a charged sodium channel blocker that enters via large pore ion channels to specifically block nociceptors, reverse these effects. Optogenetic activation of $Tac1^{+}$ vagal sensory neurons also produce inflammation leading to mucus secretion and mucin imbalance. Our results indicate that airway nociceptors from sensitized animals sense allergens, which in turn release neuropeptides that induce mucus secretion. Silencing nociceptor neurons with QX-314 resolves neurogenic inflammation and mucus metaplasia and targeting the nervous system represents therefore a new therapeutic strategy for airway allergic diseases.

Abstract: Sensory vagus nerve fibers transmit action potentials to the central nervous system in response to changes in the body's metabolic and physiological status. Here we developed a method for recording compound action potentials in the cervical vagus nerve of adult mice. For vagus nerve recordings, animals were induced (isoflurane at 2%) and maintained (isoflurane at 1.75%) in the supine position. The left cervical branch of the vagus nerve isolated from the accompanying carotid bundle, and was placed over three custom-built silver hook electrodes (n=72) or in a commercially available bipolar sling cuff electrode (n=25) with 150 μm inner diameter (CorTec, Germany). Electrophysiological signals were digitized (sampling rate, 32 kHz) through a data acquisition system (Digital Lynx 4SX, Cheetah v5 software, Neuralynx, Bozeman, MT) and referenced to an animal ground electrode placed between the skin and right salivary gland. Ten minutes of baseline vagus nerve activity was recorded (hook electrode: 4.19 spikes/s ± SEM 0.87 spikes/s, cuff electrode: 4.86 spikes/s ± SEM 2.65 spikes/s). Recordings with a cuff electrode demonstrated a significantly lower background electrical activity as compared to the hook electrode ($p<.001$). Next, we determined whether there are any strain-specific differences in the baseline vagus nerve activity by comparing vagus nerve activity between adult Balb/c and B6.129s mice. No significant difference was observed in the spike rate over time or the total power between strains. To assess whether nutritional status affects the baseline vagus nerve activity animals were fasted prior to the recording. Non-fasted mice demonstrated a significantly higher amount of total spikes over the 10-minute period ($p<0.5$) as compared to the fasted group. Changes in the vagus nerve activity were then recorded in response to the administration of an inflammatory mediator. Following acquisition of baseline activity, animals received increasing amounts of bacterial lipopolysaccharide (LPS), and compound action potentials were recorded in the vagus nerve. Administration of LPS induced a significant increase in the vagus nerve activity. These studies report a novel method for recording changes in the cervical vagus nerve activity in mice.

Title: Investigating the effects of inflammation and minocycline on central glutamate receptors and the metabolome

Authors: *S. CHAN[1], F. PROBERT[2], D. C. ANTHONY[2], P. W. J. BURNET[3];
[2]Pharmacol., [3]Psychiatry, [1]Univ. of Oxford, Oxford, United Kingdom

Abstract: Background and Objective: Given the strong association between pro-inflammatory cytokines and psychiatric disorders, drugs with anti-inflammatory properties, such as minocycline, have gained interest as possible therapeutic agents. However, the mechanisms underlying their psychotropic properties are unclear. At the molecular level, studies linking the pro-inflammatory cytokine IL-1β to NMDA receptors suggest that central glutamate neurotransmission may be involved. We therefore examined the effect of minocycline and inflammation on glutamate receptor gene expression in the mouse brain. In addition, we used metabolomics to screen for other small molecules that may be affected by this drug.
Methods: Minocycline or saline was administered to male CD1 mice for seven days, followed by 24 hour-treatment with the inflammatory agent LPS, or saline. Region-specific central glutamate receptor gene expression was determined with in-situ hybdridisation. Statistical analyses were conducted with two-way ANOVA to determine the main effects of LPS and minocycline, as well as interactions between minocycline and LPS.
^{1}H-NMR spectroscopy was used to investigate the peripheral and central effects of minocycline on metabolites. Mice were treated with an acute dose of saline or minocycline for two hours before tissue and plasma harvesting. Samples were ran on a 700MHz system and processed to obtain spectra.
Results: LPS administration decreased NR2A (-33.44%, $p<0.01$) and NR2B (-13.76%, $p<0.05$) mRNA in the CA1 region of the hippocampus. This effect was modulated by pre-treatment with minocycline, with a significant minocycline x LPS interaction for NR2A ($F_{1,15} = 16.411$, $p<0.01$) and NR2B ($F_{1,15} = 18.319$, $p<0.01$) mRNA.
Preliminary metabolomic analyses have revealed significant differences between control and treatment groups by PCA and PLS-DA (predictive q^2 value>0.4) in plasma samples. Common brain metabolites have been identified in the brain extracts, and samples are currently being analysed. A second study involving 7-day pre-treatment with minocycline followed by administration with LPS will be conducted. We predict that clear metabolic profiles will be seen for each group, with the minocycline/LPS-treated group possibly modulating changes seen in the saline/LPS-treated group.

Conclusion: As dysregulation of glutamate receptors has been linked to the pathology of psychiatric disorders, it is possible that minocycline functions by modulating NMDA receptors. However, as minocycline has been shown to affect many targets, looking at changes in the metabolome would enable us to identify other non-immune pathways that may be involved.

Title: Immune regulation and mesenchymal stromal cell-produced pain relief: 1. promotion of anti-inflammatory phenotype

Authors: S. IMAI[1,2], W. GUO[1], S. ZOU[1], F. WEI[1], R. DUBNER[1], *K. REN[1];
[1]Neural and Pain Sci., Univ. of Maryland Sch. of Dent., Baltimore, MD; [2]Dept. of Clin. Pharmacol. & Therapeut., Kyoto Univ. Hosp., Kyoto, Japan

Abstract: Recent studies have pointed to a promising pain-relieving effect of mesenchymal stromal cells in animal models of persistent pain. A single transfusion of autologous bone marrow stromal cells (BMSCs), a major type of mesenchymal stromal cells, attenuates behavioral pain hypersensitivity after tissue or nerve injury and the pain attenuation lasts for months. BMSCs are known to alter inflammatory responses to injury. To understand cellular mechanisms underlying BMSC-produced pain relief, we studied the effect of BMSCs on pro- and anti-inflammatory cytokines in a rat model of myogenic orofacial pain. We focused on rostral ventromedial medulla (RVM), a key structure in endogenous pain modulation that has been shown to be involved in BMSC-produced pain relief. Injury was induced by ligation of one masseter muscle tendon (TL) of the rat via an intraoral approach. We have shown that TL induces persistent pain that can be attenuated by BMSCs. BMSCs were collected from the rat and cultured. At 1 w after TL, BMSCs (1.5 M cells/rat, i.v.) were infused and RVM tissues were

collected. Western blot and immunostaining showed that BMSCs reversed TL-induced upregulation of IL-1β expression in the RVM at 8 w, but not at 1 w, after BMSC infusion. Interestingly, the suppressor of cytokine signaling 3 proteins, a feedback inhibitor of signaling pathways related to cytokine transcription, was significantly upregulated at the 8 w time point. On the contrary, the levels of an anti-inflammatory cytokine IL-10 were increased in the RVM at 1 and 8 w after BMSC infusion. Double immunofluorescence showed that RVM IL-10 colocalized with neuronal marker NeuN and astrocytic marker GFAP. Since resident microglia may be modulated to express alternatively activated anti-inflammatory M2 phenotype after BMSC treatment and IL-10 is an activator of M2 phenotype, we further examined M2 marker in the RVM. RT-PCR showed that CD206 (mannose receptor), a marker of M2 macrophages/microglia, was upregulated in the RVM of TL rats after BMSC treatment. Immunostaining showed that CD206 selectively co-localized with CD11b, a microglial marker, in the RVM. Consistently, we found increased gene expression of M2 markers *CD206*, *CD163* and *Irf4* (Interferon regulatory factor 4) and decreased gene expression of proinflammatory M1-related genes *Irf5* and *Cxcl10* in peripheral blood monocytes derived from BMSC-treated TL rats. Together with our previous behavioral observations, these results suggest that BMSCs facilitate the acquisition of the M2 antiinflammatory phenotype in the RVM as well as induce M2 polarization in periphery in injured animals. These effects of BMSCs should contribute to their pain-relieving effect.

Title: Neuronal regulatory RNAs and neuropsychiatric lupus

Authors: *A. IACOANGELI[1], I. MUSLIMOV[1], H. TIEDGE[1,2];
[1]Physiol. and Pharmacol., [2]Neurol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Systemic lupus erythematosus (SLE) is an autoimmune disease affecting an estimated 2 million US Americans. Neuropsychiatric SLE (NP-SLE), a common occurrence in lupus patients, is characterized by neurological manifestations including psychosis and seizures. Regulatory Brain Cytoplasmic (BC) RNAs are translational regulators at the synapse. Mice lacking BC1 RNA are susceptible to hyperexcitability and epileptogenesis. BC RNAs are delivered to synapto-dendritic subdomains by heterogeneous nuclear ribonucleoprotein A2 (hnRNP A2). hnRNP A2 recognizes a dendritic transport element (DTE), a GA motif located in the 5' region of BC RNAs that is required for dendritic targeting. Sera of lupus patients have been reported reactive to double stranded DNA and double-stranded RNA. We found that 77% of screened SLE patients had a strong immune response to BC RNAs. Using electrophoretic mobility shift assays (EMSAs), we observed that IgGs from SLE sera formed complexes with BC200 RNA and BC1 RNA. The majority of lupus patients showing strong immune reactivity to BC RNAs were NP-SLE patients with neurological manifestations. Complex formation was not detected with IgGs from patients with other systemic or localized autoimmune diseases (e.g. rheumatoid arthritis or multiple sclerosis). Autoantibodies against BC RNAs (anti-BC abs) bind to the DTE that is recognized by hnRNP A2. Competition assays revealed that hnRNP A2 and anti-BC abs interact with DTEs of BC RNAs in a competitive manner. Hypothesizing that anti-BC IgG competition with hnRNP A2 compromises dendritic BC RNA transport, we co-microinjected sympathetic neurons in culture with radiolabeled BC RNAs and anti-BC IgGs. We observed that dendritic BC RNAs transport was inhibited in the presence of anti-BC abs. Delivery of BC RNAs to dendritic subdomains was not affected when IgGs from non-SLE subjects were used in the co-injection experiments.
The data indicate that anti-BC IgGs, competing with hnRNP A2, disrupt delivery of regulatory BC RNAs to dendrites. Such competition may impact BC RNA functional activity at the synapse.

Title: Age-associated circadian dysregulation in rats may sensitize neuroinflammatory responses

Authors: *L. K. FONKEN, M. M. KITT, A. D. GAUDET, R. M. BARRIENTOS, L. R. WATKINS, S. F. MAIER;
Univ. of Colorado, Boulder, CO

Abstract: Aged animals exhibit diminished molecular and behavioral circadian rhythms. Both aging and circadian disruption sensitize neuroinflammatory processes. Thus, here we explored whether aging is associated with disrupted diurnal rhythms in neuroinflammatory processes. These experiments were conduced with F344XBN rats and specifically focused on the hippocampus as potentiation of the inflammatory response is particularly robust in the aged hippocampus. Here we show that hippocampal tissue isolated from adult (4 mos.) rats showed increased markers of microglia activation (Iba1 and CD68 mRNA expression) during the middle of the light phase. In contrast, there were no diurnal differences in markers of microglial activation in aged (25 mos.) rats; aged rats exhibited constitutively elevated Iba1 and CD68 mRNA expression. Interestingly, there were no diurnal differences in GFAP expression in young or aged rats. Consistent with previous findings, there was an overall elevation in GFAP in aged rats. Next, we explored whether aging is associated with disrupted diurnal rhythms in microglia isolated from the hippocampus. Hippocampal microglia were isolated from adult and aged rats every 6h. While microglia from young rats rhythmically expressed core circadian clock genes, microglia from aged rats had atypical non-rhythmic expression of several clock genes, including *Per1* and *Per2*. Furthermore, unstimulated (non-LPS treated) microglia from young rats exhibited robust rhythms of *TNFα* and *IL1β* mRNA, with peak expression during the middle of the light phase. In contrast, unstimulated microglia isolated from aged rats had tonically elevated inflammatory cytokines that were not regulated by time-of-day. Similarly, diurnal differences in responsiveness to both *ex vivo* and *in vivo* inflammatory challenges were abolished in aged rats. Corticosterone treatment induced Per1 expression in aged and young microglia; however, glucocorticoid rhythms are suppressed in the aged hippocampus. This suggests that changes in entrainment signals may be disrupted with aging. Overall, here we show that intrinsic microglial rhythms in clock and inflammatory genes are dysregulated with aging and may contribute to pathological neuroinflammatory responses.

Title: Involvement of hypothalamic CCL2/CCR2 chemokine system in the stimulatory effects of maternal exposure to low-dose ethanol on embryonic development of orexigenic peptide neurons in rats

Authors: *S. F. LEIBOWITZ, G.-Q. CHANG, O. KARATAYEV;
Rockefeller Univ., New York, NY

Abstract: Background: Clinical and animal studies show that maternal consumption of alcohol during pregnancy increases alcohol drinking in the offspring and also stimulates neurogenesis and density of hypothalamic neurons that express orexigenic peptides known to increase alcohol intake. With studies showing ethanol to activate the peripheral immune system and increase circulating levels of the chemokine CCL2, we recently investigated in Sprague-Dawley rats (Chang et al., 2015) the effect of ethanol on neuroimmune function in the hypothalamus. We found that maternal oral administration of ethanol (1 or 3 g/kg/day, i.g.) from embryonic day 10 (E10) to E15, compared to control isocaloric solution of maltose-dextrin, markedly increases the birth and density of neurons in the perifornical lateral hypothalamus (PFLH) that express melanin-concentrating hormone (MCH) and co-label the chemokine receptor CCR2, while also stimulating the drinking of ethanol in pubertal offspring. These findings agree with other evidence showing alcohol intake to be reduced by knockout of CCR2 and increased by PFLH injection of MCH. **Methods:** Quantitative real-time PCR and immunofluorescence histochemistry were used to further examine the relationship between the CCL2/CCR2 system and development of MCH neurons in PFLH. **Results:** Using confocal microscopy, we found that, as compared to only 30% in control rats, almost 100% of MCH neurons in PFLH co-express CCR2 in pre-adolescent offspring prenatally exposed to ethanol (1 g/kg/day, E10-E15). We also showed that peripheral administration to dams of CCL2 itself (2-4 μg/kg, s.c.) increases maternal circulating CCL2 (+45%, $p<0.05$) to the same level (530-553 pg/ml) induced by oral administration of ethanol (1 g/kg, i.g.). We then tested whether CCL2 injection has similar effects to ethanol and possibly mediates ethanol's stimulatory effects on neurons that co-label CCR2 and MCH. We found that, like ethanol, daily injections in the dam (E10-E15) of CCL2 (2 μg/kg/day), compared to its purified IgG vehicle, significantly increase in offspring ($p<0.01$) mRNA levels of MCH and density of CCR2-labeled cells in PFLH. Also, in dams administered oral ethanol (1 g/kg/day), we found daily injections (E10-E15) of the CCR2 antagonist, INCB3344 (1 mg/kg/d, i.v.), compared to its PBS vehicle to have opposite effects to CCL2, causing a reduction in both MCH mRNA and density of CCR2-labeled cells ($p<0.01$). **Conclusions:** These findings provide evidence for a stimulatory effect in offspring of maternal CCL2, like ethanol, on the density and expression of orexigenic peptide neurons in PFLH that co-express CCR2 and a role for CCR2 in mediating ethanol's effects.

Title: Nicotine mediated immunosuppression is compromised in lipopolysaccharide activated splenocytes from microsomal prostaglandin E synthase–1 knock–out mice

Authors: *P. REVATHIKUMAR, U. KARMAKAR, E. LE MAÎTRE, M. KOROTKOVA, P. JAKOBSSON, J. LAMPA;
Dept. of Medicine, Karolinska Institutet, Stockholm, Sweden

Abstract: Vagus nerve stimulation (VNS) is effective in controlling inflammation. Interestingly, we showed recently that the VNS mediated immunosuppression is impaired in mice lacking microsomal prostaglandin E synthase-1 expression (mPGES-1), a key enzyme responsible for prostaglandin (PG) E_2 synthesis. In addition, mPGES-1 KO mice display defective splenic acetylcholine release in response to VNS. Here we aim to investigate the cholinergic system of VNS treated mPGES-1 KO mice.

Methods

Animals: All experiments were performed according to local Ethical Committee guidelines. Both WT and mPGES-1 KO mice were injected with lipopolysaccharide (LPS) (2 mg/kg; i.p). After VN isolation, it was either electrically stimulated for 5 minutes (VNS) or left undisturbed (Sham). After 30 minutes, spleens were collected for NE and choline measurement.

***In vitro* studies**

(i) Splenocytes were seeded in chamber slides, treated with LPS (10ng/ml) for 20 hours and stained for choline acetyltransferase (ChAT) expression using immunofluorescence.

(ii) Splenocytes were pretreated with nicotine at 100μM for 30 minutes, later stimulated with LPS (10ng/ml) for 3, 6 and 20 hours respectively and supernatants were collected for TNF α measurement.

Results

(i) No difference was detected concerning splenic NE concentration in mPGES-1 KO mice vs WT following VNS (10.4±2.2 vs 9.6±3.4 pg/ml). However, VNS tended to increase the choline content in WT spleen by 6% (n=5) whereas no such increase was observed in mPGES-1 KO mice.

(ii) LPS treatment induced strong ChAT expression in both WT and mPGES-1 KO splenocytes. However, the % of cells positive for ChAT expression was more pronounced in WT compared to

mPGES-1 KO mice. (81.2% WT vs 55.8% mPGES-1 KO).
(iii) Nicotine treatment (3 hours only) strongly inhibited LPS induced TNF α production (25±8.7 % inhibition, $p<0.05$, $n=4$) in WT. On the contrary, nicotine failed to exhibit similar effects on activated mPGES-1 KO splenocytes.

Conclusion

VNS induces splenic NE release in both WT and mPGES-1 KO to similar extent. However, subsequent increase in splenic choline production seen in WT is absent in mPGES-1 KO. In addition, LPS treatment tends to increase ChAT expression more strongly in WT compared to mPGES-1KO. Importantly, lack of mPGES-1 expression in splenocytes reversed nicotine's immunomodulating effects on TNF α release. In summary, defective cholinergic synthesis and inability to respond to cholinergic stimulation are likely to be key aspects explaining the failure of VNS to reduce LPS induced inflammation in mPGES-1 KO mice. Our results shed light on the possible link between cholinergic and PG system that may be of clinical significance in VNS treatment.

Title: Estradiol enhances microglial reactivity in the ventromedial hypothalamus of pubertal female mice

Authors: *A. VELEZ[1], S. FOUNTAIN[2], J. D. BLAUSTEIN[1];
[1]Neurosci. and Behavior, Univ. of Massachusetts, Amherst, Amherst, MA; [2]Univ. of Massachusetts, Med. Sch., Amherst, MA

Abstract: Pubertal development is a period of drastic transformation in central nervous system. Brain regions regulating reproduction undergo significant structural changes by mechanisms that include neurogenesis, apoptosis and synaptic pruning. Microglia, the resident immune cells of

the brain, are critical for appropriate maturation of the brain. At basal conditions they nurse synaptic connections, survey the environment and secrete cytokines. However, after an immune challenge microglia undergo a drastic change in morphology to support their macrophage function clearing cellular debris and phagocytizing pathogens, increasing cytokine production and becoming antigen-presenting cells. One of the hallmarks of pubertal development is the maturation of the reproductive axis, which results in increased secretion of ovarian hormones, including estradiol. In two experiments, we tested the hypothesis that ovarian secretions influence the response of microglia to the immune stressor, lipopolysaccharide (LPS), during pubertal development. In the first experiment, female mice were ovariectomized and received an oil or estradiol capsule 7 days prior to LPS or saline injection on P42 (during pubertal development). In the second experiment, gonadally-intact females received an aromatase inhibitor or vehicle injection for 7 consecutive days prior to injection of LPS or saline on P42. Animals were euthanized 24 hours post-injection and brains were collected. Microglia were identified by immunohistochemistry using an antibody against ionized calcium binding adapter molecule-1 (Iba1), which is expressed in microglia. We measured mean Iba-1 immunoreactivity to determine relative changes in the mean area covered by microglia, which serves as a proxy of microglial reactivity. Estradiol treatment resulted in a greater increase in microglial immureactivity in the ventromedial hypothalamus (VMH), but not the arcuate nucleus (ARC). In addition, blocking estradiol synthesis decreased microglial immunoreactivity in the VMH, but not the ARC. Lastly, as expected, LPS treatment increased microglial density in the VMH and the ARC compared to saline controls. Overall, these results suggest that estradiol modulates microglial reactivity in a brain-region dependent manner.

Title: Interleukin-13 receptor alpha 1 contributes to loss of dopaminergic neurons in a model of chronic stress

Authors: *S. MORI[1], S. SUGAMA[2], W. NGUYEN[1], G. MORONCINI[3], Y. KAKINUMA[2], P. MAHER[4], B. CONTI[1];
[1]Chem. Physiol., The Scripps Res. Inst., LA Jolla, CA; [2]Dept. of Physiol., Nippon Med. Sch., Tokyo, Japan; [3]Dept. di Scienze Cliniche Molecolari, Universita' Politecnica delle Marche, Ancona, Italy; [4]Cell. Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Parkinson's disease is the second most common progressive neurodegenerative disease affecting more than 2 million people in the United States and is characterized by the loss of dopaminergic neurons in the substantia nigra pars compacta. The vast majority of Parkinson's disease is idiopathic and believed to be the result of an interaction between genes and the environment. Exposure to chronic stress has proven to be an environmental factor that can damage dopaminergic neurons but the mechanisms by which this occurs remain to be determined. Here we tested the hypothesis that interleukin-13 receptor alpha 1, the putative PARK 12 expressed in dopaminergic neurons, can contribute to the vulnerability of these cells during stress in the mouse. We found that acute restraint stress stimulates the synthesis of interleukin-13 in the substantia nigra pars compacta where this cytokine was localized in microglia as well as in neurons. We also measured and compared the effects of chronic restraint stress on nitrotyrosine and on the number of dopaminergic neurons in the substantia nigra pars compacta of mice null for interleukin-13 receptor alpha 1 and their wild type littermates. We found that the loss of dopaminergic neurons during chronic stress was delayed in *Il13ra1*$^{-/Y}$ mice indicating that interleukin-13 receptor alpha 1 is one factor that contributes to the stress-mediated damage of dopaminergic neurons.

Title: Altered experience-dependent interleukin-1 beta signaling in juvenile rats exposed to ethanol as neonates

Authors: *M. J. GOODFELLOW, D. H. LINDQUIST;
Psychology, Ohio State Univ. Dept. of Psychology, Columbus, OH

Abstract: Fetal alcohol spectrum disorders (FASD) afflict up to 5% of American school age children (May et al., 2009), many of whom experience pervasive cognitive deficits, including impaired long-term memory (Jacobson et al., 2011). Ethanol-induced neuroinflammation is a major factor in FASD etiology (Alfonso-Loeches and Guerri, 2011)—both acute and chronic increases in basal pro-inflammatory cytokine interleukin (IL)-1β expression have been detected in the hippocampus of rodents exposed to ethanol during a human 3rd trimester equivalent period on postnatal day (PD) 10 (Drew et al., 2015) and PD28 (Tiwari and Chopra, 2011). While immune molecules in the healthy brain are important for synaptic plasticity and memory (del Ray et al., 2013), aberrant IL-1β expression can interfere with long-term potentiation (LTP) maintenance and long-term memory consolidation (Rachal Pugh et al., 2001). In addition to inducing changes in basal IL-1β expression (Wang et al., 2013), neonatal neuroinflammation has been shown to exaggerate experience-dependent IL-1β release in the hippocampus of adult rats following fear conditioning, resulting in impaired associative learning and memory (Williamson et al., 2011). It is currently unknown, however, if experience-dependent release is also altered by neonatal ethanol exposure.

In this study, male and female rats are administered ethanol (5 g/kg/day; 5E) via intragastric intubation or sham intubated (SI) across a 3rd trimester equivalent period (PD4-9) and, as juveniles (PD31), submitted to a hippocampus-dependent associative learning task, trace fear conditioning (TFC). Experience-dependent IL-1β mRNA and protein is measured in the dorsal hippocampus of separate rats 2 h following the completion of conditioning; basal IL-1β expression is also measured in experimentally naïve SI and 5E home cage control rats. Consistent with prior studies in adults and adolescents (Goodfellow et al., 2016; Schreiber and Hunt, 2013), preliminary results indicate that juvenile 5E rats freeze less than SI control rats during CS-alone test trials. Current data also suggest that the observed impairments are due, at least in part, to altered experience-dependent release of IL-1β, possibly impeding LTP maintenance and memory consolidation. If correct, then pharmaceutical interventions that modify IL-1β signaling during and/or immediately after TFC may strengthen synaptic plasticity and long-term memory consolidation, resulting in improved TFC test performance in 5E rats. Positive results would also suggest that immunomodulating drugs could be efficacious treatments for cognitive dysfunction in people with FASD.

Title: Chronic cocaine self-administration alters cognitive flexibility in male HIV transgenic rats

Authors: *S. E. HEMBY[1], S. MCINTOSH[2];
[1]Basic Pharmaceut. Sci., Fred Wilson Sch. of Pharmacy/High Point Univ., High Point, NC;
[2]Basic Pharmaceut. Sci., Fred Wilson Sch. of Pharmacy/High Point Universi, High Point, NC

Abstract: HIV infection and cocaine dependence can both disrupt neural circuitry mediating executive functions involved in decision-making and cognitive flexibility. The objective of the current study was to determine the impact of chronic cocaine intake on reversal learning in the HIV transgenic rat model. Previously, our lab has shown that male HIV transgenic rats are more sensitive to the reinforcing effects of cocaine accompanied by significant changes in the affinity of the dopamine transporter in the striatum. The present study compared the acquisition and performance on an operant reversal-learning task between male HIV-1 transgenic and Fischer F344 rats before and following chronic cocaine self-administration. In addition, in vivo microdialysis was used to compare extracellular dopamine levels in the striatum during a cocaine self-administration session. Performance on reversal learning tasks was assessed prior to the initiation of self-administration procedures and following cocaine self-administration. Rats were trained to intravenously self-administer cocaine (41ug/infusion) under a fixed ratio 3 (FR3) schedule of reinforcement during daily sessions. Sessions consisted of a 3 hr or 40 maximum infusion trial that was preceded by a priming infusion. Once animals reached a total intake criterion of 220mg of cocaine, animals were assessed with reversal learning. After the second assessment of reversal learning, microdialysis probes were inserted through previously implanted guide cannula in the ventromedial striatum. In summary, results demonstrate that HIV-1 Tg rats are capable of learning an operant spatial discrimination task and to reverse the spatial discrimination. After chronic cocaine self-administration, HIV-1 Tg rats showed impairment in the reversal and retention of a previously learned spatial discrimination compared to F344 rats. Basal levels of dopamine detected in microdialysates of the HIV Tg rats (5.2 nM ± 1.2 SEM) were lower compared to the F344 rats (10.2 nM ± 2.1 SEM) [p=0.078]. During cocaine self-administration, the percent change of dopamine from baseline did not differ between the F344 and HIV Tg rats; however, the dopamine concentration for the HIV Tg rats was lower compared to the F344 rats.

Title: Sex differences in the effects of dietary emulsifiers on physiology and behavior in mice

Authors: *M. K. HOLDER[1,2], B. CHASSAING[3], N. V. PETERS[2], J. WHYLINGS[2], A. T. GEWIRTZ[3], G. J. DE VRIES[2];
[2]Neurosci. Inst., [3]Inst. for Biomed. Sci., [1]Georgia State Univ., Atlanta, GA

Abstract: The internal and external surfaces of all mammals are colonized by a diverse group of microorganisms, collectively called the microbiota. The microbiota-gut-brain axis is known to influence brain development and social behavior. Recently, dietary emulsifiers, detergent-like molecules commonly used in processed foods such as ice cream, alter the composition of the intestinal microbiota and induce chronic low-grade inflammation, obesity, and metabolic syndrome in mice. Here, we tested whether emulsifier treatment would influence the expression of anxiety-like and social behaviors in male and female mice. Upon weaning, male and female C57Bl/6 mice were placed into a new cage with water or a 1% solution of either carboyxlmethylcellulose or polysorbate 80 in the drinking water. Body weights were recorded weekly and mice were subjected to a battery of standard anxiety tests (one test per week): open field, elevated-plus maze, light-dark box, marble burying, and the three-chambered sociability. In addition, the length of the colon and weights of the colon, spleen, liver, and adipose tissue were recorded at the end of the experiment. Emulsifier treatment altered anxiety-like behavior in male mice, as indicated by reduced time in the center of the open field test and increased distance travelled in the elevated plus maze. Emulsifier treatment did not affect anxiety-related behaviors in females; however, it reduced the preference for a novel conspecific mouse in the three-chambered sociability test in female, but not male, mice. Emulsifier treatment caused a 60-80% increase in adiposity and chronic intestinal inflammation, characterized by shortened colons, in both male and female mice compared to water-treated controls. Emulsifiers also increased total body weight of males, but not females. Taken together, these results indicate that emulsifier treatment leads to more severe physiological and behavioral alterations in male mice and acts on the neural circuits underlying social and anxiety-like behaviors.

Title: The role of TRAIL in cancer-related fatigue following radiation therapy

Authors: *S. D. DETERA-WADLEIGH[1], L. R. FENG[2], L. N. SALIGAN[2];
[1]Human Genet. Branch, NIMH, [2]Natl. Insitute of Nursing Res., NIH, Bethesda, MD

Abstract: Chronic fatigue is one of the most common and debilitating side effects of cancer and cancer treatment, and yet its etiology remains elusive. The goal of this study is to understand the underlying inflammatory mechanism and identify co-occurring symptoms of chronic fatigue in non-metastatic prostate cancer men following radiation therapy (RT) completion. The initial investigation included 40 men scheduled to receive RT at the National Institutes of Health, Bethesda, Maryland. Data were collected before RT (T1) and one year after RT (T2). Fatigue was assessed using the Functional Assessment of Cancer Therapy-Fatigue questionnaire (FACT-F). Whole genome microarray and cytokine multiplex panel examined fatigue-related transcriptome and serum cytokine changes, respectively. The significantly changed cytokine from the initial investigation was validated using sera from 46 men two years after completing RT (T3) for prostate cancer at Georgetown University Hospital, Washington, DC. Further in vitro validation determined the effect of the significantly changed cytokine on cell viability as quantified by MTT assay. Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) and TRAIL decoy receptor, *TNFRSF10C* (TRAIL-R3), were significantly upregulated (fold change=1.4, p=2.5x10^{-5}) in fatigued subjects (n=15) at T2. Cognitive deficits were also observed in fatigued subjects at T2. Further, TRAIL correlated with fatigue at T3 in a separate cohort. TRAIL caused selective cytotoxicity in neuronal cells, but not in microglial and muscle cells, in vitro. Late-onset inflammation directed by TRAIL may play a role in chronic fatigue pathogenesis in prostate cancer survivors. Selective vulnerability of neurons to TRAIL may contribute to chronic fatigue-related cognitive deficits.

Title: Neuroimmune modulation of hippocampal synaptic signaling, neural circuit activity, and memory retrieval

Authors: T. E. WHITE[1], J. CZERNIAWSKI[2], G. LEWANDOWSKI[2], *J. F. GUZOWSKI[3]; [1]Neurobio. & Behavior, Univ. of California, Irvine, CA; [2]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA; [3]Dept Neurobiol/Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Altered brain cytokine expression is at the core of many distinct neurological conditions that affect memory function and cognition. In order to develop therapies aimed at maintaining proper memory function in patient populations with these various conditions, it is critical to gain multilevel insight into how cytokines impact brain function and memory. Our previous studies show that mild acute neuroinflammation induced by systemic lipopolysaccharide (LPS) administration impairs context discrimination memory retrieval and disrupts pattern separation-like activity in hippocampal neuronal ensembles. Furthermore, blocking microglial activation systemically during LPS challenge with minocycline: i) abrogates increases in proinflammatory cytokines, ii) restores neural circuit activity in hippocampus, and iii) rescues context discrimination memory. However, systemic LPS-induced elevation of cytokines is brain-wide and not specific to the hippocampus. Therefore, we tested whether blocking microglial activation selectively within dorsal hippocampus (DH) is sufficient to rescue hippocampal neural circuit activity and context discrimination. Rats were trained to criterion in a context discrimination conditioning (CDC) task and received infusion of saline or minocycline (2 μg) directly into DH 5 min prior to administration of saline or LPS (i.p; 6 h before testing). Minocycline infused directly into DH in conjunction with LPS completely blocked context memory retrieval impairment in CDC. These preliminary data provide powerful evidence that local cytokine-mediated changes within DH are sufficient for the deficits in memory retrieval following peripheral immune stimulation. In order to determine how cytokines mediate alterations in neural circuit activity, and ultimately behavior, we are examining how LPS alters synaptic function and plasticity using transcriptomic and biochemical approaches. Cellular pathway analysis of RNA microarray data from whole DH indicates dysregulation of several signaling pathways critical to memory function including glutamatergic neurotransmission, calcium signaling, actin cytoskeleton regulation, and LTP. We are now analyzing synaptoneurosomal fractions of the dentate gyrus/CA3 and CA1 hippocampal subregions of candidate proteins in these pathways, including phospho-/total cofilin and phospho-/total GluR1. Together, this multilevel analysis will provide a framework for understanding how cytokines disrupt synaptic signaling and neural circuit dynamics in hippocampus necessary for context discrimination memory function.

Title: Low grade colitis sensitizes sickness response to lipopolysaccharide in BALB/c mice

Authors: *J. KONSMAN[1,2], L. CHASKIEL[3], R. DANTZER[4];
[1]CNRS UMR 5287 INCIA / Univ. Bordeaux, Bordeaux, France; [2]CNRS UMR 5226, Bordeaux, France; [3]CNRS UMR5226, Bordeaux, France; [4]MD Anderson Cancer Ctr., Houston, TX

Abstract: The gut has been proposed as a motor in critical illness driving multiple organ dysfunction (Mittal & Coopersmith, Trends Mol. Med., 2014). Indeed, mucus erosion, changes in intestinal microbial composition, decreased expression of tight junction molecules, and impaired epithelial renewal can all contribute to propagation of inflammation during critical illness. In the present study, we set out to determine if chronic low-grade gut inflammation exacerbates subsequent sickness behavior and brain cellular activation patterns in response to bacterial lipopolysaccharides (LPS). To do so, C57BL/6 and BALB/c male mice, which are prone and resistant respectively to dextran sodium sulfate (DSS)-induced chronic colitis (Melgar et al., Am. J. Physiol., 2005), were subsequently injected intraperitoneally with LPS or saline. Food intake and social exploration were assessed at regular intervals prior and after intraperitoneal injection to assess sickness behavior, characterized by reduced food intake and social exploration, during acute DSS-induced colitis, remission, and after LPS administration. A one-week episode of moderate colitis led to temporary loss of body weight compared to control in both strains. The following four-week remission period during which animals were exposed to a low concentration of DSS was associated with a transient decrease in social exploration, but not in food intake, in C57BL/6 mice. No changes in food intake or social exploration were observed in BALB/c mice during the remission period. Subsequent intraperitoneal administration of bacterial LPS resulted in an earlier reduction in food intake in BALB/c, but not in C57BL/6, mice exposed to a low concentration of gut irritant as compared to control animals without DSS. Intraperitoneal injection as such also reduced social exploration one hour later only in BALB/c that had experienced colitis as compared to control animals of the same strain without DSS. Quantification of the cellular activation marker c-Fos in the brainstem sections of these animals is currently ongoing to establish which structures were sensitized in their response to LPS after an episode of colitis and remission. Taken together, these findings indicate that signs of sickness behavior during colitis and remission do not necessarily predict the occurrence of more severe sickness behavior during subsequent acute systemic inflammation and, conversely, that chronic

exposure to gut irritants that does not lead to concomitant sickness behavior can nevertheless sensitize neuroimmune circuits and give rise to the accelerated appearance of sickness behavior during a later episode of acute systemic inflammation.

Title: Behavioral and physiological sex-differences following cardiac arrest/ cardiopulmonary resuscitation

Authors: *M. M. GAUDIER-DIAZ, A. H. HAINES, W. H. WALKER, II, N. ZHANG, R. J. NELSON, A. DEVRIES;
Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Cerebral ischemia, caused by cardiac arrest or stroke, is a leading cause of death and disability worldwide. Thus, it is important to find ways to prevent it, facilitate recovery, and improve the quality of life of survivors. This heterogeneous condition elicits a cytotoxic and inflammatory environment, which can subsequently affect behavior. Previous research in this area has focused primarily on male mice, possibly contributing to unsuccessful clinical trials and limited treatment options. The present study aims to investigate possible sex-differences in the behavioral and physiological responses to global cerebral ischemia. To test potential sex-differences, both female and male C57/Bl6 mice experienced a cardiac arrest/ cardiopulmonary resuscitation (CA/CPR) or a sham procedure, and 4 days later tested in an open field apparatus. Then, tissue was collected for gene expression and histological analysis. Following CA/CPR, female mice display hyperlocomotion; however, this ischemia-induced characteristic behavior was resolved in the males. As expected, cerebral ischemia increased the gene expression of pro-inflammatory cytokines (TNF-α, IL-1β, and IL-6) and inducible nitric oxide (iNOS). Specifically, the CA/CPR procedure led to a significant increase in the expression of TNFα, IL-6 and iNOS among female mice, whereas in male mice it increased the expression of TNF-α and IL-1β. The data support the existence of sex-differences in the behavioral and physiological

responses to CA/CPR, and suggest that increased IL-6 and iNOS might contribute to the unresolved hyperlocomotion observed in female mice. Certainly, consideration of sex-differences will be essential for the advancement of cerebral ischemia research and treatment strategies.

Title: Environmental mold exposure alters the relationships between microglial morphology and behavior

Authors: *K. PAGE[1,2], C. MCDERMOTT[2], S. UVAYDOV[3], D. ALEBDY[4], R. PANG[5], C. F. HARDING[1,4], C. L. PYTTE[1,2];
[1]Grad. Center, CUNY, New York, NY; [2]Psychology, Queens College, CUNY, Flushing, NY; [3]Biol., [4]Psychology, [5]Chem., Hunter College, CUNY, New York, NY

Abstract: Our labs are interested in the impact of environmental mold on brain and behavior. We use C57/BL6 mice to investigate the effects of exposure to the black mold, *Stachybotrus chartarum*. We have previously shown that mold inhalation increased microglial expression of the inflammatory cytokine IL-1beta in the hippocampus and caused deficits in hippocampal-dependent memory. Microglia have the capacity to move between morphological phenotypes and

respond to pathogens or injury by transitioning from a ramified state into a primed state or a motile amoeboid state. To better understand the functional implications of microglial phenotypes we asked whether microglial morphologies were related to spatial memory or anxiety and whether these relationships were altered by mold exposure. In particular, the role of primed cells is not well understood. Therefore, we were interested in whether primed phenotypes seem to play an intermediary role between ramified and amoeboid cell types. Mice were nasally exposed to either saline vehicle or mold in saline vehicle 3 times per week for 4 weeks. Behavior was assessed using the Morris water maze and elevated plus maze. Brains were processed and immunohistochemistry was performed to quantify numbers of Iba1+ microglia in the dorsomedial dentate gyrus. Iba1+ cells were categorized into 3 morphologies: ramified, primed, and amoeboid. We found that within the vehicle control group, there were no correlations between numbers of microglia within each category and measures of spatial memory. Within the mold-treated group, numbers of ramified cells were not correlated with spatial memory. As expected, numbers of amoeboid cells were correlated with worse spatial memory. Surprisingly, numbers of primed cells were correlated with better spatial memory. Among control mice, increased numbers of primed cells were highly correlated with increased anxiety, while numbers of amoeboid microglia were correlated with lowered anxiety, though more weakly. In contrast, in mold-exposed mice, there were no correlations between numbers of microglia in any category and measures of anxiety. Thus, the relationships between the three morphological phenotypes of microglia and behavior clearly differ. These findings support the idea that primed cells may function differently from both ramified and amoeboid cells, rather than simply being intermediate between ramified and amoeboid phenotypes. Second, the same phenotype is related to different behavioral outcomes depending on mold exposure. This suggests, for example, that primed cells in mold-exposed mice have different secretory profiles than primed cells in control vehicle mice.

Title: Effect of neonatal immune activation on the developing immune system and learning in juveniles

Authors: *B. OSBORNE, S. SOLOMOTIS, J. M. SCHWARZ;
Dept. of Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Activation of the immune system in early development increases the risk for a host of disorders. Notably, some neuropsychiatric disorders (e.g. Autism and learning disorders) present a strong male bias with diagnosis occurring during juvenile development. However, there has been little investigation into the impact of factors such as sex or early-life immune activation on the development of the immune system or the ontogeny of cognitive processes, such as learning. Microglia are the resident immune cells of the brain that respond to infection by increasing the release of immune molecules. Microglia communicate with neurons and have the ability to significantly affect neural function and behavior. Previous studies demonstrate that males have significantly more microglia than females in the hippocampus, cortex and amygdala on postnatal day four (P4), suggesting that males may be more vulnerable to the long-term negative consequences of early-life immune activation than females. The current experiments examined the effect of neonatal immune activation (low dose of Escherichia coli; $1x10^6$ CFU/0.1mL/kg) on microglia function and behavior in male and female rats alone or following a second immune challenge (Lipopolysaccharide; 25µg/mL) during juvenile development. Experiment 1 investigated potential learning delays using the Context Pre-exposure Facilitation Effect (CPFE) Paradigm at P24 and P30. Experiment 2 examined proinflammatory cytokine gene expression at P24 and P30. Experiment 1 revealed no differences in learning at P24 between sex or any treatment groups and all animals could perform the task. At P30, males and females that were neonatally infected and received a second immune challenge showed a trend towards enhanced learning relative to all other groups and showed better learning relative to P24 animals. Results from experiment 2 revealed decreased inflammatory gene expression in the prefrontal cortex and hippocampus at P30 relative to P24; however, at P24 IL-1β in the hippocampus is exaggerated in neonatally infected males and females following LPS, which is not observed at P30. These data indicate that immune function is changing rapidly throughout juvenile development and early-life immune activation does alter microglia function and cognition in juveniles, but not in a sex-specific manner.

Title: The effects of doxycycline and mold exposure on neurogenesis and contextual memory

Authors: *N. C. ABREU[1], A. EL-RAZI[2], I. VORONINA[3], K. PAGE[5], A. LOPEZ[1], S. UVAYDOV[4], C. F. HARDING[2,5], C. L. PYTTE[1,5];

Abstract: People who experience repeated exposure to moldy buildings report cognitive deficits, including learning and memory impairments. Our labs have shown that mold exposure results in brain inflammation, decreased hippocampal neurogenesis, and impaired contextual memory in a mouse model. The anti-inflammatory antibiotic, doxycycline, has been shown to decrease brain inflammation, increase hippocampal neurogenesis, and improve contextual memory. We therefore tested whether doxycycline mitigated the effects of mold exposure on neurogenesis and memory. Adult mice were intranasally instilled (3 times/week, 4 weeks) with either saline vehicle or spores of the black mold *Stachybotrys chartarum*. Half of each group received either doxycycline in their chow or a matched control diet. Mice were trained on a conditioned fear task to test hippocampal-dependent contextual memory. We used immunohistochemistry to visualize immature neurons, using an antibody to doublecortin (DCX). Immature neurons were quantified in the subgranular zone, granular cell layer, and hilus of the dentate gyrus. The density of immature neurons and measures of contextual memory did not differ across the four treatments. Vehicle mice treated with the doxycycline diet showed a positive correlation between numbers of DCX+ cells in the entire dentate gyrus and the strength of contextual memory. The more immature neurons, the better their memory. This relationship was seen at both 30 minutes and 24 hours after training and was driven by numbers of neurons in the granular cell layer. In contrast, mice exposed to both mold and doxycycline showed the reverse correlation between DCX+ cells and memory. The more immature neurons, the worse their contextual memory. Interestingly, this correlation was driven by neurons in the subgranular zone and hilus. This relationship was only seen in the 30-minute test, not when long-term memory was tested at 24 hours post-training. There were no correlations between immature neurons and contextual memory in mice fed the control diet without doxycycline, either with or without mold exposure. Thus, in mice treated with a doxycycline diet, more immature neurons corresponded to better contextual memory in vehicle mice, whereas contrary to expectation, more immature neurons were correlated with decreased memory in mold-exposed mice. We propose that mold exposure in doxycycline-treated mice negatively impacted the maturation, incorporation, or function of immature neurons, such that they were associated with impaired learning.

Title: Blockage of central interleukin 6 trans-signaling prevents predator stress in the mouse

Authors: I. GONZALEZ-NATERAS[1], F. MONTERO-AMEZCUA[1], R. CUEVAS-OLGUIN[1], E. ESQUIVEL-RENDON[1], J. VARGAS-MIRELES[1], C. GONZALEZ-DEL CARPIO[1], S. ROSE-JOHN[2], *M. ATZORI[3];

Abstract: Evidence of the last decade has revealed a potential link between stress and immune system. In particular, elevation in the levels of the pro-inflammatory cytokine interleukin 6 (IL-6) has been related to a variety of neuropsychiatric conditions including schizophrenia, depression, and post-traumatic stress disorder and other anxiety-related disorders. The relationship between IL-6 and the onset stressed behavior is not yet completely understood. We and others have already shown that an important mechanism of action of central IL-6 is through the so-called trans-signaling, which operates on all nucleated cells, including neurons. In order to assess the involvement of IL-6 trans-signaling in stress-related symptoms we used a transgenic mouse in which central IL-6 signaling was blocked by overexpression of a dimerized soluble version of the IL-6 transducer soluble glycoprotein 130 (sgp130Fc) in astrocytes, through the promotor of the astrocyte marker glial fibrillary acidic protein (C57BL/6 GFAP-sgp130Fc +/+, TG mice). Stress was induced by exposure to two session of one hour each in the presence of a domestic cat (*Felis Catus*) on two consecutive days. Stress levels were assessed measured by comparing the results of Porsolt forced swimming test (PS) and the Tail Suspension (TS) test. Five wild-type (WT) and six C57BL/6 GFAP-sgp130Fc transgenic (TG) mice were used for the experiment. Paired or unpaired Student-t test were used depending on the groups compared. As expected, WT mice were sensitive to stress (PS Latency to Immobility (LtI) = 155 ± 30 unstressed vs. 61 ± 7 s stressed, $P < 0.05$; PS PS First Two Minute Immobility Time (FTMIT) = 11 ± 6 vs. 45 ± 7, $P < 0.01$, same sample; TS LtI = 80 ± 10 unstressed vs. 48 ± 9 stressed; n = 5).

More importantly, non-stressed TG animal displayed a lower PS LtI (73 ± 11 s, n = 6) compared to WT animals but similar to stressed WT as well as to stressed TG (99 ± 10 s). Complementary to the PS LtI, unstressed TG animals displayed a PS FTMIT of 31 ± 7, higher than unstressed WT but not different from stressed WT or stressed TG (18 ± 6 s). As expected for WT, the TS LtI was longer for unstressed vs. stressed animals (80 ± 10 vs. 48 ± 9 s), and TS FTMIT was shorter for unstressed vs. stressed animals (13 ± 4 vs. 41 ± 7 s). Interestingly, TG animals displayed no sensitivity to the TS test, as their unstressed TS LtI (92 ± 23 s) did not differ from unstressed WT, nor from stressed TG (96 ± 20 s). Consistently with the TS LtI, unstressed TG animals' TS FTMIT (16 ± 4 s), did not differ from unstressed WT, not from stressed TG animals' FTMIT (16 ± 6 s). Altogether, these data suggest that central IL-6 trans-signaling is involved in the effects of predator stress in the rodent.

Title: Psychomotor activation levels in mice are regulated by vasoactive intestinal peptide produced by bone marrow derived blood cells

Authors: *R. PANJWANI[1], C. R. GIVER[2], J. P. SCHRODER[3], J. FELGER[4], D. G. STEIN[5], E. K. WALLER[2];
[1]Dept. of Neurosci. and Behavioral Biol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Produced by both neurons and lymphocytes, vasoactive intestinal peptide (VIP) is a 28-amino acid neuropeptide that decreases Th1 and anti-viral immunity. VIP also plays a role in regulating neurological behavior; previous investigations have determined that VIP/peptide histidine isoleucine knockout (VIP-KO) mice exhibit altered circadian rhythms, decreased mobility, and selective cognitive disabilities. The goal of this study was to understand the role of VIP in murine behavior and determine whether VIP produced by bone marrow-derived blood cells influence neurological function. This question was addressed using radiation chimeras of

female C57BL/6J VIP-KO and wild-type (WT) mice receiving syngeneic transplants of bone marrow derived cells from either VIP-KO or WT donors. We hypothesized that the behaviors of VIP-KO mice will be changed to resemble wild-type mice in radiation chimeras engrafted with hematopoietic cells from WT mice and the behavior of wild type mice will be changed to resemble VIP-KO mice in radiation chimeras of WT mice engrafted with hematopoietic cells from VIP KO mice. Mice were observed for circadian rhythms, examined during forced swim tests (FST), and tested in contextual fear conditioning (CFC) paradigms 10-weeks post-transplant. Our hypothesis was supported and a difference was noted between transplant groups receiving WT and KO hematopoietic cells. Chimeras receiving KO bone marrow-derived cells exhibited significantly greater novelty induced locomotion. Wild type chimeras engrafted with KO cells showed significantly greater dark phase activity and swam significantly more during the FST. No difference was measured in the freeze response among radiation chimeras during the CFC. These findings indicate bone marrow-derived blood cells influence behavior and that VIP produced by blood cells is important in psychomotor activation levels. Future investigations include repeating experiments with male models and analyzing VIP content and brain histology to determine neurological function during behavioral testing.

Title: Targeted deletion of $P2X_7$ ion channels prevent Mycobacterium bovis, BCG induced depressive like behaviors in mice.

Authors: *J. C. O'CONNOR[1,2], L. REDUS[1], N. DERECKI[3], A. BHATTACHARYA[3]; [1]Pharmacol., UTHSCSA, San Antonio, TX; [2]Audie L. Murphy VA Hosp., San Antonio, TX; [3]Janssen Res. & Development, LLC, San Diego, CA

Abstract: Inflammation is implicated as a pathogenic factor in the development of depression symptoms. In mice, peripheral inoculation with the attenuated BCG strain of *Mycobacterium bovis* precipitates a depression-like behavioral phenotype due to persistent upregulation of peripheral cytokine expression, increased kynurenine metabolism and central

neuroinflammation. However, the CNS receptor-mediated mechanisms that contribute to BCG-induced depression-like behaviors are not fully understood. ATP-gated ion channels are preferentially expressed by brain microglia and contribute to neuroinflammation. We sought to determine whether $P2X_7$ contributed to the development of depression-like symptoms following BCG challenge in mice. Young adult male C57BL6/J (WT) mice or $P2X_7$ receptor null mice ($P2X_7^{-/-}$Jackson Laboratory) were inoculated with 10^7 colony-forming units of BCG or an equal volume of vehicle. All BCG challenged mice exhibited a 10%-12% reduction in body weight that steadily returned toward baseline levels by 10 days post BCG. Beginning two weeks post-BCG, mice were subjected to a series of behavioral tests spanning multiple discrete domains of depression-like symptomology. Sucrose preference was significantly reduced in BCG-challenged WT mice, and while baseline preference was slightly lower in $P2X_7^{-/-}$ mice, BCG did not reduce preference compared to vehicle treated $P2X_7^{-/-}$ controls. Similarly, BCG caused a reduction in spontaneous alternations in the Y-maze, increased time spent in the central area of an open field and reduced social interaction with a novel conspecific in WT mice, but in each of these tests $P2X_7^{-/-}$ mice were protected from BCG-induced behavioral changes. In contrast to previous reports, BCG did not increase immobility during the tail suspension test, but $P2X_7^{-/-}$ mice exhibited a general antidepressant phenotype. BCG-induced upregulation of the peripheral cytokine/chemokine response and splenomegaly were not dependent on $P2X_7$ gene deletion. Taken together, these data suggest that $P2X_7$ may play an important role in mediating the depression like behavioral effects of chronic peripheral inflammation induced by BCG.

Title: Astrocyte modulation of stress-enhanced fear learning, an animal model of post-traumatic stress disorder

Authors: *M. E. JONES[1], L. B. COOPER[2], E. B. KELLY[2], J. E. PANICCIA[2], C. L. LEBONVILLE[2], D. T. LYSLE[2];

Abstract: Neuroimmune signaling is important in learning and memory processes. Further, converging evidence suggests that neural immune interactions, including astrocyte activity, are altered following stress exposure. For example, our laboratory has shown that the severe stressor in stress-enhanced fear learning (SEFL), an animal model of post-traumatic stress disorder (PTSD), induces a time-dependent increase in interleukin-1β (IL-1β) protein and mRNA and that blocking IL-1 signaling prevents the development of SEFL. Here, we employed double labeling fluorescence immunohistochemistry to determine the cellular source of IL-1β and took advantage of recent advances in chemogenetic technology to begin to explore the role of astrocytes in SEFL. Specifically, we used glial DREADDs (designer receptors exclusively activated by designer drugs) to test whether Gi signaling in hippocampal astrocytes modulates the development of SEFL.
In Experiment 1, rats were exposed to Context A of the typical SEFL paradigm (15 2mA scrambled foot shocks over 90 minutes on a 6 minute variable interval schedule) and sacrificed via transcardial perfusion 48 hours later. Brains were extracted and tissue was processed for immunohistochemistry with primary antibodies against IL-1β and cell type specific markers for astrocytes (GFAP), neurons (NeuN), and microglia (Iba-1). Alexa fluor -conjugated secondary antibodies were used for visualization. Confocal microscopy analyses revealed significant co-localization of IL-1β and GFAP in the dorsal hippocampus in animals exposed to the stressor.
In Experiment 2, rats were infused with *AAV8-GFAP-hm4di-mcherry* directly into the dorsal hippocampus and allowed three weeks to recover from surgery and for the virus to express. Rats were then exposed to the typical SEFL paradigm and administered Clozapine-n-oxide (CNO; 3 mg/kg, s.c.) immediately, 24h, and 48h after removal from Context A. Preliminary data showed that CNO significantly attenuated fear learning to Context B on test day 1.
In summary, Experiment 1 showed that astrocytes are the predominant cellular source of stress-induced IL-1β in the dorsal hippocampus. Strikingly, our preliminary data in Experiment 2 showed that activating astroglial Gi signaling attenuated SEFL, a PTSD-like phenotype. Further studies in our laboratory are testing the effect of activating astroglial Gq signaling following the severe stressor on SEFL and whether any effects of glial GPCR signaling occur through an IL-1β-dependent mechanism.

Title: Sustained peripheral inflammation triggers anandamide hydrolysis to promote anxiety.

Authors: *H. A. VECCHIARELLI[1,2], M. MORENA[2], M. STICHT[2], C. M. KEENAN[2], W. HO[2], K. A. SHARKEY[2], M. N. HILL[2];

Abstract: There is a high degree of comorbidity between chronic peripheral inflammatory diseases and neuropsychiatric disorders, such as anxiety and depression. However, the mechanisms linking the two have not been fully elucidated. The endogenous cannabinoid system is known to regulate both inflammation and anxiety, making it a candidate system to investigate interactions between the two. This study's aim was to determine if chronic peripheral inflammation, in the form of colitis, alters central endocannabinoid levels and to determine if these changes related to inflammation-induced anxiety. Colitis was induced by administration of trinitrobenzene sulfonic acid (TNBS) intracolonically to adult, male, Sprague Dawley rats. Seven days after the induction of colitis, anandamide levels are reduced in the amygdala (-30%), hippocampus (-14%) and medial prefrontal cortex (-30%). In contrast, 2-arachidonylglycerol (2-AG) levels are increased in the hippocampus (16%) and medial prefrontal cortex (21%). We observed an increase in anxiety behaviors following colitis (approximately a 50% reduction in open arm time using an elevated plus maze), with no change in locomotor activity. This inflammation-induced anxiety was reversed by acute intracerebroventricular (ICV) administration of the fatty acid amide hydrolase (FAAH) inhibitor PF-4458945 (100 µg), which increases anandamide levels. These findings increase our understanding of the mechanisms underlying anxiety behaviors in chronic peripheral inflammatory states. They suggest that similar to stress-induced anxiety, inflammation-induced decreases in anandamide signaling are likely relevant for the change in emotional behaviors associated with chronic inflammation.

Title: Genipin attenuates LPS-induced persistent changes of emotional behaviors and neural activation in the hypothalamic paraventricular nucleus and the central amygdala nucleus

Authors: *T. YABE, Y. HIRAKI, S. NISHIDA, R. ARAKI;
Setsunan Univ., Osaka, Japan

Abstract: Sickness behavior is a series of behavioral and psychological changes that develop in those stricken with cancers and inflammatory diseases. The etiological mechanism of sickness behavior is not known in detail, and consequently there are no established standard therapies. Administration of the bacterial endotoxin lipopolysaccharide (LPS) induces sickness behavior in rodents. Genipin, an aglycon derived from an iridoid glycoside geniposide extracted from the fruit of Gardenia jasminoides, has anti-inflammatory and antidepressant activities. However, the effects of genipin on inflammation-induced changes in emotional behaviors are unknown. In this study, we examined the effects of genipin on LPS-induced inflammation in BV-2 cells and sickness behavior in mice. Pretreatment with genipin inhibited LPS-induced increases in NO production and reduced the mRNA levels of inflammation-related genes (iNOS, COX-2, IL-1β and IL-6) in BV-2 cells. Oral administration of genipin ameliorated LPS-induced depressive-like behavior in the forced swim test and social behavior deficits 24h after LPS administration in mice. LPS-induced expression of mRNAs for inflammation-related genes and the number of c-fos immunopositive cells decreased in the paraventricular nucleus (PVN) of the hypothalamus and the central nucleus of the amygdala (CeA), suggesting that genipin attenuates LPS-induced changes of emotional behaviors through inhibition of neural activation and inflammatory responses in the PVN and CeA. In conclusion, KKT ameliorated LPS-induced sickness behavior *via* suppression of neural activation in the PVN and CeA, but had little effect on LPS-induced inflammation. These results indicate that KKT has potential for treatment of sickness behavior. Our findings also suggest that suppression of neural activation in the PVN and CeA is a potential therapeutic approach for treatment of sickness behavior.

Title: A history of juvenile malaria predisposes mice towards anxiety-like responses, neuroinflammation, and decreased neurogenesis in response to adult-onset stress

Authors: *S. K. GUHA, I. SARKAR, S. SHAH, M. PATGAONKAR, S. SHARMA, S. PATHAK, V. A. VAIDYA;
Dept. of Biol. Sci., Tata Inst. of Fundamental Res., Mumbai, India

Abstract: Children residing in malaria endemic regions are particularly susceptible to malaria. Also, this early-life window is a critical-period for development and maturation of the nervous system. Exposure to inflammatory insults during this critical-period has life-long neuropsychiatric consequences. We therefore asked whether a history of juvenile mild malaria predisposed individuals towards mood-related disorders and neurocognitive deficits.
We employed a mouse model of juvenile mild malaria, and combined it with a four-week chronic unpredictable mild stress (CUS) regime during adulthood to examine latent behavioural, neuroimmune, and neurogenic consequences of the infection.
Adult mice with a history of juvenile malaria exhibited an early-onset anxiety-like behaviour in open field test and elevated plus maze when exposed to a CUS regime. These mice also had elevated stress associated serum cytokine response and microglial activation within the hippocampal neurogenic niche. Furthermore, there was a concomitant decline in adult hippocampal neurogenesis. Interestingly, while the total number of immature neurons remained the same, baseline proliferating progenitor numbers within the adult hippocampal neurogenic niche had significantly declined in mice with a history of juvenile malaria.
In conclusion, history of juvenile mild malaria predisposes individuals towards post-stress anxiety-like responses in adulthood, which is strongly correlated with both neuroinflammatory and neurogenic changes. These findings lead credence to the idea that the burden of malaria in early-life may result in sustained CNS changes that get unmasked later in life by subsequent insult(s).

Abstract: Peripheral infections often cause behavior changes and cognitive impairment. The activation of innate immune system is the primary and immediate defense by which an organism copes with infection. How infection-induced innate immune response modulates synapse plasticity and learning is unknown. In this study, we used transcranial two-photon microscopy to examine the remodeling of postsynaptic dendritic spines in the living mouse cortex after systemic administration of a synthetic double-stranded RNA, which mimics the acute phase of viral infection. We find that viral-like immune activation has potent effects on dendritic spine dynamics, increasing dendritic spine elimination and decreasing learning-dependent spine formation. Concomitantly, mice show deficits in multiple learning tasks during viral immune activation. Using in vivo cell depletion, we show that these synaptic alterations in the cortex are mediated by peripheral CX_3CR1-expressing monocytes, but not by brain-resident microglial cells. Furthermore, inhibiting TNFα production in monocytes prevents the abnormal spine remodeling and protects mice from learning deficits. Together, our study identifies CX_3CR1^+ monocytes and TNFα as key immune components that drive synaptic alterations and cognitive dysfunction during systemic infection.

Title: Toxoplasma gondii infection and blunted response to stimulant drug administration

Authors: *R. MCFARLAND[1], M. V. PLETNIKOV[2], R. H. YOLKEN[3];
[1]molecular microbiology and immunology, [2]Behavioral Neurosci., [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Infection with the neurotropic parasite *Toxoplasma gondii* has long been identified as a risk factor in the development of human psychiatric disease, particularly schizophrenia. The induction of neuro-immune responses may be behind the link between the parasite and disease, and is consistent with the most recent advances in human genetic association studies. These studies indicate changes to immune mechanisms as strong genetic risk factors for the development of schizophrenia. We have established a mouse model system that has a strong and consistent behavioral phenotype of infection. In this model we see that long-term infection with Toxoplasma creates a severely blunted response to the dopaminergic stimulant drugs cocaine and amphetamine, suggesting that the parasite is inducing brain changes which are relevant to dopamine release. The profound inhibition of the biological effects of these stimulants is the strongest and most consistent behavioral effect yet attributed to latent infection with the parasite, and one that is directly relevant to human brain function as well.

Title: Vium Digital Vivarium™ enables automated drug efficacy assessment in animal models of multiple sclerosis

Authors: *L. SCHAEVITZ, D. FORD, M. LIM;
Vium, San Mateo, CA

Abstract: Current methods for screening and evaluating new therapeutics in rodent disease models are not only labor-intensive, but are also confronted by several challenges, including the ability to consistently produce reproducible and unbiased data. To address these limitations, we created the Vium Digital Vivarium™, which monitors animals continuously for disease and health-related endpoints, without human interaction, to evaluate drug efficacy. Our intelligent sensor and camera network not only monitors health endpoints, including overall activity, breathing rate, and circadian rhythms but also stores the data in auditable electronic and videographic records. As a proof of principle, we conducted two standard studies using the mouse Myelin Oligodendrocyte Glycoprotein $(MOG)_{1-125}$ induced experimental autoimmune encephalomyeltitis (EAE) model of multiple sclerosis (MS) in the Vium Digital Vivarium. Traditionally, MS disease onset and progression in this mouse model are evaluated using Disease Activity Index scoring (DAIs), a scale-based subjective scoring system, which monitors clinical signs of two motor functions, abnormal gait and paralysis, to assess severity of the disease. Data from our platform showed significant changes in overall activity, which preceded disease onset as measured by traditional DAIs scoring. Given the clear relationship between activity and the DAIs, we are using machine learning to develop an algorithm to automatically identify disease onset and severity in MS. The DAIs and metrics from the first standard study are being used to train classifiers, while data from the second study, including standard of care drugs FTY720 and methylprednisolone, will be used to test performance of the algorithm. Here we demonstrate how a low-touch digital platform can pave new ways for more rapid, reproducible, drug discovery and evaluation, not only for MS, but also more broadly in other autoimmune diseases including Lupus as well as neurodegenerative diseases such as Parkinson's, Huntington's, and ALS.

Title: Early life depletion of microglia programs lifelong mood-related behavior and brain development

Authors: *L. H. NELSON[1], S. WARDEN[2], K. M. LENZ[3];
[1]Ohio State Univ., Columbus, OH; [2]Dept. of Psychology, [3]Dept. of Psychology and Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Microglia, the brain's resident immune cells, regulate normal processes of brain development, including synaptic pruning, axon outgrowth, proliferation, and progenitor pool size (Schafer et al., 2012 Neuron; Squarzoni et al., 2014 Cell Reports; Cunningham et al., 2013 J Neurosci; Shigemmoto-Mogami et al, 2014 J Neurosci). Perinatal perturbations such as early life stress (ELS) increase microglial activation and alter mood-related behavior (Roque et al., 2012 Brain Behav Immun; Wigger et al., 1999 Physiol Behav), but it is unknown if microglia influence the basal development of mood-related behavior or brain circuits. The neonatal male brain has more activated microglia than the female brain (Lenz et al., 2013, J Neurosci; Schwarz et al., 2012 J Neurochem), and males are generally more sensitive to early life perturbations, but whether microglia contribute to sex differences in the development of mood related behavior is also unknown. We hypothesized that microglia contribute to early life programming of mood-related behavior, and used a microglial depletion strategy to test this hypothesis in male and female rats. We used central infusion of liposomal clodronate (2μL icv; Encapsula Nanoscience) on postnatal day (P) 1 and P4 to induce microglial apoptosis during the neonatal period. We analyzed the depletion and recolonization of microglia via densitometry of Iba1 immunostaining. Approximately 90% of microglia were depleted brain-wide by P2, and microglia recolonized the brain at P12. Following microglial depletion, animals were grown to adolescence or adulthood for behavioral testing, including anxiety tests (the elevated plus maze and open field), behavioral despair testing (forced swim test), and HPA axis tone following acute restraint stress. We found that clodronate treated rats had lower anxiety as adolescents and adults, decreased despair-like behavior as adults, and lower restraint-evoked corticosterone levels in females, with few sex differences observed. These results suggest that microglia are important for the developmental programming of mood-related behavior. We are currently using Golgi-Cox staining to and single cell reconstruction to assess if neonatal microglial depletion impacts dendritic spine density in the amygdala, hippocampus, prefrontal cortex, and bed nucleus of the stria terminalis. Future research will determine how ELS affects microglial function during development, and whether microglial depletion is protective against the programming effects of ELS on adult mood-related behavior. These studies give important insight into the role microglia play in normal development of brain and behavior.

Title: Attenuation of TLR4 signalling prevents behavioural alterations induced by a short alcohol binge during adolescence

Authors: *J. W. JACOBSEN[1], F. BUISMAN-PILJIMAN[1], D. BARRATT[1], S. MUSTAFA[1], M. R. HUTCHINSON[2];
[1]Pharmacol., [2]Ctr. for Nanoscale BioPhotonics, Univ. of Adelaide, Adelaide, Australia

Abstract: Background
Adolescence is a crucial neurodevelopmental period. During this stage, brain regions governing novelty and pleasure seeking are still immature. This increases the propensity for adolescence to engage in risky behaviours such as, binge drinking. Unfortunately, these same brain regions are susceptible to alcohol. Consequently, binge drinking can perturb neurodevelopment causing detrimental consequences in adulthood. However, current animal models are limited in their portrayal of the human condition nor do they consider the role of immune signalling. Therefore, the aims of this experiment were to develop a better animal model of adolescent alcohol exposure and to characterise its effects on immune signalling and later life alcohol-related behaviours.
Methodology
Between postnatal days 22 and 25, balb/c mice received an oral gavage of alcohol (0.5 – 3.5g/kg) daily, replicating a short alcohol binge paradigm. Control mice received volume-matched gavages of saline. Mice were weaned (P30), separated in to single sex cages and allowed to mature undisturbed until adulthood (P56 – 70). Mice subsequently underwent elevated plus maze (anxiety), conditioned place preference (alcohol wanting/seeking) and "drinking in the dark" (binge drinking).
Results
Four doses of alcohol during adolescence dose dependently increased alcohol-induced conditioned place preference ($p<0.0001$) in adults. Further, compared to saline controls, adolescence alcohol exposure augmented alcohol intake in adults ($p=0.018$). However, this model did not effect basal elevated plus maze times ($p>0.05$). Subsequent analysis of nucleus accumbal mRNA, revealed an increased expression of TLR4-related mRNAs in mice who received alcohol during adolescence compared to saline ($p<0.01$).
To further elucidate the role of TLR4, (+)-Naltrexone, an antagonist was administered 30mins before or after the adolescent binge paradigm. When tested in adulthood, (+)-Naltrexone treated animals had attenuated binge alcohol consumption later in life ($p<0.0001$), but did not alter other

responses.

Conclusions

This study highlights that even a small amount of alcohol, when given during a critical neurodevelopmental period, can potentiate alcohol wanting/seeking behaviour and alcohol intake later in life. Interestingly, attenuation of TLR4 before or after adolescent exposure reduced only binge alcohol intake. Given that these behaviours are governed by distinct brain regions, it suggests, a regional specific role for TLR4.

Title: Robust continuous estimation of cardiac output and systolic time intervals using a moving ensemble method

Authors: *M. CIESLAK[1], W. S. RYAN[2], W. MEIRING[3], V. BABENKO[4], H. ERRO[4], Z. M. RATHBUN[4], J. BLASCOVICH, PhD.[2], S. T. GRAFTON[2];

Abstract: Impedance cardiography (ICG) is a non-invasive method used to measure cardiac output and systolic time intervals during psychophysiology experiments. Autonomic responses to motivation, stress and task engagement can be captured using this technique. However, ICG practitioners currently must choose between two extremes of analyzing beat-by-beat signals or methods that reduce each epoch of data into a single ensemble averaged heartbeat. Beat-by-beat measurements are contaminated with respiratory artifacts and random noise, while ensemble averaging is unable to capture transient changes that occur within an epoch. Here we describe a recently developed moving ensemble method that combines the noise-removing aspects of ensemble averaging while maintaining the ability to detect transient changes in cardiac output and systolic time intervals. Open source software for applying the moving ensemble method is provided.

Study 1 recorded ICG data from 30 individuals during two repetitions of a cold pressor. Study 2 acquired ICG data from two individuals over four days where multiple tasks were run in a counterbalanced order. Tasks included a valsalva maneuver, a cold pressor and a video game. We show that the moving ensemble method captures fast changes in cardiac output and systolic time intervals that are missed by fixed-window ensemble averaging.

Title: The NeuroCorrelates of steady state blood pressure and heart rate in healthy humans

Authors: *L. BARNDEN[1], R. BURNET[2], P. DEL FANTE[4], R. KWIATEK[5], B. CROUCH[3], Z. SHAN[1];
[1]NCNED, Menzies Hlth. Inst. Queensland, Griffith Univ., Southport, Australia; [2]Endocrinol., [3]Nuclear Med., Royal Adelaide Hosp., Adelaide, Australia; [4]Healthfirst Network, Adelaide, Australia; [5]4Division of Med. Subspecialities, Lyell McEwin Hosp., Adelaide, Australia

Abstract: In healthy humans, normal inter-subject variation in steady state Heart Rate (HR) and Blood Pressure (BP) may be mediated by normal variability in the brain nuclei that control autonomic nervous system activity. The neurocorrelates of HR and BP have been investigated under mental and emotional stress, but not under steady state conditions. In this cross-sectional study, SPM5 voxel-wise regressions were performed between structural brain MRI levels and steady state BP and HR in 23 subjects. MRI included grey matter volume (GMvol) and white matter volume (WMvol) images from voxel based morphometry, and T1- and T2-weighted spin-echo (T1w and T2w) images. Steady state systolic BP (sysBP), diastolic BP (diaBP) and pulse pressure (PP), and HR, all in two postures (erect and reclining) were extracted from 24 hour BP monitoring. Voxel-wise MRI regressions were adjusted for age and the appropriate global value. Significant clusters for MRI vs BP or MRI vs HR were identified via corrected cluster P (ccP) after imposing a false discovery rate (FDR) of 0.05 to account for the 64 regressions performed. Correlations between pairs of the HR and BP measures were significant between the erect and reclining values for each measure, and between all BP measures in the erect posture and in the reclining posture (except between erect diaBP and erect PP), but not between HR and any BP. In the voxel-wise analysis, FDR < 0.05 was satisfied for ccP < 0.005. We identified 6 significant

clusters, all from WMvol regressions, with three from each posture. WMvol associations occurred in the right prefrontal cortex (erect and reclining HR), the medial prefrontal cortex (reclining sysBP and reclining diaBP) and the caudal pons - inferior cerebellar peduncle (erect sysBP and erect diaBP). In a healthy population, normal variability in relative local WM volume contributes to the normal variability in BP and HR.

Title: Protective effects of training status on autonomic modulation and blood pressure during acute exercise in normotensive adults and elderly

Authors: *A. S. ZAGO, G. F. M. MARTINS, L. P. BARBOSA, L. L. CESAR, A. M. JACOMINI, R. F. SILVA, S. L. AMARAL;
Dept. of Physical Educ., Univ. Estadual Paulista, Bauru, Brazil

Abstract: Increases in sympathetic activity (SA) and reductions in vagal activity may be considered one of the causes for the high incidence of hypertension (HT) in elderly. In the opposite way, regular exercise training has the capacity to reduce blood pressure (BP) by improving cardiac autonomic modulation. However, increases in SA observed during acute exercise may cause a huge increase on BP, exposing the participant to any cardiovascular events. Although it is well established at the literature, little is known about the effects of a good level of training status (TS) in preventing the high elevation of BP during exercise. The purpose of this study was to evaluate the cardiac autonomic modulation and BP in normotensive adults and elderly with different levels of TS during the rest and acute exercise. Adults (n=14, 54±8 years old) and elderly (n=21, 70±5 years old) with no cardiovascular disease performed an incremental test on treadmill to estimate maximal oxygen uptake (VO_2max). Blood pressure and heart rate variability (HRV) were measured during acute exercise. Autonomic modulation was evaluated by normalized low (LFnu) and high-frequency (HFnu) components of the R-R variability accessed by RS800 heart rate monitor (polar®) during rest (10min) and acute exercise (40 min walking at 50-60% of VO_2max). All participants were divided according to VO_2max in TS1 (low VO_2max) and TS2 (high VO_2max) according to American Heart Association. In the adults group, differences were found in LF (TS1=85±5 vs TS2=61±24 nu, $p<0.02$) and HF (TS1=14±2

vs TS2=38±5 nu, p<0.03) at rest moment. Besides these different results, systolic (SBP) and diastolic BP (DBP) were similar between both groups (TS1=112±6/78±6 and TS2=113±9/74±7 mmHg). During exercise, no significant changes were observed in LF (TS1=70±8 vs TS2=77±10 nu), HF (TS1=29±3 vs 27±3 nu) or BP (TS1=137±8/76±5 and TS2=144±14/77±9 mmHg) between groups. In the elderly group, no differences were found for LF (TS1=39±6 vs TS2=57±8 nu) and HF (TS1=59±12 vs TS2=42±8 nu) either at rest or during exercise (LF - TS1=55±14 vs TS2=70±6 and HF - TS1=44±14 vs TS2=29±6 nu). Blood pressure was similar between groups at rest (TS1 = 113±8/62±8 and TS2 = 112±15/63±11 mmHg), however during acute exercise the DBP was lower in TS2 compared with TS1 (TS1=137±11/80±4 and TS2=137±14/70±9 mmHg, p<0.05). These results suggest that normotensive individuals, with better training status, can perform a low intensity acute exercise with similar increase of cardiac autonomic balance and smaller increase of DBP, compared with lower training status, even though walking at higher speed on treadmill, which may contribute to avoid cardiovascular events during exercise.

Title: Cognitive and mood deficits and associations between symptoms and disease severity in early-diagnosed, treatment-naïve obstructive sleep apnea

Authors: L. EHLERT[1], B. ROY[2], D. KANG[3], M. WOO[2], R. AYSOLA[4], *R. KUMAR[1,5,6,7]; [1]Dept. of Anesthesiol., [2]Sch. of Nursing, [3]Dept. of Med., [4]Dept. of Pulmonary Med. and Critical Care, [5]Brain Res. Inst., [6]Radiological Sci., [7]Bioengineering, Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Obstructive sleep apnea (OSA) is a serious health condition accompanied by repeated blockage of upper airway, with continuous diaphragmatic efforts to breathe during sleep. Brain regions with structural changes emerge in early-diagnosed, without-treatment OSA subjects in

areas that control cognitive and mood functions. However, the status of cognitive and mood functions and relationship between those symptoms and disease severity in early-diagnosed, treatment-naive OSA subjects is unclear. Our aim was to examine cognitive and mood functions and associations between cognitive and mood scores to disease severity [oxygen saturation nadir (SaO_2 nadir) and apnea hypopnea index (AHI)] in recent-diagnosed, non-treated OSA subjects. We studied 21 early-diagnosed, treatment-naïve OSA (age, 48.4±10.7 years; body mass index, 31.2±5.0 kg/m^2; AHI, 36.5±20.7 events/hour; 18 male) and 19 control subjects (age, 52.8±10.8 years; body mass index, 26.5±3.5 kg/m^2; 15 male). Cognitive functions were examined with the Montreal Cognitive Assessment (MoCA) test, depressive symptoms with the Beck Depression Inventory II (BDI-II), and anxiety symptoms with the Beck Anxiety Inventory (BAI). MoCA values < 26, and BDI-II and BAI values >10 are considered abnormal scores. The AHI and SaO_2 nadir values were derived from overnight polysomnography study of all OSA subjects. No significant differences in age or gender appeared between OSA groups. However, OSA subjects had significantly higher body mass index over controls. MoCA scores were significantly reduced in OSA compared to controls (OSA vs controls; 25.9±2.8 vs 27.4±1.7, p = 0.04). BDI-II (6.6±7.4 vs 1.7±2.0, p = 0.008) scores were significantly increased, but BAI scores (4.7±6.5 vs 1.8±2.2, p = 0.07) showed increasing trend in OSA over controls. Significant positive correlations appeared between SaO_2 nadir and MoCA scores (r = 0.56, p = 0.008), and negative correlations emerged between AHI and MoCA scores (r= -0.47, p = 0.03). However, no significant correlations appeared between BDI-II and BAI scores and AHI and SaO_2 nadir values. Early-diagnosed, treatment-naïve OSA subjects show significantly reduced cognitive function and enhanced mood symptoms, and significant associations between cognitive scores and disease severity. The findings of significant relations between cognitive scores and disease severity indicate that higher AHI or lower O_2 saturation may contribute significantly to cognition in the condition.

Title: Sympathetic blockade markedly prolongs EEG coherence and delays the onset of cardiac arrest after asphyxia

Authors: *F. TIAN[1], T. LIU[1], G. XU[1], D. LI[1], T. GHAZI[1], T. SHICK[1], A. SAJJAD[1], M. WANG[1,2], P. FARREHI[1], J. BORJIGIN[1];

Abstract: Sudden cardiac arrest is a leading cause of death around the world. Currently, there are no pharmacological therapies that are effective in preventing sudden cardiac death. Previous studies suggest that overactivation of the sympathetic nervous system plays an important role in mediating sudden cardiac death. Surgical disconnection of the sympathetic efferent signaling via spinal cord transection at cervical level 7 (C7X) significantly extends the survival of both the brain and the heart. The objective of this study is to test the effectiveness of two sympathetic blockers, atenolol and phentolamine, in preventing sudden cardiac death in CO2-mediated asphyxic cardiac arrest model. Rats were divided into 4 groups, which received either atenolol plus phentolamine (10mg/kg, 10mg/kg, n=11), atenolol alone (10mg/kg, n=8), phentolamine alone (10mg/kg, n=7), or saline (n=10), 30 minutes before the onset of asphyxia. EEG (from 6 cortical loci) and EKG signals were simultaneously collected from each rat during the entire process. We found significant increase in EEG coherence duration and EKG signal duration in rats received drugs. Remarkably, rats injected with atenolol plus phentolamine had the most significant increase in EEG coherence duration and EKG signal duration. These results demonstrate that simultaneous blockade of alpha- and beta-adrenergic signaling significantly prolonged the detectable activities of both the brain and the heart during asphyxic cardiac arrest and may offer an effective approach for preventing sudden cardiac death and extend the survival of patients.

Title: Alteration of cardiac autonomic function in patients with newly diagnosed epilepsy

Authors: *R. K. GOIT;
Nepalgunj Med. Col., Banke, Nepal

Abstract: Objective: The aim of the study was to determine if heart rate variability (HRV) showed any changes in patients with newly diagnosed epilepsy in comparison with controls. **Methods:** Adult male patients, aged 30-50 years, who had never previously received treatment with antiepileptic drugs were eligible for inclusion in this study. Resting electrocardiogram (ECG) at spontaneous respiration was recorded for 5 min in supine position. Time domain analysis, frequency domain analysis and Poincare plot of HRV were recorded from ECG. **Results:** In time domain measures, the square root of the mean of the sum of the squares of differences between adjacent RR intervals (RMSSD) and percentage of consecutive RR intervals that differ by more than 50 ms (pNN50) were significantly less in patients with epilepsy. In frequency domain measures, high frequency [(HF) ms^2], HF (nu) and low frequency [LF (ms^2)] were significantly less in patients with epilepsy while LF (nu) and LF/HF were significantly high in patients with epilepsy. In Poincare plot, standard deviation perpendicular to line of Poincare plot (SD1) and standard deviation along the line of entity in Poincare plot (SD2) were significantly less in patients with epilepsy. **Conclusion:** These data suggest that epilepsy patients have an impact on the cardiac autonomic function as measured by HRV.

Title: Sex and hormonal status influence the redistribution of the AMPA GluA1 receptor subunit in estrogen receptor beta containing paraventricular hypothalamic neurons following slow-pressor angiotensin II hypertension

Authors: *A. C. OVALLES[1], J. MARQUES-LOPES[1], T. A. VAN KEMPEN[1], M. J. GLASS[1], C. IADECOLA[1], E. M. WATERS[2], T. A. MILNER[1,2];

[1]Feil Family Brain and Mind Res. Inst., Weill Cornell Med., New York, NY; [2]Harold and Margaret Milliken Hatch Lab. of Neuroendocrinology, The Rockefeller Univ., New York, NY

Abstract: Hypertension incidence is greater in men than young women, but this relationship reverses as women transition to menopause. A sex-dependent susceptibility to hypertension is recapitulated in rodents following "slow pressor" angiotensin II (AngII) infusion: blood pressure increases in young male, but not young female mice. Slow pressor AngII in the accelerated ovarian failure (AOF) mouse model, which mimics human menopause including the peri-menopause transition, increases blood pressure in peri- and post-AOF mice (Marques-Lopes et al., NEN 2016). Sex-differences in AngII-induced hypertension were reflected by a sex-dependent redistribution of GluN1 to the plasma membrane in estrogen receptor β (ERβ) hypothalamic paraventricular (PVN) neurons. GluN1, a NMDA receptor subunit, is activated by glutamate and leads to recruitment of the AMPA receptor. AMPA, like NMDA, is involved in hypertension regulatory mechanisms. This experiment analyzed the redistribution of GluA1, an AMPA receptor subunit, in ERβ PVN neurons following slow pressor AngII-induced hypertension in males and AOF mice. AOF was induced by injections of 4-vinylcyclohexene diepoxide (VCD; 130mg/kg i.p.) for 15 days in 55 day-old ERβ-enhanced green fluorescent protein (ERβ-EGFP) reporter female mice. Four groups of mice: 1) young (2 mo old) female mice, 2) peri-AOF mice (58 days post-VCD), 3) post-AOF mice (129 post-VCD); and 4) young (2 mo old) male mice were implanted for 14 days with osmotic minipumps containing AngII (600ng/kg/min) or saline, and blood pressure was recorded by tail-cuff plethysmography. Mouse brains were fixed by aldehyde perfusion and PVN sections were labeled for GFP with immunoperoxidase and GluA1 with silver-intensified gold (SIG) and examined by electron microscopy. AngII infusion increased blood pressure in males, peri-, and post-AOF females but not young females. At baseline (i.e., saline), males had significantly more total and cytoplasmic GluA1-SIGs in ERβ-GFP dendrites when compared to all female groups. After AngII infusion, GluA1-SIG distribution in ERβ-GFP dendrites did not change in males. In contrast, the pattern of redistribution of GluA1 SIGs in the females did not reflect the changes in blood pressure after AngII infusion: the total, cytoplasmic and plasmalemmal density of GluA1 SIGs increased in young and post-AOF females but decreased in peri-AOF mice after AngII. The pattern of GluA1 redistribution contrasts that of GluN1 suggesting different roles for each receptor subunit in response to hypertension. In addition, these results support a growing body of evidence that sex dependent mechanisms are in place to influence hypertension.

Title: Renalase expression and regulation in PC12 cells

Authors: *C. R. WILLIAMSON[1], S. KHURANA[4], T. C. TAI[4,1,2,3];
[1]Biol., [2]Chem. and Biochem., [3]Biomolecular Sci., Laurentian Univ., Sudbury, ON, Canada;
[4]Med. Sci. Div., Northern Ontario Sch. of Med., Sudbury, ON, Canada

Abstract: Increases in catecholamine (CA) synthesis and secretion by chromaffin cells are often associated with hypertension. The CAs adrenaline, noradrenaline, and dopamine are important regulators of blood pressure through their interaction with adrenergic and dopaminergic receptors. Recently, renalase has been regarded as a secretory protein that may protect against increased levels of circulating CAs. However, the molecular, cellular and physiological mechanisms explaining the protective effects of renalase are poorly understood. The adrenal gland is a major site for CA biosynthesis, however, the regulatory role of renalase in this tissue has not been previously investigated. The purpose of this study is to examine the regulation of renalase in adrenal pheochromocytoma-derived PC12 cells and further to determine its role in CA biosynthesis. The regulation of renalase will also be compared to known regulators of CA biosynthesis. It is hypothesized that renalase secretion is part of a feedback mechanism regulating CA biosynthesis in chromaffin cells. Therefore, renalase may be upregulated when CA biosynthesis-triggering signals are activated. To examine this, PC12 cells were treated with phorbol 12-myristate 13-acetate (PMA), forskolin (Fsk), dexamethasone (Dex), cobalt chloride ($CoCl_2$), adrenaline, or nicotine in a time and dose-dependent manner. Following treatments, standard RT-PCR protocols were used to quantify mRNA for renalase. Preliminary data suggests that PMA, Dex, or Fsk did not influence the expression of renalase at the concentrations and time points examined. In contrast, EGR-1 mRNA was upregulated after 1 hour with 80nM PMA (1.5-fold; $p < 0.01$), and 6 hours with 10μM Fsk (1.4-fold; $p < 0.001$); PNMT mRNA was upregulated at 6 hours and 12 hours with 1μM Dex (>8-fold; $p < 0.001$). These results present the novel finding that renalase is expressed in PC12 cells. However, its regulation in chromaffin cells is not altered by the PKC activation by PMA, PKA activation by Fsk, or cortisol signaling stimulated by Dex. Overall, this study aims to provide a first step in understanding if renalase has a role in the regulation of CA biosynthesis.

Title: Chronic inhibition of catalase attenuates the overexpression of AT1 receptor and proinflammatory cytokine mRNA in the hypothalamus of hypertensive rats.

Authors: ***M. R. LAUAR**, D. S. A. COLOMBARI, L. A. DE LUCA JR., P. M. DE PAULA, E. COLOMBARI, C. A. F. ANDRADE, J. V. MENANI;
Dept Physiol. and Pathol., UNESP, Araraquara, Brazil

Abstract: Increased expression of AT1 receptor and proinflammatory cytokines like tumoral necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) are present in the central areas involved in cardiovascular control in hypertensive animals. In rats with 2-kidneys, 1-clip (2K1C) hypertension, chronic subcutaneous (sc) administration of the catalase inhibitor 3-amino-1,2,4-triazol (ATZ) reduces mean arterial pressure (MAP) and improves autonomic modulation. In the present study, we analyzed if chronic sc administration of ATZ modifies mRNA expression of AT1 receptors and proinflammatory cytokines in the hypothalamus in 2K1C hypertensive rats. Male Holtzman rats (initial weight 150-180 g, n=7/group) received a silver clip around the left renal artery to generate 2K1C hypertension. Six weeks after the surgery, rats received ATZ or saline sc for 7 days before MAP recording and hypothalamic AT1 receptor, TNF-α and IL-1β mRNA analysis. Baseline MAP increased in 2K1C rats compared to sham (209 ± 4, vs. 99 ± 2 mmHg, respectively). ATZ (600 mg/kg/day) reduced MAP (162 ± 10 mmHg) and the mRNA expression of AT1 receptors (0.74 ± 0.04, vs. saline 1.2 ± 0.2 fold change), TNF-α (0.87 ± 0.1, vs. saline 8.0 ± 1.9 fold change) and IL-1β (0.81 ± 0.11, vs. saline: 1.8 ± 0.75 fold change) in 2K1C hypertensive rats. The results suggest that the anti-hypertensive effects of ATZ are associated with reduction of AT1 receptor, TNF-α and IL-1β mRNA overexpression in the hypothalamus.

Title: Pharmacological evidence that NaHS inhibits the vasopressor responses induced by stimulation of the preganglionic sympathetic outflow in pithed rats

Authors: ***A. SACHEZ-LOPEZ**, S. HUERTA-DE LA CRUZ, E. J. GUTIÉRREZ-LARA, J. H. BELTRAN-ORNELAS, D. CENTURIÓN;
Farmacobiología, Cinvestav-Coapa, Mexico, Mexico

Abstract: It has been reported that i.v. administration of NaHS, a donor of H2S, elicited dose-dependent hypotension although the mechanisms are not completely understood. In this regard, several mechanisms could be involved including the inhibition of the vasopressor sympathetic outflow. Thus, this study was designed to determine the potential capability of NaHS to mediate inhibition of the vasopressor responses induced by preganglionic sympathetic stimulation. For this purpose, Wistar rats were anaesthetised, pithed and cannulated for drug administration. In animals pre-treated with gallamine, the effect of i.v. infusion of NaHS (310 and 560 μg Kg^{-1} min^{-1}) or its vehicle (phosphate buffer) was determined on the vasopressor responses induced by: (1) sympathetic stimulation (0.03-10 Hz); (2) i.v. bolus injections of exogenous noradrenaline (0.03-3 μg Kg^{-1}); or (3) methoxamine (1-100 μg Kg^{-1}). The vasopressor responses induced by preganglionic sympathetic stimulation were dramatically and dose-dependently inhibited by i.v. infusion of NaHS (310 and 560 μg Kg^{-1} min^{-1}), but not by vehicle, particularly at high frequencies. In marked contrast, the vasopressor responses to exogenous noradrenaline or methoxamine were not inhibited by the above doses of NaHS or its vehicle. The above results, taken together, demonstrate that NaHS inhibited the vasopressor responses induced by preganglionic sympathetic outflow by a prejunctional mechanism. This is the first evidence demonstrating this effect by NaHS and may contribute, at least in part, to the hypotension induced by NaHS.

Title: Intraneural interrogation of vagus nerve activity

Authors: A. KANNEGANTI, A. S. DESHMUKH, *M. I. ROMERO-ORTEGA;
Bioengineering, Univ. of Texas at Dallas, Richardson, TX

Abstract: Somatic peripheral nerve intraneural multielectrode interfaces have been extensively used to decode and encode underlying neural activity towards neuromodulation and advanced bionic systems applications. However, the intraneural activity of autonomic nerves is not well understood, despite of their clinical relevance as exemplified by vagus nerve stimulation, which is approved for the treatment of various pathological conditions including stroke, obesity, epilepsy, and hypertension. A limiting factor in using intraneural electrodes in the rat autonomic nerves is their small size. Here we use indwelling microelectrodes to evaluate the vagus nerve activity in response to inflammatory cytokines. This is important as this cholinergic anti-inflammatory pathway plays a key role in maintain homeostasis via neuro-endocrine-immune axis. Slanted microelectrode arrays were implanted into the left cervical vagus nerve of adult female Lewis rats. Intraneural recordings were done in acute anesthetized animals (N=6). Omniplex neural data acquisition system (Plexon Inc.,) was used to record the single unit and multi-unit activity, and offline filtering followed by PCA (Principal component Analysis) based spike sorting, was used to identify individual spikes. Multiple distinct biphasic single unit spikes were observed with peak-to-peak voltages ranging between 80-150μV. At the end of each study session, lidocaine was applied topically and suppression of the spikes was used to confirm the neuronal activity. Multiple spikes identified across animals showed a repetitive burst-firing pattern that temporally correlated with breathing. Interrogation of the modulation in the inherent vagal activity in response to systemic and local delivery of inflammatory cytokines TNFα, IL-6 and Il-4 in rodent animal model is currently under investigation. Preliminary results show an observable change in firing rate in response to cytokine administration. In summary, we report on the use of indwelling microelectrode arrays to interrogate the inherent neuronal activity in the vagus nerve and use it to evaluate their activity in relation to respiration and inflammation

Title: Combined administration of insulin and leptin significantly increased Fos production in the arcuate nucleus and renal sympathetic nerve activity

Authors: H. HABEEBALLAH, N. ALSUHAYMI, M. STEBBING, T. JENKINS, *E. A. BADOER;
Sch. of Hlth. and Biomed. Sci., RMIT Univ., Melbourne, Australia

Abstract: Leptin has sympatho-excitatory effects on renal sympathetic nerve activity (RSNA). Insulin also induces increases in RSNA. The aim of this study was to investigate the effects of the intracerebroventricular (ICV) administration of insulin and leptin together on RSNA, mean arterial pressure (MAP), heart rate (HR) and distribution of Fos protein in autonomic brain nuclei. Anaesthesia in male Sprague-Dawley rats was induced with isoflurane (2-5%) in O_2 and maintained with urethane (1.4-1.6 g/kg iv). RSNA, MAP, and HR were recorded before and for 180 minutes after the ICV injection of saline (control, n=5), leptin (7 µg, n=5), insulin (500 mU, n=4), and the combination of both insulin and leptin (leptin was administered 15 minutes after insulin, n=4). At the end of each experiment the animals were perfused and the brains processed immunohistochemically to detect Fos, a protein marker of increased neuronal activation. RSNA was increased significantly more when leptin and insulin were administered together compared to either leptin or insulin alone. Insulin alone significantly increased HR by (47±11 b/min), however, the presence of leptin prevented that HR response. No change in MAP was observed with any treatment. Fos production was examined in the following brain nuclei; arcuate nucleus (ARC), hypothalamic paraventricular, supraoptic, lamina terminalis and in autonomic nuclei in the medulla oblongata. Only in the arcuate nucleus did ICV injection of leptin and insulin together increase the number of Fos-positive cell nuclei significantly more than the increases observed following leptin or insulin alone. The results suggest that in conditions where leptin and insulin are elevated, such as obesity, the enhanced effects on RSNA may be contributing to the elevation of RSNA seen in such conditions and this may contribute to the cardiovascular complications. Further, the results suggest that the arcuate nucleus is an important common site of cardiovascular integration where both leptin and insulin interact

Title: Cardiovascular control by neurons of the rostral ventrolateral medulla in conscious rats

Authors: *I. C. WENKER[1], C. ABE[2], R. L. STORNETTA[1], P. G. GUYENET[1];
[1]Pharmacol., Univ. of Virginia, Charlottesville, VA; [2]Gifu Univ., Gifu, Japan

Abstract: The rostral ventrolateral medulla (RVLM) contains excitatory neurons that are believed to be critical for blood pressure (BP) control. In anesthetized animals, these baro-regulated neurons are extremely active and essential to maintain BP, but their contribution in conscious animals is less clear. In conscious rats, optogenetic activation of an RVLM subpopulation (the C1 neurons) increases BP and sympathetic nerve activity (SNA), but selective destruction of these neurons alters BP very little. This lack of effect could be explained by adaptive changes or by the fact that the C1 neurons contribute little to BP at rest in the conscious state. Thus, we decided to measure the contribution of the RVLM neurons to BP maintenance in intact conscious animals using transient and reversible inhibition. To do this, RVLM neurons were bilaterally transduced to express the light-driven proton pump Archaerhodopsin (ArchT) by viral vector injection and optical fibers were surgically implanted to deliver green laser light (530 nm, 5-7 mW) to the RVLM. Expression of ArchT was driven by either CamKIIa, a pan-excitatory neuron promoter, or PRSx8, a synthetic promotor specific to the C1 neuronal population, resulting in two experimental rat populations; CamK-ArchT (n=5) and C1-ArchT (n=8) rats. Four weeks after viral delivery, telemetric BP probes were implanted. After recovery, rats were placed in a plethysmography chamber on top of a wireless receiver, to record cardiorespiratory parameters. As proof-of-principle, single-unit recordings in 3 anesthetized rats revealed that a majority (7/11) of barosensitive were reversibly inhibited (82.6 ± 11.6 % reduction, $p = 0.01$). In both CamK-ArchT and C1-ArchT conscious rats under normoxic conditions (21% FiO_2), bilateral inhibition for 10 s had virtually no effect on BP. However, the ArchT-induced hypotension increased significantly during hypoxia (Cam-ArchT: -13.1 ± 1.2 mmHg in 12% O_2 versus -5.2 ± 0.8 in 21% O_2, $p = 0.0006$, C1-ArchT: -20.9 ± 3.2 mmHg in 12% O_2 versus -3.4 ± 1.0 in 21% O_2, $p = 0.0001$), but not during hypercapnia (Cam-ArchT: -7.2 ± 0.7 mmHg in 6% CO_2 vs. -5.2 ± 0.8 in 0% CO_2, $p = 0.080$, C1-ArchT: -6.4 ± 1.0 mmHg in 6%

CO_2 vs. -3.4 ± 1.0 in 0% CO_2, p = 0.207). Even though Cam-ArchT and C1-ArchT rats exhibited opposite respiratory effects due to ArchT inhibition, similar cardiovascular effects were observed, indicating the pressor response was not due altered respiratory activity. In conclusion, whether targeting all RVLM excitatory neurons or C1 neurons specifically, RVLM neurons seem to be relatively inactive in normoxic unstressed rats, but become activated during hypoxia to prevent BP from falling, presumably by increasing SNA.

Title: Ventrolateral medullary pathways mediate cardiovascular responses to activation of the ventral tegmental area.

Authors: *J. CIRIELLO;
Univ. Western Ontario, London, ON, Canada

Abstract: Activation of the ventral tegmental area (VTA) elicits sympathoinhibitory responses. However, the brainstem pathways mediating these effects on the cardiovascular system are unknown. In this study, experiments were done in alpha-chloralose anaesthetized, paralysed and artificially ventilated rats to investigate the medullary pathways mediating the mean arterial pressure (MAP), heart rate (HR) and renal sympathetic nerve (RSN) responses elicited by l-glutamate (Glu) stimulation of VTA neurons. In the first series, microinjection of Glu at depressor sites was found to induce c-fos expression within the caudal ventrolateral medulla (CVLM), bilaterally. In contrast, little c-fos expression was observed within other medullary areas, including the rostral ventrolateral medulla (RVLM). In the second series, to investigate whether CVLM mediated the VTA depressor responses, bilateral injections (100 nL) of the synaptic blocker cobalt chloride ($CoCl_2$; 5 mM) were made into CVLM. The $CoCl_2$ injections significantly attenuated the MAP (~ 82 %), HR (~ 74 %) and RSN (~87%) responses elicited by stimulation of VTA. Control injections of the vehicle into CVLM or injections of $CoCl_2$ into regions immediately dorsal to the CVLM region, bilaterally, did not alter the magnitude of the cardiovascular responses to VTA stimulation. On the other hand, bilateral injections of $CoCl_2$ into the rostral ventrolateral medulla (RVLM) similarly attenuated the VTA responses. In

addition, to determine whether gamma aminobutyric acid (GABA) and/or glutamate containing systems were involved in mediating these effects through the CVLM, bilateral injections of the $GABA_A$ antagonist bicuculline methiodide (Bic; 0.4 mM) or the non-specific glutamate receptor antagonist kynurenic acid (KYN 0.15 M) were made into CVLM or RVLM. RVLM injections of Bic significantly attenuated the MAP**,** HR and RSN responses to VTA stimulation, whereas, bilateral injections of Bic into CVLM did not alter the VTA responses. Bilateral injections of the $GABA_B$ antagonist phaclofen or baclofen (5 mM) into the same CVLM or RVLM regions did not alter the cardiovascular responses to stimulation of the VTA. Finally, bilateral injections of KYN into the CVLM significantly attenuated the MAP, HR and RSN responses, whereas KYN injections into RVLM had no effect on the cardiovascular responses to VTA stimulation. Taken together, these data suggest that VTA activates a descending glutamatergic pathway that in turn activates GABAergic neurons in CVLM that inhibit RVLM sympathoexcitatory neurons that control the vasculature and heart through the activation of $GABA_A$ receptor mechanisms. This work was supported in part by HSFO.

Title: Ketamine and amphetamines inhibit neurogenic nitrergic vasodilation of porcine isolated basilar arteries

Authors: M.-F. CHEN[1,2], S.-Y. LAI[3], P.-C. KUNG[3], Y.-C. LIN[3], H.-I. YANG[1], P.-Y. CHEN[1], *T. J.-F. LEE[4,1,5];

Sch., Springfield, IL; [5]Col. of Life Sci., Tzu Chi Univ., Hualien, Taiwan

Abstract: Chronic abuse of ketamine and amphetamines is associated with incidence of hypertension and strokes involving activation of sympathetic activities. Large cerebral arteries at the base of the brain from several species receive dense sympathetic innervation which upon activation causes predominant parasympathetic-nitrergic vasodilation with increased regional blood flow via axo-axonal interaction mechanism. The present study was designed to examine effects of ketamine and amphetamine analogs on axo-axonal interaction-mediated neurogenic nitrergic vasodilation in porcine basilar arteries using techniques of blood-vessel myography, patch clamp and two-electrode voltage clamp, and calcium imaging. In U-46619-contracted basilar arterial rings, nicotine (100 μM) and transmural nerve stimulation (TNS, 8 Hz) elicited neurogenic nitrergic vasodilations. Ketamine and amphetamine analogs concentration-dependently inhibited nicotine-induced nitrergic vasodilation without affecting that induced by TNS. Ketamine and amphetamine analogs also concentration-dependently blocked nicotine-induced inward currents in Xenopus oocytes expressing alpha3beta2-nicotinic acetylcholine receptors (nAChRs), and nicotine-induced inward currents and calcium influxes in rat superior cervical ganglion neurons. The potency in inhibiting both inward-currents and calcium influxes is comparable among the analogs. These results indicate that ketamine and amphetamine analogs, by blocking nAChRs located on cerebral perivascular sympathetic nerves, reduce nicotine-induced, axo-axonal interaction-mediated neurogenic dilation of the basilar arteries. Chronic abuse of these drugs may interfere with normal sympathetic-parasympathetic interaction mechanism resulting in diminished neurogenic vasodilation (supported by MOST and Tzu Chi Foundation).

Title: Assessing fear memory by modelling conditioned bradycardia and respiratory responses

Authors: ***G. CASTEGNETTI**[1], A. TZOVARA[1], M. STAIB[1], P. C. PAULUS[2], N. HOFER[1], D. R. BACH[1,3];

[1]Dept. of Psychiatry, Psychotherapy and Psychosomatics, Univ. of Zurich, Zurich, Switzerland; [2]Dept. of Psychology, TU Dresden, Dresden, Germany; [3]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Across species, cued fear conditioning is a common experimental paradigm to investigate aversive Pavlovian learning. While fear-conditioned stimuli (CS+) elicit overt behaviour in many mammals, this is not the case in humans. Instead, autonomic nervous system activity is used to quantify fear memory in humans, typically measured by skin conductance responses (SCR). Here, we investigate whether heart period responses (HPR) and respiratory amplitude responses (RAR), evoked by the CS+, are suitable as measures of fear memory in humans. Heart beats are identified from electrocardiogram or pulse oximetry, and RAR from a single-belt chest bellows system. Peak-scoring reveals fear-conditioned heart rate deceleration (bradycardia) and distinguishes CS+ from non-reinforced stimuli (CS-) in each of four datasets. RAR differ between CS+/CS- across conditions only in one out of three analysed datasets. We then develop a Psychophysiological Model (PsPM) for fear-conditioned responses in each modality. These PsPMs are inverted to yield estimates of autonomic input into the cardiac or the respiratory system. We show that the sensitivity to distinguish CS+ and CS- (predictive validity) is higher for model-based estimates than peak-scoring analysis, both for HPR and RAR. Model-based estimates of RAR significantly discriminate CS+/CS- in all three analysed datasets. Finally, we compare the predictive validity of the best performing model-based implementation of these modalities to SCR. We show that HPR significantly outperforms both SCR and RAR, which in turn perform similarly. Our work provides two novel tools to investigate fear memory in humans and potentially allows direct comparison between species.

Title: Chronic stress is associated with augmented urinary bladder neuronal sprouting

Authors: *B. M. MCDONNELL[1], A. KULLMANN[1], A. WOLF-JOHNSON[1], A. KANAI[1], L. RODRIGUEZ[2], L. BIRDER[1];
[1]Med., Univ. of Pittsburgh, Pittsburgh, PA; [2]Inst. of Urology, Univ. of Southern California, Los Angeles, CA

Abstract: *Background:* A hallmark of functional pain syndromes such as interstitial cystitis/bladder pain syndrome (IC/BPS) is pain in the absence of other demonstrable pathology. There is ample evidence that acute stress increases bladder pain and urgency in these individuals. Recent findings support increased bladder hyperalgesia and urinary frequency in rats exposed to chronic (10 day) water avoidance stress (WAS). Though underlying mechanisms have not been fully explored, studies have shown that nerve growth factor (NGF) plays an important role in hyperalgesic responses in both somatic and visceral structures. Further, stress is known to affect the expression levels of neurotrophic factors. In addition, over-expressing NGF has also been shown to result in neural sprouting which may be involved in mechanisms underlying hyperalgesia and pain.
Purpose: In order to understand how changes in peripheral neural innervation may contribute to bladder hyperalgesia and pain in this model, we examined changes in sensory and autonomic innervation of the bladder.
Methods: Adult female Wistar-Kyoto rats (12 wks age, 200-250 gm) were placed on a pedestal in a water water-filled container. All procedures were conducted with approval of University of Pittsburgh Institutional Animal Care and Use Committee. Animals were exposed to WAS (or handled controls) one hr/day x10 days between hours 8 AM-12 PM to minimize circadian effects. To investigate the density and distribution of fibers in bladder we used immunocytochemistry to process bladder cross cryosections (20uM; postfixed following bladder removal from deeply anesthetized rats prior to sacrifice; n=3 rats), specifically against calcitonin gene related peptide (CGRP; sensory fibers); growth associated protein 43 (sprouted nerve fibers) and tyrosine hydroxylase (TH; sympathetic fibers) and DAPI to label nuclei.
Results: Our findings reveal a significant increase (approx. 2-fold) in CGRP staining in WAS bladders (vs. control) with the greatest density within the bladder mucosa. We also find augmented GAP43 (approx. 2-fold) staining as well as TH (approx. 1.5-fold) staining in WAS bladders (vs. control), the latter surrounding the vasculature. The increase in neural sprouting following chronic WAS also correlated with elevated NGF bladder expression.
Conclusions: Alterations in both sensory and autonomic neural innervation in the bladder may represent an important mechanism that contributes to hypersensitivity/urgency in IC/BPS models of bladder pain.

Title: Electrical stimulation to increase colonic activity

Authors: *D. J. BOURBEAU[1,2,3], K. AAMOTH[4], K. GUSTAFSON[4,1,3];
[1]DVA, Cleveland, OH; [2]Physical Med. and Rehabil., MetroHealth Med. Syst., Cleveland, OH; [3]Cleveland FES Ctr., Cleveland, OH; [4]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: Neurogenic bowel dysfunction is a common condition for persons with spinal cord injury that significantly disrupts daily bowel management and impairs quality of life. We aim to develop an approach using functional electrical stimulation to restore bowel function for persons with spinal cord injury. The objectives of this pilot study were to determine if reflex colonic activity can be elicited via electrical stimulation of the colon and to identify the effect of stimulation variables, such as stimulation pattern and electrode location. Experiments were conducted in seven neurally intact cats under chloralose anesthesia to maintain reflexive activity. Proximal colon, distal colon, and rectal pressures were recorded via balloon catheters. Proximal colon, distal colon, and rectum were stimulated with continuous and burst patterns. Constant frequency, surface colon stimulation (20-40 Hz, 30 s) evoked localized colon contractions in the colon segment directly below the electrodes in all cats. Burst pattern stimulation (5-15 pulses at 100 Hz every second) also evoked colonic responses in 3/3 animals. 20 Hz stimulation produced ischemia and a tetanic colon contraction. Burst pattern stimulation did not alter tissue appearance, and colonic pressures increased more slowly and included a slow ripple. Pressures increased with increasing stimulus amplitude, frequency, pulse width, and burst number. Rectal stimulation did not evoke significant responses. Proximal colon surface stimulation resulted in only proximal colon pressure increases. Distal colon surface stimulation generated both distal and proximal colon pressure increases. Isoflurane anesthesia eliminated proximal pressures and reduced distal pressures, suggesting that reflex pathways were activated via distal colon stimulation. Colonic pressures can be produced via both direct and reflex pathways using electrical colon stimulation. A neural stimulation approach has the potential to restore colonic activity.

Title: Identifying brain networks controlling micturition and continence in mouse

Authors: ***A. M. VERSTEGEN**[1], L. GUO[2], J. C. MATHAI[2], V. VANDERHORST[3], M. L. ZEIDEL[2], J. C. GEERLING[3];
[1]Medicine; Endocrinol., Beth Israel Deaconess Med. Center; Harvard Medi, Boston, MA; [2]Medicine; Nephrology, [3]Neurol., Beth Israel Deaconess Med. Center; Harvard Med. Sch., Boston, MA

Abstract: Lower urinary tract symptoms (LUTS) are extremely common and enormously debilitating. A significant component of LUTS is due to failure of nervous control of bladder function, or failure of neural pathways to compensate for bladder dysfunction. However, it is not clearly understood how the brain controls bladder filling and voiding or how the micturition reflex is inhibited if the timing for voiding is not right. Prior studies have shown that the pontine micturition center (PMC, aka Barrington's nucleus) directly controls voiding. Within the PMC, neurons expressing corticotropin releasing hormone (PMC^{CRH}) project axons directly to sacral spinal cord nuclei that control bladder contraction and sphincter relaxation. Here we show that PMC^{CRH} neurons are critical for voiding, and identify a network of afferent neurons, across several forebrain and brainstem regions, which directly modulate PMC^{CRH} and affect voiding behavior. First, stimulating PMC^{CRH} neurons using Gq DREADDs produces urinary frequency in awake-behaving mice and on the anesthetized cystometrogram (CMG). Conversely, selectively ablating these neurons using diphtheria toxin A leads to urinary retention and eliminates the CMG voiding reflex. Next, to identify input connections to the PMC, and specifically those controlling PMC^{CRH} neurons, we used CTb and modified rabies. To confirm which retrogradely labeled neurons target PMC^{CRH} neurons specifically, we performed viral anterograde tracing. Afferents to PMC^{CRH}neurons are located in PAGvl, the preoptic area, the lateral hypothalamic area, and other sites. We confirmed monosynaptic connectivity using electrophysiological recordings for select sites. Then, to test the functional consequence of afferent neuron activity, we manipulated the activity of these clusters of neurons or by stimulating their axon terminals within the PMC. We used a novel non-invasive assay for mouse voiding: micturition video

thermography (MVT), to track voiding behavior in these awake-behaving mice. In select cases we combine MVT with telemetric measurement of bladder pressure or urethral sphincter EMG. After MVT we repeat these manipulations during an anesthetized CMG. Taken together, we have identified a network of neurons that can control urinary voiding and continence through PMC^{CRH} neurons. Next, we will determine the necessity of select afferent sites for voiding, and the effects of removing their modulatory input for continence. This information will help us understand how forebrain, brainstem and spinal inputs converge to control bladder filling and voiding, and will allow more detailed studies of the neurologic mechanisms of LUTS in mice and humans.

Title: Impact of decentralization on cholinergic transmission and neuronal excitability in mouse major pelvic ganglia

Authors: *C. W. KYI[1], D. J. SCHULZ[2];
[1]Biol. Sci., [2]Div. of Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: Damage to the pelvic nerve due to complications from surgeries carried out in the pelvic area often results in micturition and erectile dysfunctions. We are interested in the impact of loss of input due to damage to the nerves innervating the major pelvic ganglia (MPG) on the excitability, firing properties, and cholinergic neurotransmission of the post-ganglionic neurons of the MPG. The MPGs of mice contain postganglionic neurons innervating urinary bladder, the genitals and distal colon. Pelvic ganglia primarily receive cholinergic parasympathetic inputs from the preganglionic neurons in the sacral cord through pelvic nerve, with a smaller number of sympathetic neurons receiving inputs from the lumbosacral cord through the hypogastric nerve. The axons from the pelvic ganglion synapse onto postganglionic neurons on the target organ, releasing acetylcholine (ACh - parasympathetic) and noradrenaline (sympathetic) to impact target function and activity. We studied the effects of loss of input to postganglionic MPG neurons via unilateral transection of both pelvic and hypogastric nerves in adult mice. We employed molecular and electrophysiology techniques to examine ipsilateral decentralized MPGs, contralateral intact MPGs, and sham-operated adult Swiss Webster mice of both sexes.

To determine impacts of decentralization on synaptic strength between pre- and post-ganglion neurons of the MPG, we measured excitatory postsynaptic potentials (EPSPs) and excitatory postsynaptic currents (EPSCs) in response to local application of ACh. We further characterized the major subunits involved in the cholinergic transmission by measuring ACh-activated currents before and after application of subunit-specific blockers. To investigate impacts of injury on excitability of the MPG neurons, we measured passive properties of these neurons, as well as firing patterns in response to DC current injection. We also measured the mRNA abundance of α2, α3, α4, α5, α6, α7, β2 and β4 nicotinic receptor subunits in whole MPGs using quantitative PCR (qPCR). Our preliminary data indicate that after acute decentralization (1-3 days), the mRNA transcript numbers for α3, α7, and β4 were significantly decreased, while the remainder remain unchanged. These results suggest that acute injury results in downregulation of receptor subunits responsible for cholinergic transmission in the MPG, and may have impacts for long-term recovery of bladder function following pelvic nerve injury.

Abstract: The brain receives and processes stimuli from the viscera to adjust autonomic output and regulate glucose metabolism as part of body homeostasis. Visceral stimuli are detected by free nerve endings of the Vagus nerve and are transmitted to the hindbrain via sensory neurons. However, it is still unknown what signals activate vagal sensory neurons in the pancreas and which neural circuits process this information. We are developing tools to characterize the molecular and functional profile of vagal sensory neurons that innervate pancreatic islet. We use *in-vivo* and *in-situ* Ca^{2+} imaging of the nodose ganglion in combination with retrograde tracing from the pancreas to identify specific subpopulations of the vagus nerve that respond to islet-derived substances and to determine the molecular nature of sensory stimuli. In addition, we will

implement pharmacogenetic approach to manipulate islet sensory innervation to study its role in glucose metabolism. We will use adeno-associated viral vectors, that express synthetic G-protein coupled receptor (DREADD-GPCR) that can be activated by physiologically inert molecule (CNO). The virus will be injected into the pancreas or nodose ganglion, and depending on the activatory or inhibitory nature of DREADD-GPCR we will stimulate or inhibit activity of sensory neurons that innervate pancreatic islet. Thus we have a model where we can characterize and manipulate islet-specific neural circuits. Altogether we expect this study to provide insight into pancreatic sensory innervation and its contribution to glucose metabolism.

Title: Anxiogenic effect of probiotics, prebiotics and synbiotics on healthy juvenile rats

Authors: *J. A. BRAVO[1], C. BARRERA-BUGUEÑO[1], J. ESCOBAR-LUNA[1], O. REALINI[1], R. SOTOMAYOR-ZÁRATE[2], M. GOTTELAND[3], M. JULIO-PIEPER[1];

Abstract: Interventions on the gut microbiota have an impact on healthy animal behavior. Indeed, the use of probiotics and prebiotics has been shown to alter behavior in adult animals and healthy volunteers, but little is known on the effects of such interventions in younger individuals. In order to evaluate this, weaned male Sprague-Dawley rats (post-natal day 21, PND21) were fed with the probiotic *Lactobacillus casei* L-54-2-33 (10^4 cfu's/ml), the prebiotic inulin (16mg/ml), and the mixture of both (synbiotic) for 14 days. All treatments were added to the drinking water, while control rats were given water alone. On PND34, behavior was evaluated in the open field (OF) test, and on PND35 animals were subjected to the elevated plus maze (EPM) test. 30 mins after the EPM rats were decapitated; trunk blood was collected for plasma corticosterone

(CORT) measurements and brains were collected to determine hippocampal expression of 5-HT_{1A} mRNA through *in situ* hybridization.
There was no difference in weight gain between treated and control rats. Behavioral analyses revealed that animals treated with the probiotic, prebiotic and synbiotic had fewer entries to the central area of the OF arena and spent more time in the periphery of the apparatus in comparison to control animals. In the EPM, synbiotic fed rats spent more time in the open arms in comparison to probiotic and prebiotic fed rats. In addition, higher levels of stress-evoked CORT were observed in probiotic fed rats in comparison to control animals, while no increase in plasma CORT was observed in synbiotic fed rats in comparison to controls. Interestingly, basal levels of CORT evaluated in a different cohort that was not exposed to behavioral tests, were higher in prebiotic fed rats in comparison to control animals. Also in this last cohort, densitometric analyses revealed that 5-HT_{1A} mRNA expression was increased in the dentate gyrus and cornus ammonis 1 and 3 of synbiotic fed rats in comparison to all other groups. Together these results suggest that interventions in the microbiota of young healthy animals evoke behavioral changes in response to stressful situations, which seem to be independent of hypothalamus-pituitary-adrenal axis activation. Synbiotic fed animals had higher levels of hippocampal 5-HT_{1A} transcript in comparison to all other groups, and moreover, this group was the only one to have reduced anxiety-like behaviors in the EPM. These latter results suggest that there is a complex interaction between endogenous and exogenous bacteria and prebiotic compounds, having different effects on the microbiota-gut-brain axis. In addition, the animal's age might also influence the behavioral outcome of such interventions.

Title: Differential effects of SSRIs on rat intestinal permeability and innate immune response markers

Authors: *M. JULIO-PIEPER, J. EYZAGUIRRE-VELASQUEZ, C. GONZALEZ-ARANCIBIA, L. OLAVARRIA-RAMIREZ, J. ESCOBAR-LUNA, C. BARRERA-BUGUEÑO, J. A. BRAVO;
INSTITUTO DE QUIMICA, PONTIFICIA UNIVERSIDAD CATOLICA DE VALPARAISO, VALPARAISO, Chile

Abstract: Acute and chronic psychological stress has been associated with increased gut permeability. Antidepressant drugs have been used to ease gastrointestinal symptoms that are frequently comorbid with anxiety and depression. Here, the focus has been to treat gut dysmotility and abdominal pain; however, the effects of antidepressant therapy on gut permeability remain unexplored. Selective serotonin reuptake inhibitors (SSRIs) have anti-inflammatory effects and can inhibit toll-like receptor (TLR) activity. Because inflammatory/immune mediators are key modulators of epithelial permeability, we aimed to investigate whether the SSRIs sertraline and citalopram are able to prevent experimentally-induced intestinal barrier deterioration in the rat.
We have previously used protein malnutrition (4% instead of 26% protein in a control diet) to disrupt rat gut barrier function without elevating plasma corticosterone. After weaning at postnatal day (PND) 21, animals received control diet until PND 39. Thereafter, they were separated into a control group, which received the same diet until PND 60, and a low protein (LP) group, which was fed a low protein diet from PND 40 to 60. Simultaneously, LP rats were received sertraline (30 mg/kg/day, p.o.) or citalopram (20 mg/kg/day, p.o.) from PND 40 to 60. Control and non-treated LP rats received saline daily by oral gavage. Intestinal tissue was collected to evaluate transepithelial electrical resistance (TEER) as a functional measure of gut permeability. Mucosal levels of tight-junction protein occludin and phospho-IRF3, a transcriptional factor linked to TLR-3 activation, were analyzed by western blot.
LP rats displayed reduced TEER, decreased occludin levels and increased phospho-IRF3 levels in ileum and colon. Sertraline significantly prevented TEER reduction in LP rat colon. A similar but non-significant trend was observed in the ileum of sertraline-treated LP rats and both ileum and colon of citalopram-treated LP rats. The decrease in occludin was significantly prevented only by citalopram in the colon of LP animals; however none of the drugs improved occludin levels in the ileum. Regarding phospho-IRF3, sertraline did not prevent its increase in the gut of LP rats; on the other hand, citalopram had a protective effect but only in LP rat ileum.
Our results show that two SSRIs induce distinct and significant effects on gut permeability. This, together with the reduction in phospho-IRF3, a molecule associated to the innate immune response, indicates that barrier protection and anti-inflammatory effects of SSRIs on non-neuronal cells could be an additional mechanism in the relief of gastrointestinal symptoms.

Title: Cisplatin causes up regulation of orexin R-1 receptor and serotonin in nodose ganglion of the least shrew (Cryptotis parva)

Authors: *M. S. AL-TIKRITI, W. KHAMAS, S. CHEBOLU, N. DARMANI;
Col. of Osteo. Med. of the Pacific/Anatomy, Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Previously we have found that cisplatin has significant impact on the enterochromaffin cells of gastrointestinal tract (GIT) and brainstem emetic nuclei function via release of several emetogenic neurotransmitters/mediators including 5-HT, substance P (SP). Vagal afferent neurons residing in the nodose ganglia (NG) is the primary sensory neurons that receive signals arising from the gut lumen and project to the nucleus of solitary tract (NTS) of the brainstem.. This has been shown by immunocytochemical techniques in rat and cat, and is the major afferent projection of the vagus nerve, whose cell bodies are located inside the (NG). The purpose of this study was to determine whether a small vomit competent species, the least shrew, shares a similar biochemical and anatomical profile observed in other species, and whether or not cisplatin extends its effect on the neurons of nodose ganglia. Thus, we used serotonin immunocytochemistry technique to detect serotonergic neurons, and OX-R1antibodies against orexin-1 receptors, since Orexin-A and -B are brain gut peptides that stimulate food intake via Orexin-R1 and -R2 receptors. We used six shrews; three were used as control and the others were injected with cisplatin (10 mg/kg- i.p.) which were sacrificed 24 hours post injection. The whole heads were decalcified with 2% formic acid for 2 weeks after fixation with 10% buffered neutral formalin for 5 days. The samples were processed for paraffin embedded blocks and sectioned at 10 μm thickness. The data shows that the least shrew shares similar findings with the rat, cat and human by having co-localized serotonergic neurons and by expressing OX-R1 in cells of the nodose ganglia. In addition, cisplatin causes severe damage to the ganglionic cells as manifested by shrinkage and pyknotic nuclei of the nodosal neurons. Interestingly, OX-R1 was expressed in three different population of cells; large neurons show less activities, medium size, and glial (satellite) cells express more as shown by immunostaining. The present study provides new information regarding serotonin and OX-R1 receptors in the neurons as well as satellite cells of the nodose ganglia and their role in physiological central effects that is mediated by afferent vagal fibers following cisplatin treatment.

Title: Progressive lower urinary tract dysfunction in mice with alkaline ceramidase 3 deficiency

Authors: *J. SCHRANDT[1], W. F. COLLINS, III[2], C. MAO[3];
[1]Pharmacol., [2]Neurobio. & Behavior, [3]Med., Stony Brook Univ., Stony Brook, NY

Abstract: We have previously demonstrated that alkaline ceramidase 3 (Acer3) activity in the nervous system increases with age, suggesting a critical role in age-related maintenance of sphingolipid homeostasis. Knockout (KO) of Acer3 increases the concentration of long-chain ceramides, especially in older mice, and prevents the age-related increase in sphingosine and S1P concentration in the mouse nervous system. At the same time, Acer3 KO mice develop progressive urine retention with age, which is more pronounced in female mice. Since sphingolipid levels of the nervous system are more impacted than those of the bladder in Acer3 KO mice, we studied how Acer3 affects (1) bladder size to characterize the morphological phenotype and (2) the micturition reflex to assess possible changes in the neural control of the lower urinary tract (LUT). To this end, wild-type (WT), heterozygous (Het), and KO mice received monthly ultrasounds of the bladder to measure changes in bladder size over time. Female WT, Het, and KO mice also underwent cystometric studies at 4 and 6 months of age in order to identify possible early physiological changes that may contribute to LUT dysfunction. The ultrasound data indicate that the bladders of Acer3 KO mice begin to enlarge at around 6 months of age and lack any gross abnormalities, e.g., bladder stones. For cystometry, mice were anesthetized with isoflurane (1.5-2%) for the initial surgical procedure to insert a catheter into the dome of the bladder and then maintained with urethane (1.2-1.5 g/kg) for the duration of the recording. Micturition reflexes were elicited by continuous intravesical infusion of saline into the bladder, and bladder pressure data were recorded for 1.5-2 hours after establishing a steady-state pattern of reflex micturition. Cystometric data indicate that 4-month-old Acer3 KO mice lack strong voiding bladder contractions and exhibit frequent non-voiding bladder contractions. The Acer3 KO mice also are unable to fully evacuate the bladder during continuous slow infusion of saline into the bladder, resulting in residual volume and enlarged bladder. The changes in reflex micturition demonstrated with cystometry occur prior to onset of gross bladder pathology indicated with ultrasound, suggesting that Acer3 deficiency disrupts the neural control of micturition and potentially produces a novel model of age-related underactive bladder syndrome.

Title: Acute intermittent hypoxia-induced long-term facilitation of micturition-related external oblique muscle activity

Authors: M. CATEGE[1], N. P. PHAGU[1], I. C. SOLOMON[2], *W. F. COLLINS, III[1];
[1]Neurobio. and Behavior, [2]Physiol. and Biophysics, Stony Brook Univ., Stony Brook, NY

Abstract: Exposure to acute intermittent hypoxia (AIH) produces a sustained increased in respiratory motor output (long-term facilitation (LTF)). This AIH-induced neural plasticity has been reported for both respiratory and nonrespiratory-related motor outputs. The goal of the present study is to characterize possible similar effects of AIH on the external oblique (EO), an expiratory abdominal muscle active during micturition. To this end, bladder intravesical pressure along with external urethral sphincter (EUS) and EO EMG activity were recorded in urethane-anesthetized (1.4 g/kg), spontaneously breathing adult female Sprague Dawley rats. In addition, EMG recordings were acquired from the diaphragm to identify periods of inspiration and expiration and to assess AIH-induced respiratory LTF. Reflex micturition events were elicited by continuous infusion of saline into the bladder, and the rate of infusion was adjusted to achieve a baseline bladder inter-contraction interval of approximately 4 minutes. Following 30-40 minutes of breathing room air (21% O2; baseline recording), rats were exposed to a single bout of AIH consisting of three five-minute episodes of hypoxia (10% O_2; 90% N_2) each separated by five-minute exposures to room air. Data acquisition continued for at least 90 minutes following the AIH exposure. EO activity was associated with both micturition and respiration and occurred primarily at the peak of bladder contraction during the period of EUS bursting (i.e., active voiding). Further, during EO activation tonic activity as well as phasic discharges during expiration were observed. During baseline recording, the amplitude and duration of EO activity varied both within and between rats. During AIH, EO activity was attenuated, particularly during the episodes of hypoxia. However, EO activity was markedly facilitated (both amplitude and duration) for up to 60 minutes following AIH. Sustained EO LTF was also observed in rats that exhibited little or no EO activation during baseline recording. In every case, the enhanced EO activation following AIH continued to be associated with active micturition and exhibit both tonic and/or phasic expiratory patterns of activity. These results are consistent with the

hypothesis that AIH initiates a generalized systemic motor LTF that includes spinal somatic motor systems.

Title: Histomorphometry of postganglionic and sensory neurons of the vagina of nulliparous and pregnant rats

Authors: N. MIRTO-AGUILAR[1], N. XELHUANTZI[2], J. PALACIOS[3], *M. JUAREZ[4], Y. CRUZ[5];
[1]Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico; [2]Facultad de Ciencias de la Salud, [3]Doctorado en Ciencias Biológicas, [5]Ctr. Tlaxcala de Biología de la Conducta, [4]Univ. Autonoma Tlaxcala, Tlaxcala, Mexico

Abstract: The female reproductive organs undergone anatomical and histological changes associated with their reproductive status. The aim of this study was to describe the morphological features of urogenital tract in pregnant and virgin rats. Five pregnant and four virgin rats were studied. The vaginal wall of 17-18 day of pregnancy or virgin rat was injected with 5 µl of horseradish peroxidase wheat germ agglutinin (HRP) and after 48/72 hours of injection, the left major pelvic ganglia (MPG) and the right dorsal root ganglia (DRG's) were obtained. We founded that the postganglionic neurons innervating the vagina are localized in the middle region of the MPG. The vaginal sensory neurons were mainly founded in the L6 and S1 DRG's. The pregnancy did not modify the number of vaginal postganglionic neurons (862.0±42.4 *vs* 849.0±52.30, p=0.8) neither their morphometric characteristics: soma area (pregnant 90.7±2.1 μm^2 *vs* virgin 134.9±2.3μm^2, p=0.1), diameter (11.9±0.3 µm *vs* 13.6±1.1µm, p=0.4). The pregnancy did not modify the number of the sensory neurons (L6, 35.5±15.8 *vs*

virgin 46.8±30.7, t=21 p=0.9; S1, 64.6±37.4 *vs* 75.1±68.5, t=19, p=0.9), neither their morphometric features: soma area (L6 = 440.1±76.1 μm^2 *vs* 391 ±43.4 μm^2, p=0.3; S1 (371.0 ±36.9 μm^2 *vs* 377.2 ±12.5 μm^2, p=0.9); diameter (L6, 26.3± 1.4 µm *vs* 24.7±0.4 µm, p=0.2 and S1, 24.03±1.9 µm *vs* 25.1±0.9 µm, p=0.7). Our results showed that despite the several physiological and morphological pregnancy related changes, and in contrast to the described reduction in the vaginal innervation in pregnant rats, there is no evidence of anatomical changes in autonomic or sensory vaginal neurons.

Title: Modulation of blood glucose by the dorsal vagal complex

Authors: ***C. R. BOYCHUK**, J. A. BOYCHUK, K. C. HALMOS-SMITH, B. N. SMITH; Physiol., Univ. of Kentucky, Lexington, KY

Abstract: The brainstem dorsal motor nucleus of the vagus (DMV) contains the preganglionic parasympathetic motor neurons that provide motor output to most subdiaphragmatic viscera important in regulating metabolism. The DMV serves as the final central modulatory point for descending parasympathetic activity, and its activity is tightly controlled by GABAergic inhibitory synaptic input arising from the nucleus tractus solitarius (NTS). Thus inhibitory, GABAergic neurotransmission from the NTS contributes significantly to parasympathetic visceral control. Together with area postrema, the DMV and NTS make up the dorsal vagal complex (DVC), a brainstem site critical in mediating the gut-brain-liver circuit controlling systemic [glucose]. Specifically, GABA neurons in the NTS are glucose sensing, and elevated glucose increases GABA neurotransmission in the DMV. Chronic hyperglycemia also induces a variety of neuroplasticity events within the DVC. Therefore, we hypothesized that modulating GABA neuron activity in the DVC causes changes in peripheral blood [glucose] through an efferent vagal pathway. This hypothesis was tested by integrating in vitro electrophysiology with acute drug infusion and chemogenetics using designer receptors exclusively activated by designer drugs (DREADDs) in the whole animal. Preliminary electrophysiological results

confirm previous reports that GABA neurons in the NTS respond to changes in [glucose] through specific intracellular mechanisms, including glucokinase (GCK) activation. Acute local infusion of a $GABA_A$ receptor agonist or a GCK activator indicated that modulating glucose sensitivity or GABA receptors in the DVC can elevate blood [glucose]. Chemogenetic manipulation of GABA neurons in the DVC also resulted in significant changes in blood [glucose]. After chronic hyperglycemia (3-5 days), both electrophysiological and in vivo data suggest that these GABAergic vagal circuits undergo significant plasticity. These studies are the first to demonstrate that GABAergic signaling in the DVC regulates systemic glucose homeostasis. Defining the glucoregulatory functions of the DVC provides a fresh perspective on our understanding of autonomic control of energy homeostasis and will likely translate to novel therapeutic targets for diabetes.

Title: Spinal cord stimulation may improve the voiding function in rodent with dopaminergic brain lesion injury

Authors: J.-C. YEH, J. MAO, *H. H. CHANG;
Urology, USC, Los Angeles, CA

Abstract: Neurodegenerative disorders often have an impact on urodynamics; Parkinson's disease (PD) is one of said disorders that specifically involves voiding dysfunction. Spinal cord stimulation (SCS) is currently used as a therapeutic option in the clinic for the management of neuropathic pain and spasticity. As it relates to urodynamic studies, the SCS technique has been successful for promoting micturition through reducing urethral resistance in the rodent model of spinal cord injury. The present study aimed to examine the effect of SCS on micturition following a dopaminergic brain lesion in rodents that mimics PD. Female Sprague-Dawley rats underwent injection of 6-OHDA (n=4) or vehicle (n=4) at four injection sites bilaterally targeting the dorsal striatum. SCS was then performed directly between the L2 and L6 spinal levels at 28 days following the injury. Cystometry and external urethral sphincter (EUS) electromyography

were obtained while the rats were under urethane anesthesia. Prior to the SCS the PD rats showed detrusor over-activity and a significant increase in the maximum intravesical pressure (IVPmax); the amplitude and area under the curve (AUC) of EUS activity during filling and voiding were increased as compared with the sham rats. Following the baseline recordings, the bladder was then infused with room temperature saline to distend it to a volume of over 60% of bladder capacity. SCS was then performed at the L2-6 spinal levels for the duration of 1 min (40 Hz, 0.2 ms pulse duration, and 2-6 volts). The evoked voiding contraction was observed approximately 30-65 seconds after SCS. The IVPmax, amplitude, and the AUC of EUS activity during voiding were all significantly decreased in the PD rats as compared to the spontaneous voiding contractions as recorded without the aid SCS; IVPmax, amplitude, and the AUC of EUS for PD rats following SCS more closely resembled the data collected for the sham rats. The preliminary results indicate that SCS on the spinal levels of L2-6 in the rats with dopaminergic brain lesion could elicit the bladder contractions accompanying decreased EUS activity. Implications are that SCS on the spinal levels of L2-6 could potentially improve voiding function through the reduction of urethral resistance in patients with Parkinson's disease.The authors thank Dr. DP Holschneider's Laboratory at USC for assisting with the surgical injection of 6-OHDA.

Title: Uncontrolled diabetic hyperglycemia is resolved by vertical sleeve gastrectomy in a murine model of type 1 diabetes

Authors: *K. HALMOS, C. R. BOYCHUK, B. N. SMITH;
Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Recent evidence supports the emerging hypothesis that brainstem autonomic neurons are affected by and contribute to systemic glucose regulation. Provocatively, activation of vagal afferent terminals at the level of the gut results in altered blood [glucose] in a manner that involves a brain-centered glucose regulatory system. Moreover, most GABAergic neurons in the brainstem nucleus tractus solitarius (NTS), which receive primary vagal afferent synaptic information, are sensitive to changes in [glucose] in a glucokinase (GCK)-dependent fashion and GCK expression and glucose-sensitivity are reduced in the NTS after several days of continuous hyperglycemia in the streptozotocin (STZ)-treated mouse. Vertical sleeve gastrectomy (VSG) and other bariatric surgeries can result in resolution of type 2 diabetes in humans and animal models, but information about effects of VSG on type 1 diabetes is scarce. Here, we used the STZ-treated mouse model of type 1 diabetes to determine effects of VSG on uncontrolled hyperglycemia, brainstem GCK expression, and markers of hepatic gluconeogenesis to test the general hypothesis that an insulin-independent, brain-centered glucose regulatory system contributes to systemic glucose regulation after bariatric surgery. Uncontrolled hyperglycemia (>300 mg/dl) was maintained for 3-5 days in STZ-treated mice, at which time VSG or sham surgery was performed. After VSG, blood [glucose] was normalized in ~80% of mice, an effect that was evident within three days and persisted for >4 weeks. Correspondingly, molecular expression of GCK in the vagal complex, which is reduced after several days of hyperglycemia, was reinstated to control levels after VSG. These outcomes were independent of reduced caloric intake after VSG and were mimicked by insulin treatment in STZ-treated mice. Indicators of hepatic gluconeogenesis (e.g., PEPCK, G6P) were significantly altered after STZ treatment and were reinstated to normal levels after VSG. Thus, VSG resolves uncontrolled hyperglycemia in a manner that involves reinstatement of glucose-sensitivity in the vagal complex in this model of type 1 diabetes. These data are consistent with a role for brainstem control of systemic glucoregulation involving a vagally-mediated gut-brain-liver circuit.

Title: Sensory urethral innervation in male rats

Authors: *R. JUAREZ MENDIETA[1], I. JIMENEZ[2], Y. CRUZ[1];
[1]Ctr. Tlaxcala Biologia de la Conducta, Univ. Autonoma De Tlaxcala, Tlaxcala, Centro, Mexico;
[2]Ctr. de Investigación y Estudios Avanzados, Inst. Politécnico Nacional, México, Mexico

Abstract: In rats, the male urethra is divided into four regions: prostatic, membranous, diverticulum and penile urethral. Approximately half of the urethra is surrounded by the external urethral sphincter (EUS). The aim of the present study was to determine the afferent innervation of the urethra of the male rat. In the Experiment one, the reflex EUS electromyographic (EMG) activity induced by urethral stimulation was used as indicator of afferent innervation. The EUS EMG activity was recorded in eight animals during mechanical stimulation of the penile urethra and prostatic urethral regions, before and after the neurectomy of the sensory branch of the pudendal nerve (SBPdN) or the viscerocutaneous branch of the pelvic nerve (VBPvN). In the Experiment two, evoked action potentials were recorded in the dorsal roots of L5, L6 and S1 segments during mechanical or electrical stimulation of the urethra. The Experiment one results showed that the SBPdN neurectomy eliminated the reflex activity of the EUS induced in response to stimulation of the penile urethra. The EUS EMG activity induced during stimulation of the prostatic urethra decreased ($p<0.05$) in amplitude and frequency after the SBPdN neurectomy. In contrast, the neurectomy of the VBPvN increased the EUS EMG activity induced in response to stimulation of the penile urethra, but eliminated the EMG response to prostatic urethral stimulation. In the Experiment two was found that mechanical or electrical stimulation of the penile or prostatic urethra evoked action potentials in the L6 dorsal roots. When the penile urethra was stimulated at 20 and 15 mm deep, the first component of the potential appeared with a latency of 1.6 ms ± 0.08 and 1.5 ± 0.08 ms, respectively. We conclude that the urethral afferents of the male rat travel through the VBPvN and the SBPdN, with the latter as the main pathway. The urethral sensory information is mostly integrated at the L6 spinal cord segment.

Title: Development of skull-mounted port for bladder infusion during cystometry in unanesthetized, freely-moving rats

Authors: *J. S. CARP, J. R. WOLPAW;
NY State Dept. of Hlth., Natl. Ctr. For Adaptive Neurotechnologies, Albany, NY

Abstract: Cystometry for evaluation of lower urinary tract (LUT) function is often performed in awake, restrained animals with implanted catheters to avoid the influence of anesthesia. Because the stress of restraint may influence LUT function, we are developing methods for infusing saline into the bladders of awake, freely-moving rats and comparing their cystometric data with those of head-restrained rats. Female rats (n=4) were each implanted with a suprapubic catheter secured in the bladder dome. The catheter was routed subcutaneously to a Delrin access port (22 mm high x 10 mm diameter) with a silicone rubber septum mounted on the skull with dental cement and screws. In two rats, a bolt was attached to the skull to allow the animals to be restrained by securing the bolt to a rigid frame. Drinking water contained 5-7 mM trisodium citrate to reduce precipitate formation around the implanted catheter tip and in the bladder. After a 1-2 week recovery, rats were placed periodically in large cages and a 19-ga Huber needle was inserted through the port septum to allow continuous infusion of room-temperature sterile saline at 0.2 ml/min into the bladder while measuring pressure. Recording sessions lasted 30-60 minutes, after which each rat received a 0.5-ml injection of a citrated antibiotic lock solution into the port. To date, recordings have been made from two freely moving rats (9 and 5 sessions over 8 and 4 weeks, respectively) and two head-restrained rats (5 and 3 sessions over 7 and 2 weeks, respectively). Although pressure artifacts were evident during movement, these disappeared when the rats assumed a quiet quadrupedal stance during voiding, during which contraction pressure (CP), inter-contraction interval (ICI), and contraction duration (CD) were determined. Comparing freely-moving and head-restrained rats, ICI was similar (5 vs 6 min, respectively), CP was higher (35 vs 28 mm Hg, respectively), and CD was shorter (9 vs 15 s, respectively). These results suggest the feasibility of maintaining a patent fluid catheter to the bladder for several weeks, allowing longitudinal study of LUT function in the same subject. Further study will determine how long the recordings remain viable, and whether addition of citrate to drinking water and the port promote catheter patency.

Title: Effect of parasympathetic or sympathetic denervation on intestinal epithelial stem cell proliferation

Authors: *E. A. DAVIS[1], M. C. WASHINGTON[3], H. PHILLIPS[2], A. I. SAYEGH[3], M. J. DAILEY[1];
[1]Neurosci., [2]Vet. Clin. Medicine, Col. of Vet. Med., Univ. of Illinois at Urbana-Champaign, Champaign, IL; [3]Dept. of Biomed. Sciences, Col. of Vet. Med., Tuskegee Univ., Tuskegee, AL

Abstract: The mammalian intestinal epithelium is critical for nutrient absorption, hormone release and immune function. Stem cells located in the intestinal epithelial crypts proliferate and differentiate to produce mature cells that serve these functions. Via this process, complete turnover of the epithelium occurs every few days. Previous studies show that the parasympathetic (PNS) and sympathetic (SNS) nerves play a role in this turnover process, as surgical ablation of each branch alters stem cell proliferation. These studies, though, did not control for the surgically-induced decreases in food intake and did not investigate segmental differences in autonomic control along the proximal to distal axis of the intestine. Given that we have found that the amount of food intake can dictate the rate of stem cell proliferation and that there are anatomical differences in PNS and SNS innervation along the intestinal axis, we wanted to evaluate the PNS and SNS control of intestinal stem cell proliferation independent of changes in food intake and in each segment of the intestine. Adult male Sprague Dawley rats underwent 1) bilateral subdiaphragmatic vagotomy to denervate PNS nerves (n=12) or 2) bilateral subdiaphragmatic celiacomesenteric ganglionectomy to denervate SNS nerves (n=12). Control groups for both surgical denervations included 3) a sham surgery, *ad libitum* fed group (n=8) and 4) a sham surgery, pair-fed group that was fed equal kcals to the surgical group to control for any surgical-induced changes in food intake (n=8). Three weeks after surgery, animals were given an intraperitoneal bromodeoxyuridine (BrdU) injection and sacrificed 6 hours later. Intestinal tissue was excised and immunohistochemically processed to visualize BrdU positive cells, an indication of cell proliferation. PNS denervation induced an expected decrease in food intake, but Brdu positive cells and
the proliferation ratio (positive cells/total crypt cells) were significantly increased compared to the sham, pair-fed animals ($p<0.05$). Segmental differences show a pronounced effect in the jejunum, but no significant difference in the ileum. SNS denervation resulted in a significant increase in the proliferation ratio compared with the sham surgical group in the duodenum and jejunum, but not in the ileum ($p<0.05$). These data suggest that anatomical differences in PNS and SNS intestinal innervation result in a differential effect on stem cell proliferation, leading to changes in the regenerative capacity of the epithelium and integrity in the tissue function.

Title: Network dynamics underlying the encoding of visceral sensorimotor information

Authors: *A. MANOHAR[1], A. CURTIS[2], S. ZDERIC[2], R. VALENTINO[2];
[1]Stress Neurobio., [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Neural networks with bi-directional communication between the brain and viscera are critical for regulating bladder function. Urodynamic status must be communicated to distributed brain regions that increase arousal, redirect attention and modify behavior prior to micturition. Despite its importance, the process by which the brain encodes visceral signals is relatively unexplored. Barrington's nucleus (BN), in the pons, initiates micturition through projections to preganglionic parasympathetic neurons that innervate the detrusor. BN neurons can coordinate peripheral and central components of micturition through its projections to the norepinephrine nucleus, locus coeruelus (LC), which innervates the prefrontal cortex (PFC) that governs executive function. Using multisite recordings we sought to understand the central encoding of visceral sensory information that yields the appropriate behavioral output. Rats were implanted with multi-wire electrodes to record single unit activity and/or local field potentials in the PFC and either the BN or LC. Neuronal and network activity were recorded simultaneously with bladder pressure (cystometry) in awake freely behaving animals. LC neuronal discharge showed a multi-fold increase approximately 30s prior to micturition threshold and this was temporally linked to PFC desynchronization. At this time LC network activity shifted into a prominent theta oscillation that was associated with PFC desynchronization and LC-PFC coherence was increased specifically in the theta band. The initiation of LC theta oscillations may be a signal to shift attention and initiate voiding behaviors prior to micturition. Further, contrary to the notion that BN functions as a switch, BN neurons discharged spontaneously and exhibited synchronized bursting at different frequencies occurring right before and after the peak in the bladder pressure suggesting an underlying code for sensory and motor aspects of visceral function. Together, these results underscore the complex synchronization of pontine and cortical neurons with bladder afferent information that is required to maintained coordination between voiding behavior and urination. Dysregulation of this network could be a prominent signature underlying bladder pathology.

Title: Reflexive inhibition of bladder function via saphenous nerve stimulation in anesthetized rats

Authors: *Z. MOAZZAM, P. B. YOO;
Inst. of Biomaterials and Biomed. Engin., Univ. of Toronto, Toronto, ON, Canada

Abstract: Overactive bladder (OAB) is characterized by symptoms of urinary frequency, urgency and incontinence. Percutaneous tibial nerve stimulation (PTNS) is a minimally invasive yet effective treatment where electrical pulses are delivered at 20 Hz coupled with amplitudes set below the foot twitch threshold (< 1T). However, recent animal studies report that tibial nerve mediated bladder reflexes require stimulation amplitudes exceeding 2T. The discrepancies in clinical and physiological data prompted the current study where we hypothesized the presence of a low-threshold bladder-inhibitory pathway that is co-activated during clinical PTNS therapy. Given the anatomical placement of the percutaneous electrode, we conjecture contributions from the saphenous nerve (SAFN) as a potential mechanism for PTNS-mediated therapeutic efficiency. We conducted 77 stimulation trials in 19 urethane-anesthetized adult rats (Sprague-Dawley) with urodynamic fills. The SAFN trunk was instrumented caudal to the knee joint where a bipolar stimulating nerve cuff electrode was implanted. Bladder function was characterized by changes in multiple urodynamic parameters (e.g., bladder contraction rate (BCR)). Finite durations of electrical pulses were applied at low amplitudes (i.e., 25 μA) while the frequencies ranged between 2 Hz - 50 Hz. The pulse width was set at 200 μs for all trials. Our findings suggest that SAFN stimulation at low amplitudes can effectively inhibit on-going bladder activity at all frequencies tested. Short (10 min) stimulation trials conducted at 20 Hz resulted in the most consistent changes during both intra-stimulation (50.2±4.7% decrease in BCR) and post-stimulation (38.7±5.9% decrease in BCR). The inhibitory effects of 10 minute stimulation trials were observed to abate shortly following termination of the stimulus. Conversely, prolonged SAFN stimulation (40 min) at 10 Hz significantly decreased the average

evoked contraction amplitude (49.0±10.5%) along with an increase in the voiding threshold (17.6±4.8%) during stimulation leading to complete inhibition of periodic bladder contractions during the post-stimulation phase. Such strong inhibitory effects were observed to last for an approximate period of 40 - 50 minutes post-stimulation. These novel pre-clinical findings suggest the presence of a highly sensitive reflex pathway that can elicit strong and consistent bladder inhibitory effects during both acute and prolonged conditions. Future work is needed to fully characterize this reflex pathway and determine the clinical feasibility of translating SAFN stimulation as an efficacious neuromodulation alternative for OAB patients.

Title: Unilateral denervation of the genitourinary tract induces signs of sexual, urinary dysfunction and infertility in male rats

Authors: J. ARELLANO[1], F. CASTELÁN[2], J. CUATECONTZI[2], *Y. CRUZ[2];
[1]Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico; [2]Univ. Autonoma Tlaxcala, Tlaxcala, Mexico

Abstract: Introduction and Objectives. The urogenital tract (UGT) is the anatomical substrate of micturition, sexual behavior and fertility. In male rats the autonomic innervation of the UGT is mainly provided by the major pelvic ganglion (MPG), which innervates the bladder, urethra and sexual accessory glands. The somatic component is represented by the motor branch of the sacral plexus (MBSP), which innervates the external urethral sphincter and the perineal muscles (ischiocavernosus and bulbospongiosus). The objective of this study was to determine whether autonomic or somatic unilateral denervation of the UGT induces signs of urinary/sexual dysfunction and/or infertility.

Methods. Eighteen adult Wistar male rats were maintained on a 12/12 light/dark cycle with food and water provided *ad libitum*. The animals were sexually trained and assigned to the following groups (six animals per group): left MPG ablation (MPGA), left MBSP transection (MBSPT) or sham surgery (SH). Urinary and sexual functions were evaluated before, as well as at 1 and 3 weeks after surgery. Fertility was determined at 12 weeks post-surgery. A closed circuit video with infrared cameras was used to record micturition and copulatory parameters. Urinary function was tested during the last 6 h of the dark phase by placing rats in a wired-floor cage and voided urine was collected in a plastic container. Sexual behavior was assessed by placing the male rat with a receptive female rat in a Plexiglas cylinder arena. Fertility was evaluated by determining the percent of pregnant females housed with a male for two weeks.
Results. Pre-surgery the rats presented ~ 5 voids/6h. Three weeks after the surgery voiding frequency in the MPGA and MBSPT animals increased (SH=7$\pm$1.3; MPGA=10.55$\pm$0.9; MBSPT=12.5$\pm$1.7; $p<0.05$), while voiding volume decreased significantly (SH=0.66$\pm$0.17; MPGA=0.4$\pm$0.05; MBSPT=0.3$\pm$0.04; $p<0.05$). In the MBSPT group, 20% of animals did not reach ejaculation. The number of intromissions decreased in both denervated groups ($p<0.05$) and fertility was only affected in MBSPT (63% of pregnant females). Conclusion. Unilateral autonomic or somatic denervation of the UGT induces signs of urinary and sexual comorbidity in male rats.

Abstract: Diabetes is a growing global disease. One of the main natural body adaptations to high blood glucose levels caused by diabetes is glycosuria. Glycosuria is a condition where excess blood glucose is excreted into urine. In recent years, the role of kidney (renal) nerves in blood

glucose control through glycosuria has been identified. We hypothesized that renal nerve activity can be influenced by electrical stimulation to regulate glycosuria. In this study, renal nerves of the left kidney in male Long-Evans rats were accessed and encircled by a nerve cuff electrode. Ureters of the left and right kidneys were cannulated to obtain separate urine samples. Electrical stimulation (2 Hz, 10 V) was applied on renal nerves of the left kidney for 30-40 minutes. A bolus dose of glucose was administered through the jugular vein after 2 minutes into stimulation. Urine samples were collected at 5- or 10-minute intervals and an assay kit was used to quantify urinary glucose excretion. Across sampling periods the stimulated left kidney generally had much less total urine glucose excreted, typically 45-94% lower than the unstimulated right kidney output. Our results so far suggest that renal nerves stimulation can modulate urinary glucose excretion. Future experiments are required to confirm the effects of renal nerves stimulation on glycosuria and further explore the stimulation parameter space.

Title: Prostaglandin E2 installation as an overactive bladder model in cats

Authors: ***C. L. LANGDALE**[1], J. A. HOKANSON[1], A. SRIDHAR[5], W. M. GRILL[1,2,3,4]; [1]Biomed. Engin., [2]Electrical and Computer Engin., [3]Neurobio., [4]Surgery, Duke Univ., Durham, NC; [5]Bioelectronics R&D, GlaxoSmithKline, Stevenage,, United Kingdom

Abstract: Overactive bladder (OAB), as described by the International Continence Society, is defined as urgency, with or without urge incontinence, usually with frequency and nocturia. Animal models are essential for advancing our understanding of bladder function as well as developing novel therapeutic treatments for OAB. Due to the inability to identify urgency in animals, symptoms such as detrusor over-activity, frequency, and voiding parameters (bladder capacity (BC) etc…) are used as proxies for the symptoms of OAB. There are a number of animal models in rats and mice that result in symptoms of OAB (induced hypersensitive/irritation, genetic, bladder outlet obstruction, and neurogenic models). However, OAB models in the cat, which is commonly used to evaluate lower urinary tract function due to

the similarity to humans, are limited. Acetic acid (AA)-induced bladder irritation model in the α-chloralose anesthetized cat has been routinely used as an OAB model, and produces symptoms of OAB including increased frequency of voiding and decreased BC. However, an apparent limitation to the AA infusion model is the associated damage to the bladder urothelium and urethral epithelium, which may have unintended consequences. Alternative OAB models for evaluating therapeutic targets in cats are needed. We hypothesized that intravesical infusion of PGE2, a rat OAB model, will cause OAB symptoms similar to acetic acid infusion in cats. Acute α-chloralose (65 mg/kg) anesthetized female cats were studied using in vivo cystometry (CMG). A PE-90 catheter was placed to measure bladder pressure and for intravesical infusion of saline and PGE2 (1, 5, and 10 μM). Bipolar electrodes were placed on the EUS to record electromyogram (EMG) activity during CMGs. In a subset of experiments, pelvic nerve (PEL) stimulation was delivered after 5 μM PGE2 infusion at different amplitudes (0.8, 1.0, and 2.0 times evoked PEL-EUS reflex threshold) and frequencies (1 and 10 Hz). PGE2 dose dependently decreased BC, with a 50% reduction in BC at 5 μM. No apparent changes in either EUS EMG or voiding efficiency were noted. Additionally, PEL stimulation restored BC in an amplitude dependent manner. These findings suggest that PGE2 may be an alternative OAB model to evaluate therapeutic targets in cats.

Title: Wireless monitoring and optogenetic modulation of bladder function

Authors: ***A. D. MICKLE**[1], J. YOON[2], S. M. WONG[2], S. PARK[2], K. N. NOH[2], K. MEACHAM[1], J. ROGERS[2], R. W. GEREAU, IV[1];
[1]Pain Ctr. and Dept. of Anesthesiol., Washington Univ., Saint Louis, MO; [2]Dept. of Materials Sci. and Engin., Univ. of Illinois at Urbana-Champain, Urbana, IL

Abstract: Millions of people in the United States suffer from bladder dysfunction and pain caused by interstitial cystitis/bladder pain syndrome and overactive bladder. The underling pathologies for many of these diseases are poorly understood and this is the primary reason most current treatments are ineffective. To address this issue, we have designed and tested an implantable wireless optoelectronic system to monitor and modulate bladder function. This new technology eliminates the need for implantation of potentially-damaging bladder catheters or electrodes, and provides unique access to bladder functionality in the awake, freely-moving rat. We utilized a combination of viral delivery of opsins and a novel strain gauge that measures dynamic changes in bladder circumference, to modulate and monitor bladder function, respectively. Our hyper-conformal strain gauge wraps around the bladder and as the bladder expands changes in geometry of the device linearly increases resistance. We show that this change in resistance correlate to traditional bladder activity measurements like intravesicular pressure. We attached microscale light emitting diodes (LED) to the strain gauge that can be used to activate light-sensitive opsins for optogenetic regulation of neuronal activity. The strain gauge and LEDs connect with an implantable Bluetooth base station that allows for wireless control and monitoring of bladder activity. Implementation of this new technology will provide unique access to understanding bladder functionality without need for implantation of potentially damaging bladder catheters or electrodes. This technology could thus lead to novel insights into the mechanisms of bladder control and pain. Additionally the refinement of this novel technology and virally delivery methods for optogenetic channels could lead to development of future therapies for bladder dysfunction. This work was funded by a grant from the NIH Common Fund's SPARC program, U18EB021793 to RG and JR.

Title: Autonomic control of bladder function is regulated by TREK-1, a two-pore domain potassium channel

Authors: *R. H. PINEDA, R. B. MEACHAM, A. P. MALYKHINA;
Surgery/ Urology Res., Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: *Background.* Regulation of urinary bladder function depends on coordinated activity between the nerves and smooth muscle cells in the bladder wall. The mechanisms of mechanosensitivity and mechanotransduction during the storage and voiding phases of the micturition cycle are currently not well understood. Previously, we characterized the expression and function of two-pore domain potassium (K_{2P}) channels in the normal human bladder, and confirmed that TREK-1 is the predominantly expressed member of the family on both bladder smooth muscle cells and bladder sensory neurons. In the present study, we sought to determine the key regulatory elements of the cell membrane and cytoskeleton which affect TREK-1 expression and function in the human urinary bladder, as well identify any differences in TREK-1 between normal and overactive urinary bladders. *Methods:* We used freshly dissociated detrusor smooth muscle cells obtained from 17 human donors and patients with detrusor overactivity (DO). Molecular (RT-PCR and Western), histological, immunohistochemical, electrophysiological (whole-cell patch-clamp) and pharmacological approaches were used to evaluate regulatory mechanisms affecting expression and/or function of TREK-1 channels in the human bladder. *Results:* Lower levels of TREK-1 expression were detected in patients with DO in comparison with normal bladders. The average level of expression in control bladders was twice higher than in the DO group ($p \leq 0.05$). Expression of TREK-1 was also tested in single isolated bladder smooth muscle cells picked up by patch pipette with large diameter to avoid contamination by other cells types (neurons, macrophages etc). The changes in channel expression correlated with a distortion in caveolin patterns suggesting a possible connection between the channel and cell cytoskeleton. *Conclusion:* Decreased expression of TREK-1 channel in the human detrusor is associated with detrusor overactivity. Physiologically, these changes are associated with smaller bladder volumes, decreased bladder capacity and development of the sensation of urgency, all of which are often observed in patients with overactive bladder. Title: OAB ithout an overactive bladder: insights from an acute prostaglandin E2 rat model

Authors: *J. A. HOKANSON[1], C. LANGDALE[1], A. SRIDHAR[2], W. GRILL[1];
[1]Biomed. Engin., Duke Univ. Dept. of Biomed. Engin., Durham, NC; [2]GlaxoSmithKline, Stevenage, United Kingdom

Abstract: Animal models of overactive bladder (OAB) enable the testing of therapies to treat the symptoms of OAB. Intravesical administration of Prostaglandin E2 (PGE2) was previously proposed as a model of OAB. Administration of PGE2 intravesically in healthy women causes a strong desire to void. In rat models intravesical PGE2 administration decreases bladder capacity, but its mechanism of action has not been well explored.

Female Wistar rats aged 15 - 23 weeks were anesthetized (urethane, 1.2 g/kg S.C.) and single fill cystometrograms were conducted with saline or PGE2 (100 μM). Wires were inserted percutaneously into the pelvic floor to record the activity of the external urethral sphincter (EUS). Additional experiments were conducted with suture placed around the bladder neck to allow administration of PGE2 exclusively to either the bladder (isovolumetric preparation) or the urethra.

Intravesical administration of PGE2 decreased bladder capacity (-17 ± 7.5%, p = 0.040, n=10). This decrease coincided with, and was sometimes preceded by, an increase in EUS EMG during bladder filling.

There was no clear increase in the number of large non-voiding contractions or change in bladder compliance (p=0.62, n = 10) following PGE2 installation. In isovolumetric preparations in which PGE2 was administered only to the bladder there was no change in the bladder capacity (p = 0.10, n = 7).

Infusing PGE2 into the urethra led to a large decrease (69% ± 10%, n = 3) in urethral infusion pressure, signaling a dramatic decrease in urethral tone.

These results suggest that urethral relaxation, not bladder activation, is driving the decrease in bladder capacity following intravesical PGE2 administration. The increase in EUS EMG may be compensatory to try to maintain continence during bladder filling.

Targeting the urethra, particularly urethral smooth muscle, may be a promising new avenue for the design of drugs and devices that treat OAB.

Abstract: The aim of this study was to examine GABA, glycine and opioid neurotransmitter mechanisms underlying the inhibition induced by sacral neuromodulation (SNM) of nociceptive bladder overactivity in cats under α-chloralose anesthesia. Initial bladder capacity was determined by repeated cystometrograms (CMGs) using saline infusion. Intravesical infusion of 0.5% acetic acid (AA) irritated bladder and induced nociceptive bladder overactivity. AA irritation significantly ($P<0.01$) reduced bladder capacity to 59.5±4.8% of saline control. S1 or S2 dorsal root stimulation at threshold intensity for inducing leg or anal twitch inhibited bladder overactivity and significantly ($P<0.01$) increased bladder capacity to 105.3±9.0% and 134.8±8.9% of control, respectively. Picrotoxin (a $GABA_A$ receptor antagonist, i.v.) blocked S1 inhibition at 0.3 mg/kg and removed S2 inhibition at 1.0 mg/kg. Picrotoxin (0.4 mg, i.t.) had no effect on sacral inhibition, but produced significant ($P<0.05$) bladder inhibition after the stimulation. Naloxone (an opioid receptor antagonist, 0.3 mg, i.t.) significantly ($P<0.05$) reduced bladder capacity and removed the post-stimulation inhibition unmasked by i.t. picrotoxin. Strychnine (a glycine receptor antagonist, i.v.) at 0.03-0.3 mg/kg significantly ($P<0.05$) increased AA control bladder capacity but did not change sacral inhibition. Picrotoxin (0.3 mg, i.v.) after strychnine (0.3 mg, i.v.) significantly ($P<0.05$) increased AA control bladder capacity and completely removed sacral inhibition. These results indicate that $GABA_A$ receptors play an

important role in sacral neuromodulation of nociceptive bladder overactivity at a supraspinal site, while glycine receptors are not involved. Opioid receptors play a role in post-stimulation inhibition unmasked by blocking spinal $GABA_A$ receptors.

Title: Chronic monitoring and stimulation of the lower urinary tract during sedated and awake testing

Authors: ***S. E. ROSS**, A. OUYANG, A. KHURRAM, A. A. A. JIMAN, Z. J. SPERRY, C. J. STEPHEN, T. M. BRUNS;
Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Patients with bladder dysfunction refractory to standard treatments may benefit from a closed-loop neuroprosthesis for bladder control. A greater understanding of lower urinary tract (LUT) neurophysiology can inform the development of such a device. While a plethora of information exists on acute LUT nerve interfaces, literature on long-term interfacing with LUT neurons is lacking. To this end, we are developing a chronic interface that integrates monitoring of bladder pressure and LUT activity with stimulation of peripheral pathways. Under isoflurane anesthesia, penetrating microelectrodes (32-channel arrays, Blackrock Microsystems) are implanted in sacral dorsal root ganglia (DRG) at the S1 and S2 levels and cuff electrodes are placed on the pudendal nerve. Supra-pubic bladder catheters for saline infusion and bladder monitoring are also implanted. Electrode and catheter connectors are tunneled subcutaneously to the midline rostral to the tail and enclosed in a custom-made external housing mounted percutaneously to the iliac crests. After recovery from surgery, animals are tested for ~2 hrs, 2-3 times per week either under sedation (dexmedetomidine, 0.04 mg/kg) or awake. Neural activity and bladder pressure are recorded (Ripple Grapevine system) under various test conditions. The DRG or pudendal nerve are also electrically stimulated at 1 - 33 Hz to drive LUT activity. LUT activity has been recorded for 4 to 11 weeks in four animals. Microelectrode impedances have remained stable with, on average, 83 % ± 0.12 % of the total number of channels per test session

having values between 10 kΩ and 500 kΩ. Data analysis is still ongoing, though up to 18 bladder afferents have been identified in a given animal (correlation coefficient > 0.2) with a trend showing more bladder afferents emerging after the second week of implant. Some channels have consistently showed bladder afferent activity for up to 41 days and we have been able to track individual units for up to 37 days. Distension-evoked and pudendal stimulation-driven bladder emptying has been observed during which urethra flow afferents have been identified. Voiding during awake sessions was also observed. Our chronic setup allows us to track LUT afferents under varying bladder conditions and drive spinal circuits using electrical stimulation. We can monitor LUT activity in both sedated and awake conditions and are working on improvements in our chronic setup. From this work we hope to gain a better understanding of LUT neurophysiology, including during awake conditions, and evaluate the feasibility of such a set-up for closed-loop neuroprosthesis control.

Title: Transient receptor potential vanilloid 4 channels modulate Ca^{2+} signals in interstitial cells of Cajal at urothelial-lamina propria junction of rat pups.

Authors: *M. A. VIZZARD[1], M. T. NELSON[2], T. J. HEPPNER[2];
[1]Neurolog. Sci., [2]Pharmacol., Univ. Vermont Col. Med., Burlington, VT

Abstract: The urinary bladder wall contains interstitial cells of Cajal (ICCs) that may play a role in bladder function by modulating communication between nerve fibers and smooth muscle or acting as pacemakers. Transient receptor potential vanilloid 4 (TRPV4) channels allow cation influx and may be involved in sensing stretch or chemical irritation in urinary bladder. A layer of ICCs expressing platelet-derived growth factor receptor (PDGFR)-alpha-immunoreactivity and exhibiting a branching, stellate morphology was identified at the interface of the urothelium and lamina propria. In this study we investigated the role of TRPV4 channels to modulate Ca^{2+} signals in urothelial-lamina propria junction ICCs. Urothelium was removed from rat pups (< 3 weeks old), cut into strips, and mounted on sylgard blocks. The urothelial strips were loaded with a Ca^{2+} fluorescent dye (Fluo-2 AM leak resistant) for 90 minutes (37^{o} C) to measure Ca^{2+} events. The sylgard blocks with attached urothelial strips were placed in a special imaging chamber and superfused with PSS (37^{o} C). Ca^{2+} events were recorded for a period of 60 seconds in control and after drug treatment. Analysis of Ca^{2+} events was performed post hoc using software developed by Dr. Adrian Bonev (UVM). A region of interest (ROI) was placed over the cell and changes in Ca^{2+} fluorescence within the ROI were compared to baseline (F/F_o). ICCs, located between the basal cell layer and the uppermost level of the lamina propria exhibited slow changes in Ca^{2+} that sometimes appeared to travel to neighboring cells through branched processes. To test for the presence of functional TRPV4 channels the TRPV4 agonist GSK1016790 (100 nM) was applied to the urothelium through the superfusing PSS. In paired recordings, GSK1016790 increased the number of Ca^{2+} events from 127 to 295 (132% increase) (n = 100 cells, 5 paired fields; 15-20 cells/field) whereas the TRPV4 antagonist GSK2193874 (1 μM) decreased the number of Ca^{2+} events from 131 to 94 (38.2% decrease) (n = 94 cells, 6 paired fields; 11-25 cells/field). The amplitude and duration of Ca^{2+} events were not significantly changed by the TRPV4 agonist (control, 1.6 ± 0.07 F/F_o, 2.5 ± 0.25 sec; GSK1016790, 1.5 ± 0.03 F/F_o, 2.3 ± 0.19 sec, n = 35 cells); however the antagonist did significantly decrease the amplitude, but not the duration of Ca^{2+} events (control, 2.1 ± 0.09 F/F_o, 1.8 ± 0.07 sec; GSK2193874, 1.8 ± 0.07 F/F_o*, 3.2 ± 0.19 sec, n = 57 cells, mean ± S.E.M., *$p \leq 0.05$), in paired recordings, respectively. These findings suggest that TRPV4 channels modulate Ca^{2+} signals in this population of ICCs and may contribute to ICC activity and bladder function.

Title: Connectome and putative function of MET-positive neurons in the vagal motor complex

Authors: *A. K. KAMITAKAHARA[1], H.-H. WU[1,2], P. LEVITT[1,2];
[1]Children's Hosp. Los Angeles, Los Angeles, CA; [2]USC, Los Angeles, CA

Abstract: Children with Autism Spectrum Disorder (ASD) are three times more likely to have associated gastrointestinal disturbances (GID), however the biological mechanisms contributing to this overrepresentation are unknown. One genetic commonality for both ASD and GID is a promoter variant in the human *MET* receptor tyrosine kinase (*MET*) gene that is significantly enriched in families of children with both ASD and co-occurring GID. The presence of this promoter variant results in reduced *MET* gene expression, which has been shown to critically impair a number of neurodevelopmental processes, including neocortical and enteric neuron dendrite growth, hippocampal synapse maturation, and spinal motor neuron survival. MET is expressed by a subset of developing brainstem autonomic neurons that innervate the GI tract. To determine whether MET signaling impacts the establishment of vagal inputs to the GI tract, we characterized the subpopulation of neurons that express MET by projection target, and assessed MET function through conditional deletion of the *Met* gene in developing motor neurons. Immunohistochemistry in Met^{EGFP} mice revealed that both EGFP and MET protein are expressed by a subset of neurons in the dorsal motor nucleus of the vagus (DMV), and by the vast majority of nucleus ambiguus (nA) neurons in the compact part of the nucleus beginning approximately on E11.5, shortly after these neurons are generated. Innervation targets of MET neurons in the brainstem vagal motor nuclei were determined through injection of the retrograde tracer, cholera toxin B, into sites along the GI tract. This revealed anatomically distinct subsets of MET neurons in the DMV, which segregate by projection target. MET expressing neurons rostral to the obex were located medially and projected to the stomach, whereas MET expressing neurons caudal to the obex were located laterally and projected to the cecum. In addition, the muscular layers of the esophagus of Met^{EGFP} mice contained EGFP+ axonal projections, likely arising from neurons in the nA. To test the neurodevelopmental functions of MET in vagal brainstem motor neurons, MET was conditionally deleted from developing motor neurons in $Isl1^{cre}; Met^{flox/flox}$ mice. On embryonic day 16.5, an approximate 50% reduction in the number of neurons in the nA was observed in $Isl1^{cre}; Met^{flox/flox}$ mice compared to control mice, suggesting that MET is required for formation of the nA. Ongoing analysis of the density of GI innervation by vagal MET

neurons in *Isl1^{cre}; Met$^{flox/flox}$* mice will advance understanding of how the reduced contribution of nA impacts autonomic innervation in the developing GI tract and give insight into increased GID risk in ASD.

Title: Detection of nausea in rats using the monitoring of facial expression.

Authors: *K. YAMAMOTO, S. TATSUTANI, T. ISHIDA;
Osaka Univ., Suita, Japan

Abstract: Patients receiving cancer chemotherapy experience nausea and vomiting. They are not life-threatening symptoms, but their insufficient control reduces the patient's quality of life and become a risk factor for refusal to undergo further therapy. To identify preventing methods of nausea and vomiting in preclinical study, objective evaluation of these symptoms in experimental animals is required. Unlike vomiting, nausea is defined as a subjective feeling described as recognition of the need to vomit; thus, determination of the severity of nausea in experimental animals is considered to be difficult. However, since we observed that rats make a grimace after administration of cancer chemotherapeutic agents, cisplatin, we hypothesized that changes of facial expression are used as a method to detect nausea. In this study, we examined to detect the changes of facial expression of rats after administration of cisplatin. Furthermore, we investigated the effect of anti-emetic drugs on the prevention of cisplatin-induced changes of facial expression in rats.
Male Wistar/ST rats were housed in individual cages with free access to food and tap water, and their facial expression was continuously recorded by infrared video camera. On the day of the experiment, rats received cisplatin (0 or 3 mg/kg, i.p.) with or without a daily injection of a 5-HT_3 receptor antagonist (granisetron: 0.1 mg/kg, i.p.) or a neurokinin NK_1 receptor antagonist (fosaprepitant: 2mg/kg, i.p.), and their eye-opening degree (L/W ratio: the ratio between longitudinal and wide length of eye) was analyzed by the recorded video image.
Intraperitoneal injection of cisplatin significantly induced decrease of L/W ratio after 6 hours of the injection of cisplatin and the decrease continued for 2 days. The acute phase (day 1), but not

the delayed phase (day 2), of decrease of L/W ratio was inhibited by treatment of granisetron; however, fosaprepitant abolished both phases of changes of L/W ratio.
The profiles of facial expression are similar to clinical evidence of cisplatin-induced nausea in humans. These findings indicated that the changes of facial expression has the potential to detect nausea in experimental animals.

Title: Pudendal nerve stimulation elicits oscillations in vaginal blood flow

Authors: *I. C. RICE[1,2], L. L. ZIMMERMAN[1,2], S. E. ROSS[1,2], M. B. BERGER[3], T. M. BRUNS[1,2];

Abstract: Female sexual dysfunction is a widespread clinical problem that affects over 25% of women. The mechanisms of female arousal are not well understood, and there are few treatment options. Neuromodulation for bladder and bowel dysfunction has shown the potential for improving symptoms of sexual dysfunction, supporting the potential of a targeted nerve stimulation approach. The purpose of this study is to investigate the use of pudendal nerve stimulation in female rats as a means for understanding and developing potential treatments for female sexual dysfunction.
Under ketamine anesthesia, platinum-wire hook electrodes were placed on the pudendal nerve and secured with Kwik-Cast. Stimulation was performed with varying frequencies (1-40 Hz) and amplitudes (0.5-3 V). Stimulation was delivered for either 1-2 minute periods with 1-10 minute breaks, or for 20-30 minute periods with 20-30 minute breaks. Changes in vaginal blood flow, a standard proxy for arousal, were measured with a laser Doppler flowmetry probe inserted into the vagina and angled against the anterior wall. Vaginal luminal diameter (VLD) was measured as a secondary indication of arousal.
5-10 Hz pudendal stimulation often resulted in large increases (2-10x) in vaginal blood perfusion. Low frequency oscillations (0.01-0.9 cycles per second) were observed and maintained for up to 10 minutes following stimulation. During experiments where stimulation was delivered for shorter periods (1-2 minutes) and a response to stimulation was noted, 11-19

stimulation periods (over 1-2.5 hours) were necessary before an oscillatory blood flow response was observed. When the stimulation time was increased to 30 minutes, an oscillatory response was usually seen after either the first or second stimulation period. Concurrent with the oscillatory blood flow response, a VLD increase (1.3-1.8x) was observed in several of the experiments, as a result of both short and long stimulation periods.
To our knowledge, this is the first time that slow oscillations in vaginal blood flow due to peripheral nerve stimulation have been reported. Our study supports pudendal stimulation as a potential method for inducing increases in vaginal blood flow. The secondary indication of VLD increase further indicates that the oscillatory increases in vaginal blood flow may be an arousal response. Implementation of this technique could contribute to a treatment for female sexual arousal dysfunction by improving vaginal blood flow.

Title: EMG analysis of external urethral sphincter in awake spinal cord injured rats during urodynamic assessment

Authors: *M. P. SCHNEIDER, A. K. ENGMANN, T. M. KESSLER, M. E. SCHWAB; Univ. of Zürich, Zürich, Switzerland

Abstract: We recently developed a urodynamic set-up allowing repetitive, long term urodynamic measurements of both bladder and external urethral sphincter function in the same rat under fully awake conditions (Schneider MP et al., BJU International 2015). We now

assessed the development of lower urinary tract dysfunction as a consequence of large spinal cord injuries (SCI) in adult rats over 6 weeks.
A urodynamic catheter into the bladder and external urethral sphincter electromyography (EMG) electrodes were implanted into female Lewis rats. Two weeks after implantation, baseline urodynamic investigation showed a normal, fast, large volume voiding response to bladder filling. For the analysis of external urethral sphincter EMG activity profiles, fast Fourier transformation was used to generate heat plots with power per frequency and time. In intact rats, the external urethral sphincter showed strong peak activity in the high frequency range (21-500Hz, representing striated muscle activity) at the high filling state immediately before voiding, as well as after voiding. High frequency activity was low during micturition. In contrast, slow wave bursting activity (3-20Hz, representing smooth muscle activity) was prominent during voiding.
Spinal cord injured rats underwent a microsurgical subtotal transection at the level of T9 which destroyed the grey, dorsal white and dorsolateral white matter completely and bilaterally, sparing only 10-20% of the ventral white matter. 14 of these 15 rats developed detrusor sphincter dyssynergia (DSD) characterized by high tonic high frequency sphincter EMG activity during the voiding phase, which resulted in dripping and interrupted release and very prolonged voiding phases. These characteristics are closely analogous to the one's seen in severely spinal cord injured patients. Studies are on-going to unravel the underlying lesion induced neuronal changes in the spinal cord, the primary afferent fibers and the remaining descending tracts.

Title: Evaluating sexual arousal in a female rat model with tibial nerve stimulation

Authors: *L. ZIMMERMAN[1,2], I. C. RICE[1,2], M. B. BERGER[3], T. M. BRUNS[1,2]; [1]Biomed. Engin., [2]Biointerfaces Inst., Univ. of Michigan, Ann Arbor, MI; [3]Obstetrics and Gynecology, Univ. of Michigan Hlth. Syst., Ann Arbor, MI

Abstract: The aim of this research is to determine if tibial nerve stimulation can have an effect on sexual arousal, using a female rat model. Currently, there are limited treatments for women suffering from female sexual dysfunction (FSD), a condition which can include deficits in desire,

arousal, and lubrication. In clinical trials involving percutaneous tibial nerve stimulation (PTNS) for bladder voiding dysfunction, female patients sometimes note an additional effect of positive impact on sexual function. However, there have been no studies attempting tibial nerve stimulation specifically for sexual function, separate from bladder function research. In ketamine-anesthetized female rats, we isolated and stimulated the tibial nerve on one side with platinum-iridium wire hooks. The stimulation frequency was between 10-20 Hz with an amplitude that was 2-5 times the threshold for causing a distal muscle response. Stimulation was delivered for 30 minute periods, with 20-30 minute breaks, across 3-4 hours. Vaginal blood perfusion was measured with laser Doppler flowmetry as the primary proxy for arousal. Vaginal luminal diameter was measured as a secondary indication. After thirty-minute periods of stimulation on the tibial nerve, large increases in blood perfusion (up to 10x average pre-stimulation amplitudes) with low frequency oscillations (0.1-0.6 cycles per second) were observed and maintained for several minutes. The oscillations are similar to those reported in clinical studies of vaginal blood flow during sexual arousal. Large increases in vaginal luminal diameter (up to 3.4x pre-stimulation diameter) were also observed, indicating that the modulations in blood perfusion may be due to arousal rather than pelvic floor contractions. These preliminary results suggest that tibial nerve stimulation may contribute to a therapeutic approach for a genital arousal component of FSD.

Title: High-salt intake decreases intestinal Na^+/K^+-ATPase activity in normotensive rats but not in hypertensive Dahl salt-sensitive rats

Authors: *M. TANDAI-HIRUMA, T. KEMURIYAMA, Y. NISHIDA;
Physiol., Natl. Def Med. Col., Saitama, Japan

Abstract: The specific mechanisms by which high-salt cause salt-sensitive hypertension have been clarifying. Oral high-salt is first sensed by the brain to enhance the production of endogenous ouabain followed by chronical enhancement of the secretion of cardiotonic steroids from adrenal. Those affect target peripheral organs by both inhibiting the pump activity of

Na^+/K^+-ATPase (NKA) and activating the intracellular signaling pathway via NKA. In the proximal renal tubules (PRT) of normotensive Sprague-Dawley (SD) rats, those enhance the endocytosis of basolateral NKA and luminal Na^+/H^+ exchanger 3 to stimulate natriuretic response, which is suppressed in hypertensive Dahl salt-sensitive (DSS) rats. On the other hand, we observed that 4 weeks of high-salt intake increased the intestinal secretion of Na^+, Cl^-, and water in SD but not in hypertensive DSS rats. Since the mechanism of an intestinal ion transport has many similarities with PRT, the aim of this study is to elucidate whether high-salt intake change intestinal NKA activity in hypertensive DSS rats. Male DSS and SD rats were divided into two groups; one fed on a high-salt diet (DSSH and SDH), and the other fed on a regular diet (DSSR and SDR) for 4 weeks. The intestinal adsorption-secretion balance was accessed by examination of feces materials. Feces were scored from 1 to 4 based on color, texture, and amount. Normal feces, exceptionally loose feces, loose feces, and loose & partially watery feces were given an Index 1, 2, 3, and 4, respectively. Next, to compare the effect of high-salt diet on NKA activity between DSS and SD rats, the intestinal mucosa-submucosal preparations from each group were mounted on the Ussing chamber to measure short-circuit current (I_{sc}) induced by nystatin to permeabilize mucosal side in the presence or absence of mucosal Na^+. Nystatin-induced I_{sc} in the presence of mucosal Na^+ represents basolateral Na^+ outward current driven by NKA and we ascertained that this current almost all varnished in the absence of mucosal Na^+. Feces Index was significantly higher in SDH than that in SDR, while no significant difference was found between DSSH and DSSR, indicating that high-salt diet activate water secretion in SD but not in DSS rats. Furthermore, high-salt diet significantly decreased nystatin-induced I_{sc} in SD (129.4 ± 6.9 for SDH versus 179.7 ± 7.3 $\mu A/cm^2$ for SDR) but not in Dahl (208.7 ± 10.8 for DSSH versus 198.4 ± 9.6 $\mu A/cm^2$ for DSSR) rats indicating that high-salt diet decreases NKA activity in SDH but not in DSSH. These results imply that unchanged basolateral NKA activity even on high-salt diet is one of the causes of the inconsistent intestinal ion transport in hypertensive DSS rats.

Title: Estrus-cycle dependent variations regulate sensitivity of rat urinary bladder urothelial cells

Authors: *A. S. WOLF-JOHNSTON, F. A. KULLMANN, L. A. BIRDER;
Sch. of Med., Univ. Pittsburgh, Pittsburgh, PA

Abstract: Introduction: A growing body of evidence suggests that symptoms in many chronic pelvic pain syndromes may be influenced by fluctuation in hormones- in particular estrogen (E2). Studies have shown that urinary bladder epithelial (urothelial-UT) cells, which line the bladder lumen, express E2-receptors. In addition, rapid or non-genomic effects of E2 may play a role in release of mediators and/or activation of signaling pathways. The goal of this study was to examine the mechanisms by which E2 alters urothelial sensory functions.
Methods: UT cells (UTCs) were cultured from rat urinary bladders using previously described methods in accordance with approval by the University of Pittsburgh Institutional Animal Use and Care Committee. Phosphorylated (p-) p38 expression was examined in whole cell lysates isolated from UTCs or bladder mucosal tissue and subjected to western blotting using a standard protocol. ATP release was examined by collecting effluent following application of chemical stimuli (TRPV1 agonist capsaicin- 10 μM; βE2-100 nM) with or without pretreatment with E2 antagonists. Statistical significance was considered with $p < 0.05$.
Results: Capsaicin evoked ATP was potentiated in the presence of 100nM b-E2 and release was prevented with either Tamoxifen (1μm) or ICI-182,780 (3μm), two estrogenic antagonists. We also find β-E2 increased the expression of (activated) p38 MAPK. The degree to which pp38MAPK expression was increased after β-E2 exposure was linked with estrus cycle. The increase in pp38MAPK was increased in UTC collected from rats in estrus, but not from rats in diestrus or proestrus.
Conclusions: Our preliminary findings suggest that estrogens (via beta-receptors) can acutely alter responsiveness of bladder epithelial cells to chemical stimuli. Studies have shown that estrus cycle dependent fluctuations can have profound effects on algogenic mediators and on pain thresholds. Thus, our findings of augmented levels of stress-kinase expression seen in rats in estrus suggest that variations in gonadal hormones may contribute to pain fluctuations in female patients with visceral pain disorders.

Title: A novel method to non-invasively determine the post-void residual in continuous serial cystometrograms

Authors: *Z. C. DANZIGER, W. M. GRILL;
Biomed. Engin., Duke Univ., Durham, NC

Abstract: A serial cystometrogram (SCMG) is the process of continuously filling the bladder to induce multiple voiding cycles. This technique is commonly used to understand better the behavior of the lower urinary tract in disease models and to assess the urodynamic response of animals to treatments. While multiple informative urodynamic parameters can be measured during a SCMG, there is no easy, non-invasive way to measure the post-void residual volume (PVR). Currently, obtaining PVR from a SCMG requires either ignoring the unknown ureter flow into the bladder, which systematically underestimates PVR, or removing the PVR after each void to measure it directly, which is not physiological and disrupts the system being studied. Therefore, standard urodynamic parameters that require PVR for their calculation, such as voiding efficiency and bladder capacity, are not readily available.
We developed a procedure to estimate accurately the PVR for each void in a SCMG without the need to remove PVR from the bladder during the experiment. The procedure is derived from a recursive mass-balance equation on the bladder, and uses available measurements to estimate the ureter contribution to bladder volume and calculate PVR. We validated the accuracy of the procedure with numerical simulations and with in vivo SCMG experiments in urethane-anesthetized rats. The estimation procedure is at least as accurate as withdrawing PVR from the bladder for direct measurements. We also assessed the physiological effects of measuring PVR after each void in a SCMGs in an *in vivo* rat model of acetic acid-induced cystitis, and found that it results in an increase in the variability of bladder capacity as compared to our non-invasive procedure. The novel estimation procedure provides a way to calculate PVR in SCMGs that is more accurate than currently available methods, preserves the natural physiological conditions in the lower urinary tract by not removing PVR after each void, and does not irritate the bladder through repeated invasive measurements. Further, our estimation procedure requires no experimental setup or equipment beyond that of a typical SCMG study. The estimation procedure is a very useful new tool for basic science research in *in vivo* animal studies of lower urinary tract function.

Title: Kalman filter decoding of bladder pressure from dorsal root ganglia activity

Authors: *A. OUYANG, S. E. ROSS, T. M. BRUNS;
Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: A closed-loop bladder neural prosthesis provides the potential to alleviate bladder dysfunction problems by delivering neuromodulatory stimulation at desired pressures to control bladder excitation and relaxation. Previous studies have shown that bladder sensory neural signals can be recorded from sacral-level dorsal root ganglia (DRG). These neural signals can be used to infer information about the bladder pressure. In this study, we evaluate the effectiveness of a Kalman filter estimator as an approach to predict bladder conditions, including bladder pressure, pressure rate and baseline pressure, using sacral-level DRG neural signals as input. We acquired neural recordings from S1 and S2 DRG microelectrodes during acute alpha-chloralose anesthetized feline procedures. We also monitored bladder pressure while saline was infused at 2ml/min until the bladder was full. The performances of linear regression and a linear Kalman filter estimator were evaluated and compared. A Kalman filter was selected due to its ability to reduce statistical noise from the imperfect measurements and potentially improve upon linear regression. For each experiment, in MATLAB, a training model was developed using unsorted neural data from an early bladder fill (training). This model was then applied to neural data from a later bladder fill to estimate the pressure (testing). Across nine training bladder fills, a Kalman filter (4.0 cmH_2O root-mean-squared error) had a better fit than linear regression (9.0 cmH_2O root-mean-squared error). The training model was applied to a test bladder fill data set in four cases, and again led to a lower estimate (Kalman: 10.6 cmH_2O; Linear: 12.8 cmH_2O). Training and testing of the Kalman filter model only added a few programming steps, which did not increase the computation time. Data analysis is on-going. These results suggest the potential of a Kalman filter to be used in estimating bladder pressure for a closed-loop bladder neuroprosthesis based on DRG activity.

Title: Central inhibition of initiation of swallowing by systemic administration of diazepam and baclofen in anaesthetized rats

Authors: *T. TSUJIMURA[1], S. SAKAI[1], T. SUZUKI[1], K. TSUJI[1], J. MAGARA[1], B. J. CANNING[2], M. INOUE[1];
[1]Niigata Univ. Grad. Sch. of Med. and Dent. Sci., Niigata City, Japan; [2]Johns Hopkins Asthma and Allergy Ctr., Baltimore, MD

Abstract: Purpose: We hypothesized that glutamate receptor antagonists and GABA receptor ligands, which are used clinically for multiple disorders, may modify swallowing function. The aim of present study was to investigate the effects of memantine, diazepam, baclofen and dextromethorphan on swallowing evoked by multiple stimuli delivered directly to the upper gastrointestinal tract or by electrical stimulation of the superior laryngeal nerve (SLN). Materials and Methods: Urethane-anesthetized male Sprague Dawley rats were used. Swallows were evoked by upper airway (UA)/pharyngeal distension, punctate mechanical stimulation using a von Frey filament, capsaicin or distilled water (DW) applied topically to the vocal folds, and electrical stimulation of a SLN in anesthetized rats and were documented by recording electromyographic activation of the suprahyoid and thyrohyoid muscles and by visualizing laryngeal elevation. The effects of intraperitoneal or topical administration of each drug on swallowing function was studied. Results & Discussion: Systemic administration of diazepam and baclofen, but not memantine or dextromethorphan, inhibited swallowing evoked by mechanical, chemical and electrical stimulation. Both benzodiazepines and $GABA_A$ receptor antagonists diminished the inhibitory effects of diazepam while a $GABA_B$ receptor antagonist diminished the effects of baclofen. Topical applied diazepam or baclofen was without effect on swallowing. These data indicate that diazepam and baclofen act centrally to inhibit swallowing in anesthetized rats.

Abstract: The functions of the testis, spermatogenesis and steroidogenesis, are regulated by the gonadotropins and other factors, as serotonin. In testis, Leydig cells synthesize serotonin, which in turn acts as an autocrine regulator of testosterone secretion. Amphetamine derivate, pCA, has neurotoxic effects on the serotonergic system. The chronic administration of pCA to prepubertal male rats results in lower concentrations of serotonin in the hypothalamus and diminution in the spermatognenesis. In addition, a single injection of pCA to prepubertal male rats decreases testosterone secretion 72 hours after the treatment and this changes in testosterone did not correlate with modifications in LH secretion, suggesting a direct effects of the drug on the testis. Therefore, we analyzed the effects of pCA injection on the sperm quality.
Thirty-day-old male rats of the CIIZ-V strain from our own breeding stock were allocated at random to one of the following groups: animals injected vehicle or PCA (0.03mg), (0.06mg) or (0.12mg) dissolved in 20 microL of 0.1% of NaCl in both testis. An untouched control group was included. The rats were autopsied at 65 days of age. The vas deferens were dissected and its content obtained and placed in Hanks' balanced solution, incubated for 30 m. The mitochondrial activity and DNA fragmentation were evaluated by flow cytometry. The number of sperm and of abnormalities were measured in a Newbauer's chamber.
We did not observe differences between the control and vehicle injected rats. The injection of 0.06 or 0.12 mg of pCA resulted in lower weight of the testis than in vehicle injected group (0.06 mg: 1.50+/-0.027 gr; 0.12mg: 1.51+/-0.05 gr vs. 1.60+/-0.03gr, $p<0.004$ analysis of variance). The percentage of normal spermatozoa was lower than in vehicle group (0.06 mg: 77.19; 0.12mg: 65.49 vs. 96.21 $p<0.05$). In pCA injected group the number SYBR positive cells measured by flow cytometry was lower than in control (0.03mg: 16.67+/-2.86; and 0.06mg: 14.80+/-3.27 vs. 32.91+/-5.51), suggesting a decrease in normal condensed DNA in spermatozoa. Mitochondrial activity in pCA injected animals was similar to control.

Present results suggest that serotonin participates in the modulation spermatogenesis, both in sperm quality and quantity.

Title: plasticity in trpv4 expression and function in micturition reflex pathways during postnatal rat development

Authors: ***B. M. GIRARD**, S. MALLEY, M. VIZZARD;
Anat. and Neurobio., Univ. of Vermont Dept. of Neurolog. Sci., Burlington, VT

Abstract: The storage and periodic elimination of urine exhibit marked changes during prenatal and postnatal development but the mechanisms underlying these changes are largely unknown. Prior to maturation of the nervous system, urine is presumably eliminated from the urinary bladder by non-neural mechanisms. As the central nervous system continues to mature during the postnatal period, reflex voiding is brought under voluntary control involving higher brain centers. Transient receptor potential cation channel vanilloid family member 4 (TRPV4) is expressed in a variety of tissues/cells, including the urinary bladder and sensory neurons, but developmental regulation of expression has not been studied. We demonstrate developmental expression of TRPV4 in bladder sensory neurons (Fastblue (FB) labeled) and urothelium+suburothelium from postnatal and adult rat. TRPV4 channels are strong candidates for mechanosensors in the urinary bladder. In contrast, we propose a novel paradigm whereby the TRPV4/Ca^{2+} signaling complex acts as a brake to the mature micturition reflex during the early postnatal period. Using Q-PCR and immunohistochemistry and confocal imaging, we demonstrate expression of TRPV4 transcripts in postnatal (P) rats (P3, P5, P10, P12, P21, Adult) in urothelium+suburothelium and dorsal root ganglia (DRG). TRPV4-immunoreactivity is

expressed in whole mounts and sections (7 μm) of urothelium and in FB-positive sensory neurons in lumbosacral DRG retrogradely labeled from the urinary bladder in postnatal and adult rats. We performed open cystometry in conscious postnatal (P5-P12) rat pups with intravesical infusion of saline before and after intravesical infusion of TRPV4 antagonist, HC067047 (1 μM). Before TRPV4 blockade, P5-P12 rat pups only voided with perigenital stimulation. After TRPV4 blockade with HC067047, P5-P12 rat pups void with intravesical infusion of saline in absence of perigenital stimulation. These studies demonstrate that intravesical instillation of the TRPV4 antagonist, HC067047, turns on a mature micturition reflex (distention-induced) in early postnatal rat pups. The TRPV4 antagonist is highly lipophilic; thus, intravesical infusion may affect several tissue/cell types in the urinary bladder, including the urothelium, interstitial cells of Cajal, sensory nerves and detrusor smooth muscle. Understanding the mechanisms that underlie the transition of the neonatal bladder to a mature urinary bladder with efficient storage and elimination is important for understanding childhood and adult voiding dysfunction and reemergence of immature voiding reflexes after injury.

Title: Polysomnographic characterization of nocturnal sleep in Cynomolgus macaques

Authors: *A. V. GOONAWARDENA[1], M. DI ZAMBOTTI[2], A. R. WILLOUGHBY[2], C. GLAVIS-BLOOM[1], I. M. COLRAIN[2], T. L. WALLACE[1], T. S. KILDUFF[1];
[1]Ctr. for Neurosci., [2]Ctr. for Hlth. Sci., SRI Intl., Menlo Park, CA

Abstract: Macaques are a diurnal species that exhibit consolidated night-time sleep with evidence of NREM and REM sleep similar to humans. Since many psychiatric medications can affect sleep, we sought to determine whether Cynomolgus macaques are a useful species in which to conduct polysomnographic sleep/wake studies with translational potential to humans. Adult, male Cynomolgus macaques (n=4) were implanted with telemetry transmitters for electroencephalography (EEG) and electromyography (EMG) and 12-h recordings during the dark period were initiated prior to light offset. EEG activity during wake, NREM and REM was scored in 30s epochs using the guidelines of the American Academy of Sleep Medicine (2007)

for scoring human sleep records and was quantified across polysomnographic measures and by spectral frequencies. Vehicle-treated macaques showed a sleep onset latency (SOL) of 12.6±2.8 min after light offset, 120.8±11.7 min of Wakefulness after initial sleep onset (WASO), and a Sleep Efficiency (SE) of 81.0±1.9%. Of the total sleep time (TST), most time was spent in N2 and N3 NREM stages (84%). The mean number of NREM/REM cycles in the vehicle-treated monkeys was 11±0.7 per night. Caffeine (10mg/kg, im) was administered immediately prior to the dark phase to induce wakefulness at a time of day when sleep pressure was high. Consistent with the stimulant properties of the drug, caffeine prolonged SOL compared to controls and decreased SE greatly as TST and the amount of both REM and NREM sleep were reduced. In addition, spectral power within the conventional frequency bands was calculated for each vigilance state, and, as expected, relative delta (1-4Hz) power was higher during NREM than both REM sleep and Wake in vehicle-treated macaques. Similarly, the relative theta (4-8Hz) power was higher during REM than NREM sleep and wakefulness. Furthermore, alpha (8-12Hz), beta (15-30Hz) and gamma (30-100Hz) power during Wake were greater than during NREM sleep. Caffeine-treated animals showed a significant decrease in delta and increases in alpha and sigma during NREM sleep compared to controls. In summary, the general features of human sleep are present in macaques, however, the NREM/REM cycle is shorter resulting in more cycles per night. Macaques respond to caffeine with longer SOL, less NREM and REM sleep, "lighter" N3 sleep and increased REM latency, similar to reports in humans. Together, these results indicate that Cynomolgus macaques show sleep characteristics consistent with humans under both normal conditions and after treatment with a psychostimulant.

Title: Statistical source separation of rhythmic LFP patterns during sharp wave ripples in the macaque hippocampus

Authors: *J. F. RAMIREZ-VILLEGAS[1,2], N. K. LOGOTHETIS[1,3], M. BESSERVE[1,4]; [1]Physiol. of Cognitive Processes, Max Planck Inst. For Biol. Cybernetics, Tuebingen, Germany; [2]Grad. Sch. of Neural & Behavioral Sci., Eberhard-Karls Univ. of Tübingen, Tuebingen, Germany; [3]Ctr. for Imaging Sciences, Biomed. Imaging Inst., The Univ. of Manchester,

Manchester, United Kingdom; [4]Empirical Inference, Max Planck Inst. for Intelligent Systems, Tuebingen, Germany

Abstract: Sharp wave-ripples (SWR), episodes in the hippocampal CA1 local field potential (LFP) combining a low-frequency deflection (sharp wave) and a high-frequency oscillation (ripple), are thought to mediate memory consolidation. These events are paradigmatic episodes of the interaction between neuronal ensembles across distinct substructures of the hippocampal formation. However, the detailed neuronal ensemble mechanisms underlying this phenomenon remain largely unknown. This question arises partly due to inherent difficulties in inferring network-level dynamics from neuronal population measurements such as LFP. To address this question, we analysed *in-vivo* intracortical recordings of the CA1 of macaque monkeys. We devised a statistical source separation technique in order to disentangle the spatio-temporal signature of multichannel LFP in peri-SWR time windows of 1s. The first results of our study revealed that SWR complexes in CA1 can be approximated by a linear combination of four main oscillatory components with distinct spectral signatures. We found that SW (5.4-14.2 Hz) and gamma (31.7-68.1 Hz) components are expressed by *stratum radiatum*, while ripple (96.9-125.5 Hz) and supra-ripple (188.3-199.4 Hz, 95% confidence intervals) oscillations originate in stratum pyramidale. We then devised a model of the macaque's CA3-CA1 network. The network consists of two layers, each with 200 pyramidal-neuron and 20 peri-somatic interneuron models of two compartments. The model was able to predict a large number of features of *in-vivo* SW episodes. In particular, we found that SW (5.6-7.5 Hz), gamma (23.2-34.0 Hz), ripple (155.8-167.4 Hz) and supra-ripple (174.4-194.7 Hz, 95% confidence intervals) are also the main oscillatory components of modelled SWR. Our model suggests that SW and gamma components arise from CA3 bursting in *stratum radiatum*, while ripple oscillations originate from local interactions between pyramidal cells and interneurons. Notably, CA1 interneurons, also entrained by CA3-gamma oscillations, are responsible for the high-frequency component of the LFP activity, thus establishing the population signature of supra-ripple LFP during SWR. Our experiments suggest that SW, gamma, ripple and supra-ripple rhythms are specific markers of the phenomena occurring in neuronal activity during SWR that can be automatically extracted from LFP data with our approach. Finally, this approach establishes a relationship between neuronal activity over meso- and microscopic scales that can be used to investigate network properties such as excitation-inhibition balance without resorting to single unit analysis.

Title: The expression of dreams: Emotional facial expressions during REM sleep associated to dream mentation in depressed and healthy women

Authors: *A. P. RIVERA[1,3], I. RAMÍREZ SALADO[2], E. LÓPEZ RUIZ[2], J. GONZÁLEZ OLVERA[3], F. AYALA GUERRERO[3], J. PIÑA[2], A. SILVA CABALLERO[2], B. REYES ARANGUREN[2], D. CASTRO NIETO[2], A. JIMÉNEZ ANGUIANO[3];
[2]Lab. de Cronobiología y Sueño, [1]Inst. Nacional De Psiquiatria Ramon De La Fuente, Mexico, Mexico; [3]Doctorado en Ciencias Biológicas y de la Salud, Univ. Autónoma Metropolitana, Mexico, Mexico

Abstract: Introduction: There is a strong association between facial muscle contractions (FMC) and emotional dream mentation (EDM) of awakenings from REM sleep compared to those of NREM sleep, thus being a reliable biomarker of emotional modality (valence) and intensity (arousal) of dreams. Notably, several alterations of phasic and tonic components of REM sleep are present in patients with Major Depressive Disorder (MDD). Yet, the possible association between FMC and EDM in patients with MDD remained to be explored.
Objective: To analyze FMC during REM sleep in female patients with MDD and its association with EDM as compared with those of female controls.
Method: One 8h standard sleep PSG recording was obtained from 10 healthy women and from 10 women with MDD without treatment. Facial EMG recordings were obtained from right and left Corrugator (Corr) and Zygomatic Major (Zyg) muscles. Experimental awakenings exploring EDM were performed during *in vivo* REM sleep stages that lasted at least three minutes. Awakenings were determined by a FMC that lasted more than 100 ms and by the amplitude of any facial muscle that exceeded by 500% its background activity. Following sleep, FMC were quantified, mean voltage (μv) per muscle during REM sleep was obtained and differences between MDD and controls were statistically evaluated. EDM global scores were obtained through the Dream Content Questionnaire with five blind judges. Correlation coefficients were calculated for FMC and EDM global scores and differences between groups (control vs. MDD) were evaluated by Friedman and Post Hoc tests.
Results: Mean voltage of both Corr and Zyg was significantly abolished in MDD group. Mean frequency of Zyg was diminished in the MDD while Corr's mean frequency was higher compared to controls. EDM in MDD was more negative and with lower intensity (e.g. sadness) than in controls, in which emotions ranged from high negative (e.g. anger), high positive (e.g. joy) to low positive (e.g. calm), while low negative was significantly diminished or absent. In controls, high positive EDM was positively associated to FMC of the Zyg and high negative EDM correlated with FMC of the Corr, whereas in MDD only Corr activity showed an association to low negative EDM.
Conclusions: The present study confirmed that FMC and EDM during REM sleep are specifically modified by MDD. We suggest that the neurophysiologic mechanisms altered in depression, i.e. impairment of amygdala-prefrontal cortex connectivity may be modifying dream content towards lower negative levels, and thus the inhibition of facial muscle activity may be a

direct reflect of this alteration, serving as a specific affective and not somatic biomarker of depression.

Title: Sleep amount is a potential biomarker for predicting behavioral responses in a mouse model of PTSD

Authors: ***C. L. GRAY**, L. PINCKNEY, E. N. OLIVER, K. N. PAUL, J. C. EHLEN; Morehouse Sch. of Med., Atlanta, GA

Abstract: Sleep disorders are often comorbid with psychological disorders like post-traumatic stress disorder (PTSD). However, the relationship between sleep and the development and maintenance of the behavioral hallmarks that accompany these disorders are mostly unknown. Previously, we determined that increased sleep prior to social defeat predicted susceptibility. In the present study, we examined sleep following social defeat to determine the influence of sleep on stress-induced avoidance behavior. Our hypothesis is that post-defeat sleep is protective against stress-induced behavioral changes. We implanted C57Bl6/J mice with electroencephalography and electromyography electrodes, recorded baseline sleep and then subjected the implanted mice to 10 days of social defeat stress using a resident-intruder paradigm. Social avoidance testing and sleep recordings were then performed immediately after social defeat. We determined that resilient mice (mice that exhibit no decrease in social investigation post-defeat) displayed significantly increased sleep (NREM and REM) during the active period. Susceptible mice (which exhibit a significant decrease in social investigation post-defeat) exhibited no such increase in sleep. Resilient mice also had significantly decreased NREM delta power during their rest period post-defeat, indicating reduced sleep pressure in these mice. These results indicate that susceptible mice are unable to alter their post-defeat sleep,

whereas increased sleep post-defeat confers a protective effect. We are currently investigating the effects of sleep manipulation in this model to determine if our findings were due to sleep homeostasis or other mechanisms influencing sleep. Understanding how sleep affects behavior using our current model will allow us to develop treatments for psychological disorders such as PTSD that evidence changes in both behavior and sleep.

Department of Anesthesiology

Title: Sleep deprivation after trauma imparts resilience to post-traumatic stress disorder (PTSD)

Authors: *J. DEAN[1], J. DELORME[2], G. POE[3], Y. ARIAS-DELPHI[4];
[1]Mol. and Integrative Physiol., Univ. of Michigan Dept. of Mol. and Integrative Physiol., Ann Arbor, MI; [2]Neurosci., [3]Anesthesiol., Univ. of Michigan, Ann Arbor, MI; [4]Univ. of Puerto Rico Ponce, Ponce, Puerto Rico

Abstract: Post-traumatic stress disorder (PTSD) is a debilitating depressive and anxiogenic mental state that develops following exposure to extremely traumatic events such as sexual assault and active military service in warfare. The Department of Veterans Affairs estimates that 22 United States military veterans commit suicide every day. The mechanism that determines those who are resistant or vulnerable to developing PTSD is currently unknown. Since alterations of the sleep cycle are an intrinsic component of aberrant mental health, they may serve as electrophysiological biomarkers predicting the development of PTSD symptomology. Because rapid eye movement (REM) sleep plays a critical role in memory consolidation and emotional regulation, we hypothesized REM sleep deprivation could exacerbate the PTSD phenotype. To investigate this, we placed male Sprague Dawley rats in a sleep-deprivation bin with multiple small platforms over water for 6 hours prior to (RD-B SPS; n=6) or after (RD-A SPS; n=6) implementing the single prolonged stress (SPS) rodent model for PTSD and measured fear memory extinction versus controls consisting of non-SPS (n=6) and SPS-treated rats never sleep

deprived (n=6). The SPS model establishes phenomenolocigal similarity (face validity), a corresponding theoretical framework (construct validity), and the ability to predict that a pharmacological agent will have the same amelioration on symptoms in both the animal model and in humans (predictive validity) (Yamamoto et al. 2009). SPS consisted of 2 hours of restraint, 20 minutes of forced swim in 24°C water, 15 minutes of recuperation, and exposure to ether until the loss of consciousness. Animals were then individually housed for 7 days of isolation and freezing levels on a fear-associated memory test were evaluated thereafter. The results of the study found the RD-A SPS condition to ameliorate the PTSD-like phenotype by impairing extinction recall (44.7% freezing) to below that of non-SPS controls (52.1% freezing). The PTSD-like phenotyope was highest in the SPS-only group (69.7% freezing), while the RD-B SPS condition did not significantly rescue animals from the effects of SPS (62.1% freezing). These data suggest that REM sleep-deprivation immediately following a traumatic event may prevent consolidation of the traumatic memory. A possible mechanism for adaptive fear-response may thus be an insomnia-response, that perhaps may be lacking or absent in those most susceptible to developing PTSD.

Title: Brief body-mind training improves sleep quality

Authors: *Y. TANG[1], X. DING[2], R. TANG[3];
[1]Psychology, Texas Tech. Univ., Lubbock, TX; [2]Dalian Nationalities Univ., Dalian, China;
[3]Washington Univ. in St. Louis, St. Louis, MO

Abstract: Research supports the claim that mindfulness meditation — practiced widely for the reduction of stress and promotion of health — exerts beneficial effects on physical and mental health, and cognitive performance. However, some studies also indicated that mindfulness meditation had moderate effects on anxiety, depression and pain, and low effects on stress/distress and mental health-related quality of life such as sleep quality. One major issue is that the methodological quality of meditation studies is relatively low, and some were cross-sectional studies using waitlist control and few were actively controlled longitudinal studies

using RCT design. In our series of RCT studies, we have been using one form of mindfulness meditation - the Integrative Body-Mind Training (IBMT) and relaxation training (RT) as an active control. We found that few hours of IBMT significantly improves attention, emotion, cognitive performance and reduces stress hormone cortisol. Several hours of IBMT changes brain structure associated with self-control ability. We hypothesize that better self-control will improve sleep quality. 225 healthy college students (age of 18-23 years old) without any training experience participated in the current study (115 in IBMT group, 110 in RT group). There were no differences in gender, age and education between two groups. The Pittsburgh Sleep Quality Index (PSQI) is an effective instrument used to measure the quality and patterns of sleep. It differentiates "poor" from "good" sleep quality by measuring seven components: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medications, and daytime dysfunction over the last month. We used PSQI to test whether 5 hours of IBMT (30 min per session for 10 sessions) could improve sleep quality in a college students population in comparison with the same amount of RT. Our results indicated that IBMT group showed significant improvements in global PSQI, sleep latency and sleep disturbances. RT group also showed improvements in global PSQI and sleep latency. Compared to RT, IBMT showed greater improvement in sleep latency. In sum, both IBMT and RT help improve sleep quality, but IBMT is also helpful for sleep disturbances..

Title: Intensive practice during the day induces task-specific performance errors: the differential effects of nap and quiet rest

Authors: *A. B. NELSON[1], M. T. CHAN[2], J. LIN[2], P. PANDAY[2], J. BORKOWSKI[2], H. CHEN[2], M. GADALLA[2], B. O. THOMSON[2], G. TONONI[3], C. CIRELLI[3], M. F. GHILARDI[2]; [1]Dept. Physiology, Pharmacol. & Neurosci., [2]CUNY Med. Sch., New York, NY; [3]UW Madison, Madison, WI

Abstract: In a previous work (J Neurosci, 2015, 35: 4487), we found that when sleep-deprived subjects practiced a task for a prolonged time, their performance was more negatively affected in

tests that shared neural bases with the original practice than in other tasks. The increased rate of these errors became evident only after seventeen hours awake and worsened thereafter. These and other results in sleep-deprived animals suggest that such performance errors might be related to the occurrence of local sleep during wake. Here we postulate that local sleep is task-specific, is present without sleep deprivation, is induced by intensive training and reversed by a nap. Sixteen subjects were tested on two separate days from 8 am to 8 pm. One day they performed a task involving significant attentional and working memory load (VSEQ) and the other day a task of visuomotor learning with reaching movements (ROT). In both days, tasks were performed in blocks of 45 minutes in two 4-hour sessions, one in the morning and the other in the afternoon. After each block of either VSEQ or ROT, we assessed performance in a brief visual working memory test (*mem*), which shares the same neural substrates and characteristics as VSEQ and in a motor reaching test (*mot*), which taps into motor function akin to ROT. After the morning session, eight subjects slept for 90 minutes (NAP) and eight subjects rested quietly with eyes closed (REST). High density EEG was recorded throughout the experiment. In the last tests of the morning, performance in *mem* degraded more in the VSEQ session, while performance in *mot* was worse in the ROT sessions for both groups. In the afternoon sessions, *mem* performance specifically worsened in the REST group during the VSEQ session. Conversely, performance in *mot* worsened in the REST group during the ROT session. Analyses of the nap showed that slow wave activity, a measure of sleep intensity, was higher after the ROT task than after VSEQ with topographical differences between the two sessions. These results demonstrate that even, in absence of sleep deprivation, intense training during the day in normal subjects may lead to task-specific impairments, as performance decayed in the test that corresponded to the primary task performed. Most importantly, we found that a short nap but not a similar period of quiet rest protected against performance deterioration.

Title: Insufficient sleep time is associated with low thyroid stimulating hormone levels in a sample of young mexican population

Authors: B. PÉREZ[1], R. SAÑUDO-TORRES[2], A. PAVÓN-ROSADO[1], S. ABURTO[1], R. AYALA-MORENO[2], *M. A. MELGAREJO[1];
[1]Facultad de Medicina, Univ. Veracruzana, Xalapa, Mexico; [2]Facultad de Ciencias Químicas, Univ. La Salle, Ciudad de México, Mexico

Abstract: Sleep is a necessary periodic process, and it also plays an important role in the normal function of the neuroendocrine system. Thyroid Stimulating Hormone (TSH) is a polypeptide hormone secreted by the thyrotrope cells of the anterior pituitary. Its plasma concentrations exhibit a circadian rhythm with a peak around the time of sleep onset. Chronic sleep deprivation is common in modern life; to be in this state implies that the nervous system is counteracting the sleep-wake cycle and body homeostasis. Some studies confirmed the consequences of this, but the relationship between thyroid function and sleep deprivation it remains unclear. Therefore the aim of the present study was to investigate associations between total sleep time and TSH levels in a sample of young Mexican Population. For this purpose a total of 69 students of Veracruzana University (18-25 years) participated. The study was conducted in according to standards established by the declaration of Helsinki as well as their applied the informed consent. All subjects completed a questionnaire Pittsburght for quality and quantity of total sleep. Thyroid Stimulating Hormone, Thyroxine (T4) and free thyroxine (FT4) levels were measured using commercial kits (Diagnóstica Internacional). Data were classified and analyzed with sigmaPlot 11.0. The results suggest that subjects who slept less than 6h presented low TSH levels (µUl/ml) (2.265±0.204 SEM) in comparison with the subjects who sleep more than 7h (3.016±0.241SEM) $p < 0.05$. In contrast, we did not find statistical differences between sleep hours with T4 and FT4. Our results suggest that the reduction of total sleep time may contribute to decrease Thyroid Stimulating Hormone levels and this condition might promote deregulation of neuroendocrine parameters at early age.

Title: Aberrant brain functional network integrity in adolescents with insomnia

Authors: ***M.-H. PARK**[1], S. PARK[2], B. PARK[3], B.-N. KIM[4];
[1]Dept. of Psychiatry, Seoul St. Mary's Hospi, Seoul, Korea, Republic of; [2]Dept. of Psychiatry, Seoul Natl. Hosp., Seoul, Korea, Republic of; [3]Dept. of Statistics, Hankuk Univ. of Foreign Studies Seoul, Seoul, Korea, Republic of; [4]Dept. of Psychiatry and Behavioral Science, Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Background: It has been reported that 20-30% of adolescents suffer from insomnia. Previous studies showed that sleep problems are closely related to cognitive function such as memory, attention and executive function and that is supported by previous structural and functional neuroimaging studies.
Purpose: To investigate the whole-brain functional interactions and network organization of these interactions in adolescents with insomnia and control subjects.
Methods: We acquired resting-state functional MRI data from 47 adolescents with insomnia and 15 controls. Data were processed using standard procedures, and group analyses were performed using ANCOVA (covariates, age and gender) and nonparametric permutation tests. The severity of insomnia was measured by the insomnia severity index (ISI).
Results: The insular resting-state FC differences between adolescents with insomnia and control groups are displayed in Figures 1.
Some areas of FC showed negative correlations with the ISI total scores (Figure 2).
Conclusions: In this study, we showed several aberrant brain FC characteristics in adolescents with insomnia. These findings suggest that brain dysfunction in adolescents with insomnia extends to spontaneous resting conditions, and cognitive and affective deficits in adolescents with insomnia may stem from the altered FC and brain network organization, which may contribute to other psychiatric consequences and daily functional deficit associated with the condition.

Figure 1. Significantly decreased and increased functional connectivity in adolescents with insomnia over control subjects.

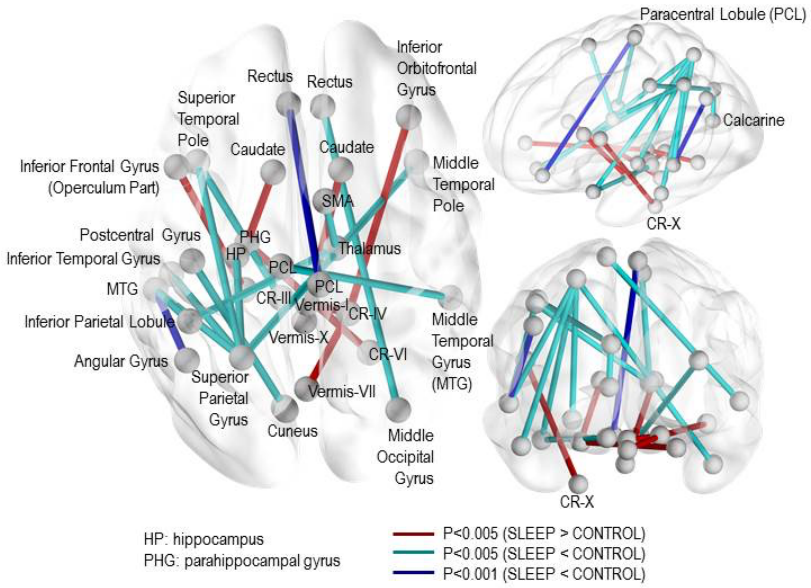

Figure 2. Correlation between functional connectivity and the ISI-total scores with age, sex covariates.

Title: Investigation of sleep quality and executive functioning in Hong Kong adolescents

Authors: *J. Y. HO[1], Y. T. CHAN[1], A. K. C. SUEN[2], E. Y. Y. LAU[3], R. L. T. LEE[1], P. H. LEE[1], R. C. C. CHANG[4];

Abstract: Sleep deprivation is believed to affect cognition in healthy adults but the effect of poor sleep quality on healthy young adolescent is unclear. We aim to investigate the effect of poor sleep quality on the executive functions of adolescents. In this pilot study, 47 junior Hong Kong high school students were recruited. They wore motionlogger watches and filled in sleep diary for 7 consecutive days and then completed five neuropsychological tests and a questionnaire for (1) a sleep-wake habit by Chinese Version of the Pittsburgh Sleep Quality Index (CPSQI), (2) Sleep Quality Index (SQI), (3) Epworth Sleepiness Scale (ESS), and (4) Depression Anxiety Stress Scale (DASS). Our results showed that over half of the students had poor sleep quality (58.8%, CPSQI less than 5); however, the mean of CPSQI is still marginally at score of 4.6. Less than half of the above students (45.8%) had a comparatively higher chance of dozing due to sleepiness by ESS results. DASS score demonstrated that students experienced mild-to-moderate depression and anxiety level (mean = 13.64). Adolescents with poor emotions and higher ESS score tended to have lower interference score in Stroop. Higher score in DASS, ESS and SQI were directly associated with the sleepiness in psychomotor vigilance test. Whilst DASS does not solely correlate to sleepiness in Psychomotor vigilance test (PVT) and The Stroop test, it also has a direct relationship with the number of too fast attempts in PVT. PSQI score is also positively-correlation with the number of moves and total time consumed in Tower of London test. From the results, sleep quality of the adolescents was just marginally normal. Their emotion was alarming and most of them exert depressed and anxious condition. We will further investigate how sleep quality affects executive functions.

Title: Measures of cognition and sleep in infants, using dEEG: frontal sleep spindle spectral frequency is negatively correlated with cognition in 3.5-month-old infants

Authors: *S. PETERS, A. A. BENASICH;
The Ctr. For Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ

Abstract: The first year of life encompasses several major transitions with respect to both sleep and cognition, however, very little is known about how these two measures correlate over infancy. Infancy is a period of rapid change in the spectral components recorded from scalp EEG during sleep. These changes include the appearance of slow wave activity (SWA); the onset and peak of sleep spindle microstructure activity; and a transition from neonate sleep patterns to more adult-like sleep macrostructure (~ 3-months). Sleep spindles have long been considered a measure of maturation in infants; more recently SWA has been a focus of developmental sleep researchers, as a predictor of both cortical maturation and skill development. However, there is a pressing need for better understanding of the changing features of sleep spindles at these early ages, including their topography, frequency, and hemispheric synchronicity, particularly as characterized by dense-array EEG. Current literature is based on use of a minimal electrode array, and to date, no studies have measured concurrent sleep and behavior in a longitudinal sample. The present study aims to measure and characterize daytime sleep, concurrent with standardized behavioral measures of cognition, language, motor, and social-emotional development, in typically developing infants. Our design includes both cross-sectional and longitudinal groups, and here we describe results from a subset of 13 (6 female) longitudinal subjects at two ages: 3.5 and 6.5 months. Data is collected using 124-channel Hydrocel EEG nets (EGI, Inc.) during a 30 to 45 minute nap. Sleep macrostructure (REM and NREM) is scored, based on 17 anatomically mapped EEG channels and manually scored sleep behavior. Segments of stage 2 and 3 NREM sleep is extracted for analyses. Artifact-laden segments and channels are

removed, interpolated, and the data is referenced to a whole-head average. After FFT analyses, absolute power values are reported for standard frequency ranges, as spectrograms. Visually, clear maturational changes are seen in topography across the power spectrum, with some trait-like patterns appearing in the sigma (12-15Hz) band. We focus here on a cluster of frontal channels in the sigma range, which include the typical spindle frequencies, and match the peak activity from our sample. Within subjects, a significant maturational increase is seen in both peak frequency and power. Frontal spindle peak frequency is negatively correlated with cognitive performance at 3.5 months. This pilot study is ongoing, and is the first to characterize infant sleep spindle topography concurrent with behavioral measures in typically developing infants.

Title: No entrainment of endogenous brain rhythms to 1Hz sinusoidal tACS in human intracranial EEG

Authors: B. LAFON[1], *L. C. PARRA[2], D. FRIEDMAN[3,4], S. HENIN[3,4], L. MELLONI[3,4], G. BUZSAKI[3,5], O. DEVINSKY[3,4], A. LIU[3,4];
[2]Biomed. Engin., [1]City Col. of New York, New York, NY; [3]New York Univ. Sch. of Med., New York, NY; [4]NYU Comprehensive Epilepsy Ctr., New York, NY; [5]NYU Neurosci. Inst., New York, NY

Abstract: Transcranial alternating current stimulation (tACS) is emerging as a non-invasive technique with applications in clinical therapy and cognitive research. Non-REM (NREM) sleep, and in particular slow-wave sleep (SWS), may support the consolidation of hippocampal dependent memories via the coordinated activity of slow oscillations (~1Hz) and spindles (~10-15 Hz). Previous studies argue that tACS applied during sleep may enhance the coordination between these rhythms to improve declarative memory recall. We sought to understand how applied transcranial electrical fields, delivered in an alternating or oscillatory manner (tACS)

would affect endogenous rhythms during NREM sleep, as measured in 4 patients undergoing invasive monitoring for epilepsy surgery. We expected that 1Hz sinusoidal tACS would entrain endogenous slow oscillations (0.75 Hz - 1 Hz) during sleep and modulate endogenous spindle activity power accordingly. We applied 1 Hz tACS at intensities ranging from 0.5 mA to 2.0 mA, using a frontal-occipital montage, in 4 patients undergoing invasive monitoring, during NREM sleep. Based on measurements and modeling, we estimated that the electrical fields at the cortical surface reach approximately 0.5 V/m, with maximal stimulation intensities of 2.0 mA. The interaction between spindle activity and slow oscillations was analyzed during endogenous sleep (across two different nights) and during 1Hz tACS. The cross frequency coupling between the slow and spindle rhythms was tested using a mean vector strength and spindle detection algorithm. During NREM sleep, spindle activity in 259 electrodes out of the 477 electrodes tested (among all subjects) was significantly modulated by endogenous slow oscillations, after correcting for multiple comparisons. Seventy five percent (75%) of the electrodes were consistently entrained from one night of sleep to the next. However, during applied TACS, spindle power was significantly modulated in only 3 out of the 477 electrodes tested. We conclude that 1 Hz TACS applied during sleep at commonly used stimulation intensities does not entrain spindle oscillations during NREM sleep. This negative finding may result from the weak electrical fields which reach the cortical surface.

Title: Prevalence of sleep disorders in a mexican children population

Authors: ***S. ABURTO**, E. VENTURA-ARIZMENDI, B. PÉREZ, E. AGUILAR, R. MENDOZA-AMARO, A. NAVARRETE-MUNGUÍA, M. MELGAREJO;
Facultad de Medicina, Univ. Veracruzana, Xalapa, Mexico

Abstract: An adequate good quality sleep is important for optimal health and functioning throughout life. In adults, reduced sleep duration and sleep disturbance have been demonstrated to be associated with cognitive deficits and mood disturbance. There is evidence that these same

effects occur in children but sleep duration and the potential consequence of sleep disturbance in children have received little attention in sleep studies. Several studies around the world have demonstrated a high prevalence of sleep disorders in children, being between 25 and 40 percent, sleep disorders varies with age and ethnicity, however the consequences seem to be universal, sleep disorders found associated with negative effects like poor school performance and changes in their social relationship, expressing irritability, mood swings and increased vulnerability to the adoption of addictive behaviors. Therefore, in practical terms, sleep disorders are associated with poor health and many psychosomatic symptoms. In Mexico, do not exist studies about the quality and sleep disorders in a child population; therefore the aim of the present study was to investigate the prevalence of sleep disorders in a sample of Mexican children population. For this purpose a total of 602 elementary school students (5-13 years) participated. The study was conducted according to the standards established by the declaration of Helsinki as well as their applied the informed consent. All subjects completed a questionnaire BEARS sleep screening algorithm, SDSC the Sleep Disturbance Scale for Children and PSQ Pediatric Sleep Questionnaire. 602 children participated in the study, 306 boys (50.8 percent, mean age = 8.36 ± 0.123) and 296 girls (49.3 percent, mean age = 8.38 ± 0.122). There were no differences in age by gender distribution ($p = 0.93$). The sleep disorders in relation to gender we observed that the prevalence is higher in males (35.94 percent) than females (29.39 percent). The results show that of the total population 32.7 percent have a sleep disorder, 44.6 percent of these have Sleep-Wake Transition Disorders, 40.6 percent Sleep Breathing Disorders and 26.3 Disorders of Excessive Somnolence. The subjects may be included in one or more groups because they can present more than one sleep disorder. The results indicate that the prevalence of sleep disorders in Mexican children correspond to statistics worldwide. However were highly prevalent the disorders in the transition of sleep-wakefulness. This high prevalence may conduct to learning and memory problems, even diseases such as obesity, diabetes mellitus and metabolic syndrome in an adult age.

Title: Spectral analysis of EEG activity during weekend recovery sleep

Authors: ***S. J. MORTON**[1,2], C. M. DEPNER[2], E. L. MELANSON[3,4], J. R. GUZZETTI[2], K. P. WRIGHT, Jr[2,4];
[1]Psychology and Neurosci., [2]Dept. of Integrative Physiol., Univ. of Colorado Boulder, Boulder, CO; [3]Dept. of Geriatric Med., [4]Div. of Endocrinol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Many individuals obtain insufficient sleep at night during the work week and extend their sleep duration on the weekends in an attempt to recover. Sleep EEG changes in response to short sleep durations and total sleep deprivation (TSD). The impact of *ad libitum* weekend recovery sleep on sleep architecture has yet to be investigated. Thus, the aim of the current analysis was to investigate the effects of weekend recovery sleep on sleep architecture after a simulated work week of short sleep. Sleep was assessed using a combination of standard sleep staging and quantitative EEG power spectral analyses. 36 participants (18 females) aged 25.5±4.7y (mean±SD) were randomized into three study conditions, each lasting 13 days: control (9h sleep/night), sleep restriction (5h sleep/night), or weekend recovery (5 days of 5h sleep/night [simulated work-week], 2 days of *ad libitum* weekend recovery sleep with an enforced minimum of 10h time in bed [simulated weekend], followed by another 3 days of 5h sleep/night). Each condition began with 3 baseline nights (9h sleep/night). There was a significant interaction between night and hour of the sleep opportunity such that both delta and theta activity were significantly higher in the sleep restriction and weekend recovery conditions compared to baseline ($p < 0.05$). No significant changes in EEG activity were observed across days for the control condition. For all conditions, spectral analyses showed delta power was highest in the first three hours of the sleep opportunity and decreased thereafter. Overall, changes in delta and theta power during sleep restriction and weekend recovery sleep were consistent with higher homeostatic sleep pressure and recovery.

Title: Interaction of menstrual cycle and heart rate variability on sleep dependent memory consolidation

Authors: *N. SATTARI, L. WHITEHURST, M. NAJI, E. MCDEVITT, S. MEDNICK; UCR, Riverside, CA

Abstract: Sleep benefits the transformation of new information into long-term memories. Recent studies have indicated that menstrual phase may influence this process (Genzel et al., 2012). Also, studies have shown that menstrual phase may impact autonomic regulation during sleep (de Zambotti et al., 2013), and autonomic activity may also play a role in sleep-dependent memory consolidation (Whitehurst et al., 2016). Here, we investigated the interaction of menstrual cycle, autonomic activity measured by heart rate variability (HRV) on sleep-dependent memory consolidation. We used a declarative face-name association task (FNA) to compare memory performance in women during two phases of their menstrual cycle: 1) high hormones, WH (days 8 to 21) and 2) low hormones, WL (days 1 to 7 and 22 to 28), and men. 18 healthy females recorded their menstrual cycle daily for four weeks. In a within-subjects design, women completed a verbal recognition memory test before and after a 90-minute polysomnographically (PSG)-recorded nap on two separate occasions: high hormone and low hormone. We used paired t-tests to compare women in each phase on sleep and HRV variables as well as memory performance (d-prime). We also, used independent-samples t-tests comparing women in each phase to men (n=18). Bivariate correlations were used for sleep and HRV variables and performance. There was no difference in pre-nap performance (p=.8), but WH performed better than WL after the nap (p=.03). Post-nap d-prime was similar in WL and men (p=.6), whereas it was enhanced in WH compared to men (p=.02). There was no significant difference in sleep stages between WL and WH (all p>.05) but men had less REM sleep compared to WH (p=.03). HRV analysis revealed that men had higher total power (p=.07) in Stage 2 sleep along with more LF-HRV compared to WH (p=.05) reflecting increased sympathetic nervous system activity. HRV did not differ between women in both phases. In WH improvement in performance (pm-am) was correlated with both LF-HRV (r= .7, p=.008) and HF-HRV (r=.6, p=.02) in stage 2 as well as LF-HRV (r= .7, p=.03) and HF-HRV (r=.6, p=.04) in stage 3. We found that menstrual cycle and cardiac autonomic activity may influence the magnitude of sleep-dependent consolidation, whereby WH show less forgetting with a nap compared with WL while this improvement has a positive relationship with their sympathetovagal activity during Non-REM sleep. Compared with WH, men performed significantly worse on this paired associates memory

task, while showing increase sympathetic arousal during their nap. Our findings suggest that both sex hormones and HRV should be considered while looking at sleep-dependent memory consolidation.

Title: Neural correlates of sleep-dependent consolidation of visual perceptual learning: an ERP study

Authors: ***M. AHMADI**[1], E. A. MCDEVITT[1], M. A. SILVER[2], S. C. MEDNICK[1];
[1]Univ. of California Riverside, Riverside, CA; [2]Univ. of California Berkeley, Berkeley, CA

Abstract: Previous studies showed that both daytime naps and nighttime sleep facilitate consolidation of perceptual learning (PL) of a visual texture discrimination task (TDT) in humans. More specifically, this type of PL is retinotopically-specific and requires sleep to be consolidated (Stickgold et al., 2000; Mednick et al., 2003). Neuroimaging studies of TDT learning have shown changes in primary visual cortex (Walker et al., 2005; Pourtois et al., 2008) and in higher-level visual cortex, as well as changes in neural networks responsible for higher cognitive processes such as attention (Wang et al., 2016). In this study, we investigated how sleep facilitates PL by assessing neural changes associated with PL during encoding and retrieval of TDT. Subjects trained on TDT and, after two nights of sleep, they were tested on the same task. High-density electroencephalography (hdEEG) was recorded during encoding, retrieval, and sleep. We studied the ERP components C1 (early sensory processing), P1 and N1 (later sensory processing, modulated by top-down spatial attention) and P3 (cognitive processing). Our preliminary results show a significant decrease in C1 amplitude at retrieval, relative to encoding, in the parieto-occipital region (electrode POz). Although there were no significant changes in P1 amplitude with PL, N1 was significantly lower during retrieval at occipital and parietal sites. The difference in N1 amplitude between encoding and retrieval was positively correlated with behavioral threshold at right parietal cortex. We further analyzed P3 and found a significant increase in P3 amplitude associated with training at all parietal and occipital electrode sites.

Additionally, performance improvement was correlated with right lateralized ERP potentials when target was presented at right visual field. We conclude that sleep-dependent benefits of PL may be more related to changes in top-down attentional control and cognitive processes than to plasticity in early visual cortical areas.

Abstract: Introduction: The discovery of complex heart-brain neural interaction has prompted examination of the relationship between heart rate variability (HRV), a non-invasive measure of cardiac autonomic activity, and electroencephalography (EEG) during wake and sleep. In this study, we examined temporal coupling between EEG and heart inter-beat intervals (IBI, time-series of RR intervals, where R is one of component of ECG) during a daytime nap. **Methods**: 38 healthy subjects took a polysomnographically-recorded nap at 1:30-3:30PM. Slow oscillation (SO, <1 Hz) events during wake, Stage 2, slow wave sleep (SWS), and rapid eye movement (REM) sleep were identified based on the thresholding method. We then examined separately EEG/IBI activity time locked to the SO peaks. We aligned RR time-series (temporally smoothed by averaging in 0.5-sec bins) to half negative peak of the SO events in 10-second windows. We then compared changes in the averaged RR signal relative to the SO event with paired t-tests. Next, we aligned SO power to trough events in RR time-series. The correlation coefficient between average RR troughs and average SO power was calculated at the lag of the cross-correlation peak. **Results**: In Stage 2 sleep, we observed a 6.4% decrease ($p < .001$) in RR interval (or an increase in Heart Rate) beginning ~1 second *before* SO negative peak, reaching its minima ~2.5 sec after the negative peak. It was followed by a 3.8% increase ($p < .001$) in RR

interval until it reached a maxima ~5 sec after negative peak of SO. In stage 3, the relative timing of SO and RR was shifted and the amplitude of RR changes was smaller. Thus, RR interval started to decrease around time of SO negative peak until it reached it minima ~1.5 sec later (1.5% decrease, $p < .001$); it then reached its maxima ~6.5 sec after SO negative peak (1.0 % increase). In Stage 2 sleep, we discovered a correlation (0.86, $p < .001$) between power of SO and RR interval with peak delay of 0.66 sec; RR interval change was leading slow oscillation. Similarly, in Stage 3 correlation was 0.76 ($p < .001$) with 0.55 sec lag between SO power and RR interval change events. **Conclusion**: Our results demonstrate strong coupling between SO power and RR time-series during Stage 2 and SWS. Prior studies have reported RR changes follow SO events, however our analysis in contrast revealed that SO power follows changes in RR intervals after a delay. Further causality analysis is needed to understand the interactions between autonomic nervous system and central nervous system during sleep and wake.

Title: The impact of psychostimulants and hypnotics on cognitive performance in neurotypical adults

Authors: *L. N. WHITEHURST[1], L. BATELLI[2], S. AGOSTA[2], S. MEDNICK[1]; [1]Psychology, Univ. of California, Riverside, Riverside, CA; [2]Ctr. for Neurosci. and Cognitive Systems, Italian Inst. of Technol., Rovereto, Italy

Abstract: Introduction: Off-label use of psychostimulants (e.g. Adderall and Ritalin) for cognitive enhancement is becoming more prevalent in the US, particularly on college campuses. However, research examining the efficacy of these drugs as "smart pills" is mixed. Further, psychomstimulants decrease sleep, which has been shown to be important for cognition. As a result hypnotics are often used in conjunction with stimulants to promote sleep. To date, no studies have examined the combined effect of stimulants and hypnotics on sleep and cognition in healthy neurotypicals. We examined the effects of a single dose of dextroamphetamine (DAMP vs. placebo (PBO)) during the day and zolpidem (ZOL vs PBO) during the night on verbal

memory and sustained attention, in a double-blind, placebo controlled, cross-over design.
Methods: 20 (11F) healthy subjects were tested in four conditions (DAMP/PBO, DAMP/ZOL, PBO/ZOL, PBO/PBO), one week apart. On each day, baseline performance was obtained for the word pair associates task (WPA1, subjects encoded 60 word pairs, followed by an immediate test) and a multiple object tracking task (MOT1, visual tracking of multiple moving targets among distractors). Drug (20 mg of DAMP or PBO) was administered at 9:00AM and MOT was retested 75 minutes post-drug (MOT2). At 9:00PM, recall for 20 word pairs (WPA2) and MOT (MOT3) were tested. Subjects were either administered 10mg of ZOL or PBO, and slept overnight in the lab while they were EEG-monitored. The next morning, subjects completed a final session of WPA3 and MOT4 tasks. We calculated change in performance across sessions with a difference score for both tasks.
Results: We found no effect of DAMP on WPA over 12 hours of wake compared with PBO ($p = .26$). After sleep, the PBO/ZOL group performed better than all other groups ($p = .029$), with no differences in other conditions. Additionally, DAMP/PBO showed the worst performance after a 12-hour overnight sleep period ($p = .09$). For MOT, the DAMP condition showed a 10% increase in performance at MOT2 compared to PBO ($p = .037$) and this performance boost persisted over 12 hours (MOT3, $p = .08$). However all benefits of DAMP for MOT disintegrated after sleep ($p = .33$).
Conclusion: Here, we show that healthy young adults show task specific enhancement with psychostimulants, with increased attentional processing but no benefit on declarative memory. Interestingly, these drug benefits did not persist following a night of sleep. These data suggest there may be important interactions between stimulant drugs and sleep-related consolidation that should be considered.

Title: Modulating acetylcholine during sleep consolidation of episodic memory and perceptual learning

Authors: *E. A. MCDEVITT[1,2], M. AHMADI[1,2], M. A. SILVER[3,4,5], S. C. MEDNICK[1,2];
[1]Sleep and Cognition Lab., Riverside, CA; [2]Psychology, Univ. of California, Riverside, CA;

[3]Helen Wills Neurosci. Inst., Berkeley, CA; [4]Sch. of Optometry, Berkeley, CA; [5]Vision Sci. Grad. Group, Berkeley, CA

Abstract: The neurotransmitter acetylcholine (ACh) regulates consolidation of both episodic memory and perceptual learning (PL), but previous studies suggest a different role for ACh for these two types of memory (Gais et al., 2004; Rokem & Silver, 2010). Specifically, low levels of ACh, as in non-rapid eye movement (non-REM) sleep, may be optimal for episodic memory consolidation (Hasselmo & McGaughy, 2004), whereas increased cholinergic transmission, as in REM sleep, is hypothesized to set the appropriate neural dynamics for consolidation of PL (Mednick et al., 2003). We assessed the effects of cholinergic enhancement on sleep consolidation of episodic memory and visual PL by administering the cholinesterase inhibitor rivastigmine, which increases synaptic levels of ACh, during a period of overnight sleep. Twenty young, healthy subjects participated in a randomized, double-blind, placebo-controlled crossover study. On the morning of Day 1, subjects were trained on a declarative (word paired-associates) task and non-declarative PL (texture discrimination) task. Rivastigmine (1.5 mg) or placebo was then administered before electroencephalogram (EEG)-recorded sleep on Night 1. On the morning of Day 3, after a second night of sleep with no additional drug, subjects were tested on both tasks. For word paired-associates, immediate recognition test performance was greater than chance ($p<.001$) in both drug conditions, indicating that subjects learned the word pairs. Across days, there was a significant amount of forgetting ($p<.001$), but recognition performance remained above chance on Day 3 ($p<.001$). However, there was no difference in the amount of forgetting between drug conditions ($p=.2$). For texture discrimination, thresholds improved between Days 1 and 3 ($p=.02$), but there was no effect of cholinergic enhancement, with rivastigmine and placebo conditions showing equivalent magnitude of PL ($p=.9$). In summary and contrary to our hypotheses, there was no effect of cholinergic enhancement for sleep consolidation of either episodic memory or PL. Further analysis of sleep EEG recordings will allow assessment of the impact of rivastigmine on sleep features. Additionally, we will verify whether our results replicate with a 24hr retention interval that includes only one night of sleep following drug administration. It is possible that a single low dose of a cholinesterase inhibitor is not effective for boosting ACh during sleep. Another possibility is that our behavioral measures were not sensitive enough to detect an effect of cholinergic enhancement on learning. Further research is needed to elucidate the complex relationships among sleep, memory and ACh.

Title: Medial prefrontal white matter changes associate with sleep quality in patients with Chronic Fatigue Syndrome

Authors: *Z. SHAN[1], R. KWIATEK[2], R. BURNET[3], P. DEL FANTE[4], D. R. STAINES[1], S. M. MARSHALL-GRADISNIK[1], L. R. BARNDEN[1];
[1]NCNED, Menzies Hlth. Inst. Queensland, Griffith Univ., Southport, Australia; [2]Div. of Med. Subspecialities, Lyell McEwin Hosp., Elizabeth Vale, Australia; [3]Endocrinol. Dept., Royal Adelaide Hosp., Adelaide, Australia; [4]Healthfirst Network, Woodville, Australia

Abstract: Introduction: Chronic fatigue syndrome (CFS), sometimes referred to as myalgic encephalomyelitis (ME), is a debilitating illness with a variety of presenting features. Unrefreshing sleep is one of commonly observed features in CFS patients. However, the brain structural substrate of unrefreshing sleep in CFS remains elusive. This study explored the relationship between brain structure and sleep quality in patients with CFS.**Methods:** 38 patients with CFS (34.14 ± 9.85 years old) and 13 normal controls (NCs) (34.8± 8.73 years old) were recruited. All subjects completed the Hospital Anxiety and Depression Scale (HADS) and the Pittsburgh sleep quality index (PSQI) questionnaire. Brain magnetic resonance imaging (MRI) yielded global and regional grey matter (GM) and white matter (WM) volume images from voxel based morphometry, magnetization transfer contrast (MTC) T1 weighted intensities, T1 weighted (T1w) and T2 weighted (T2w) spin-echo signal intensities. We tested for inter-group differences and correlations between each pair of these measures. Voxel based regressions of regional brain MRI measures were performed with the PSQI scale adjusted for age, anxiety and depression, and the appropriate global measure. **Results:** There was no significant difference between CFS patients and NCs in total GM volumes ($P = 0.41$), total WM volumes ($P = 0.68$), or age ($P = 0.82$). CFS patients had significantly higher PSQI (lower sleep quality) ($P < 0.001$), anxiety ($P = 0.005$) and depression ($P < 0.001$) than NCs. Total GM volumes were significantly correlated with total WM volumes (0.65, $P < 0.001$) and age (-0.48, $P < 0.001$). The PSQI scales were significantly correlated with depression (0.48, $P < 0.001$) and anxiety (0.45, $P< 0.001$). The depression scales were significantly correlated with anxiety scales (0.63, $P < 0.001$). Regionally, we found a significant decrease in WM volumes (family wise error adjusted cluster level P value, $P_{FWE} < 0.05$) in the left inferior fronto-occipital fasciculus (IFOF) in CFS patients. In CFS patients, negative correlations were observed between PSQI and MTC intensities ($P_{FWE} < 0.05$)

and between PSQI and T1w intensities ($P_{FWE} < 0.05$) in the medial frontal cortex. The same correlations were observed when CFS patients and NCs were pooled. In the same medial frontal cortex location, both MTC and T1w intensities were lower in CFS patients compared with NCs (uncorrected $P < 0.001$).**Conclusion:** These findings confirmed WM deficits at the IFOF in CFS patients reported in our previous longitudinal study. This study is the first to report that sleep disruption in CFS is mediated by brain structural differences.

Title: Sleep apnea symptoms and depression in young adults

Authors: *R. WILLIAMSMORRIS[1], F. BARRIENTOS[2], T. REYNOSO[3];
[1]Psychology, Southern Adventist Univ., ooltewah, TN; [2]Southern Adventist Univ., Collegedale, TN; [3]Southern Adventist Univ., Collegedale, Bangladesh

Abstract: The purpose of this study was to examine both sleep apnea symptoms and depressive symptoms in a sample of 93 students enrolled at Southern Adventist University. Specifically, we examined the linear relationship between sleep quality and depressive symptoms as expressed by the students and compared their scores on both depression and sleep quality to their membership in certain groups: age, gender, ethnicity and academic major.1. There will be gender differences in depressive symptoms. Women will report more depressive symptoms than men. 2. What is the linear relationship between sleep and depressive symptoms? 3. What is the linear relationships among age, depressive symptoms, and sleep? 4. Are there gender, ethnic, and academic major differences in sleep and depressive symptoms? The sample of convenience consisted of 93 student participants (42 male), median age 21 (range 18 to 53), representing mainly Humanities academic discipline, and 3 major ethnic categories: White, Black/African American, Hispanic/Latin/a, Other Race designations. Results showed that1. There will be gender differences in depressive symptoms. Women will report more depressive symptoms than men. 2. What is the linear relationship between sleep and depressive symptoms? Yes, positive and statistically significant ($r(93) = .55$, $p = .000$) explain r-squared.3. What is the linear relationships among age, depressive symptoms, and sleep?Older students have more sleep quality problems; age not related to depression,4. Are there gender, ethnic, and academic major differences in sleep

and depressive symptoms? No (ns), although women report more sleep quality problems and show more depressive symptoms and Blacks had the poorest sleep quality scores and Hispanics the lowest depressive symptoms. Humanities had poorer sleep quality than other majors but lower depressive symptoms.

Title: Altered regional cortical thickness in children with obstructive sleep apnea syndrome

Authors: *R. A. MA[1], L. KHEIRANDISH-GOZAL[3], M. F. PHILBY[4], R. KUMAR[2,5], D. GOZAL[3], P. M. MACEY[1,5];

Div., [4]Section of Pediatric Sleep Medicine, Dept. of Pediatrics, The Univ. of Chicago, Chicago, IL; [5]Brain Res. Inst., David Geffen Sch. of Med. at Univ. of California Los Angeles, Los Angeles, CA

Abstract: Introduction: Pediatric obstructive sleep apnea syndrome (OSAS) is highly prevalent condition, and is associated with increased risk of impaired cognitive performance. Adults with OSAS manifest brain injury linked with their clinical symptoms, and animal studies mimicking OSAS, lead to regional neuronal losses, suggesting that pediatric OSAS patients may also show brain alterations. In an earlier study, we found that regional gray matter volume was reduced in selected cortical and brainstem regions in OSAS children. In the present study, we aimed to assess regional cortical thickness changes in pediatric OSA patients over controls.
Methods: We evaluated 16 pediatric OSAS participants (8 male, mean age (±SD) = 8.1±2.2 years), with polysomnographic evidence of OSA (AHI=11.1±5.9 events/hr), and 141 control subjects (64 male, 8.2±2.0 years), 132 of whom were from the NIH Pediatric MRI database, and others were matched in age, gender, ethnicity, and BMI. High resolution T1-weighted images were assessed for regional cortical thickness alterations using FreeSurfer software. Comparisons between OSAS and control groups were performed vertex-by-vertex using ANCOVA, with age and gender as covariates ($P<0.05$, false discovery rate correction for multiple comparisons).
Results: Regional cortical thinning in OSAS group was present in the superior and medial

frontal, prefrontal, and parietal cortices, and medial occipital cortex, consistent with the previously identified locations of gray matter volume reduction. Additionally, multiple isolated regions of increased cortical thickness in OSAS patients appeared in the bilateral precentral gyrus and left central gyrus, and small regions in the insular cortices. The posterior cingulate and sub-genu of the anterior cingulate cortices, extending into medial prefrontal areas also showed increased thickness in OSAS, as did the medial temporal lobes.
Conclusions: Pediatric OSAS is associated with regions of thinner cortex, consistent with chronic changes including neuronal and cellular loss, and isolated areas of increased cortical thickness, suggesting acute tissue changes including inflammatory or glial responses to ongoing hypoxic exposures or fragmented sleep. Since the duration of the disease in OSAS patients is unknown, the pathological processes leading to cortical thinning may have been operational for several years. The short and long-term consequences of these cortical changes and their reversibility with therapy remain to be delineated.
Support: This work was supported by the Herbert T. Abelson Chair in Pediatrics.

Title: Nucleus accumbens regional volume changes in newly-diagnosed obstructive sleep apnea patients vary by sex

Authors: *J. PRASAD[1], J. A. OGREN[2], R. KUMAR[3,4], R. AVSOLA[5], F. L. YAN-GO[6], M. A. WOO[7], M. THOMAS[8], R. M. HARPER[9,4], P. M. MACEY[10,4];
[1]UCLA Sch. of Nursing, Univ. of California Los Angeles, Los Angeles, CA; [2]Neurobio., [3]Anesthesiol. and Radiological Science, David Geffen Sch. of Med. at UCLA, [4]Brain Res. Inst., [5]Med. (Division of Pulmonary Critical Care), [6]Neurol., [7]Sch. of Nursing, [8]Dept. of Radiological Sci., [9]Brain Res. Institute, Neurobio., [10]UCLA Sch. of Nursing, UCLA, Los Angeles, CA

Abstract: Introduction: Obstructive sleep apnea (OSA) patients experience emotional dysregulation, such as anhedonia accompanying depressive symptoms, which is present in half of these patients. The shell of the nucleus accumbens (NAc) helps mediate pleasurable feelings,

as well as aversion and maternal behavior. Several adjacent brain structures are damaged in OSA, but it is unclear whether the NAc, or its subregions are affected. We used surface-based analysis to assess subregional NAc volume differences, and evaluated those differences by sex, since depression aspects differ between males and females in OSA. **Methods:** We collected high-resolution T1-weighted images from 66 newly-diagnosed, untreated OSA (mean age±SD: 46.3±8.8yrs; mean AHI±SD:34.1±21.5 events/hour; 30 male) and 59 healthy control (46.8±9.0 yrs; 38 male) subjects. We combined T1-weighted images (1.0 mm^3 resolution) of healthy controls from two large MRI datasets (IXI and OASIS), for a total of 979 controls (46.5±9.9 years; 426 male). We used "FSL FIRST" software to segment the NAc and assess regional surface-based structure. NAc volumes were scaled for total brain size, based on registration to a common space (6 parameter affine registration), and included age and total intracranial volume (TIV) as covariates (ANCOVA; $P<0.05$, permutation testing correction for multiple comparisons). **Results:** Left and right NAc showed regional volume increases in male, but not female OSA over controls, accounting for head size, TIV, and age ($P<0.05$, corrected for multiple comparisons). The left NAc showed a small surface region (4 mm^2) of increase in the superior lateral mid-NAc, likely reflecting core changes, with a maximum effect size in OSA of 0.20 mm. The right NAc showed extensive surface regions (61 mm^2) of volume increase across the anterior-inferior NAc, likely reflecting shell changes in the lateral, anterior and medial areas, and core in the mid-anterior, inferior portion, with some increases extending superiorly in the mid-to-posterior aspect. The maximum effect size was 0.38 mm in the inferior aspect.**Conclusions:** The NAc in OSA shows increased regional volumes in male, but not female OSA patients, with the right structure especially affected. Volume increases suggest inflammation and glial activation; absence of volume decreases suggests little long-term injury in OSA. The reasons for the sex differences are unclear. However, given the greater levels of anhedonia-related symptoms in female OSA patients, the findings suggest that volume change and relationship to loss of pleasurable feelings are not simple, and likely involve multiple other brain regions.

Title: Obstructive sleep apnea is accompanied by altered neurochemical levels in the midbrain and hypothalamus

Authors: *P. M. MACEY[1,2], M. K. SARMA[3], R. NAGARAJAN[3], J. A. OGREN[4], R. AYSOLA[5], R. M. HARPER[4,2], M. A. THOMAS[3];
[1]UCLA Sch. of Nursing, Univ. of California at Los Angeles, Los Angeles, CA; [2]Brain Res. Inst., [3]Radiological Sci., [4]Neurobio., [5]David Geffen Sch. of Medicine, Div. of Pulmonology, UCLA, Los Angeles, CA

Abstract: Introduction: Obstructive sleep apnea (OSA) is associated with structural alterations in brain tissue and altered neural function in both limbic and cortical regions as well as brainstem areas and the cerebellum. Since the midbrain and adjacent hypothalamus contain many integrative nuclei, they are critically involved in physiological functions that are disrupted in OSA. To directly identify whether the functional state of these regions is altered in OSA, we assessed neurochemical levels within the midbrain/hypothalamic region. **Methods:** We used two-dimensional magnetic resonance spectroscopy (2D-MRS) to measure multiple neurochemicals in the midbrain/hypothalamus of OSA and control patients. We studied 14 OSA patients (mean age±SD:54.6±10.6years; AHI:35.0±19.4;SAO_2min:83±7%), and 26 healthy control participants (50.7±8.5years) using a recently-developed non-uniform undersampled (NUS) compressed sensing-based four dimensional echo-planar J-resolved spectroscopic imaging (4D-EP-JRESI), which enables evaluation of more metabolites than traditional 1D MRS/MRSI. We localized the midbrain using high-resolution T1-weighted anatomical scans. Acquired data were post-processed with a custom MATLAB-based program, and metabolite ratios with respect to creatine peak were calculated using a modified prior knowledge fitting (ProFit) algorithm. Independent samples t-tests were used to assess OSA-control differences. **Results:** In the right midbrain and hypothalamus, the OSA group showed decreased N-acetylaspartate (NAA; OSA: 1.24±0.43, Control: 1.47±0.41; p=0.03), a marker of neuronal viability. Increases in OSA over control subjects appear in levels of glutamate (Glu; OSA: 1.23±0.57, Control: 0.98±0.33; p=0.03), ascorbate (asc; OSA: 0.56±0.28, Control: 0.42±0.20; p=0.03), and myo-inisotol (mI; OSA: 0.96±0.48, Control: 0.72±0.35; p=0.03). No differences between groups appeared in γ-aminobutyric acid (GABA) or taurine (Tau). **Conclusion:** The midbrain and hypothalamus in OSA patients show decreased NAA, which likely indicates neuronal injury. Higher Glu levels may reflect excitotoxic processes, and higher mI is consistent with glial activation, as that chemical is prominant in such cells. Asc may be high in response to the oxidative stress from intermittent hypoxia in OSA. Additionally, Asc and Glu are both involved with glutamatergic processes, which are likely present in the midbrain in OSA patients.

Title: Wake high-density EEG spatiospectral signatures of insomnia

Authors: *E. J. VAN SOMEREN[1], M. COLOMBO[2], Y. WEI[2], J. RAMAUTAR[2];
[2]Sleep & Cognition, [1]Netherlands Inst. For Neurosci., Amsterdam, Netherlands

Abstract: Objectives. Insomnia is characterised by fragmented sleep and hyperarousal. Whereas diagnostic criteria include daytime complaints, studies mostly focused on sleep EEG. We systematically evaluated wake high-density (HD) EEG signatures of insomnia during resting state and in response to external (auditory) and internal (heartbeat) stimuli.
Methods. Fifty-four people with insomnia were compared to 48 controls without sleep complaints, recruited from www.sleepregistry.nl. During the evening hours, HD-EEG was assessed using a 256-electrode system during an active auditory oddball task and during 5 minutes of eyes open and 5 minutes of eyes closed resting-state. Simultaneous electrocardiography allowed for heartbeat evoked potentials (HEP) analyses.
Results. During adaptation to frequent tones, the auditory N100 amplitude decreased in controls but not in people with insomnia. Heartbeat evoked potential analysis indicated that eye closure attenuated the frontal HEP amplitude in a late (372-492 ms) time window. In people with insomnia, eye closure attenuated this late part of the HEP amplitude significantly less. Resting-state spectral power analyses indicated that insomnia is characterised by low power in the upper alpha range (11-12.7 Hz) during eyes open over restricted bilateral frontal and left temporal regions. During eyes closed, people with insomnia show high power in the beta-gamma range (16.3 to 40 Hz) over extended prefrontal, central and parieto-occipital regions.
Conclusions. Increased high-frequency power in insomnia is not limited to sleep-EEG, suggesting a 24-hr deficiency to suppress cortical activation. This interpretation is also supported by the attenuated power in the upper alpha band, given the inhibitory role of alpha. Auditory ERP findings suggest that people with insomnia insufficiently adapt to frequent stimuli. The lack of adaptation is also supported by the enhanced late HEP amplitude.

Title: "Somnivore", a user-friendly platform for automated sleep scoring of animal and human polysomnography data

Authors: *G. ALLOCCA[1], L. A. JOHNSTON[1], D. R. FREESTONE[2], A. L. GUNDLACH[1]; [1]Florey Dept. of Neurosci. and Mental Hlth., [2]Med., The Univ. of Melbourne, Parkville, Australia

Abstract: Objective: The low-throughput nature of manual scoring of sleep data is a major factor restricting the pace and potential of sleep research. Automated scoring approaches developed previously have failed to provide sufficient accuracy or 'usability' for sleep scientists lacking engineering or specialist computing expertise. Moreover, all previous approaches have only been validated on baseline data and no single approach has been validated for mouse, rat and human data analysis. Methods: We have developed a user-friendly platform for real-time automated scoring of polysomnography data, named Somnivore. Using a GUI-based approach in the Matlab™ platform we have deployed a support vector machine (SVM) to analyse features from polysomnography inputs (EEG, EMG, EOG, ECG, temperature, etc.) into the various sleep stages. The SVM is trained for each individual subject via a brief session of manual scoring. The system has been validated using mouse, rat and human data collected across a number of different treatments and genotypes and scored by members of collaborating laboratories from Australia, Europe and USA. Results: With minimal training time, overall scoring agreement rates were consistently above 90% in all species and treatment groups. F-scores in rats and mice were >0.9 for wake, >0.9 for NREM and >0.85 for REM. For human data, F-scores were >0.85 for wake, >0.35 for N1, >0.88 for N2, >0.85 for N3 and >0.91 for REM.Conclusions: Somnivore provides accurate, reliable, high-throughput scoring and analysis of polysomnography data in a range of experimental situations from normal and genetically modified physiology to drug pharmacology, in both animal and human subjects.

Abstract: Every night the human brain produces thousands of slow oscillations and spindles during non-REM sleep. Previous studies indicate that slow oscillations generated in the cortex group spindles generated in the thalamus. Cortico-thalamic mechanisms underlying these sleep phenomena, however, remain poorly characterized in humans. Using simultaneous cortical and thalamic bipolar depth recordings in patients undergoing evaluation for epilepsy (2 women, 1 man), we demonstrate a cortico-thalamo-cortical loop whereby: 1) cortical slow oscillation downstates lead thalamic downstates; 2) thalamic downstates hyperpolarize thalamic cells, thus triggering spindles; and 3) thalamic spindles are focally projected back to cortex. In earlier models, thalamic H and T currents were assumed to be continuously available, permitting spontaneous spindling; our findings indicate, in contrast, that thalamic currents are not available until the cells are further hyperpolarized in a thalamic downstate. In earlier models, cortical spindle occurrence was supposed to be gated by cortical upstates. In contrast, we find that spindle occurrence is gated by the thalamic downstate, and thus, cortical spindles begin on the down-to-upstate transition when their contribution to memory consolidation can be maximized.

This archetypical cortico-thalamo-cortical sequence provides the global physiological context for memory replay and consolidation during non-REM sleep.

Title: Repeating circular waves enable strengthening of large-scale neural assemblies during sleep spindles in human cortex

Authors: *L. E. MULLER[1], G. PIANTONI[2], D. KOLLER[1], S. S. CASH[2], E. HALGREN[3], T. J. SEJNOWSKI[1];

Abstract: During sleep, the thalamus generates a characteristic pattern of transient, 11-15 Hz sleep spindle oscillations, which synchronize the cortex through large-scale thalamocortical loops. Spindles have been increasingly demonstrated to be critical for sleep-dependent consolidation of memory, but the specific neural mechanism for this process remains unclear, particularly in the presence of long axonal conduction delays. Evidence from human electroencephalography (EEG) and animal recordings suggests large-scale coherence occurs across the cortex during spindles in natural sleep, but their specific spatiotemporal structure is not well understood. In this work, we study electrocorticogram (ECoG) recordings of patients during stage 2 sleep and apply computational methods to characterize spatiotemporal dynamics.

We find that cortical spindles are spatiotemporally organized into circular wave-like patterns, traveling preferentially in the temporal-parietal-frontal (TPF) direction. These activity patterns extend over tens of milliseconds, placing the neural assemblies they synchronize on a timescale relevant to spike-time dependent synaptic plasticity. The waves travel with a peak speed between 3-5 m/s, within the range of conduction speeds of the short and long association fibers, allowing spikes emitted in distant cortical areas to align with the local spindle-associated population burst. Finally, we show these circular patterns repeat over hours of sleep with millisecond temporal precision, enabling reinforcement of large-scale neural assemblies through hundreds of reverberations. These results provide a novel mechanistic account for how global sleep oscillations and synaptic plasticity can strengthen networks distributed across the cortex to store coherent and integrated memories.

Title: The influence of intra-dorsolateral striatum injection of an NMDA receptor agonist or antagonist on extinction of response learning in the plus-maze

Authors: *J. GOODMAN, R. RESSLER, M. G. PACKARD;
Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: Extensive evidence indicates that acquisition of response learning is critically mediated by the dorsolateral striatum (DLS). Recent evidence from our laboratory indicates that, like initial acquisition, extinction of response learning may similarly depend on DLS function. However, the precise neurotransmitter systems involved remain unknown. NMDA receptor activity has been critically implicated in multiple kinds of learning and memory, including initial

acquisition of response learning and extinction of conditioned fear. Thus, the present study examined whether NMDA receptor activity in the DLS may also be implicated in extinction of response learning. Adult male Long-Evans rats were initially trained in a response learning version of the plus-maze, in which they were reinforced to make a consistent turning response (e.g. turn left) at the choice point to retrieve food reinforcement at the end of a separate goal arm (East or West). Following initial acquisition, animals were given two days of extinction training, which was conducted in a manner identical to initial acquisition except without the reinforcer present. In experiment 1, immediately after the first day of extinction training, animals received bilateral intra-DLS infusions of the NMDA receptor antagonist AP5 (2μg/kg) or saline. On the second day of extinction training, animals that had received post-training AP5 displayed more perseverative turning responses and lower running latencies, relative to animals that had received post-training saline. Experiment 2 was conducted in a similar manner, except animals received post-training intra-DLS administration of the NMDA receptor partial agonist D-cycloserine (DCS; 10μg or 20μg/kg dose) or saline. Animals given 20μg DCS, but not 10μg DCS, displayed higher latencies and fewer perseverative turning responses, relative to animals given post-training saline. The present findings indicate that NMDA receptor activity in the DLS governs bidirectional effects on extinction of response learning. Whereas blocking DLS NMDA receptors with AP5 impairs extinction of response learning, stimulating NMDA receptors with D-cycloserine enhances extinction of response learning. Considering that DLS-dependent habit memory may underlie some symptoms of human neuropsychiatric disorders (e.g. drug addiction), the present findings may be useful in developing pharmacological treatments that combat the habit-like behavioral features of these disorders.

Title: Effectiveness of extinction protocols depends on the memory system engaged during acquisition

Authors: ***R. RESSLER**, J. GOODMAN, M. PACKARD;
Psychology, Texas A&M, College Station, TX

Abstract: Previous research suggests that extinction of learned maze behavior in rodents may occur without the overt performance of the previously acquired response. Previous studies have

demonstrated that confining an animal to a previously rewarded goal location in the absence of reward, a protocol known as latent extinction is sufficient to produce the extinction of behavior. Despite this, it is unknown the latent extinction protocol is effective in extinguishing all types of memory acquired in a maze. In this study we examined the effectiveness of latent extinction in two separate plus-maze tasks, each of which was designed to engage anatomically distinct neural constructs. First, adult male Long-Evans rats were trained in a hippocampus-dependent place learning task. In this task animals are begun from different starting positions (North/South) and are trained to approach the same spatial location (East) in order to obtain a food reward. In another experiment, a separate group of rats was trained in a dorsolateral striatum-dependent response learning task in which rats were again started from different positions and were required to make a consistent egocentric body-turn response to obtain the food reward. After training, the animals received either latent or response extinction. For latent extinction animals were confined to the previous goal location in the absence of reward. For response extinction, animals were given the opportunity to execute the original running approach response toward the empty goal location. The results indicate that relative to no extinction, latent extinction was effective in extinguishing memory acquired in a place learning task but was ineffective in extinguishing memory acquired in a response learning task. In contrast, response extinction was effective in extinguishing memory acquired in both the place and response learning tasks. These results suggest that the extinction of maze behavior may occur without the explicit performance of the previously acquired response, as is the case with latent extinction, however the effectiveness of this protocol may be dependent on the type of memory being extinguished. The present findings suggest that behavioral treatments, specifically those modeled after response extinction protocols, may be particularly useful in treating human psychopathologies associated with striatum-dependent processes (e.g., drug addiction and relapse).

Title: Selective effects of dorsal and ventral medial prefrontal cortex inactivation during instrumental reward seeking

Authors: *J. P. CABALLERO[1], D. E. MOORMAN[1,2];
[1]Neurosci. and Behavior, [2]Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Previous research has shown that, in rodent medial prefrontal cortex (mPFC), the dorsal mPFC (typically prelimbic) promotes the expression of conditioned fear and drug-seeking behavior, and the ventral mPFC (typically infralimbic) promotes inhibition of these behaviors. However, both ventral and dorsal mPFC are activated during reward seeking and extinction, and these established roles may not apply to all forms of motivated behavior. Additionally, this model does not take into account possible mPFC hemispheric differences which some groups have demonstrated previously. In order to better understand the roles of dorsal and ventral mPFC in motivated behaviors we performed bilateral and unilateral pharmacological inactivation of dorsal and ventral mPFC during reward seeking, fear conditioning, and extinction learning. Male Long-Evans rats were first trained to perform a fixed ratio 1 (FR1) sucrose seeking task where each nosepoke resulted in a tone cue and the delivery of 0.1 ml 15% sucrose. Responding was extinguished following acquisition of stable task performance. After extinction, rats received cue-induced reinstatement of sucrose seeking. During each phase of the task, rats received bilateral dorsal or ventral mPFC inactivation, or inactivation of only left or right dorsal or ventral mPFC. A subset of rats then underwent cued fear conditioning in which a new set of tone cues signaled footshock. Following conditioning, rats underwent extinction learning and recall. Rats received bilateral inactivations during extinction learning. During FR1 sucrose seeking we observed no effect of inactivation of either dorsal or ventral mPFC on numbers of nosepokes or well entries. Inactivation of left, right, and both hemispheres of dorsal mPFC decreased latency between nosepoke and reward collection ($p < 0.0001$ in all cases). Bilateral inactivation of ventral mPFC also decreased nosepoke-to-reward reaction time ($p<0.05$), as did left ($p<0.0001$) but not right ($p=0.0964$) hemisphere inactivation. Sucrose extinction, reinstatement and fear conditioning data are currently being analyzed. These preliminary results argue against a general hypothesis that dorsal or ventral mPFC selectively drive execution or inhibition of all motivated behaviors. Instead, they suggest that these areas may influence certain aspects of motivated behavior such as speed-accuracy tradeoff. Our results also demonstrate possible differential hemispheric contributions of mPFC subregions during reward seeking. Further analysis will confirm the extent of these subregion-by-hemisphere interactions in different aspects of motivated behavior.

Title: When and where learning is taking place? Multisynaptic changes in strength during different behaviors related to the acquisition of an operant conditioning task by behaving rats

Authors: *J. DELGADO-GARCIA;
Pablo Olavide Univ., Seville, Spain

Abstract: Although it is widely assumed that brain circuits are modified by new experiences, it is still unanswered which types of change in synaptic efficacy takes place in cortical and subcortical circuits during the very moment of the acquisition process. Rats were trained to the acquisition of an operant conditioning task using a fixed ratio (1:1) schedule. Animals were trained in a modified Skinner box provided with light beams to detect animals' approaches to the lever and to the feeder. Behaviors related (as approaching the lever, pressing the lever, eating) and unrelated (exploring, motionless, grooming) to the learning task were also recorded and quantified. Animals were chronically implanted with stimulating and recording electrodes in hippocampal, prefrontal, and subcortical sites (n = 14) putatively relevant to the acquisition of this learning task. Field postsynaptic potentials were evoked during the performance of the above mentioned behaviors and across the whole (i.e., before, during, and after) acquisition process. Afferent perforant pathways to the hippocampus, and the intrinsic hippocampal circuit (with the exception of CA3-CA1 synapses) where eventually modified in synaptic strength during the performance of the above-mentioned behaviors. CA3-CA1 synaptic weights were only changed when learning have already acquired asymptotic values and during the performance of appetitive (i.e., going to the lever) and consummatory (i.e., eating the pellet) behaviors. In contrast, afferent (hippocampal) and efferent (accumbens septi, basolateral amygdala and reuniens nuclei) circuits of the medial prefrontal cortex where significantly modified in synaptic strength across training sessions, mostly at the moment of the largest change in the learning curve. Performance of behaviors non-directly related to the acquisition process (i.e., exploring, grooming) also evoked changes in synaptic strength at prefrontal-related circuits. Results indicate the specific and timed modification in synaptic weights of different cortical and subcortical circuits during the acquisition of an associative learning task, involving behaviors related and un-related to the learning situation.

Title: Early exposure to a high-fat diet negatively impacts learning and memory in female rats and is ameliorated by enriched environments

Authors: *A. K. SUTER, S. HUSSAIN, N. RAMIREZ, C. DAWSON, S. MOMI, S. VILLARREAL, L. FINK, A. HUSSAIN, M. CHAUDHRY, I. C. SUMAYA;
Psychology, California State Univ. Bakersfield, Bakersfield, CA

Abstract: The positive impact that enriched environments have on laboratory rodents has been well established. Among other outcomes, rats kept in enriched environments have consistently shown improvements in learning and memory. Because the underlying mechanism of action of learning improvements is thought to be hippocampal neurogenesis, important to our research are the emerging data showing a reduction in neurogenesis in rats fed a high fat diet. Corroborating these findings, we found high fat diets to negatively impact spatial learning in male rats and used enriched environments to ameliorate these effects (Sumaya et al., 2014). Because there have been reports showing a high fat diet affects neurogenesis differentially between male and female rats, the aim of this research was to investigate the long-term effects of a high fat diet early in development on learning and memory in females kept in enriched environments. Female rats were randomly placed in either standard cages (SC) or enriched environments (EE) at 2 mo of age and then were fed either Regular Chow (RC: 11% fat) or a Western Diet (HF: 39% fat, 44% carbs, 17% protein kcal, Modified AIN-93G, Research Diets) for 55 days. We then measured spatial learning errors in the 8-arm radial maze at 4, 10, 16, and 24 mo of age. Errors in the 8-arm maze task (averaged over the 8 days: 1 trial per day) were significantly greater in the HF group having its most detrimental effects in the groups that were housed in SC at 4 mo of age (HF: 7.80±1.07 vs. RC: 3.13±0.63 errors). At 10 mo of age, rats kept in SC and fed a HF diet did not differ on errors as compared to their controls on RC. And, regardless of diet and age, the rats housed in EE showed the least amount of errors at all testing points (RC at 4 mo: 3.13±0.63; 10 mo: 1.44±0.41 errors) (HF at 4 mo: 4.80±0.62; 10 mo: 2.20±0.50 errors). Similarly, at both 16 and 24 mo, the rats kept in SC and fed a HF diet did not differ on errors as compared to their controls on RC. And, again regardless of diet and age, the rats housed in EE showed the least amount of errors at all testing points (RC at 16 mo: 1.45±.25; HF: 2.1±0.32 errors, RC at 24 mo: 0.82 ±.28; HF: 1.33±0.24 errors). These data provide first time evidence that 1) increases in fat

intake contributes to deficits in female rodent learning and memory at the early developmental stages, and 2) enriched environments can counteract the negative effects of a high fat diet on female rodent learning and memory.

Title: The effect of extinction on the specific and general forms of the Pavlovian-instrumental transfer (PIT) effect.

Authors: *D. E. ALARCON, A. R. DELAMATER;
Sch. of Psychology, Brooklyn Col. - CUNY, Brooklyn, NY

Abstract: In the Pavlovian-instrumental transfer (PIT) effect a conditioned stimulus (CS), cue that signals a motivationally significant outcome, increases instrumental performance. Studies suggest that PIT can take a *specific* or a *general* form. In the specific, CS presentations increase responding if the CS and the responses were paired with the same outcome. But in the general form, CS presentations increase performance if the CS and responses were paired with an outcome from the same motivational valence, even though they have different sensory properties.

Research on the neural mechanisms of PIT indicate that both forms are determined by different mechanisms. For example, different regions of the amygdala and nucleus accumbens contribute to each of these forms. In rats with lesions in the basolateral amygdala or accumbens shell, the specific but not the general PIT is abolished. But in rats with lesions in the central nucleus of the amygdala or accumbens core, the CS produces the specific but not the general PIT effect (Corbit & Balleine, 2005; 2011).

Studies on specific PIT indicate that it is highly resistant to extinction procedures aimed at weakening the association between the CS and outcome (Delamater, 1996). However, there are no equivalent studies examining extinction of general PIT. If different neural mechanisms are involved in both forms of PIT then it is possible that extinction treatments may affect each form

differentially.
The studies reported here assessed the effect of extinction on specific and general PIT. Rats were trained to perform one response to obtain an outcome. Then two CSs were each paired with either the same or different outcome than the instrumental response, and two other CSs were not reinforced. Then half of the animals received non-reinforced presentations of the CSs (extinction), while the remaining animals only received context exposure. After this, subjects performed the instrumental response in the presence of the CSs.
In the control group the CS paired with the same outcome as the instrumental response elevated performance (specific PIT), but this effect was larger in the extinction group. Similarly, the CS paired with a different outcome also elevated responding (general PIT), which was more evident in the extinction group. The specific PIT was larger than the general, but both forms were reduced at a similar rate across multiple repeated PIT tests. The results suggest that extinction did not undermine either specific or general PIT effects, and, indeed, enhanced the expression of these effects, most likely by eliminating competing goal tracking CRs. Like specific PIT, general PIT also shows strong resistance to the effects of extinction.

Title: Model of dopamine neurons processing temporal difference errors

Authors: *D. R. SCHUWEILER, P. A. GARRIS;
Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Temporal difference errors (TDEs) bidirectionally signal the differences between predicted and actual rewards and are used by the temporal difference learning algorithm (TDL) to update predictions about future rewards, *i.e.*, learn. Positive TDEs occur when actual events are better than predicted, *e.g.*, in response to unpredicted rewards and reward-associated cues. Negative TDEs occur when events are worse than predicted, *e.g.*, when predicted rewards or cues do not occur. A well-accepted hypothesis of mesolimbic dopamine (DA) neuron function posits that these neurons encode TDEs as the amplitude of phasic changes in action potential firing and transmit these signals to target neurons as the amplitude of phasic changes in extracellular DA. Mesolimbic DA neurons have a basal firing rate, ≈4 Hz, that briefly increases to ≈40 Hz when an animal encounters unpredicted rewards and reward-associated cues. This

slow basal rate potentially challenges the hypothesis that DA neurons bidirectionally encode TDEs, because there is a floor effect for the firing rate decrease caused by negative TDEs. Electrophysiological evidence suggests that, unlike positive TDEs, negative TDEs may alternatively be encoded by the duration of a pause in action potential generation. Neurochemical evidence suggests, however, that both positive and negative TDEs are signaled by the amplitude of a phasic change in extracellular DA. It has yet to be determined if asymmetric encoding of TDEs by DA neuron firing could cause bidirectional DA signaling of TDEs to target neurons. To determine if the changes in DA neuron action potential firing caused by TDEs could also cause bidirectional changes in extracellular DA we conducted a computational modeling experiment. We functionally coupled a TDL model to a model of DA neuron action potential generation, and in turn, a model of extracellular DA. Our models reveal that encoding of negative TDEs by pause duration, but not amplitude, is sufficient for bidirectional changes in extracellular DA. Thus, TDL remains a viable framework for understanding the function of mesolimbic DA neurons. Surprisingly, our models reveal that the amplitude of the reduction in extracellular DA while no action potentials are generated is not increased by greater DA uptake, but instead by greater action potential-dependent DA release. This paradoxical result is due to the effects of DA release increasing, and uptake decreasing, basal extracellular DA combined with the concentration-dependency of DA uptake. These results highlight the utility of our models for understanding the complex regulation of DA signals and generating novel predictions about reinforcement learning.

Title: Altered metabolism but no change in working memory in rats subjected to a high-fat/high-sucrose diet

Authors: *H. M. MURPHY[1], C. H. WIDEMAN[2];
[1]Dept Psychol, [2]Biol., John Carroll Univ., Cleveland, OH

Abstract: For over thirty years, diets consisting of high fats and sugars have contributed to increased rates of obesity, type 2 diabetes, and metabolic syndrome. In addition, studies have found that they are associated with impaired cognition. The present study investigated the effects of a high-fat/high-sucrose (HFHS) diet on body weight, caloric intake, blood glucose levels, adiposity, spatial working memory, and anxiety-like behavior. Ten female rats were habituated

to a control diet for one week. Subsequently, the rats were divided into two groups: a high-fat/high sucrose (HFHS) diet group and a control diet group. This experimental phase continued for four weeks. During the last week of the experiment, a Morris Water Maze (MWM) was utilized to study trial-dependent spatial working memory. All maze sessions were conducted during the dark phase of the circadian cycle utilizing red light. Each rat was given one session consisting of two trials each day. The first was the sample trial in which the animal discovered the location of the platform by trial and error and the second was the test trial in which the animal was required to recall the location of the platform. Time to reach the platform was recorded in each trial. During the sample trial, the animal was given 90s to find the platform. After locating the platform, the animal was allowed to rest on the platform for 15s. If the animal did not find the platform within the 90s period, it was guided to the platform and allowed to rest for 15s on the platform. Following the rest period, the animal was picked up and put back into the starting location and given 90s to find the platform in the test trial. The platform was relocated every day. Because of relocation, no learning of the platform position from the previous day could be transferred to the test trial of the next day; hence, recall on each day during the test trial was dependent on the sample trial of that day and measured only temporary or working memory. During all MWM sample and test trials, anxiety was rated on a scored scale of 0 - 3 by assessing rat behavior prior to being lowered into the water maze. At the conclusion of the experiment, blood glucose levels and renal and mesenteric adiposity were measured. The current study found that rats on the HFHS diet had significantly greater: percent increase in body weight, daily caloric intake, blood glucose concentration, and adiposity. No significant difference was found between groups in terms of spatial working memory. A noteworthy finding, however, was that HFHS rats showed a significant increase in anxiety-like behavior between successive MWM trials. Further research is needed as the popularity of the HFHS diet continues to increase.

Abstract: Background: The psychological domain of Approach-Avoidance attempts to capture an individual's behavioral response to appetitive and aversive stimuli in the environment to measure how individuals weigh the threat of aversion against the possibility of reward. To study the functional neurobiology of approach-avoidance behavior in healthy individuals, we have developed a new experimental paradigm, the Aversive-Reward Conflict (ARC) task, that integrates both risk and reward.
Methods: 21 healthy volunteers performed the fMRI task In this task, participants choose between a high reward ($0.06 - $0.96) combined with a specific probability (low, medium, high) of electric stimulation and a low reward ($0.01) with no probability of electric stimulation. As such, participants have the option to completely avoid an aversive experience in every trial. We employed a Bayesian regression model to estimate a per-trial decision boundary which was entered as parametric modulation into fMRI analysis.
Results: Group level analysis of trials at the decision boundary shows bilateral activation in dorsolateral prefrontal cortex, dorsal anterior cingulate , posterior cingulate and insula. Analysis for the slope term, showing modulation from the decision boundary, shows deactivation in dlPFC, dACC, PCC and insula. Analysis of risk and reward conditions show greater activation in left anygdala for high risk and caudate and putamen for high reward, respectively.
Conclusions: The results highlight the important interactions between reward valuation and cognitive control systems during simultaneous risk and reward processing. Increased activation in the above regions for high conflict trials and decreased activation for low conflict trials confirm previous findings about the role of the dlPFC, dACC and insula in the processing of conflicting stimuli during decision making. Negative correlations between reward and BAS scores for high risk show that individuals with lower appetitive dispositions require a higher reward to pursue the risky option. This result shows that the ARC task effectively taps into the approach-avoidance domain in creating response conflict.

Title: Rewarding stimulation of the medial prefrontal cortex activates extensive brain regions: an optogenetics-fMRI study

Authors: *Y. HU, A. TALISHINSKY, H. LU, S. IKEMOTO, Y. YANG;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Recent deep brain stimulation (DBS) study in major depression patients suggested an important role of white matter bundles connecting medial prefrontal cortex (MPFC) in treatment efficacy. Animal research suggests this region in positive emotion or reward. To better understand brain circuits responding to the stimulation, in the present study, we incorporated optogenetics and functional magnetic resonance imaging (fMRI) to investigate MPFC-mediated behavior. Channelrodopin2-expressing adeno-associated virus (AAV-ChR2) or control virus (AAV-eYFP) was injected into the ventral MPFC (vMPFC) in two groups of rats (experiment n=15, control n=7), respectively. Animals were trained to press lever for optogenetics stimulation (a 25-Hz train of 8 pulses). All animals then underwent fMRI scanning in a Bruker Biospin 9.4T scanner, keeping anesthetized with a combination of isoflurane (0.5%) and dexmedetomidine hydrochloride (0.015 mg/kg/hr). Stimulation trains were delivered in a block-design pattern with 20s stimulus on and 40s off. FMRI data were acquired using a T2*-weighted EPI sequence (TE/TR = 13/1000 ms, TR = 1000 ms, segment = 2, FOV = 35 × 35 mm^2, matrix size = 64×64, slice thickness = 1 mm, slice number = 15). Brain activation and its relationship with rewarding behavior were examined. Stimulation of vMPFC activated many areas along known projections of the MPFC. Specifically, the entire MPFC, including the medial orbital, prelimbic, and infralimbic regions were activated. The stimulation also activated cortical and subcortical regions that receive the vMPFC afferents, including the agranular insular area, anterior cingulate area 2, tenia tecta, amygdala, ventral striatum, septal area, bed nucleus of stria terminalis, midline anterior thalamic areas, preoptic area, and hypothalamus. Lever press behavior was positively correlated with brain activation of hypothalamus ($r=0.76$, $p=0.01$), anterior insula ($r=0.69$, $p=0.028$) and ventral striatum ($r=0.64$, $p=0.047$). Our study revealed that stimulation of the vMPFC activates extensive brain regions, and some of the activation was correlated with the lever press behavior. The vMPFC corresponds to the subcallosal cingulate, which has been an effective target of deep brain stimulation for the treatment of depression. Our finding may shed light on circuits involved in therapeutic effects of DBS. This research was supported by the Intramural Research Program of the NIH, NIDA

Title: Functional states of hippocampal and prefrontal circuits characterizing the acquisition of an operant conditioning tasks and related and unrelated behaviors in alert behaving rats

Authors: *A. GRUART;
Pablo de Olavide Univ., Seville, Spain

Abstract: A general assumption of contemporary neuroscience is that learning is stored in the brain in the form of more-or-less stable changes in synaptic strengths in selected cortical/subcortical sites. Nevertheless, a still-open question is whether synapses included in hippocampal and medial prefrontal circuits, present similar changing rates in synaptic efficacy during the acquisition of operant conditioning tasks in behaving rats. In the present study, we have recorded activity-dependent changes in synaptic strength —namely, the slope of the chronically evoked field postsynaptic potentials (fPSPs) in 13 selected synapses: perforant path (PP)-dentate gyrus (DG), PP-hippocampal CA3 area, PP-hippocampal CA1 area, DG-CA3 rostral, DG-CA3 caudal, CA3-contralateral CA1, CA3-ipsilateral CA1, CA1-thalamic reuniens nucleus (REU), CA1-subiculum, CA1-medial prefrontal cortex (mPFC), mPFC-basolateral amygdala, mPFC-nucleus accumbens septi, and mPFC-REU. Changes in synaptic strength evoked at the mentioned synapses were recorded during behaviors related (approaching to the lever, lever pressing, approaching the feeder, eating) and unrelated (exploring, motionless, grooming) to the acquisition process. We characterized two types of evolution patterns: (1) synaptic-timing states during each selected behavior; and, (2) behavioral-timing states related to each synapse. Results indicate that whereas the synaptic strength in the main inputs and in the intrinsic synapses of the hippocampal circuit do not change significantly along the operant conditioning, the synaptic strength in the main outputs (except for CA1-SUB) and in the extrinsic synapses increases significantly in parallel with the acquisition rate of the associative learning task. Furthermore, these dynamical changes were similar for the different types of behavior (locomotor, stationary, appetitive, consumatory, exploratory) considered here. Thus, the precise and timed activation of multiple synaptic contacts during an operant conditioning task evoked a definite and specific dynamic map of synaptic states characterizing behaviors related and unrelated to the learning process.

Title: Methylphenidate shifts healthy volunteers towards a reward-sensitive strategy during learning-based decision-making

Authors: *K. M. HARLE[1], C. HYSEK[2], S. ZHANG[3], A. YU[2], M. PAULUS[2];
[1]Dept. of Psychiatry, UCSD, La Jolla, CA; [2]UCSD, San Diego, CA; [3]UCSD, Cognitive Science, CA

Abstract: ***Introduction***: Computational approaches such as Bayesian ideal observer models have the potential to more powerfully and accurately delineate the cognitive dysfunctions associated with psychiatric disorders, as well as the improvement of such dysfunctions with pharmacological or behavioral treatments. Having recently observed decision-making abnormalities in occasional and dependent stimulant users with such methods, here we use a similar Bayesian modeling approach to quantify the impact of a common prescription stimulant, methylphenidate (MPH), on exploratory reward-based decision-making.
Methods: 24 healthy volunteers received an acute oral administration of placebo or 40 mg MPH (1 month apart) and after about 120 minutes completed 20 games of a 3-armed bandit task. In each game, they repeatedly choose between three arms with fixed but unknown reward rates, with the goal of maximizing total reward. The task was formalized as comprising a learning component, which updates estimated reward rates based on ongoing observations (modeled by iterative Bayesian inference), and a strategic component, which choses among options based on current expectations about reward rates (modeled by 4 decision policies: Win-stay/Lose-shift (WSLS), ε-Greedy, τ-Switch, Softmax). **Results:** Significantly more individuals were best fit by a learning-based Softmax strategy than by a learning-independent WSLS strategy during MPH administration ($p<.05$). For Softmax users, task completion under MPH administration was associated with a higher reward sensitivity bias (Beta=4.99), i.e., higher propensity to choose the option estimated to be most rewarding, relative to completing the task under placebo (Beta=3.39, $p=.02$). Softmax parameter under MPH administration was further positively correlated with monetary gains in the task ($r=.64$, $p<.05$).
Conclusions: MPH may promote utilization of a more reward-sensitive strategy and higher reward responsiveness in learning-based decision-making. MPH has recently been found to enhance extinction learning; this study shows that it may also affect reward-based learning. The computational approach helps to better delineate how MPH changes learning strategies and can be used to provide a rationale for this or similar drugs to be used in psychiatric disorders that show significant learning dysfunctions such as ADHD and depression.

Title: The effects of chemogenetic inactivation of the medial prefrontal cortex during Pavlovian appetitive conditioning

Authors: ***S. E. KEEFER**, G. D. PETROVICH;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Learned environmental cues that predict food can override internal, physiological signals and stimulate eating in the absence of hunger. The medial prefrontal cortex (mPFC) is recruited during cue-food associative learning and is necessary for overeating in the presence of these learned cues. However, less is known about the role of the mPFC across different stages of learning. The current study examined whether the mPFC is necessary during the initial and well-learned stages of Pavlovian cue-food acquisition by using DREADDs (designer receptors exclusively activated by designer drugs), a chemogenetic method of neuronal inactivation. Male, Long-Evans rats received bilateral injections into the mPFC of an adeno-associated virus (AAV) expressing inhibitory DREADD (AAV5-hSyn-HA-hM4D-IRES-mCitrine) in order to selectively silence mPFC neurons during specific conditioning sessions. Rats underwent six sessions of Pavlovian appetitive conditioning, one session per day. Each conditioning session included 8 presentations of a 10s tone (conditioned stimulus, CS) follow by immediate delivery of 2 palatable food pellets (unconditioned stimulus) distinct from standard chow. Thirty minutes prior to session 3 (early learning) and session 6 (well-learned), rats received an i.p. injection of either clozapine N-oxide (CNO; biologically inert, DREADD-selective ligand, 3 mg/kg) or vehicle. Preliminary results indicate that during conditioning session 3, inactivation of the mPFC decreased overall motivation to approach the food cup, measured as percentage of time rats spent expressing food cup behavior (conditioned response) during the 10s prior to the onset of the CS (pre-CS), during the CS, and during the 10s after the offset of the CS (post-CS) when food pellets are available. Even though there was an overall decrease to approach the food cup throughout session 3, inactivation of the mPFC resulted in a more selective responding during the CS in the second half of the session, as indicated by an elevation score (CS minus pre-CS

responding). No significant differences were found during conditioning session 6, suggesting the mPFC may not be essential in the expression of well-learned cue-food associations. These results indicate a role for the mPFC in Pavlovian appetitive conditioning, specifically during the initial motivation to learn cue-food associations.

Title: DREADD inactivation of medial prefrontal cortex neurons disrupts renewal of Pavlovian conditioned responding to food cues in male rats

Authors: *L. C. ANDERSON, G. D. PETROVICH;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Cues associated with food can stimulate appetite and food consumption independently of hunger and this non-homeostatic eating is a contributor to the rise in obesity in our society. Renewal, or reinstatement, of responding to food cues after extinction may explain the inability to resist palatable foods and change maladaptive eating habits. Recently, we examined recruitment (Fos induction) of the medial prefrontal cortex during context-dependent renewal in male rats. We found higher Fos induction within the infralimbic and prelimbic regions of the ventromedial PFC (vmPFC) in rats exhibiting renewal of responding compared to a control group. Here, we examined whether the vmPFC is necessary during renewal using the chemogenetic methodology DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) to silence vmPFC neurons during the test for renewal. Male, Long-Evans rats received bilateral stereotaxic injections into the vmPFC of a viral vector containing the gene for a synthetic inhibitory G-protein-coupled receptor (AAV5-hSyn-HA-hM4D-IRES-mCitrine) or a control viral vector (AAV5-hSyn-EGFP). After recovery rats were trained in a within-subjects Pavlovian context-dependent renewal protocol. Rats were trained to associate a tone (conditioned stimulus, CS) with food (unconditioned stimulus) in 5 acquisition sessions (one session per day) in Context A. Acquisition was followed by 2 extinction sessions with CS-only presentations in Context B. Rats were tested for renewal of responding with CS-only presentations in Context A and Context B, counterbalanced for order, on separate days. 30 minutes prior to each test, rats

were injected with clozapine N-oxide (CNO, biologically inert, DREADD-selective ligand; 3mg/kg, i.p.) or vehicle. Rats either received CNO on both days or vehicle on both days. The resulting groups were: DREADD+CNO, DREADD+Vehicle, and Control Virus+CNO. The measure of learning was an increase in the expression of food cup behavior (conditioned response, CR) during CSs. Renewal of responding was determined by significantly higher CRs in the acquisition context (Context A) compared to the extinction context (Context B). There was a main effect of Context and Group interaction in a Repeated Measures ANOVA ($p<0.05$). *Post hoc* tests revealed the DREADD+CNO group failed to show higher CRs in Context A compared to B. Both the DREADD+Vehicle and Control Virus+CNO groups exhibited higher CRs in Context A. Silencing vmPFC neurons with DREADDs disrupted renewal of food cup responding, indicating that the vmPFC is critical in renewal of Pavlovian conditioned responding to food cues.

Title: The effect of intermittent versus continuous training on the incentive salience of a Pavlovian alcohol cue

Authors: *F. R. VILLARUEL, S. HEFFERNAN, M. CHAHINE, N. CHAUDHRI; Concordia Univ., Montreal, QC, Canada

Abstract: Pavlovian cues that predict alcohol can support sign-tracking and function as conditioned reinforcers, indicating that they acquire incentive salience. Moreover, intermittent alcohol exposure can facilitate alcohol intake and preference. We hypothesized that an intermittent schedule of Pavlovian training would also promote the attribution of incentive salience to a conditioned stimulus (CS) that predicted alcohol.
Male, Long-Evans rats were acclimated to 15% ethanol (EtOH) in the home-cage and then divided into two groups, one that received training every weekday (Monday to Friday), and a

second that received training on alternate days of the week (including weekends). Both groups received 27 Pavlovian conditioning sessions. In each session, a retractable lever-CS (10 s) was paired with the delivery of EtOH (0.2 mL per lever-CS; 12 trials per session) into a fluid port for oral consumption.

Rats rapidly learned to approach the fluid port during presentations of the lever-CS, referred to as a 'goal-tracking' conditioned response. Gradually however, goal-tracking responses diminished as rats started approaching and interacting with the lever-CS (referred to as a 'sign-tracking' conditioned response). Interestingly, from sessions 10 to 18 sign-tracking was augmented in rats that received intermittent training. Control groups that received unpaired presentations of the lever-CS and EtOH failed to develop goal- or sign-tracking responses, regardless of training schedule. Thus, the development of conditioned responding required a predictive relation between the lever-CS and EtOH.

Following Pavlovian conditioning, rats were tested in a conditioned reinforcement procedure in which nosepokes into an 'active' aperture lead to presentations of the lever-CS (2.5 s), while nosepokes into an 'inactive' aperture had no programmed consequence. Presentations of the lever-CS did not significantly enhance active nosepokes relative to inactive nosepokes. However, rats that previously received paired presentations of the lever-CS and EtOH exhibited more sign-tracking responses when the lever-CS was presented as a result of active nosepokes, compared to rats in unpaired groups.

Thus, the schedule of Pavlovian training can influence the attribution of incentive salience to an alcohol cue as measured by sign-tracking. Future experiments will compare continuous Pavlovian training (everyday) with an alternate day schedule; examine the extinction and reinstatement of sign-tracking and goal-tracking; and investigate the impact of different schedules of reinforcement on responding with conditioned reinforcement.

Title: Simple paradigm for investigating the learning of cost-benefit associations in monkeys.

Authors: T. VANDE CASTEELE[1], J. ARSENAULT[1,2], *W. VANDUFFEL[3,1,2];
[1]K.U. Leuven, Leuven, Belgium; [2]Athinoula A. Martinos Ctr. for Biomed., Mass. Gen. Hosp., Charlestown, MA; [3]Radiology, Harvard Med. Sch., Charlestown, MA

Abstract: In most instances, before a reward can be consumed effort must be expended to acquire it. Converging behavioral data show that when subjects make cost-benefit decisions, they weigh the value of potential rewards against the perceived costs of their effort. Studies have linked dopaminergic (DA) signaling to these calculations. For instance, while response properties of primate DA neurons reflect the value of cues associated with reward (Schultz et al., 1997), these responses are reduced when the effort associated with a cue is increased (Varazanni et al., 2015). In addition to DA neurons themselves, their target sites like the striatum and prefrontal cortex, are also critical in cost-benefit processing (Friedman et. al., 2015). With the advent of techniques allowing for the reversible perturbation of specific pathways within primates (Kinoshita et al., 2011), it is now possible to causally investigate the role of specific neural circuits within the primate in cost-benefit processing. To help investigate this, we aimed to develop a simple behavioral task to examine cost-benefit behavior in primates, with the primary goals that the task: 1) was easy to learn, 2) demonstrated cost-benefit decision making, 3) exhibited learning of new cost-benefit associations, 4) was affected by manipulations in reward magnitude (a surrogate for DA signaling). Therefore we designed a paradigm in which, after fixating on a central point (500 ms), monkeys were given a choice between 2 visual cues. Cues were positioned randomly in 2 of 4 possible positions to avoid spatial response biases. To select a cue, monkeys had to saccade to this cue and maintain fixation for a period of time. The duration of fixation determined the effort level (cue A = 1 s; cue B = 5 s; cue C = 9 s) and juice amount determined the reward level. To manipulate reward magnitude, we ran one variant of this paradigm with lower reward values (cue A = 0.11 ml; cue B = 0.54 ml; cue C = 0.98 ml) and the other with higher reward values (cue A = 0.16 ml; cue B = 0.81 ml; cue C = 1.46 ml). For each session 3 new visual cues were used and a randomized pair of cues were displayed on a given trial. We found that 1) animals were able to quickly learn this task, 2) during all sessions cue B became the preferred cue demonstrating a trade-off between the low effort cue (cue A) and the high reward cue (cue C) -possibly reflecting a preference for 'middle options' as seen in humans (Rodway et al., 2011), 3) preference for cue B increased during a session, 4) preference for cue B increased more quickly during higher reward sessions. These initial behavioral experiments pave the way for future studies investigating the causal role of specific pathways in cost-benefit processing.

Title: Lateral habenula plays a role in the process by which no association between two events is learned

Authors: *D.-H. KIM, B.-R. CHOI, J.-S. HAN;
Konkuk Univ., Seoul. 05029, Korea, Republic of

Abstract: In the reward conditioning, midbrain dopaminergic system (DA) is activated by reward delivery while lateral habenula (LHb), which known as major inhibitory center of DA system, is working in opposite manner with DA system. Previous studies have showed that DA system is involved in Pavlovian appetitive conditioning. However, no study has done to reveal a role of LHb in Pavlovian appetitive conditioning. Therefore, the present study was conducted to examine the role of LHb in Pavlovian appetitive conditioning. In a paired group, light was presented for 10 sec and immediately delivered two reward pellets, and 8 trials per one session for 64 min with 8 min variable inter-trial interval and conditioning was performed for 8 days. In an unpaired control group, the same number of lights and food pellets were pseudorandomly presented using an unpaired procedure in which the CS and US were non-contingent. And in a truly random control (TRC) group, presented 4 paired light-food and 8 unpaired stimuli (4 unpaired lights and 4 unpaired foods) with pseudo-random order. Three control groups (light or food only received group and naïve group) were included to exclude chance that alterations of neural activity by stimuli presentation and apparatus exposure. We measured two conditioned responses (CR), food-cup response and orienting response. Both CRs were increased in paired group, but not in unpaired group. And theses conditioned responses in TRC group were increased, but these response levels were an intermediate point between levels of paired group and levels of unpaired group. Next, we measured the neuronal activity by c-fos expression levels with immunohistochemistry in LHb and other brain area, substantia nigra pars compacta (SNc) and ventral tegmental area (VTA) and basolateral amygdala (BLA), central amygdala (CeA). LHb neuronal activity was only increased in unpaired group, but, was not increased in paired and TRC groups. And, neuronal activity of other brain areas (SNc, VTA, BLA and CeA) was increased in paired group, but not in unpaired group. Additional experiment using the retrograde tracer cholera toxin B subunit revealed that these c-fos expressed neurons in LHb were projected to SNc or VTA. Most c-fos expression neurons in unpaired group were also projected to SNc or VTA. These results suggest that the LHb play a role in the process by which no association

between two events is learned, in opposition to the midbrain dopaminergic neurons involved in the process by which an association between two events is learned. Supported by the Korea Research Foundation Grant funded by the Korean Government (NRF-2014R1A1A2058480) to Jung-Soo Han

Title: Nicotine enhances Pavlovian conditioned responding in male and female rats

Authors: *S. J. STRINGFIELD[1,2], A. C. MADAYAG[2], J. XU[2], C. A. BOETTIGER[2,3], D. L. ROBINSON[1,2];
[1]Curriculum in Neurobio., [2]Bowles Ctr. for Alcohol Studies, [3]Psychology and Neurosci., Univ. of North Carolina, Chapel Hill, NC

Abstract: In Pavlovian conditioned approach behavior, animals often demonstrate the conditioned responses (CRs) of sign tracking and goal tracking in which they approach and interact with a conditioned cue or the location of reward delivery, respectively. Sign tracking is associated with the attribution of incentive salience to the conditioned cue and has been linked to multiple measures of addiction vulnerability. Nicotine administration during Pavlovian conditioning increases the likelihood that an animal will display a CR. Sex differences in CRs have been described in animal models, with females sometimes exhibiting more sign tracking. Sex differences in epidemiological studies of male and female smokers have been reported, which are supported by sex-dependent effects in animal models of nicotine reinforcement. We aimed to measure sex differences in the nicotine-induced enhancement of CRs, either due to sex differences in inherent biological factors or in the effect of nicotine on the development and expression of this behavior. We hypothesized that nicotine would enhance CRs in both sexes, and that nicotine-exposed females would show even greater sign tracking than would males. To test this hypothesis, adult male and female Sprague Dawley rats were trained to associate a 30 s

presentation of a compound light and lever cue with subsequent delivery of a sucrose reward over 29 training sessions, each consisting of 15 cue-reward pairings. Rats in the nicotine exposure group received 0.4 mg/kg nicotine SC prior to each session, and a control group received saline injections. We report that nicotine enhanced both sign tracking and goal tracking CRs in both males and females, with females showing faster CRs, but no interaction between sex and nicotine was found. On measures of sign tracking, nicotine-exposed rats exhibited decreased latency to press the lever, and increased lever presses and probability of pressing the lever. For measures of goal tracking, nicotine-exposed rats showed an increase in receptacle elevation score (i.e., receptacle entries during the cue minus entries before the cue). Females displayed CRs faster than males, as indicated by a main effect of sex on latency to press the lever and an interaction of sex by day on latency to enter the receptacle. Thus, we replicate previous findings indicating that nicotine enhances conditioned responding, and extend this effect to females. In addition, we identified sex differences in the expression of these CRs. Future studies will use this cohort of male and female rats to investigate putative differences in gene expression correlated with both nicotine exposure and the expression of CRs.

Title: Characterization of rapid reacquisition of contextual fear behavior following post-extinction reconditioning in C57BL/6J mice and Long Evans rats

Authors: *A. WILLIAMS[1], K. M. LATTAL, 97210[2];
[2]Behavioral Neurosci., [1]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Associative learning is mainly studied from the perspective of initial conditioning, when new associations are established, or extinction, when those associations are inhibited. Although extinction eliminates behavior, it does not eliminate the original association. One piece of under-studied evidence for this is rapid reconditioning or reacquisition; very brief conditioning episodes (defined as 'reconditioning') can restore the behavior that is eliminated during extinction. The behavioral model used here allows for direct comparison of contextual fear acquisition and reacquisition in two species of rodents. We find that following moderate extinction, rodents display a persistent and rapid reacquisition of fear behavior relative to animals being conditioned for the first time. Following massive extinction, C57BL/6J mice do not rapidly reacquire fear following reconditioning, but Long Evans rats display rapid reacquisition regardless of the amount of extinction prior to reconditioning. Further, we show that the rapid reacquisition of fear is context-specific and not a sensitized or reinstated response to the unconditioned stimulus (footshock) in an alternate context. Finally, preliminary inactivation studies (muscimol + baclofen microinjections) explore the role of the extended amygdala (anterior bed nucleus of the stria terminalis) in the rapid reacquisition of contextual fear. These results suggest that post-extinction reconditioning differs behaviorally from initial conditioning in that reconditioning results in the rapid reacquisition of fear behavior contingent upon the amount of extinction received and the species of rodent. Rapid reacquisition of fear behavior provides a potential behavioral correlate of post-traumatic stress disorder symptoms, such as exaggerated startle response and hypervigilance, through which to study the behavior, neurobiology, and potential therapeutic targets of specific PTSD symptoms.

Title: Delta and low theta band mediates tone fear conditioning under urethane anesthetized rats

Authors: *E. F. OLIVEIRA[1], M. B. REYES[2];
[1]CMCC/UFABC, Sao Bernardo Do Campo, Brazil; [2]CMCC, Univ. Federal do ABC, Sao Bernardo do Campo, Brazil

Abstract: The Memory is a universal characteristic with high adaptive value present in vertebrates and invertebrates. Electrophysiological and behavioral evidences suggest that fear conditioning - which is related to implicit memory process - can be acquired under anesthesia. Additionally, the amigdalo-nigro-striatal pathway is assumed to play an important role in the acquistion of associative learning. Here, we ask the role of dorsal striatum in the acquisition of tone fear conditioning under anesthesia. To investigate this question, the local field potential (LFP) in the dorsal striatum of urethane-anesthetized wistar rats was recorded. We looked for changes in electrophysiological activity related to the acquisition of a fear conditioning protocol. The task consisted of 5 s two Conditioned Stimulus (CS), which could be either a Tone or White Noise randomly presented and counterbalanced. The stimuli were assigned as CS+ (paired with Unconditioned Stimulus (UCS)) or CS- (not paired with UCS). UCS where 1 mA foot-shock with 1 s duration delivered in the last 1 s of CS+. Recordings were made in 3 phases: 1) Pre-pairing: 60 presentations of both CS+ (without US) and CS-, to establish a baseline; 2) Paring: 60 pairings between CS+-UCS and 60 CS- presentations); 3) Post-pairing: 60 CS+ (without UCS) and 60 CS- presentations. Our main found is an increase in power for delta and low theta showed up for both CS+ and CS-, both in the pre-pairing and post-pairing CS presentation. Looking to the time that this increase in power lasted and subtracting the duration of post-pairing from the duration in pre-pairing periods, we found that the increase in CS+ in post-pairing was significantly longer than CS- in delta and low theta band, but not for high theta (8 - 12 Hz). Our results suggest that tone fear conditioning can be acquired under anesthesia, with delta and low theta band mediating the retrieval process. Additionally, CS+ and CS- appears to be discriminated. It is arguable that CS+ can have a transfer effect to CS-, in this case CS- should have the same electrophysiological signature as CS+, which is not the case. Therefore, we conclude that, even under anesthesia, rats can learn tone fear conditioning and discrimante CS+ and CS-.

Title: Basal ganglia output controls active avoidance behavior

Authors: S. HORMIGO, G. VEGA-FLORES, *M. A. CASTRO-ALAMANCOS;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Engrained avoidance behavior is highly adaptive when it keeps away harmful events and can be highly maladaptive when individuals elude harmless situations in anxiety disorders, but the neural circuits that mediate avoidance are poorly understood. We found that the output of the basal ganglia, through the substantia nigra pars reticulata (SNr), controls active avoidance. We employed chemogenetics and optogenetics to control the activity of SNr cells in a vesicular GABA transporter-IRES-Cre mouse strain. This allowed to express hM3Dq-DREADD, hM4Di-DREADD, channelrhodopsin-2 (ChR2), or a variant of archaerhodopsin -ArchT- in SNr cells. Neurons expressing hM3Dq are excited, while neurons expressing hM4Di are inhibited, after i.p. injections of clozapine N-oxide. Neurons expressing ChR2 are excited by blue light, while neurons expressing ArchT are inhibited by green light. The results show that SNr excitation blocks avoidance to a conditioned sensory stimulus while preserving the ability to escape the harmful event. Conversely, SNr inhibition facilitates avoidance to the conditioned stimulus and suffices to drive avoidance without any conditioned sensory stimulus. The results highlight a midbrain circuit that gates avoidance responses, which can be targeted to ameliorate maladaptive avoidance in psychiatric disorders.

Title: Personality traits contribute to voluntary pain-related avoidance behavior

Authors: *Y. NISHI[1], M. OSUMI[1], S. NOBUSAKO[1], K. TAKEDA[2], S. MORIOKA[1];
[1]Kio Univ., Kitakatsuragi-Gun, Japan; [2]Hokkaido Univ., Sapporo-Shi, Japan

Abstract: Introduction There are people avoiding a pain excessively in chronic pain patients. Their avoidance behaviors cause a vicious circle toward chronic pain. However, it is not revealed what kinds of personality traits are related to avoidance behaviors. Therefore, this study aimed to investigate the type of personality traits which contribute avoidance behaviors.
Method Twenty-four healthy participants performed a task to paint rectangular displayed on a touch panel with a touch pen as conditioned stimulus (CS). A trial continued 30 sec after beginning to paint. The task consisted of several phases: 5 practice trials, 5 acquisition trials, and

20 test trials which were separated into 4 blocks. Only in acquisition phase (CS+), participants were instructed to paint over 15 sec in each trial while there was no time constraint in practice phase (CS-) and test phase (CS+). The CS+ was followed by the painful electrocutaneous stimulus as the unconditioned stimulus only during painting. In each trial, auditory startle probes were performed after onset of paint and each peak amplitude were transformed to z-scores (startle responses). We calculated the time in which participants do not paint (avoidance time) at every phases. In addition, they answered State-Trait Anxiety Inventory (STAI) and revised temperament and character inventory (TCI-R) before this experiment. Participants were classified according to avoidance time using cluster analysis (Ward' method). To compare each score of STAI, TCI-R, avoidance time and startle responses among classified subgroups, t-test or Mann Whitney U-tests were used. Moreover, to compare scores of startle responses among each phase, the Friedman test was used. The Bonferroni correction was used to adjust the p-values obtained in the post hoc analyses (avoidance time; $p<0.01$, startle responses; $p<0.002$).
Results and Discussions In the result of clustering, participants were divided in two subgroups as follows; cluster 1 (n=6), cluster 2 (n=18). Startle responses of both subgroups enhanced significantly in acquisition phase compared to practice and test phases, but there were no significant differences between both subgroups. Avoidance time of cluster 1 was significantly longer than that of cluster 2 in all phases. Cluster 1 was significantly higher in STAI-trait and harm avoidance item involved in TCI-R than cluster 2. Also Cluster 1 was lower in novelty seeking item involved in TCI-R than cluster 2. Nevertheless, both subgroups were caused fear conditioning of pain in this study, they showed different pain-related avoidance behavior. Consequently, their avoidance behavior were different depending on each personality trait.

Title: Sub-second fear discrimination in rats: Adult impairment in adolescent heavy alcohol drinkers

Authors: ***M. A. MCDANNALD**, K. M. WRIGHT, A. DILEO;
Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: The ability to accurately discriminate safety from danger is vital. However, discrimination should not only be accurate, but should also emerge rapidly following encounters. Rapid fear discrimination may be independent from the general ability to discriminate and more susceptible to adolescent heavy alcohol drinking, which increases the lifetime risk for post-traumatic stress disorder. Despite its importance, we unaware of any study assessing the rapidity with which fear discrimination emerges following cue onset in any mammal. Here we sought to uncover the normal rapidity of fear discrimination and its possible impairment in adolescent heavy alcohol drinkers in rats. We gave rats voluntary access to alcohol throughout adolescence and identified heavy drinkers. In adulthood, we assessed rapid fear discrimination in a paradigm in which three cues were associated with three different probabilities of shock: safety p=0.00, uncertainty p=0.25 and danger p=1.00. Normal rats readily acquired sub-second fear discrimination, showing differential fear to safety, uncertainty and danger cues ~450-550 ms following onset. Adolescent heavy alcohol drinkers were impaired in sub-second fear discrimination, with discrimination not emerging until ~2100-2600 ms following cue onset. The deficit in adolescent heavy drinkers was not a general learning decrement, as these rats showed excellent discrimination later in the cue. These results provide the first evidence of sub-second fear discrimination in rats. Further, these results mark rapid fear discrimination as an ability critical to normal function and relevant to post-traumatic stress disorder.

Title: Optogenetic analysis of prefrontal contributions to contextual fear memories

Authors: ***A. ASOK**[1], D. V. GAGLIARDOTTO[2], A. M. HUGHES[2], J. SCHULKIN[3], J. B. ROSEN[2];
[1]Dept. of Neurosci., Columbia Univ., New York, NY; [2]Dept. of Psychological and Brain Sci., Univ. of Delaware, Newark, DE; [3]Dept. of Neurosci., Georgetown Univ., Washington DC, DC

Abstract: The medial prefrontal cortex (mPFC) has received considerable attention for its role across different phases of fear-learning and memory, particularly expression and extinction. While there has been substantial progress in understanding how the mPFC regulates fear to

discrete cues (e.g., tones and lights), less is known about the mPFC's involvement in learning fear to a context. Therefore, the present study examined the effects of mPFC inhibition during acquisition on the long-term retention and extinction of contextual fear. Rats received bilateral infusions of a pan-cellular optogenetic neural silencer CAG-ArchT-EGFP (ArchT) or a CAG-EGFP control virus. Three weeks later, optical fibers were bilaterally implanted above the injection site. One week later, rats were conditioned using a multi-trial contextual fear conditioning paradigm (five shocks spaced three minutes apart) on day one and tested for freezing to the context-alone on days two and three. The mPFC was only silenced on day one during contextual fear acquisition. Optogenetic silencing of mPFC cells during acquisition did not affect pre-conditioned freezing to the context or the rate of acquisition. However, ArchT rats showed enhanced freezing relative to controls during the light-free context-alone retention test on day two. Preliminary data also found that the enhanced freezing persisted when rats were tested again in the same context on day three, suggesting extinction is disrupted in ArchT rats. Furthermore, ArchT and control rats did not differ during acquisition or retention when re-conditioned (without optogenetic silencing) in a novel context, indicating that laser inhibition did not cause permanent cellular damage. Interestingly, despite two days of non-reinforced exposure to the original training context, ArchT rats exhibited increased baseline freezing to the novel context relative to controls. These data suggest that (1) mPFC activity at the time of acquisition is important for the future extinction of contextual fear memories and (2) that mPFC activity at the time of acquisition may also be involved in promoting contextual specificity.

Title: The use of synthetic TMT as a psychological stressor in a rodent model of PTSD.

Authors: *B. C. MOUZON, M. ALGAMAL, J. OJO, F. CRAWFORD;
The Roskamp Inst., Sarasota, FL

Abstract: Background: Various preclinical models of post-traumatic stress disorder (PTSD) use psychological stressors such as cat odor or fox urine and feces to induce PTSD-like symptoms in

tested animals. 2,5-dihydro-2,4,5-trimethylthiazoline (TMT) is a highly volatile, water insoluble molecule that contains sulfur, an element in carnivores' diet and component of red fox feces that showed to illicit fear responses in prey animals. In naïve mice and rats, TMT induces a number of defensive and fear behaviors including freezing, indicating it is an innate threat stimulus. In this study, TMT was used as stressor alone or in combination with social and physical stressors to examine TMT effect on neuroendocrine system.
Methods: 12-month-old C57BL/6J mice were restrained using decapicone tubes for the whole duration of exposure (30 min). TMT (SRQBio, Florida, USA) was diluted to 1:10 in water and then 50 ul were dispensed on a cotton cloth per mouse. Control mice received water with no restrain instead of TMT. Mice were sacrificed 30 min after the end of exposure period. Plasma was collected for evaluation of corticosteroid and catecholamine concentrations.
Discussion:This work has high translational potential for patients affected by both PTSD or innate fear/phobia. Investigation using TMT as a threatening stimulus for rodents is critical to study and understand the nature and timing of treatment strategies to treat PTSD.

Title: Female rats acquire and recall a conditioned safety signal more rapidly than males.

Authors: *A. R. FOILB, J. BALS, M. SARLITTO, J. P. CHRISTIANSON;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Veridical detection of safe versus dangerous cues is critical to survival and aberrant fear discrimination is a symptom of posttraumatic stress disorder (PTSD). More females are diagnosed with PTSD than males and clinical evidence suggests that women with PTSD have difficulty inhibiting fear responses. However, preclinical research into sex differences in safety learning is quite limited. Here, intact male and normally cycling female rats received fear discrimination training where a danger signal conditioned stimulus (CS+) co-terminated with a mild footshock and a safety signal (CS-) indicated the absence of shock. 24 h after conditioning

rats were given a discrimination test in the conditioning context in which freezing, an index of fear, was assessed during randomized presentations of the context alone, the CS+, or CS-. Importantly, all rats learned to discriminate between CS+ and CS-, yet females displayed a more robust phenotype evidenced by less freezing to the CS- compared to males within both the conditioning session and the subsequent recall test. This pattern suggests sex differences exist within the neural circuits that encode and recall safety information, which is the focus of ongoing study.

Title: Inactivation of the obitofrontal cortex impairs fear discrimination

Authors: M. C. SARLITTO, A. R. FOILB, *J. P. CHRISTIANSON;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Survival depends on flexible behavioral adaptation to shifting environmental risks and opportunities. PTSD is typified by inappropriate responses to environmental risks and so delineating the mechanisms which permit acquisition, recall, and flexible use of aversive and safe associations is critical to unraveling the neural bases of trauma-related disorders. In the realm of desirable associations (such as stimulus-reward pairings), the orbital frontal cortex (OFC) is critical for integrating outcome expectancies with flexible behavioral responses. To test the role of the OFC in cognitive flexibility within an aversive learning domain, we developed a fear discrimination procedure in which adult male rats readily shift behavioral responses depending on the presentation of either a shock paired conditioned stimulus (CS+) or a safety cue (CS-). We then used either reversible pharmacologic inactivation with the $GABA_A$ receptor agonist muscimol or chemogenetic silencing with the kappa-opioid DREADD (CamKII-KORD) to disrupt OFC functioning during fear discrimination recall tests. Muscimol significantly diminished the ability of adult male Sprague Dawley rats to discriminate between safety and danger cues. However, chemogenetic silencing had no effect. These contradictory findings

suggest there may be a part played by the OFC in modulating fear in response to changing dangerous and safe environments, but further investigation is needed to identify the specific population of OFC neurons involved.

Title: Brain-wide patterns of fos expression during fear learning correlate with emotional state rather than specific sensory stimuli

Authors: *J. CHO[1], S. RENDALL[2], J. GRAY[3];
[1]Genet., [2]Harvard Med. Sch., Boston, MA; [3]Harvard Med. Sch., BOSTON, MA

Abstract: In the hippocampus, *Fos* mRNA induction during learning identifies neural ensembles that encode a specific physical location, revealing a memory trace. In sensory cortex and other brain regions, the extent to which *Fos*+ neurons induced during associative learning correspond to a specific sensory representation is unknown. Here we generate high-quality brain-wide maps of *Fos* expression during auditory fear conditioning and recall, revealing 10-fold increases in *Fos*+ cells in a majority of 140 brain regions analyzed in fear conditioned mice. Contrary to the expectation that *Fos*+ neurons reveal specific sensory representations during learning, the brain-wide pattern of *Fos* expression following footshock alone recapitulates the pattern of brain-wide *Fos* expression seen following fear learning. The brain-wide pattern of *Fos* expression following fear recall is highly similar to that following fear conditioning, with no specificity for auditory areas. Our data suggest that *Fos* expression in sensory cortex and many other brain areas marks neuronal ensembles that represent distinct emotional states rather than specific sensory associations.

Title: Diffuse traumatic brain injury enhances fear learning and dynamically alters processing within the auditory fear circuit

Authors: *A. N. HOFFMAN[1,2,3], J. LAM[1], Y. CAI[2], D. A. HOVDA[2,3,4], C. C. GIZA[2,3,5], M. S. FANSELOW[1,6];
[1]Psychology, [2]Neurosurgery, Brain Injury Res. Ctr., [3]Steve Tisch BrainSPORT Program, [4]Med. and Mol. Pharmacol., [5]Mattel Children's Hosp., [6]Psychiatry and Behavioral Sci., UCLA, Los Angeles, CA

Abstract: Traumatic brain injury (TBI) is labeled the signature injury of troops in recent combat operations, a population often exposed to stressful stimuli and emotional trauma. While TBI is typically known to impair learning and memory for neutral events, traumatic fear memories are enhanced after TBI, consistent with increased prevalence of comorbid TBI and post-traumatic stress disorder (PTSD) and other affective conditions such as general anxiety and depression. Changes in sensitivity to sensory stimuli are common after TBI, and might influence the encoding of traumatic events. Our lab has shown enhanced contextual fear after lateral fluid percussion injury (LFPI) when fear conditioned after injury with white noise (WN) cues, but not low frequency tones, paired with footshocks. Altered sensitivity to noise cues paired with footshocks might underlie overall enhanced contextual fear after injury. Therefore, we hypothesized that LFPI enhances contextual fear to WN-signaled conditioning due to injury-induced altered auditory processing. To determine how WN alone affects behavior after LFPI, injured and sham adult male rats were pre-exposed to WN stimuli (75dB) prior to fear

conditioning and subsequently tested for contextual and cued fear. Interestingly, LFPI rats showed significantly elevated freezing to both the WN and context during the pre-exposure session, as well as to the context after cued conditioning. We then investigated whether WN alone after LFPI alters functional activity and astrocyte reactivity within the well-defined auditory fear circuit including the lateral amygdala (LA), auditory thalamus (MGN), and auditory cortex (A1) as well as the dorsal dentate gyrus (DG) of the hippocampus by using Arc immediate early gene and GFAP immunohistochemistry. Data showed that noise-exposed LFPI rats had significantly elevated Arc induction in the ipsilateral LA, which is known as the sensory interface of the amygdala in fear conditioning. In contrast to the LA, Arc expression was reduced in ipsilateral A1 and DG in LFPI groups. Furthermore, GFAP expression was significantly greater in LFPI groups in the LA, A1, and MGN, with the greatest increases ipsilateral to the injury. These data provide implications for altered sensory processing after TBI, where otherwise neutral stimuli may adopt aversive properties and impact encoding of traumatic memories and contribute to adverse effects on psychological health and affective comorbidities.

Title: Lesions of the ventromedial prefrontal cortex reduce stress enhanced fear learning in a stimulus specific manner

Authors: *Z. T. PENNINGTON[1], A. S. ANDERSON[1], M. S. FANSELOW[2];
[1]Psychology, [2]Psychology and Psychiatry, UCLA, Los Angeles, CA

Abstract: Post-traumatic stress disorder is associated with both sensitization of stress systems and reductions in the volume and activity of the ventromedial prefrontal cortex (vmPFC). In order to address the causal contribution of the vmPFC to the sensitization of stress systems following traumatic stress, we assessed the impact of pre-training vmPFC lesions on two variations of a model designed to examine how acute traumatic episodes enhance subsequent

reactivity and learning about stressors. In Experiment 1, animals were given either 0 or 15 shocks during a 90-minute session in a distinct environment (Context A). After fear of Context A was assessed, all animals were given a single auditory startle stimulus in a novel environment (Context B), and fear of Context B was then examined. Animals shocked in Context A showed enhanced freezing in Context B following startle exposure relative to animals that had not been shocked, evidence of enhanced fear learning. Lesioned animals did not differ from controls with respect to shock reactivity or freezing in Context A. Additionally, they did not differ in their startle responses. However, lesioned animals that had received shock showed reduced fear relative to controls in Context B following startle exposure. This data is indicative of a counterintuitive reduction in stress sensitization by lesions of the vmPFC. As our laboratory has previously shown that vmPFC lesions can reduce contextual conditioning, Experiment 2 was carried out to assess the stimulus specificity of the observed effect. Animals were again given 0 or 15 shocks during a single 90-minute session (Context A). Subsequently, they received a single tone-shock pairing in a novel context (Context B), and fear of the tone-shock context, as well as the tone itself, was assessed. Here, although animals initially receiving 15 shocks froze more to both the tone-shock context and the tone alone, lesioned animals did not differ from controls. These data suggest that lesions of the vmPFC may selectively contribute to enhanced learning about contextual stimuli paired with an aversive event following acute traumatic stress.

Title: Genetically encoding an *In vivo* tag of synaptic plasticity associated with memory

Authors: *D. B. WEATHERILL[1], R. TANNA[2], K. C. MARTIN[3], S. CHATTARJI[4], M. S. FANSELOW[1];
[1]Psychology, [2]Ecology & Evolutionary Biol., [3]Biol. Chem., UCLA, Los Angeles, CA;
[4]Neurobio., Natl. Ctr. For Biol. Sci., Bangalore, India

Abstract: Due to the complexity of the mammalian brain, it has proven challenging to identify key sites of synaptic plasticity associated with memory in mammals. An approach to doing so would allow these sites to be probed for a causal role in memory recall. In recent years, several

groups have developed genetically-encoded methods for identifying neurons in rodents whose activity is involved in memory recall. However, such methods still leave open the question: at what site(s) within these neurons forming the neural circuit representing a memory is the memory actually stored? To address this question, we have developed a genetically-encoded method for selectively stabilizing an *in vivo* TimeSTAMP tag during a specified time window only at rodent synapses that have undergone synaptic plasticity. The TimeSTAMP tag consists of the fluorescent protein, mVenus, with a Hepatitis C Virus (HCV) NS3 protease flanked by two NS3-protease-specific cleavage sites fused between two structural domains of the fluorescent protein. We have shown that treatment with the HCV-NS3-specific protease inhibitor, asunaprevir, inhibits cleavage of the TimeSTAMP tag when fused to the synaptically-localized protein CaMKIIα. Inhibition of this cleavage allows the tag on newly synthesized TimeSTAMP fusion proteins to fold into a functional fluorescent protein. Moreover, in human embryonic kidney 293T cells, asunaprevir-induced stabilization/fluorescence of the TimeSTAMP tag can be completely blocked through co-expression of a fusion protein consisting of a drug-insensitive form of the HCV NS3 protease fused to the synapto-nuclear messenger protein, CRTC1. In neurons, as CRTC1 translocates away from activated synapses to the nucleus, fluorescent TimeSTAMP-tagged CaMKIIα should be restricted not only to the time window of asunaprevir treatment but also to synapses that have undergone synaptic plasticity. Following validation of this method in cultured neurons, it will be used *in vivo* to examine how auditory fear conditioning memory traces differ following weak versus strong training protocols.

Title: Incubation of Pavlovian fear responding: behavioral and neural correlates of recent and remote memory using between- and within-subject designs

Authors: *N. ODYNOCKI, P. R. ZAMBETTI, A. M. POULOS;
Psychology, Univ. At Albany State Univ. of New York, Albany, NY

Abstract: Pavlovian contextual fear conditioning in mice has often been used to model the neuro-behavioral basis of post-traumatic stress disorder. We have previously shown in rats that under specific conditioning parameters contextual fear responding is elevated between groups tested at remote versus recent retention intervals. This heightened fear at more remote retention intervals has been attributed to the notion that aversive memories can "incubate" across time [1, 2, 3]. Given this, very little is known about whether individual rodent subjects directly exhibit fear incubation across repeated testing. In our current work utilizing adult male C57BL/6J mice, we have replicated prior between-subject findings and added a within-subjects design as an alternative relevant model for PTSD and have begun exploring its neural basis. In the within-subjects design, mice were tested at both 3 and 28 days following conditioning time to assess context fear expression during remote retention interval after having been tested at a recent retention interval. Results initially revealed that within-subjects maintained a constant level of fear across time, contrasting with the incubation observed in the between-subjects design. Upon further investigation, individual differences in fear expression were apparent as some mice displayed increased levels of fear expression, while others exhibited reduced or stable fear expression across time. This finding complements the variable development of PTSD observed in humans. Furthermore, we examined the expression of immediate early gene product, c-Fos protein and the glutamate decarboxylase 2 gene product GAD65 protein in brain areas associated with contextual fear memory such as the basolateral amygdalar nucleus anterior part [4], lateral amygdalar, dorsal hippocampus, and prefrontal cortical areas. These analyses reveal differential levels of activation across groups. [1] Diven K. Title: Neural tract tracing-based modeling of contextual fear circuits across development in rats

Authors: *A. J. SANTARELLI[1], K. N. NEGISHI[2], A. M. KHAN[2], A. M. POULOS[1];
[1]The State Univ. of New York At Albany, Albany, NY; [2]Univ. of Texas at El Paso, El Paso, TX

Abstract: Throughout development, mammalian species interact with their environment in ways that best facilitate survival. In adult mammals, both learning and responding to environmental threat are dependent upon the neural activity of the *basolateral amygdalar nucleus* (nomenclature: BLA; Swanson LW;[1]) and its corresponding afferents and efferents. We have recently identified that behavioral measures of contextual fear responding and the underlying BLA-based neural circuits differ at key development periods in the rat. Given these developmental changes, we predict that fear expression recruits the activation of distinct cortical pathways across development. To test this prediction, we infused a retrograde tracer into the BLA of male rats at postnatal day (PND) 19, 24, 35 and 90. The subjects were then exposed to a single-trial fear conditioning procedure and fear retrieval was assessed one day later. The immediate early gene product, c-Fos protein, was immunocytochemically detected and quantified throughout regions within the contextual fear circuit linked with BLA-projecting afferents. These functional connectivity data were analyzed using both principal components and stepwise regression techniques to determine the variability in freezing and BLA activity accounted for by each upstream region within the circuit. We then constrained the analysis based upon afferent activity to develop a model of fear retrieval that is consistent with the literature in adults but is novel among animals throughout PND 19, 24, and 35. We tested our model using a discriminant function analysis to predict age group membership based upon assigned weights of regions in the circuit. The analysis revealed that during the developmental emergence of fear retrieval the *lateral entorhinal area* provides the main cortical control for freezing; however, in older animals, this control shifts to the *prelimbic area*. Taken together, these data reveal age-dependent differences in the circuit regulating contextual fear retrieval. [1] Swanson LW. *Brain Maps: Structure of the Rat Brain*, 3rd ed. 2004; Elsevier

Title: Mapping time - dependent contextual processing and immediate early gene expression in hippocampal and extra - hippocampal regions in C57Bl/6J mice

Authors: *L. M. COLON, T. WINSTON, A. POULOS;
Psychology- Behavior Neurosci., Univ. At Albany State Univ. of New York, Albany, NY

Abstract: Contextual learning of fear requires a sufficient opportunity to encode the surrounding environment prior to the occurrence of an aversive footshock. It has been previously shown that this relationship between the lengths of time spent in the context prior to shock mediates level of context fear learning [1]. Numerous studies in both rat and mouse have demonstrated a vital role of the dorsal hippocampus in contextual learning [2, 3]. We sought to further examine this relationship between neural activity of hippocampal and extra-hippocampal circuits and the ability to successfully encode the conditioning context. In this study we mapped the expression of immediate early genes throughout dorsal and ventral hippocampus [4] as well as the basolateral amygdalar anterior and posterior part and the lateral entorhinal area [5] under varying placement-to-shock intervals in C57Bl/6J mice. Our preliminary results indicate increased patterns of immediate early gene expression throughout hippocampal and extra- hippocampal regions correspond with increased context exposure prior to footshock delivery.

Title: Hemodynamic changes in frontoparietal networks predict electrocortical population activity in visual cortex during aversive conditioning

Authors: *N. M. PETRO[1], L. F. GRUSS[2], S. YIN[3], H. HUANG[3], V. MISKOVIC[4], M. DING[3], A. KEIL[2];

Abstract: Visual stimuli predicting threat facilitate perceptual biases and visual cortical responses are amplified relative to neutral stimuli. Selective visuocortical amplification of threat cues accompanying these perceptual biases has been demonstrated in multiple previous studies, but the mechanisms mediating these changes are not known. The current project aimed to identify large-scale neural networks functionally related to modulating visuocortical activity during aversive conditioning. Functional MRI, EEG, and electrocardiography were recorded simultaneously during a classical conditioning paradigm in which the orientation of grating stimuli (i.e. the conditioned stimulus, CS) predicted the presence (CS+) or absence (CS-) of a cutaneous electric shock (i.e. the unconditioned stimulus, US). Phase reversal of the gratings elicited a steady-state visual evoked potential (ssVEP) measured by the EEG, which is a strong measure of stimulus evoked visuocortical activity highly resilient to noise. Single-trial estimates of the ssVEP were used to build predictive models for the concurrently recorded whole-brain blood-oxygen-level dependent (BOLD) activity. CS+ relative to CS- trials during US pairing were associated with increased ssVEP amplitude, greater heart rate deceleration, and greater BOLD activation in primary visual, anterior insular, and temporal cortices bilaterally. Modeling BOLD activity using the single-trial ssVEP indices demonstrated specific BOLD-ssVEP coupling in primary and extended visual cortex over all trials, and CS+ relative to CS- specific activation in the calcarine, left inferior parietal, and bilateral dorsolateral prefrontal cortices. These results suggest that anterior extra-visual cortical areas are functionally related to amplified visuocortical responses during aversive conditioning. Future analyses may investigate the functional relation between these structures, including whether their conditional amplification occurs in a specific temporal sequence.

Title: Fear conditioning of social stimuli at proximal and distant locations in an immersive virtual reality environment

Authors: *G. KASTRATI, J. ROSÉN, S. HULTBERG, F. AHS;
Uppsala Univ., Uppsala, Sweden

Abstract: It is well established that intrusion of the near space surrounding the body by others increases autonomic activity and defensive behaviors. The role that spatial proximity plays in fear memory formation and extinction is however not well understood. We here tested whether fear conditioning of virtual characters displayed at near location in an immersive virtual reality environment was enhanced relative to fear conditioning of geometrical objects of different colors. One character or object was always displayed at a proximal egocentric location while being followed by the delivery of a mild electric shock (Proximal CS+), whereas another character or object was conditioned at a distant egocentric location (Distant CS+). Two distance matched control stimuli were never paired with shock (Proximal CS-, Distant CS-). Skin conductance responses (SCRs) served as conditioning index. Results showed that proximal characters elicited greater SCRs than proximal objects during a habituation phase prior to conditioning. During fear conditioning, CS differentiation was lesser to proximal relative to distant CSs due to enhanced responding to the Proximal CS-. However, fear acquisition was similar to social and inanimate CSs. During extinction, SCRs were consistently greater to proximal than to distant CSs, but the SCR difference between CS+ and CS did not differ as a function of location. These results suggest that safety learning is slowed within personal space. A reason for this might be enhanced generalization of fear to threats near the body, irrespective of whether the stimuli are social or non-social.

Title: Remote but not recent pre-exposure increases generalization of fear learning in humans.

Authors: *B. D. YETTON[1], D. J. CAI[3], S. C. MEDNICK[2];
[1]Psychology, [2]Univ. Of California, Riverside, Riverside, CA; [3]Neurosci., Univ. Of California, Los Angeles, Los Angeles, CA

Abstract: Fear conditioning to a specific stimuli is stronger when an animal has been pre-exposed to the stimuli compared to when it is novel (Lubow, 1989). This pre-exposure may increase fear conditioning by forming a more robust representation of the stimuli to which fear can be associated (Rudy & O'Reilly, 1999). However, the timing of the pre-exposure moderates these effects (Kiernan & Westbrook, 1993). Rodents pre-exposed to a context either 1 day or 36 days before fear conditioning lead to greater fear response at test, and generalized to freezing in a novel, non-shocked context with longer delays (Wiltgen & Silva, 2007). Here, in humans, we investigate the effects of pre-exposure on the generalization of cued (as opposed to contextual) associated fear conditioning. 27 undergraduates (15 female, 18 years mean age) viewed 60 images from two categories (possible categories were animals, plants or tools) for 4 seconds (CS). Electric shock (US) was paired with one 80% of the images from one category at image offset, the other category received no shock (CS-). Subjects were pre-exposed for 15 minutes to CS+ stimuli either 1 or 8 days earlier. We hypothesized greater generalization of fear in the 8 day delay such that examples from the non-shocked, CS- category would elicit a stronger fear response. Using a composite of 2 convergent fear response quantification techniques (sound-evoked blink response and image-evoked skin conductance response), we find greater fear response to the non-shocked CS- items in the 8 day delay compared to the 1 day delay (independent samples t-test, $t=2.58$, $df=27$, $p<.05$). Additionally, fear levels are more robust (less variable) in the 1 day condition (1 day SD=0.32, 8 day SD=0.56), hinting at individual differences in the effects of pre-exposure at longer delays. Our results are of clinically relevance when considering the role of fear generalization in anxiety disorders (Dymond, Dunsmoor, Vervliet, Roche, & Hermans, 2015). A further non-pre-exposed control condition must be run to quantify the magnitude of the pre-exposure effect on fear conditioning.

Title: Role of the Neuropeptide Y Y1 receptor antagonist, BIBP 3226 on NPY induced resilience in socially defeated Syrian hamsters

Authors: *K. KENNIEL[1,3], T. LACEY[2], R. KINGSTON[4], C. M. MARKHAM[3];

Abstract: Our lab utilizes an ethologically relevant model of social stress whereby defeated Syrian hamsters exhibit long lasting changes in behaviors, including increased submissiveness and a complete lack of territorial aggression, even when paired with a smaller, non-aggressive intruder (NAI). A small subset of hamsters, however, appears to be resilient to the effects of social defeat stress. Recent studies have suggested that neuropeptide Y (NPY), a widely distributed, 36-amino acid peptide, may function to reduce the effects of traumatic stress in a variety of animal models. We previously demonstrated that intracerebroventricular (icv) infusion of NPY induced a state of resilience in socially defeated hamsters by reducing submissive behaviors. The goal of the present study was to determine whether this effect is mediated by the NPY Y1 receptor. Hamsters were unilaterlly implanted with guide cannula aimed at the lateral ventricles. Following recovery, they were pretreated with the NPY Y1 receptor antagonist BIBP 3226 followed by an infusion of NPY. Results show that pretreatment with BIBP 3226 reversed the resilience inducing effects of NPY as indicated by a re-ermergence of submissive behaviors. These results provide support for the hypothesis that the resilience inducing effects of NPY in socially defeated hamsters is mediated, at least in part, by the NPY Y1 receptor.

Title: The effects of exercise on resilience to social defeat stress in syrian hamsters

Authors: *C. M. MARKHAM[1,3], R. KINGSTON[2], J. BEST[3], M. EDWARDS[1];
[1]Psychology, [2]Biol., Morehouse Col., Atlanta, GA; [3]Biol., Spelman Col., Atlanta, GA

Abstract: Our lab utilizes an ethologically relevant model of social stress whereby defeated Syrian hamsters exhibit long lasting changes in behaviors, including increased submissiveness and a complete lack of territorial aggression, even when paired with a smaller, non-aggressive intruder (NAI). A small subset of hamsters, however, appears to be resilient to the effects of social defeat stress. Recent studies have suggested that voluntary exercise may promote resilience to a variety of stressors, including electric shock and chronic variable stress. However, no studies to date have examined the role of ethologically relevant stress on resilience. The aim of the present study was to determine whether voluntary exercise in the form of free access to a running wheel can inhibit the effects of social defeat in Syrian hamsters. Socially defeated hamsters were divided into the exercise (EX) or no-exercise (NEX) groups. Two weeks later, they were socially defeated and tested with a NAI. Our data indicate that hamsters in the EX group exhibited significantly lower levels of submissive behaviors compared to the NEX group, indicating that voluntary exercise promoted resilience to social defeat stress.

Title: Fear conditioning increases GABA release from cerebellar stellate cells

Authors: *C. DUBOIS, S.-Q. LIU;
Dept. of Cell Biol. and Anat., LSUHSC, New Orleans, LA

Abstract: Post-Traumatic Stress Disorder (PTSD) is one of the most common psychiatric disorders and is associated with an increased risk of major depression, panic disorder and generalized anxiety disorder. One of the characteristics of PTSD is generalization of conditioned fear. It is thus important to understand the synaptic mechanisms underlying associative fear learning. The cerebellum is critical for fear memory consolidation and fear conditioning increases GABAergic transmission onto Purkinje cells, the sole output of the cerebellar cortex. Because inhibitory interneurons in the cerebellar molecular layer also innervate each other, we hypothesized that fear conditioning enhances inhibitory neurotransmission between interneurons and changes the activity of the interneuronal network. This is expected to alter the balance between excitatory and inhibitory inputs to Purkinje cells and thus information processing in the cerebellar cortex.

The conditioning paradigm consisted of 8 pairings of a 10 s tone (CS) which co-terminated with a 1 s foot-shock (US). Control groups included naïve mice never exposed to the CS or the US, and mice exposed to the US and CS 30 min apart (unpaired group). GABA release was evaluated by recording inhibitory postsynaptic currents (IPSCs) in stellate cells 15 h after the conditioning paradigm.

We found that the amplitude of evoked IPSCs (eIPSCs) was increased after fear learning indicating an enhanced inhibitory transmission. The paired pulse ratio of eIPSCs was decreased, which indicated a presynaptic effect. Spontaneous IPSCs frequency was consistently increased after fear conditioning without any change in amplitude. Furthermore, TTX-insensitive IPSC frequency, but not amplitude, was increased after conditioning suggesting that GABA release from stellate cells was potentiated by fear learning. Finally, the paired pulse ratio and amplitude of eIPSCs was not modified by the unpaired protocol. Spontaneous and miniature IPSCs frequencies were also not different from naïve animals. Together these results indicate that the stress induced by the conditioning was not responsible for the increase in GABA release from stellate cells.

We conclude that GABA release from cerebellar stellate cells is increased after associative fear conditioning but not stress alone. This suggests an important role of inhibitory neurotransmission in the consolidation of associative fear memory.

Title: Sex-specific modulation of trace fear acquisition by pituitary adenylate cyclase activating-polypeptide signaling in the medial prefrontal cortex.

Authors: *A. J. KIRRY, M. R. HERBST, S. E. POIRIER, R. C. TWINING, M. R. GILMARTIN;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Women are more than twice as likely as men to develop post-traumatic stress disorder (PTSD), yet the neurobiological basis of this sex difference is unknown. Recently, pituitary adenylate cyclase activating-polypeptide (PACAP) signaling has been implicated in PTSD in females: a single nucleotide polymorphism in the gene encoding the PACAP type-1 receptor (PAC1R) is associated with PTSD symptom severity in women but not men (Ressler et al., 2011). PACAP is a highly conserved peptide important for mediating adaptive stress responses, and dysregulation of PACAP may contribute to maladaptive stress in PTSD. Additionally, aberrant PACAP signaling may contribute to PTSD through modulation of emotional learning. The PAC1R genetic polymorphism is associated with increased reactivity of fear circuitry to threat-related cues and impaired discrimination of threat and safety cues (Ressler et al., 2011, Stevens et al., 2014). Very little is known about how PACAP signaling normally participates in learning and memory, and previous work has focused primarily on male subjects. Here we examined the contribution of PACAP signaling in the prefrontal cortex of female and male rats to the acquisition of trace fear conditioning, an associative learning paradigm that requires the prefrontal cortex, hippocampus, and amygdala - memory structures which are also implicated in PTSD. Given that the medial prefrontal cortex (mPFC) mediates the effects of acute stress on learning selectively in females (Maeng et al., 2013), PACAP signaling in this region may be particularly relevant for fear learning in females. Adult Long-Evans rats were implanted with bilateral cannulas in the prelimbic area of the mPFC. Rats received injections of the PAC1R antagonist PACAP 6-38 (1, 2, or 3 mM, 0.5uL) into the prelimbic mPFC prior to trace conditioning in which a white noise conditional stimulus (CS) was paired with a foot shock unconditional stimulus (UCS) delivered after a 20-sec stimulus free trace interval. Rats were tested drug-free the following day to assess learned fear to the CS and the training context. We found that blocking PAC1R signaling in the prelimbic mPFC during training impaired the

formation of memory to the CS, but not context, in females, but not males, and the data suggest the influence of individual differences in the modulation of learning by PACAP. Prelimbic PACAP 6-38 did not impair performance in a delayed alternation working memory task, suggesting that prefrontal PACAP may selectively modulate prefrontal-dependent emotional learning. These results provide support for a sex-specific role of PACAP signaling within the prefrontal cortex in emotional memory formation.

Title: Neural dynamics of fear conditioning

Authors: *S. YIN[1], Y. LIU[3], A. KEIL[2], M. DING[1];
[1]Biomed. Engin., [2]Dept. of Psychology, Univ. of Florida, Gainesville, FL; [3]Univ. of California, Davis, Davis, CA

Abstract: Work in the rodent models of fear conditioning has demonstrated the importance of the amygdaloid complex in mediating defensive responses to conditioned threat cues. In human imaging studies of aversive conditioning, however, activation of the amygdala is often not observed. In addition, roles of such brain structures as dACC and insula in fear learning remain not well-understood. We recorded simultaneous EEG-fMRI data from 18 subjects during a classical differential fear conditioning paradigm. Two Gabor patches (45° and 135°) were used as conditioned stimuli (CSs). One Gabor patch, the CS+, was occasionally paired with an aversive human scream (US; 25% reinforcement rate), whereas the other Gabor patch, the CS-, was never paired with the US. Single-trial BOLD responses to CS+unpaired and CS- were estimated using the beta-series method in three ROIs: amygdala, insula, and dACC. Representational dissimilarity matrix (RDM) was computed for each ROI using a moving window approach. We report the following results. First, activities in the three ROIs significantly declined over the course of the conditioning session, suggesting habituation. Second, the extent of activity decline in the amygdala, but not in the dACC and insula, predicted behavioral changes assessed by heart rate. Third, concomitant with the BOLD activity decline, representational

dissimilarity also declined significantly, suggesting reduced distinctiveness of the two cues in their evoked multivoxel patterns. We further analyze and report changes in EEG patterns and correlate these changes to the concurrently recorded BOLD to assess their anatomical underpinning.

Title: Virtual burrow assay for measuring aversion to conditioned stimuli

Authors: ***C. E. SCHOONOVER**, A. J. P. FINK, R. AXEL;
Neurosci., Columbia Univ., New York, NY

Abstract: Traditional assays of aversive classical conditioning often rely upon measures of behavioral phenomena that play out over many seconds, such as time spent freezing or avoidance of a conditioned stimulus. These quantities are difficult to relate to the neuronal events that govern them, which unfold on a timescale of milliseconds. We have developed an assay with the aim of detecting behavioral transitions at a temporal resolution that permits comparison with neuronal processing. The Virtual Burrow Assay (VBA) is designed to simulate the naturalistic scenario in which a mouse at the threshold of its burrow continuously evaluates whether or not to retreat to safety. It consists of a light enclosure (virtual burrow) affixed to a frictionless rail that a head-fixed mouse can displace along its body's anterior-posterior axis. A laser displacement sensor tracks the position of the burrow, yielding a continuous one-dimensional variable. This allows determination of when an animal retreats in response to a given stimulus, pulling the enclosure around its body ("ingress"). Following classical conditioning, in which a CS+ odorant is paired with foot-shock and a CS- odorant is not, mice ingress in response to the CS+ alone, a behavior that extinguishes after repeated presentation. The VBA thus affords single-trial determination of whether a given stimulus evokes an aversive response and resolves the precise timing of ingress, permitting examination of the neuronal state that precedes this behavioral transition. The assay likely accommodates modalities other than olfaction and is compatible with

standard electrophysiological and optical methods for measuring and perturbing neuronal activity.

Title: Parametric characterization of a novel one way active avoidance learning on a treadmill using head fixed mice

Authors: ***H. JIE**[1], T. GEILLER[3], S. ROYER[3], J.-S. CHOI[2];
[1]Korea Univ., Seoul-City, Korea, Republic of; [2]Korea Univ., Seoul, Korea, Republic of; [3]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Avoidance is a key diagnostic criterion for fear-related disorders. Here we developed a one-way active avoidance (OWAA) learning using head-fixed mice on a treadmill (modified from Royer et al., 2012). In Exp1, effect of auditory vs. visual conditioned stimulus (CS) on OWAA learning was tested using either a visual (LED, 20 lux) or an auditory (1 kHz, 90 dB) stimulus that preceded the upcoming air puff (0.1 mPa, 4.6 L/m, via 3 mm nozzle) unconditioned stimulus (US). The US was avoidable by walking forward (criterion: 2 cm) or stopping (criterion: 5 s) to the CS, depending on the paradigm (Go or No-go, respectively). Animals ran on a treadmill 40 minutes a day for 1 to 3 days, and then were given 3 to 10 CS-only trials as a habituation. Training consisted of 30 trials per day, for two consecutive days. The CS lasted a maximum of 15 s, and the US was presented after 10 s of the CS onset time. The US lasted a maximum of 5 s. In each sensory modality, animals were divided into two training groups; Go or No-go. When the visual CS was used, the avoidance rate of No-go group (n=11) was significantly higher than that of Go group (n=11, $F[1,20] = 6.590$, $p < .05$). When the auditory CS was used, the avoidance rate of the No-go group (n=10) was also significantly higher than that of Go group (n=10, $F[1,18] = 5.694$, $p < .05$). In addition, when we analyzed rate of change of avoidance, the visual CS group was significantly higher than the auditory CS group ($F[1,19] = 4.812$, $p < .05$). To find out whether the location of visual stimulus could change the OWAA learning, we conducted Exp 2. We manipulated location of the visual CS along the midsagittal line of the mouse head, dividing it into two different angles while maintaining the distance equal; 20°, 70°. The experimental procedure was identical to Exp 1 except criterion (10 cm in Exp 2) to

make the task difficult. The avoidance rate was higher for the 70° group (n=5) than the 20° group (n=4, $F[1,7] = 11.866$, $p < .05$). Taken together, these results suggest that the visual stimulus could induce acquisition of OWAA learning easily than the auditory stimulus when the location was controlled precisely, unlike previous studies that visual stimulus was presented at ceiling of chamber. These results indicate that not only CS modality but also spatial location of stimulus is important to learn OWAA in mice.

Title: Behavioral correlates of neuronal allocation in auditory fear conditioning

Authors: *J. L. STRAIGHT, C. MCINTYRE;
Behavioral and Brain Sci., Univ. of Texas At Dallas, Dallas, TX

Abstract: One proposed mechanism for linking related memories is their allocation to overlapping ensembles of neurons throughout the brain. Recent studies suggest that transient, experience-dependent increases in cellular excitability may provide a mechanism to link memories that are qualitatively and temporally connected. Rats exposed to a novel context one hour before weak inhibitory avoidance (IA) training develop robust long-term memories. This enhancement has been attributed to synaptic tagging and capture, by which plasticity-related proteins generated in response to the novel context help strengthen the weak IA memory. Interestingly, novel context exposure less than one hour before weak IA training does not promote long-term memory formation. These findings have been replicated using several learning tasks, but the temporal dynamics by which novelty affects neuronal allocation in aversive memory formation are not fully understood. We exposed rats to a novel context and tone 30min or 5min before auditory fear conditioning (AFC) to a different context and tone. One day later, rats were given retrieval tests for both experiences and freezing was measured. Here, we show that novel context and tone exposure 5min, but not 30min, prior to AFC enhances learning. This observation suggests that neuronal allocation may be altered in the 30min condition. To test this hypothesis, we will use *Arc* catFISH to examine the relationship between neuronal ensembles activated by both retrieval tests. Our results add to the behavioral tagging literature and suggest that neuronal allocation is dynamically regulated following exposure to novelty.

Title: The role of acid sensing ion channel 1A in Pavlovian reward learning

Authors: ***A. GHOBBEH**[1], S. ALAM[1], R. J. TAUGHER[1], R. FAN[1], R. T. LALUMIERE[2], J. A. WEMMIE[1];
[1]Psychiatry, [2]Psychological and Brain Sci., The Univ. of Iowa, Iowa City, IA

Abstract: Acid Sensing Ion Channel 1A (ASIC1A) contributes to synaptic transmission and plasticity, is abundant in the amygdala, and is required for Pavlovian fear conditioning. ASIC1A is also abundant in the nucleus accumbens (NAc) and recent studies suggest that ASIC1A in the NAc plays a role in addiction-related behaviors to cocaine and morphine. Because the nucleus accumbens is known to be critical for other reward-related behaviors including Pavlovian conditioning to rewards, we hypothesized that ASIC1A might contribute to reward-related learning and memory in general. We therefore tested multiple non-drug rewards utilizing a Pavlovian conditioning paradigm to explore the possible involvement of ASIC1A in reward-related learning and memory. We found Pavlovian reward conditioning to be intact in *Asic1a*$^{-/-}$ mice, relative to *Asic1a*$^{+/+}$ controls. These data suggest that despite a role in Pavlovian fear conditioning and effects on addiction-related behaviors to cocaine and morphine, ASIC1A disruption has little or no effect on Pavlovian reward learning to non-drug rewards. Together these data suggest that the role of ASIC1A in reward-motivated behaviors may be specific to drugs of abuse.

Title: Lateral habenular-projecting hypothalamic neurons regulate food preference in rats

Authors: *R. M. O'CONNOR, P. J. KENNY;
Icahn Sch. of Medicine, Mount Sinai, New York, NY

Abstract: Rates of obesity are on the rise worldwide, resulting in a growing threat to public health. Pharmacotherapies that safely reduce body weight in obesity remain elusive, partially due to our incomplete knowledge of the complex neuronal mechanisms that control food choice (palatable high-calorie versus less palatable low-calorie food). The lateral hypothalamus (LH) is considered a critical node in the maintenance of energy homeostasis. The development of obesity in rats is associated with a deficit in LH sensitivity to rewarding stimuli and a switch in preference towards palatable calorically dense food items. The habenula is a distinct set of nuclei linking forebrain and midbrain structures and is divided into two principal parts termed the medial habenula (MHb) lateral habenula (LHb). The LHb has been described as a "preference center" that exerts negative influence over motivated behaviors by inhibiting midbrain dopamine neurons. A major input to LHb originates from LH, providing a mechanism by which metabolic status can be transmitted to habenular neurons involved in regulating motivated behavior and preference. Here, we tested the hypothesis that LH projections to LHb may regulate alterations in the motivational value of food and food preference that emerge during the development of obesity. To target the LHb-LH pathway in rats, we delivered a retrograde AAV2/5-Cre-eYFP virus into LHb and cre-inducible "excitatory" (hM3Dq) DREADD into LH, thereby placing the LH-LHb pathway under experimenter control. We found stimulation of this pathway increased the motivational value of standard food pellets in rats, as measured by increased willingness to respond for food rewards. Conversely, ablation of this pathway, accomplished using Cre-inducible diphtheria toxin (DTA), decreased the motivational value of standard food pellets. Interestingly, DREADD-mediated stimulation of the LH-LHb pathway decreased consumption of palatable energy-dense food, whereas ablation of this pathway increases consumption of the palatable food; opposite effects of these manipulations were observed when only standard (less palatable) chow was made available. These data suggest that the LH-LHb system plays an important role in regulating the motivational value of, and preference for, palatable food. As such, the LH-LHb pathway may represent an important target for therapeutic intervention in obesity.

Title: Lateral habenula orexin receptor-2 signaling controls aggression reward

Authors: *M. FLANIGAN[1], H. ALEYASIN[1], A. TAKAHASHI[1,2], E. S. CALIPARI[1], C. MENARD[1], M. PFAU[1], S. J. RUSSO[1];

Abstract: Elevated interpersonal aggression and violence are common symptoms of multiple psychiatric disorders and represent a significant global health issue that lacks both sufficient therapeutic strategies and satisfactory understanding of relevant neuropathologies. Recent neuroimaging studies in humans suggest that aggression in psychiatric patients may result, in part, from the inappropriate activation of reward circuitry in social contexts. The neuropeptide orexin, which is produced exclusively in the lateral hypothalamus (LH), has been implicated in a broad array of motivational behaviors, including conditioned responses to rewarding or aversive stimuli like drugs of abuse and social stress. In this study, we use in-situ hybridization, immunohistochemistry, qPCR, in-vivo viral-mediated gene transfer, and in-vivo calcium imaging (fiber photometry) to investigate the role of orexin-containing projections to the lateral habenula (lHb) in aggression and a model of aggression reward we deem aggression conditioned-place preference (CPP). Our results indicate that orexin-positive neurons are activated during aggression, and orexin release from terminals in the lHb increases aggression and aggression CPP through indirect inhibition of the lHb. This appears to occur via activation of OxR2 on GAD65-positive neurons in the lHb. The results of this study illustrate the importance of orexin in the rewarding properties of aggression and provide a previously undefined role for orexin signaling in the lHb.

Title: Neuroanatomical and electrophysiological studies of Gad2-expressing neurons in the lateral habenula

Authors: *A. W. WALKER, L. A. QUINA, G. R. MORTON, Y.-W. A. HSU, A. WEI, E. E. TURNER;
Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA

Abstract: Background/Objectives: The habenula is a paired nucleus in the epithalamus, comprised of medial and lateral subnuclei, both of which project to the midbrain and pontine tegmentum via the fasciculus retroflexus. Recently, we established that a subset of neurons in the lateral habenula (LHb) express Gad2, an enzyme of GABA synthesis, which distinguishes them from the medial habenula (MHb) and other adjacent brain nuclei. To date, the function of LHb output circuits is not well understood, as the only intensively studied target of the LHb is the rostromedial tegmental nucleus (RMTg). Therefore, the objectives of these studies are to characterize the anatomy and physiology of Gad2 neurons in the LHb and use Gad2 as a genetic tool to dissect and specifically manipulate pathways from the LHb. **Methods:** *In situ* hybridization and immunohistochemical techniques were used to identify expression of other markers in the LHb. To establish projection patterns from LHb Gad2 neurons, transgenic mice with an IRES-Cre expression cassette targeted to the Gad2 locus ($Gad2^{Cre}$ mice) were injected with a Cre-dependent adeno-associated virus (DIO-AAV-GFP) and efferent fibers were examined at all brain levels. Finally, $Gad2^{Cre}$ mice in combination with optogenetic and whole-cell patch clamp techniques were used to understand the physiology and function of LHb Gad2 output circuitry. **Results:** LHb Gad2 neurons do not contain Gad1 or Vgat (responsible for synaptic packaging of GABA) mRNA. Rather, expression of the vesicular glutamate transporter Vglut2 throughout the LHb suggests these neurons are glutamatergic. Electrophysiological studies will further elucidate the fast neurotransmitter(s) utilized by these neurons. Analysis of efferent fibers revealed that LHb Gad2 neurons contribute few if any projections to the RMTg-VTA pathway, but instead specifically innervate hindbrain regions including the dorsal raphe, median raphe, and adjacent nuclei. Genetic and electrophysiological approaches will be used to identify the neurochemical phenotype of postsynaptic neurons. **Conclusions:** These studies have identified a unique subset of neurons in the LHb that seem to synthesize GABA but have no obvious mechanism to package GABA for synaptic release. Instead, LHb expression of Vglut2

suggests these neurons may use glutamate as their primary neurotransmitter. Furthermore, virally-mediated tract-tracing of LHb Gad2 neurons revealed exclusive projections to the raphe, with minimal innervation of the RMTg. Therefore, $Gad2^{Cre}$ mice in combination with optogenetic strategies will allow for the dissection and manipulation of a novel, genetically defined LHb-hindbrain pathway.

Title: Hypothalamic and midbrain peptidergic-aminergic pathways modulate intrinsic GABAergic signaling in the lateral habenula: a study using *In vivo* juxtacellular labelling, retrograde tracing, IHC and confocal microscopy

Authors: *L. ZHANG[1], V. S. HERNANDEZ[1], L. E. EIDEN[2];
[1]Physiology/Medicine, Natl. Autonomous Univ. of Mexico, Mexico City, Mexico; [2]Sec Molec Neurosci,, NIMH-IRP, NIH, Bethesda, MD

Abstract: We have recently reported by in vivo juxtacellularly-labelled neuron morphology the presence of axons immunopositive for vGAT, and branching inside the LHb, particularly in the medio-central subnucleus of the lateral habenula (LHbMC) in rat. The role of these neurons in escape behavior during 'meta-stress coping' was also reported (Zhang et al, Frontiers Neural Circuit 2016). The presence of peptidergic/aminergic nerve terminals in this region, particularly to the GABAergic interneurons, is of great interest in understanding peptidergic/aminergic modulation of GABAergic transmission in the habenula. By using numerous antibodies and ISH probes, we found that several peptidergic pathways to habenula are highly sub-field specific. Vasopressin immunopositive fibers of hypothalamic origin are distributed in a highly selective manner in the medial subdivision of the LHb (LHbM). The fibers were grouped mainly in three subnuclei: the superior subnucleus (LHbMS), the central subnucleus (LHbMC), and the marginal

subnucleus (LHbMMg), and the highest density of VP+ fibers was observed inside the LHbMC. We also examined the expression of other relevant neurochemical markers of hypothalamic and midbrain origin: tyrosine hydroxylase (TH), dopamine beta hydroxylase (DBH), serotonin transporter (SerT), somatostatin (SOM), enkephalin (ENK), substance P (SP), vasoactive intestinal polipeptides (VIP), pituitary adenylate cyclase activating peptide (PACAP), calretinin (CR), calbindin (CB), as well as G protein-coupled inwardly-rectifying potassium channel 1 and 2 (GIRK1 and GIRK2). A strong overlap was observed within the LHbMC between VP and midbrain aminergic projections (immunoreactivity to TH and SerT, but not DBH). These results may indicate that: (1) the LHbMC is a key region modulated by subcortical aminergic pathway; and (2) VP innervation may contribute to the robustness of the modulatory mechanism for LHb function, which is also regulated by midbrain aminergic pathways. The region of strong immunostaining for SOM, CR, and CB was also similar to VP. The expressions of ENK, SP, and GIRK1 and GIRK2 were not similar to that of VP, particularly low in LHbMC. CB immunopositive somata were predominantly located in the LHbMC, and CB+ axons seemed to project to fasciculus retroflexus. These results suggest that the pathways involving in motivations and reward, such as the hypothalamic vasopressinergic and the midbrain catecholaminergic systems, may modulate the habenular intrinsic GABAergic signaling. Title: Stimulation-induced Fos-like immunoreactivity following electrolytic lesions of the dorsal diencephalic conduction system

Authors: ***M. FAKHOURY**, D. VOYER, D. LÉVESQUE, P.-P. ROMPRÉ;
Univ. of Montreal, Montreal, QC, Canada

Abstract: Intracranial self-stimulation (ICSS) holds a great promise in understanding the neural elements involved in reward and goal-directed behaviors, and offers a valuable tool for their anatomical mapping and functional characterization. We have previously shown that electrolytic lesions of the dorsal diencephalic conduction system (DDC) result in attenuations of the

rewarding effectiveness of ICSS within multiple brain regions, including the lateral hypothalamus (LH). The present work sought to extend these findings by describing the effect of a DDC lesion on the expression of the immediate early gene c-fos following LH stimulation. For this purpose, rats were implanted with monopolar electrodes and divided into three groups; the first two groups were trained to self-stimulate at the LH, whereas the third group received no stimulation and served as a control. Among the two groups that were trained for self-stimulation, one of them received a lesion at the DDC and was tested for ICSS on the subsequent 5 days. On the last day of testing, control rats were placed in operant chambers without receiving any stimulation, and the remaining rats were allowed to self-stimulate for 1h. All rats were then transcardially perfused and their brain collected for Fos-like immunoreactivity (FLIR). As previously shown, a lesion at the DDC resulted in significant attenuations of the rewarding effectiveness of LH stimulation. Results also show a higher FLIR in several reward-related areas following LH stimulation, especially in the hemisphere ipsilateral to the stimulation electrode. Compared to non-lesioned rats, animals that received a lesion had lower FLIR in certain brain regions, suggesting that those regions that were activated by the stimulation may be functionally interconnected with the DDC.

Title: A hypothalamic circuit controlling aggressive motivation and action

Authors: ***A. L. FALKNER**[1], R. TREMBLAY[1], I. SCHMITT[1], B. RUDY[1], M. HALASSA[1], D. LIN[2];
[1]Neurosci., [2]NYU Sch. of Med., New York, NY

Abstract: Social actions, like sex or aggression, may be preceded by a motivated internal state that promotes animals to seek out opportunities to perform these behaviors. While significant progress has been made indentifying neural substrates that are involved in social action, it has been more difficult to assess the neural mechanisms of these underlying motivated or seeking states. The hypothalamus, and in particular the ventromedial hypothalamus, ventrolateral area (VMHvl), now has an established role in intermale aggression. Stimulation of this area promotes

attack and neurons in this area are active during aggressive action. We have recently expanded the role of this area to be critical for flexible "proactive" aggression-seeking behavior. Using a social-operant task, where male mice can seek out brief and repeated attack opportunities, we find that single neurons in the VMHvl respond during this motivated seeking phase in addition to the social action phase, and changes in population activity recorded using fiber photometry track changes in task learning and extinction. Optogenetic stimulation of this area accelerates trial-to-trial response initiation latency, promoting changes in moment-to moment aggressive motivation. In addition, we find a new role for an anatomically segregated population of inhibitory neurons on the lateral edge of the VMHvl (the VMHvl "shell"). These neurons send strong direct inhibitory current to VMHvl neurons and population recording of these neurons shows that activity is decreased during aggressively motivated seeking behavior. Consistent with this, optogenetic inactivation of these GABAergic neurons is also sufficient to accelerate trial-to-trial aggression seeking behavior. Lastly, we used *in vivo* FRET photometry to detect changes in chloride concentration in the VMHvl during aggression seeking behavior and found that inhibition to this area is reduced during the motivated seeking phase. Together these data suggest that local hypothalamic inhibitory input to the VMHvl behaves as a permissive gate during aggression seeking behavior and the strength of this input is relaxed as animals prepare for and seek out future aggressive action.

Title: Elaboration of hypothalamic chemoarchitecture of the adult male rat: A high spatial resolution mapping study of melanin-concentrating hormone, hypocretin/orexin, and calbindin immunoreactivities in multiple subjects

Authors: ***C. D'ARCY**[1], A. MARTINEZ[2], L. F. ARANDA[2], H. F. L. CERVANTES[2], L. E. CHACON[2], R. P. CORDERO[2], V. FERNANDEZ[2], G. A. GARCIA[2], S. HOLGUIN[2], A. JAQUEZ[2], T. G. MIRAMONTES[2], B. MONTAÑO[2], P. C. MUÑOZ[2], I. R. VALENZUELA[2], J.

S. YU[2], A. M. KHAN[2];
[1]Biol. Sci., Univ. Texas El Paso, El Paso, TX; [2]Biol. Sciences, HHMI PERSIST Program: Brain Mapping & Connectomics Track, Univ. of Texas at El Paso, El Paso, TX

Abstract: The hypothalamus is an important brain structure for the integration of autonomic, neuroendocrine, and somatomotor function. The precise circuitry and neuronal populations underlying these functions; however, remain poorly resolved in terms of spatial organization. This study expands our previous report (SfN Chicago, 2015; poster #616.08) of the distribution and interactions of hypothalamic peptides and their mapped locations to the Swanson rat brain atlas (Brain Maps: Structure of the Rat Brain, 3rd ed., 2004).A cohort of freshmen undergraduates were recruited and taught formal atlas-mapping techniques within an HHMI-funded laboratory-based course: Brain Mapping & Connectomics. The distributions of hypocretin/orexin (H/O), melanin-concentrating hormone (MCH) and calbindin (CalB) were mapped from the brains of multiple animals in order to generate a canonical chemoarchitectural atlas of the adult male rat brain. H/O and MCH both play a role in feeding control and energy homeostasis, while calbindin helps buffer calcium ion concentration throughout the brain. Using the adjacent tissue series from animals used by the previous student cohort, we extended the chemoarchitectural atlas effort by staining for H/O, MCH, and CalB using triple-label immunofluorescence. The immunoreactivities for these peptides in the hypothalamus were imaged using wide-field high resolution microscopy and mapped to the Swanson atlas using the indexed Nissl-stained tissue series as a reference for cytoarchitectural analysis.Students completed comprehensive sets of maps that allowed for expression patterns of H/O, MCH and CalB to be compared across brains while assessing individual variability. When staining in the LHA, CalB and H/O were observed to co-localize in some neurons; however, not all H/O neurons are CalB-positive and not all CalB neurons are H/O-positive. Furthermore, MCH does not co-localize with either CalB or H/O. There were appositions suggesting putative synapses between CalB-positive neurons with both MCH and H/O fibers. In addition, H/O-ipositive fibers displayed a tendency to make appositions with MCH neurons. This work marks the continuation of chemoarchitectural mapping of rat hypothalamic peptides, their novel relationships, and the contribution of freshmen to map the brain as part of a teaching lab. The chemoarchitectural atlas under development here will aid in experimental design and data interpretation for investigators studying the functionality of the rat hypothalamus.

Title: Initial chemoarchitectural analysis of the infralimbic, prelimbic, and anterior cingulate areas of cerebral cortex in the adult male rat: Novel maps within a canonical atlas space

Authors: *K. NEGISHI[1], S. N. RODARTE[2], O. KOLENC[2], A. M. KHAN[2];
[1]UNIVERSITY OF TEXAS AT EL PASO, El Paso, TX; [2]Univ. of Texas at El Paso, El Paso, TX

Abstract: A cellular level structural account for "prefrontal" cortical functions is confounded, in part, by the sheer diversity of cortical neurons, which vary in their neurophysiological, connectional, spatial, morphological and neurochemical properties. These properties also vary across cortical regions and methodological constraints prevent their simultaneous examination. Here, we identify certain chemoarchitectural features of the rat *cingulate region* (CNG; Brodmann, 1909) using a Nissl-based approach, and map this chemoarchitecture in a canonical reference atlas space for the rat brain (Swanson, Brain Maps: Structure of the Rat Brain, 3rd ed; 2004).
Specifically, we performed immunohistochemical staining to label parvalbumin (P), somatostatin (S) and hypocretin/orexin (H/O) in coronal sections spanning Swanson atlas levels 8-11. Wide-field epifluorescence microscopy was used to visualize stained fibers and cell bodies within the anterior cingulate area (ACA), the prelimbic (PL) and the infralimbic area (ILA). Areal and laminar demarcations were assigned using an adjacent Nissl-stained series and the cytoarchitectonic criteria of the atlas. Precise mapping of cell bodies and fibers was achieved by overlaying the Nissl-derived boundaries on corresponding fluorescence images, which were, in turn, aligned by their blood vessels. We also used high-resolution confocal microscopy on the same sections to examine somatic morphology and putative synaptic interactions among the immunolabeled groups.
Preliminary staining of the CNG revealed differences across the dorsoventral axis. In particular, P and S expressing neurons were denser in the ACA and a dorsal part of the PL than the ventral PL and ILA. H/O fiber staining followed the opposite trend: the highest H/O axon density was found in the ILA while dorsally adjacent structures were gradually less dense. Preliminary confocal analysis in the CNG demonstrated that there are putative appositions of H/O-labeled axons with P but not S cell bodies, suggesting that H/O projection neurons target CNG subpopulations selectively.

Our canonical maps and spatial framework can be used as a platform to contextualize neuronal features and other mapped datasets, such as cannula placements and results from tract tracing studies.

Title: Using multi-scale, mixed media methods to visualize and map electrophysiologically identified glucose-sensing neurons within canonical brain atlas space

Authors: *E. PERU[1], A. M. SANTIAGO[2], V. H. ROUTH[2], A. M. KHAN[3];
[1]Biol. Sci., Univ. of Texas At Univ., El Paso, TX; [2]Pharmacology, Physiol. and Neurosci., Rutgers New Jersey Med. Sch., Newark, NJ; [3]Biol. Sci. and UTEP Systems Neurosci. Lab., Univ. of Texas at El Paso, El Paso, TX

Abstract: Although glucose-sensing (g-s) neurons in the brain have well-characterized biophysical properties that have made them objects of intensive investigation, little is known about their precise distributions within various brain regions. In particular, it remains unknown whether g-s neurons exhibiting a particular electrophysiological fingerprint (e.g., increased excitability in the presence of glucose) are associated with unique regionalization in the brain and/or display a unique morphological phenotype. Here, we have established a working protocol to identify and morphologically characterize dye-filled electrophysiologically identified g-s neurons within tissue slices of the mouse hypothalamus, and to map these labeled neurons using the cytoarchitecture within the tissue slice as a reference.
During patch-clamp recordings g-s neurons in brain slices were dialyzed with Lucifer yellow (LY) in the recording pipette. After recording, the tissue slices were fixed in 2% formaldehyde and stored unfrozen in a cryoprotectant at –20°C until processed further. Slices were rinsed in

buffered saline, immunostained with a fluorescently tagged anti-LY antibody, and counterstained with the fluorescent Nissl stain, Neurotrace. Confocal stacks of imaged neurons were imported into Volocity software (Perkin-Elmer) to visualize the native labeled morphology of the neuron, and into Neurolucida software (MicroBrightfield) to 3-D reconstruct the neuron. Tissue slices were then stained with the Nissl stain, thionin (skipping dehydration, clearing and rehydration steps to minimize disruption of the tissue slice integrity), and imaged as a z-series under bright field illumination using a wide-field microscope equipped with a motorized stage. Careful fiducial-based alignments of the fluorescent and bright field z-series allowed visualization of the labeled neuron, in fluorescence, in relation to the cytoarchitectonic boundaries delimited by the thionin stain, in bright field. The location of each neuron was plotted onto the appropriate digital atlas plate within a mouse brain atlas (Paxinos & Franklin, *The Mouse Brain in Stereotaxic Coordinates*). This method allowed us to map neurons to the ventrolateral subdivision of the ventromedial hypothalamic nucleus. In sum, we have used a multi-scale, mixed media (fluorescence, histochemical) approach to identify, characterize, and map electrophysiologically recorded neurons within a canonical atlas space. This method should prove valuable for structure-function studies where populations of g-s neurons need to be characterized across brain regions or across different physiological conditions.

Abstract: Reward and motivation are essential components of goal-directed behaviors such as eating and drinking. While a central role of the ventral tegmental area (VTA) in reward and motivation is well established, the means by which it interacts with classic hypothalamic feeding circuits is unclear. Here, we have expanded work in our previous report (SfN, Chicago, poster 616.09) to further address this issue. We injected the retrograde tracer Fluorogold (2%; FG) unilaterally into the VTA in 59 adult male Sprague-Dawley rats and mapped the distribution of retrogradely-labeled neurons in the forebrain and midbrain onto the standard atlas templates of Swanson (*Brain Maps: Structure of the Rat Brain, 3rd ed*., 2004). Most retrograde labeling was found ipsilateral to the injection site in all cases; however, a small number of cells was also observed contralaterally at all levels. Small injections largely confined to the VTA retrogradely labeled structures in the tel-, di-, and mesencephalon. *Telencephalic* labeling was found in cortical layers 5 and 6a/b (Levels 25–30), globus pallidus (internal segment), bed nuclei of the stria terminalis, substantia innominata and subfornical organ. *Diencephalic* labeling was present in both the thalamus and hypothalamus. Thalamic labeling was primarily limited to the medial and lateral habenulae, and intermediodorsal nucleus thalamus. In the hypothalamus, most labeling was found in the LHA, although the dorsomedial, ventromedial, paraventricular and posterior hypothalamic nuclei were labeled to some degree as well. LHA labeling was found in the juxtaparaventricular, suprafornical, anteroventral, dorsal, and juxtaventromedial region (ventral zone) parts. *Mesencephalic* labeling was observed primarily in the periaqueductal gray and the medial part of the median superior central nucleus raphé. FG deposits extending beyond the VTA to encroach upon the medial lemniscus and rubrospinal tract resulted in a similar distribution of retrogradely labeled cells in the diencephalon but additionally labeled the nucleus of the posterior commissure, compact and reticular parts of the substantia nigra, medial pretectal area and anterior pretectal nucleus, superior colliculus, red nucleus, oculomotor nucleus, nucleus of Darkschewitsch and midbrain reticular nucleus. These maps contribute to our understanding of the circuit that mediates the interaction between hypothalamic behavioral control systems and those mediating reward and motivation. A better understanding of this interaction and the underlying circuitry is necessary for developing an effective animal model for the treatment of eating disorders and addictive behaviors.

Title: Further elaboration of arcuate hypothalamic nucleus circuitry based on retrograde studies in the adult male rat

Authors: *A. MARTINEZ, B. E. PINALES, A. M. KHAN;
Biol. Sci., Univ. of Texas At El Paso, El Paso, TX

Abstract: The arcuate nucleus (ARH) is an important periventricular neuroendocrine structure. It serves as an active sentinel of metabolic state, contributing critically to the regulation of energy balance. While ARH function has been intensively investigated, a complete understanding of ARH neuronal connections to and from larger network targets remains poorly understood.
To address this issue, we have continued neuroanatomical tract tracing studies of ARH circuitry (SfN 2015 Chicago, poster 616.10/U42) through the use of the retrograde tracer, FluoroGold (FG). FG injections were delivered into the rostral ARH of adult male Sprague-Dawley rats. Brain sections of animals with injection site deposits confined to the ARH, as determined by analysis of adjacent Nissl-stained tissue, were immunohistochemically stained for tracer transport and imaged at high resolution using wide-field epifluorescence microscopy. Retrogradely-labeled FG-positive neurons were plotted onto the Swanson rat brain atlas for a detailed view of the source populations for ARH afferents (Brain Maps: Structure of the Rat Brain, 3rd ed.).
Initial mapping results of an injection case confined to the ARH and approximately 200-300 microns anterior to the injection site dataset presented last year, show a marked reduction of ARH inputs relative to the more caudal site and indicate a stark rostrocaudal difference in ARH afferent input. Preliminary analysis reveals regions with sparse connectivity to the ARH to include the anteroventral preoptic nucleus, preoptic periventricular nucleus, paraventricular thalamic nucleus, and periventricular hypothalamic nucleus; with an absence of retrogradely-labeled neurons (relative to the previous case) in the bed nuclei of the stria terminalis, nucleus accumbens, medial preoptic nucleus, anterodorsal preoptic nucleus, periventricular hypothalamic nucleus posterior part, and ventral premammillary nucleus. While further studies are required to

confirm these differences, these data maps provide the first evidence of heterogeneity in ARH innervation and suggest a possible topography of ARH circuitry that is more complex than previously determined. The high-resolution mapping of these data sets to a standardized rat brain atlas provide detailed information of targetable ARH networks that may be relevant in the regulation of energy homeostasis.

Title: Migration, spatial alignment, and registration of multi-scale neuroscientific datasets related to the control of motivated behaviors within canonically defined maps of the lateral hypothalamic area

Authors: *A. E. HERNANDEZ[1], A. M. KHAN[2];
[2]Biol. Sci. and UTEP Systems Neurosci. Lab., [1]Univ. of Texas At El Paso, El Paso, TX

Abstract: Addressing how distinct neuronal populations contribute to complex behavior is a collective effort in neuroscience. However multi-scale data generated to address this question have not yet been integrated in a meaningful way. In our laboratory, we seek to *define such meaning* by contextualizing these multi-scale data spatially. We believe that by precisely aligning and visualizing these diverse datasets within single maps, one can both validate and gain insights from current and legacy datasets.
Typically, brain regions where chemicals have been injected to produce a behavioral change are almost never aligned spatially with traced axonal and molecular expression patterns documented to be present in that region. Most data, in the rat, are mapped to either the Paxinos & Watson atlas (*The Rat Brain in Stereotaxic Coordinates*; 'PW') or the Swanson atlas (*Brain Maps: Structure of the Rat Brain*; 'S'). Here, we identified published datasets that have been mapped in PW and then migrated and spatially aligned these data to S in an attempt to integrate multi-scale datasets related to motivated behaviors.
Data mining was performed using online search engines and databases. Retrieved articles

included those with mapped injection sites and molecular expression patterns in the LHA. A total of 32 mapped injection sites were extracted from four articles illustrating regions with anterograde tracer deposits, or injection sites for opioid, glutamate, and dopamine receptor analogs that affected ethanol drinking, food intake, and instrumental conditioning; respectively. Mapped somata were extracted from three articles illustrating hypocretin/orexin (H/O) and neuronal nitric oxide synthase (nNOS) expression after water deprivation, and melanin-concentrating hormone (MCH) and H/O peptide and mRNA expression in the LHA. Using a novel atlas alignment tool, stereotaxic coordinates guided the migration of PW maps to S. PW mapped injection sites for opioid, glutamate and dopamine analogs migrated to S levels 28-30, 29, and 30; respectively. All chemoarchitectural data found across these three levels were placed in register with migrated datasets.
Our visual analysis of mapped data aligned to distinct subdivisions of the LHA provided hypotheses of the relationship among nNOS, H/O, and MCH neuronal populations, their possible co-expression of opioid, glutamate and dopamine receptors, their projections to either the central amygdalar nucleus or to midbrain, hindbrain, and diencephalic regions; and their involvement in behavior. Overall, this study highlights the importance of registering diverse mapped datasets to inform future integrative studies of the LHA.

Title: High spatial resolution mapping of Agouti-Related Peptide-immunoreactive axons to a canonical rat brain atlas

Authors: ***B. E. PINALES**[1], J. D. HAHN[2], A. M. KHAN[3];
[1]Biol. Sci., Univ. of Texas At El Paso, El Paso, TX; [2]Biol. Sci., USC, Los Angeles, CA; [3]Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: Agouti-related peptide (AgRP) has a well-known role as a neuropeptide involved in feeding control and energy balance. Brain expression of AgRP is predominantly (if not

exclusively) restricted to a subpopulation of neurons in the arcuate hypothalamic nucleus. However, the extensive connections of AgRP-expressing neurons have not been described systematically. Here we used immunohistochemistry to identify AgRP-immunoreactive (-ir) axons, which were then mapped digitally to sequential levels of a canonical rat brain atlas (L. W. Swanson, 2004). Accurate mapping of data to histologically defined gray matter regions was facilitated by reference to Nissl-stained cytoarchitecture, the use of camera *lucida* drawings, and careful determination of plane of section. METHODS: Adult male Sprague-Dawley rats were used in these experiments. Briefly, fixed frozen brain sections were incubated with a rabbit polyclonal antibody raised against the 83-132 amino acid sequence of human AgRP (Phoenix). Labelling was visualized with 3,3'-diaminobenzidine, and the data were mapped with the aid of dark field microscopy. Our initial analysis focused on the forebrain, with data mapped to 13 sequential atlas levels encompassing parts of the cerebral cortex, thalamus, amygdala, bed nuclei of the stria terminalis (BST), and hypothalamus. RESULTS: Regions with the highest density of AgRP-ir axons included the BST, the paraventricular- thalamic (PVT) and hypothalamic (PVH) nuclei, and the periventricular hypothalamic nucleus (PV). Dense AgRP-ir labeling was also noted in the arcuate and dorsomedial hypothalamic nuclei, and the lateral hypothalamic area (LHA). In contrast, labeling was sparse in the anterior- and ventromedial hypothalamic nuclei; regions devoid of labeling included the cerebral cortex, amygdala, most areas of the thalamus (including the anteromedial nucleus and ventral anterior lateral complex), the suprachiasmatic hypothalamic nucleus, and some LHA subdivisions (e.g. anterior region, ventral zone). These data provide an initial series of high-spatial resolution brain atlas maps for AgRP in the rat forebrain. They may be used for comparative analysis with other data (especially data mapped to the same rat brain atlas), and to target interventions precisely to forebrain regions that receive inputs from AgRP-expressing neurons. Further planned analysis will extend the available maps to include additional parts of the brain.

Title: Involvement of lateral hypothalamus orexin circuits in cocaine demand

Authors: *C. PANTAZIS[1], E. M. MCGLINCHEY[1,2], G. ASTON-JONES[1];
[1]Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ; [2]Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: A hallmark of addiction is high motivation for the abused drug. Addiction-related motivation can be quantified through self-administration behavior under high- and low-effort conditions using a behavioral economics (BE) paradigm. In the BE paradigm, the rate of consumption is measured as the effort required to maintain the desired drug level increases. This generates a demand curve, and the slope of that curve (termed demand elasticity, or α) is inversely proportional to motivation. Previous research from our lab has shown that pharmacological inhibition of orexin receptor-1 signaling during BE performance increases demand elasticity (reduces motivation for cocaine). As orexin (also called hypocretin) neurons in the lateral hypothalamus (LH) have been linked to motivation and drug addiction, we expected that animals with higher motivation for cocaine would have greater activity in LH orexin neurons. Animals were trained on cocaine self-administration and BE, and sacrificed 90 minutes after the point of maximum responding on the demand curve (Pmax). Immunohistochemical staining was used to visualize Fos in orexin neurons, which reflects neural stimulation during the time of maximal effort/motivation (~0 to 30 min before Pmax). We found that Fos activation of orexin neurons in lateral, but not medial or perifornical, hypothalamus correlated with demand elasticity and Pmax. However, contrary to our expectations, the percentage of orexin neurons that were Fos+ positively correlated with demand elasticity, such that high motivation animals (low α) had a smaller percentage of orexin neurons that were Fos+. This may reflect a differential role of orexin in motivation for cocaine at different effort levels, or an interaction between orexin and dopamine (also involved in cocaine motivation). To explore these and other possibilities, we are investigating activities of key inputs and outputs of the orexin system using retrograde tracing and pharmacological methods to elucidate the role of the LH orexin system in cocaine demand. The results of these ongoing studies will be presented, and the role of these orexin circuits in cocaine demand will be discussed.

Title: Methylphenidate reverses attention deficits induced by chemogenetic stimulation of the locus coeruleus in rats performing a 2-alternative forced-choice task

Authors: *M. A. PRESKER, JR[1], E. M. VAZEY[2], J. ZHANG[1], A. SNYDER[2], G. ASTON-JONES[1];
[1]Brain Hlth. Inst., Rutgers - The State Univ. of New Jersey, Piscataway, NJ; [2]Univ. of Massachusetts, Amherst, MA

Abstract: Tonic noradrenergic output of the locus coeruleus (LC) is thought to mediate task engagement. Observational evidence and models of LC function posit that hyper-optimal tone results in a distractible state. Disruptions in norepinephrine (NE) signaling have also been implicated in attention-deficit/hyperactivity disorder (ADHD) and effective pharmacotherapeutics like methylphenidate (MPH) have been shown to exert their cognitive-enhancing effects via altering NE signaling. Understanding the pathophysiology of ADHD has been hampered because there are few accepted rodent models of ADHD and most studies indicating a cognitive enhancing effect of MPH have done so in neurotypical animals. Here we used a 2-alternative forced-choice (2AFC) task and designer receptors exclusively activated by designer drugs (DREADDs) to develop a reversible LC-NE-dependent inattentive ADHD -like behavioral phenotype in rats. We used an AAV with the excitatory hM3Dq DREADD gene downstream of a synthetic dopamine beta-hydroxylase promoter (PRSx8) to selectively express the DREADD and mCherry tag in NE neurons of LC of rats. We stimulated LC-NE neurons specifically by ip injection of the selective DREADD agonist, clozapine-n-oxide (CNO). In control rats, mCherry was similarly expressed without the DREADD. CNO (0, 0.1, 1, 10mg/kg ip) produced dose-dependent deficits in 2AFC task-specific measures of task engagement, attention, and accuracy in LC-hM3Dq animals compared to LC-mCherry controls. LC-hM3Dq activation did not change impulsivity measures during performance of the 2AFC task. When administered following systemic CNO (1mg/kg ip), MPH dose-dependently (0, 0.5, 1 mg/kg ip) reversed the behavioral deficits observed in LC-hM3Dq animals without altering the performance of LC-mCherry controls. These data indicate that hyperactivity of LC results in an inattentive cognitive state, supporting the hypothesis that altered NE function contributes to attention deficits in ADHD. In addition, our findings indicate that low-dose MPH can manage attentional deficits induced by LC hyperactivity. This study describes an LC-specific, dose-dependent, and reversible chemogenetic rat model of inattentive ADHD that can be useful for elucidating the neurobiological basis of this disorder and future directions for corresponding therapeutics.

Title: Intermittent access to cocaine increases demand for cocaine in an orexin/hypocretin-dependent manner

Authors: *M. H. JAMES, C. M. STOPPER, N. E. KOLL, B. A. ZIMMER, G. ASTON-JONES;
Brain Hlth. Inst., Piscataway, NJ

Abstract: ***Introduction*:** Intermittent access (InTA) to cocaine increases motivation for drug on behavioral economic (BE) demand measures (Zimmer et al., 2012). The neural mechanisms underlying these changes in motivation are unclear. The orexin/hypocretin system plays a key role in motivated responding for all drugs of abuse (Mahler et al., 2014). We have previously shown that the selective orexin-1 receptor (Ox1R) antagonist SB-334867 (SB) decreases motivation for cocaine measured with BE in high-demand animals (Bentzley & Aston-Jones, 2015), indicating that the orexin system may drive pathological drug-seeking behavior. Here, we investigated whether changes in motivation for cocaine following InTA occur in an orexin-dependent manner. We also directly compared orexin system function in animals exposed to InTA versus long-access (LgA) to cocaine, an alternative procedure associated with increased motivation for drug. ***Methods*:** Male Sprague-Dawley rats were implanted with jugular catheters for i.v. cocaine self-administration. After initial FR1 self-administration training, rats were trained until stable on a BE procedure to obtain baseline demand values (Bentzley et al., 2013). Rats were then trained for 14d on InTA (5 min access every 30 min for 6h), LgA (6h) or short access (ShA; 1h) FR1 self-administration. Following InTA, LgA or ShA self-administration, animals were again re-stablized on the BE procedure and demand was measured following counterbalanced systemic injections of the Ox1R antagonist SB (0,10,30 mg/kg). Rats then underwent extinction training followed by reinstatement tests with SB. ***Results***: InTA decreased demand elasticity (alpha parameter; increased motivation) and increased the maximum price animals paid for a mg of cocaine (Pmax) compared to ShA. A similar trend was observed following LgA but to a lesser extent than for InTA. In all InTA animals, SB dose-dependently altered cocaine demand towards baseline values. In contrast, SB only normalized demand in animals exhibiting high demand for cocaine following LgA. InTA animals exhibited higher levels of reinstatement compared to both ShA and LgA animals, and this was dose-dependently

attenuated by SB. ***Conclusions*:** InTA to cocaine increases motivation for drug and cued-reinstatement behavior to a greater extent than ShA or LgA, indicating that InTA to cocaine may confer a stronger addiction-like phenotype than LgA. These InTA-induced changes are mediated at least in part by Ox1R signaling. Supported by PHS grant 1-R01 DA006214 NHMRC fellowship 1072706.

Title: Attenuating noradrenergic or serotonergic signaling in hippocampus during initial abstinence from cocaine persistently decreases later relapse to cocaine seeking in a sex-dependent manner.

Authors: *A. S. KOHTZ, G. ASTON-JONES;
Neurosci., Brain Hlth. Inst., Piscataway, NJ

Abstract: There are substantial sex differences in cocaine addiction, demonstrated by both clinical and pre-clinical studies. Notably, females are more sensitive than males to stress-induced drug-seeking and relapse. Our lab, and others, have previously shown that the initiation of abstinence (extinction day 1, ED1) represents a stressful event involving abstinence from drug. On ED1, female rats exhibit greater cocaine-seeking behaviors compared to males. We hypothesize that the experience of ED1 can substantially influence later relapse behavior following abstinence. Our prior work shows that locus coeruleus norepinephrine (LC-NE) and dorsal raphe serotonin (DR 5-HT) systems are involved in drug-seeking on ED1. Here, we microinfused a cocktail of 5-HT 1A/1B (WAY100635 plus GR127935) or β1 and β2 adrenergic antagonists (betaxolol plus ICI-118,551) into DH on ED1, and observed drug-seeking behavior on ED1 as well as following 2 weeks of forced abstinence. In males, 5-HT antagonism was more effective in reducing drug-seeking on ED1, whereas β-AR antagonism was ineffective. Following 2 weeks of abstinence males administered 5-HT antagonists showed persistently

reduced drug-seeking, compared to males administered saline or β-AR antagonists on ED1. In females both 5-HT and β-AR antagonism in DH was effective in reducing drug-seeking on ED1, and had persistent effects on drug-seeking following 2 weeks of abstinence. We further examined chemogenetic effects of inhibiting signaling from the DR to the DH via DREADDs, and found similar effects for inhibition of DR-DH signaling to decrease ED1 drug-seeking with persistent effects on later relapse, as in the pharmacological experiments. Our results show that 1) drug-seeking during initial abstinence involves 5-HT and β-AR signaling in female DH, but primarily 5-HT signaling in male DH, and 2) reducing drug-seeking by manipulating 5-HT or β-AR signaling in DH during ED1 can attenuate later relapse. Thus, treatments that modulate 5-HT and β-AR during initial abstinence may facilitate later maintenance of abstinence. This may have significant therapeutic implications for treating drug abuse.

Title: The role of oxytocin neuron activity in drug-seeking during initial abstinence from cocaine self-administration

Authors: *B. LIN[1], A. KOHTZ[2], M. SMITH[3], G. ASTON-JONES[2];
[2]Brain Hlth. Inst., [1]Rutgers Univ., Piscataway, NJ; [3]Neurosurg., Med. Univ. of South Carolina, Charleston, SC

Abstract: The initial abstinence from a drug (Extinction Day 1, ED1) is a critical time point in the progression of addiction that our lab finds can influence later relapse. Prior studies have shown that among females in particular, cocaine seeking behaviors increase significantly during ED1 following a period of cocaine self-administration. Moreover, stress-induced relapse propensity is greater among women, compared to men. Oxytocin (OTC) and corticosterone (CORT) are neurohormones that act as important regulators of the stress response. Oxytocin neurons are primarily found in the paraventricular nucleus (PVN) and the supraoptic nucleus (SON) of the hypothalamus. PVN is separated into three divisions (Rostral, Mid, Caudal) and

projects to central regions of the brain, whereas SON projects to the posterior pituitary gland and regulates peripheral responses. We hypothesize that drug-seeking on ED1 reflects an increase in response to the stress of expected drug, and this may decrease activity of OTC neurons which could contribute to the drug seeking response during ED1. We hypothesized that such drug-seeking may be rescued by exogenous OTC to compensate for lowered OTC activity during ED1. First, we show that female rats exhibit greater increases in CORT on ED1 compared to homecage controls, than do male rats, suggesting that ED1 drug-seeking is indeed a stress-associated behavior. To investigate the activity of OTC neurons during ED1 compared to homecage controls, we stained PVN and SON sections for both Fos and OTC. We show that fewer OTC neurons are Fos active on ED1 compared to homecage controls in a sex and region specific manner. Correlation analyses reveal that rostral PVN may be involved in drug-seeking behavior in males whereas mid-PVN may be involved in drug-seeking behavior in females. Exogenous OTC administration on ED1 decreased drug-seeking on ED1 and when administered during cued-reinstatement. This ED1 treatment, however, did not have long-lasting effects on relapse behaviors following prolonged abstinence. Thus, central OTC signaling is involved in drug-seeking behavior among males and females and may reflect acute stress-dependent mechanisms of drug-seeking.

Title: A critical role for melanopsin in light deprivation-induced depression

Authors: *H. E. BOWREY, M. H. JAMES, G. ASTON-JONES;
Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: Introduction: Research suggests a profound effect of light on mood. In humans, elevated levels of light increase alertness, whereas low light decreases sleep latency. Additionally, a specific type of depression, seasonal affective disorder (SAD), is associated with decreased light availability. In rats, short day-length lighting schedules induce depression and anxiety-like behavior, and chronic light deprivation also leads to a depressive phenotype. Our lab has previously shown that this light deprivation-induced depressive phenotype is due to a locus

coeruleus (LC)-dependent mechanism (Gonzalez and Aston-Jones, *PNAS,* 2008), where light-deprivation induces apoptosis in LC monoamine cells, and loss of noradrenergic-LC cortical fibers in frontal cortex (found also in other animal models of depression). To determine the photic circuit underlying this phenotype, we examined the role of intrinsically photosensitive retinal ganglion cells (ipRGCs) on mood and LC noradrenergic (NA) cell apoptosis, following targeted ablation of ipRGCs.
Method: Male Sprague-Dawley rats received bilateral intravitreal injections of either vehicle (0.01 M PBS; N = 5) or melanopsin-saporin (Mel-SAP; N=4), a targeted toxin that selectively recognizes and eliminates ipRGCs. 10 weeks following intravitreal injections, rats were subjected to behavioral assays of mood (saccharin preference test, elevated plus maze and forced swim test). Rats were then anesthetized and perfused. Brains were sectioned and LC tissue was stained for both Poly ADP ribose polymerase (PARP) and tyrosine hydroxilase (TH, a marker of NA neurons).
Results: Mel-SAP induced a depression-like phenotype as measured by a reduced preference for saccharin and increased immobility during the forced swim test. Mel-SAP had no effect on behavior on the elevated plus maze. Mel-SAP was also associated with increased apoptosis in LC NA cells a seen with increased PARP staining.
Conclusion: These results indicate that loss of ipRGC outflow may induce neural damage in the LC NA neurons, and that this damage is associated with a depressive behavioral phenotype. This has implications for therapy to treat at least some types of depression.

Title: Collateralization of projections from neurons in the PVT to the nucleus accumbens, bed nucleus of the stria terminalis, and central nucleus of the amygdala

Authors: *X. DONG[1], S. LI[1], G. J. KIROUAC[1,2];
[1]Dept. of Oral Biology, Col. of Dent., Univ. of Manitoba, Winnipeg, MB, Canada; [2]Dept. of Psychiatry, Col. of Med., Univ. of Manitoba, Manitoba, MB, Canada

Abstract: The paraventricular nucleus of the thalamus (PVT) is a midline thalamic nucleus with dense projections to the shell of the nucleus accumbens (NAc_{sh}), dorsolateral region of the bed nucleus of the stria terminalis (BST_{dl}) and the lateral/capsular region of the central nucleus of the amygdala (CeA_l). Recent experimental evidence indicates that the PVT is involved in both appetitive and aversive behaviors through the activation of projections to NAc_{sh} and CeA_l. However, a question that has not been addressed is whether the same neurons in the PVT innervate different subcortical targets. This study was done to explore the distribution patterns and the level of collateralization of PVT neurons innervating the NAc_{sh}, BST_{dl} and CeA_l. Accordingly, we performed dual tracing experiments by injecting the retrograde tracers cholera toxin subunit B conjugated to Alexa Fluor-594 or Alexa Fluor-488 in two different subcortical targets in the same rat (different combinations of the NAc_{sh}, BST_{dl} and CeA_l). The number of single and double labeled neurons in the PVT was counted on 50 µm sections every 300 µm through the anterior - posterior extent of the PVT. Adjacent sections were also stained for NeuN to estimate the proportion of neurons in the PVT that were labeled. We found that approximately 60% of the neurons in the anterior portion of the PVT projected to the NAc_{sh} whereas 30% projected to the BST_{dl} and 10% projected to the CeA_l. In contrast, we found that approximately 40% of the neurons in the posterior portion of the PVT projected to the NAc_{sh} while 35% projected to the BST_{dl} and 25% projected to the CeA_l. The level of collateralization in the projections was notable in that nearly half of the BST_{dl} and CeA_l projecting neurons were found to also project to the NAc_{sh}. A similar degree of collateralization was also found in PVT neurons that projected to the BST_{dl} and the CeA_l. It should be noted that the tracer injections were restricted to a relatively small portion of the NAc_{sh} suggesting that the proportion of collateralization reported in this study is likely to be an underestimation. We can also conclude from the observation that a large proportion of neurons in the PVT were labeled following a small injection in the NAc_{sh} that single neurons in the PVT bifurcate extensively in the NAc_{sh} in addition to sending collateral fibers to the BST_{dl} and CeA_l. In summary, the results of the present study indicate a high degree of collateralization of projections from neurons in the PVT to the NAc_{sh}, BST_{dl} and CeA_l. This suggests the potential importance of the PVT in simultaneously coordinating the activity of key regions of the brain involved in mediating emotional and motivational behaviors.

Title: Differential activity in the circuitry of the paraventricular nucleus of the thalamus following presentation of an incentive vs. a reward-predictive stimulus

Authors: *J. L. HAIGHT[1], Z. L. FULLER[2], K. M. FRASER[2], S. B. FLAGEL[3,4];
[1]Neurosci. Grad. Program, [2]Undergraduate Program in Neurosci., [3]Dept. of Psychiatry, [4]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: The paraventricular nucleus of the thalamus serves as an interface between cortical, limbic and motor circuits. Recently, there has been increased interest in how the PVT mediates responding to presentation of food- and drug-paired cues. However, the precise role of the PVT and related circuitry in these behaviors has been difficult to identify given that Pavlovian-conditioned cues can act as both predictive and incentive stimuli. Using an animal model that captures individual variation in response to discrete reward-paired cues, we are able to parse these properties of stimulus-reward learning. When rats are exposed to a Pavlovian conditioned approach paradigm, wherein presentation of a discrete cue predicts food reward, some rats, termed sign-trackers (STs), attribute both predictive and incentive value to the cue. These rats will rapidly approach and vigorously interact with the reward-paired cue. Other rats, termed goal-trackers (GTs), treat the cue exclusively as a reward predictor. Upon cue presentation, these rats rapidly approach the location of impending reward delivery. Previous studies from our laboratory have highlighted the paraventricular nucleus of the thalamus (PVT) as a critical component of the neural circuitry mediating these behaviors. Here, we sought to explore the engagement of distinct populations of PVT efferents and afferents in sign- and goal-tracking behaviors. The retrograde tracer flourogold (FG) was injected into either the PVT or the NAc, and levels of cue-induced neuronal activity were assessed by quantifying the amount of c-fos in FG-expressing cells. This technique allows us to assess differences in activation between STs and GTs specifically in afferents to, and efferents from, the PVT. We were interested in examining afferent activity in the medial prefrontal cortex, amygdala, hypothalamus, and ventral subiculum, in addition to activity in PVT efferents to the NAc. Results show that presentation of an incentive stimulus was able to evoke greater activity in PVT afferents from the prelimbic cortex, medial amygdala, and lateral hypothalamus, as well as posterior PVT efferents to the NAc. Interestingly, presentation of a mere predictive stimulus was also able to activate PVT afferents from the prelimbic cortex. Thus, relative to goal-trackers, sign-trackers showed greater engagement of subcortical brain regions; supporting a role for the hypothalamic-thalamic-striatal axis in cue-motivated behavior and specifically in response to incentive stimuli. Further, activity in the PrL to PVT pathway may underlie the processing of the predictive qualities of reward-paired stimuli, regardless of incentive value.

Title: Lateral hypothalamus glutamatergic projections to VTA mediate escape responses and aversion in mice

Authors: *M. F. BARBANO[1,2], H.-L. WANG[2], M. MORALES[2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The lateral hypothalamus (LH) is a heterogeneous brain structure that has been classically involved in feeding, motivation and reward. Until recently, the complexity of this structure prevented the study of specific cell populations and their involvement in motivated behaviors. Novel optogenetic approaches has shown the implication of the GABAergic projections from the LH to the ventral tegmental area (VTA) in compulsive-like eating and sucrose seeking. Additionally, glutamatergic projections from LH have also been shown to regulate feeding and to produce aversion-related phenotypes. Nonetheless, the participation of glutamatergic projections from LH to VTA in reward and aversion remains poorly understood. In the present study, we addressed this question by using a combination of behavioral, optogenetic and pharmacological techniques in male VGluT2 mice. We found that VTA photoactivation of glutamatergic LH projections was not reinforcing and significantly reduced feeding in food sated mice. A place conditioning study showed that mice receiving continuous photostimulation (20 Hz) after entering a light paired chamber on a three chamber apparatus developed an aversion for this chamber during training, and also during subsequent testing, when the light was no longer available. The effect was long lasting (at least 35 days) and was also observed using a low photostimulation frequency (2.5 Hz). The behavioral phenotype didn't appear to be caused by an increase in anxiety, as evidenced by open field and defensive burying tests. Indeed, it seemed more related to the escape attempts performed by mice when the pathway was photostimulated. To test this hypothesis, we run a forced-swim experiment: as expected, control mice decreased their performance across time. On the contrary, the experimental mice maintained a constant performance as long as the glutamatergic LH terminals in the VTA were photostimulated. Pharmacological blockade of VTA glutamatergic receptors by administration of AP5 (5 µg/ µl) and CNQX (5 µg/ µl) pointed out to an involvement of NMDA receptors in this phenomenon. Our results demonstrate that activation of glutamatergic fibers originating in the LH and projecting to the VTA are implicated in the regulation of defensive behaviors, such as flight responses, as well as in mediating aversion. They are consistent with a model in which the LH,

given its unique connectivity and neurochemical expression pattern, may convey emotionally relevant information to the VTA, which, in turn, and as a key component of the mesocorticolimbic circuitry, will orchestrate goal-directed behaviors critical for survival.

Title: Comparison of stimulations of the lateral preoptic area and ventral pallidum using measures of reward, anxiety and ingestion

Authors: *R. A. REICHARD, K. P. PARSLEY, S. SUBRAMANIAN, D. S. ZAHM; Pharmacol. and Physiological Sci., St. Louis Univ. Med. Sch., Saint Louis, MO

Abstract: The roles of the lateral preoptic area (LPO) and ventral pallidum (VP) in influencing motivational state are not clearly understood. We showed previously that stimulation of the LPO increases locomotion but not threat tolerance, assessed as the willingness of animals to enter harsh illumination to obtain sweet pellets. Conversely, stimulation of VP produced only a modest increase in locomotion associated with pivoting, but substantially increased threat tolerance. It is unclear if these behaviors are motivated by reward or anxiety. To address this, effects on reward, anxiety and ingestion of infusions of the GABAA receptor antagonist bicuculline (67ng in 0.25 µl over 60 sec) into the LPO or VP were recorded. Sprague Dawley rats, having received such bicuculline or equivalent saline infusions, were subjected to conditioned place preference (CPP) and elevated plus maze (EPM) testing. Unilateral infusions of bicuculline into the LPO, in addition to robustly stimulating locomotion, were rewarding and anxiolytic, as animals spent more time in the CPP paired chamber during post- as compared to pre-conditioning (520.5s ± 33.7 vs 287.5s ± 30.3, t[11] =-4.262, p=0.001) and spent more time in open arms of the EPM (open/close = 0.594 ± 0.127 vs 0.2024 ± 0.138, t[11]=2.446, p=0.032). The reluctance of LPO infused animals to take sweet pellets in harsh lighting is surprising given these results. Consequently, rats were placed in an activity monitor in dim house lighting and given free choice to consume sweet pellets or normal chow after receiving unilateral infusions into LPO (n=6) or bilateral infusions into VP (n=5) of saline or bicuculline. Bicuculline infusions into the LPO had no effect on ingestion of pellets or chow, whereas infusions into the VP, in addition to

stimulating vigorous pivoting movements, increased consumption of sweet pellets nearly 20-fold (3.63g ± 1.15 vs 0.189g ± 0.0710, t[4]= 3.001,p=0.039), but had no effect on chow consumption. The rigorous pivoting behavior and ingestion observed following VP stimulation co-occurred in all but two cases, leaving open whether two sites are involved. In summary, stimulation of LPO increased a measure of reward, decreased a measure of anxiety, had no effect on ingestion and provided no attraction to sweet pellets in harsh lighting. In contrast, stimulation of VP induced pivoting, ingestion and threat discounting. Evidence regarding to what extent stimulation of VP alters reward or anxiety state is still pending, but preliminary results indicate that rats do not show place preference for VP stimulation.

Title: Chemogenetic activation of the lateral hypothalamus reverses early life stress-induced anhedonia

Authors: *E. J. CAMPBELL, C. D. ADAMS, C. S. MITCHELL, D. M. HODGSON, C. V. DAYAS;
Univ. of Newcastle, Newcastle, Australia

Abstract: Early life stress (ELS) is a known antecedent to the development of depression in adulthood. A cardinal symptom of depression is low motivational drive, particularly towards stimuli that are normally naturally rewarding. Maternal separation is a well-established rodent model of ELS precipitating neuroendocrine and behavioral abnormalities in adulthood, similar to what is observed in humans. Non-neuroendocrine cell populations, including those in the lateral hypothalamus (LH), have an important role in arousal and reward status as well as depression-related behaviors. Recently, we showed altered activation of stress sensitive LH cell populations after ELS however, whether these changes also manifest as deficits in motivated behavior is yet to be assessed. Therefore, we examined the effect of ELS (maternal separation) on the motivation to lever press for sucrose reward. Next we sought to test whether chemogenetic (designer receptors exclusively activated by designer drugs, DREADD) activation of lateral hypothalamic circuits could modify sucrose responding in ELS rats. Finally, we characterized the impact of DREADD on orexin and melanin concentrating hormone (MCH) hypothalamic

neuropeptide populations given their importance in reward-seeking.
Male Wistar rat pups (n=52) were removed from dams for 0hrs or 3hrs on postnatal days (PND) 2-14 (No ELS or ELS). On PND 50, rats (n = 23) were bilaterally injected with the hM3D (Gq) DREADD into the LH. On PND 70, all rats were trained to self-administer 10% sucrose during 30min sessions. Following training, rats were tested for motivation to self-administer sucrose during a 90min progressive ratio (PR) schedule of reinforcement once a day for 5 days. On the final PR day, rats were injected (i.p) with either 5% DMSO or 5mg/kg clozapine-N-oxide (CNO) and lever responding recorded. Two hours following the initiation of the final PR test, animals were sacrificed and brains processed for Fos-protein immunohistochemistry.
Our data confirmed that ELS provoked a putative state of anhedonia ie. reduced lever pressing for sucrose under a PR schedule of reinforcement ($p<0.01$). hM3D (Gq) DREADD activation of the LH with CNO recovered this anhedonic behavior in ELS rats ($p=0.04$). This recovery in sucrose-responding was associated with a significant increase in numbers of Fos-positive orexin, MCH and putative GABA neurons in the LH (all p's<0.05).
Our study highlights the importance of the LH in ELS-induced anhedonia. It also provides evidence for the involvement of several neuropeptide populations within the LH in depression-related behaviors following ELS.

Abstract: The visualization and exploration of neuroimaging data is important for the analysis of anatomical and functional images and statistical parametric maps. While two-dimensional orthogonal views of neuroimaging data are used to display activity and statistical analysis, real three-dimensional (3d) depictions are helpful for showing the spatial distribution of a functional network, as well as its temporal evolution. For our best knowledge, currently there is no neuroimaging 3d tool which can visualize both MEG, fMRI and invasive electrodes (ECOG, depth electrodes, DBS, etc.). Here we present the multi-modality visualization tool (MMVT). The tool was built for researchers who wish to have a better understanding of their neuroimaging anatomical and functional data. The true power of the tool is by visualizing and analyzing data from multi-modalities. MMVT is built as two separated modules: The first is implemented as an add-on in 'Blender", an open-source 3d visualization software. The add-on is an interactive graphic interface which enable to visualize functional and statistical data (MEG and/or fMRI) on the cortex and subcortical surfaces, invasive electrodes activity and so on. The tool can also be used for a better 3d visualization of the anatomical data and the invasive electrodes locations. The other module is a standalone software, for importing and preprocessing. The users can select the data they want to import to Blender and how they want to process it. The module support many types of analyzed data, like FsFast (FreeSurfer Functional Analysis Stream) and SPM (Statistical Parametric Mapping) for fMRI, MNE (a software package for processing MEG and EEG) raw data for MEG and FieldTrip (MATLAB software toolbox for neuroimaging analysis) data structures for the invasive electrodes. The users can also reprocess raw data using a wrappers for FaFast and mne-python (a python package for sensor and source-space analysis of MEG and EEG data).

Title: Representations of aversive risk and decision conflict in the human subthalamic nucleus and globus pallidus internus

Authors: *T. HERRINGTON[1], S. PATEL[2], K. KANOFF[3], S.-T. TSAI[2], S. ZOROWITZ[4], T. SITNIKOVA[4], K. ELLARD[4], T. DECKERSBACH[4], A. WIDGE[5], D. DOUGHERTY[4], E. ESKANDAR[2];

Abstract: BACKGROUND: Neuropsychiatric symptoms including anxiety, impulsivity, apathy and depression are common in Parkinson's disease (PD) and reduce quality of life on par with the core motor symptoms. Motor symptoms can be alleviated by deep brain stimulation (DBS) of the subthalamic nucleus (STN) or globus pallidus internus (GPi). The STN and GPi are also important nodes in associative and limbic cortical-subcortical networks implicated in impulsivity, anxiety and depression. However, the continuous, high-frequency DBS used to treat movement disorders appears not to help, and may worsen, neuropsychiatric symptoms. In this study we aimed to elucidate the role of the STN and GPi in approach-avoidance behavior, a core neuropsychiatric dimension in parkinsonian depression and anxiety. **DESIGN:** We recorded from single neurons in the human STN (n = 12 subjects, 64 neurons) and GPi (n = 5 subjects, 18 neurons) during clinical microelectrode mapping for placement of deep brain stimulation electrodes. Intraoperative electrocorticography (ECoG) recordings over the DLPFC or SMA/dACC were obtained in a subset of subjects (5 STN, 1 GPi). During recordings patients performed a novel approach-avoidance task that required subjects to accept or reject offers with independently varying levels of reward and aversive risk. **RESULTS:** Single-neuron spike rates in the STN were negatively correlated with aversive risk shortly after the offer, and positively correlated with the decision to approach risk. As subjects prepared to respond, neural responses in the STN were positively correlated with the degree of decision conflict. In contrast, single-neuron responses in the GPi did not correlate with aversive risk, approach-avoidance decision making nor decision conflict. Initial ECoG recordings suggest that theta-band power in the dACC/SMA correlates with approach behavior. **CONCLUSIONS:** Compared to the GPi, the STN may serve a unique role in evaluation of risk and approach-avoidance decision making. This function may involve the medial prefrontal cortex - STN hyperdirect pathway previously implicated in decision conflict monitoring. Alternatively, our STN recordings may have sampled more extensively from the associative and limbic connected subterritories which are in close proximity to the sensorimotor STN DBS target. Recordings from more anterior GPi, which are not obtained clinically, may have revealed greater task engagement. The engagement of the STN in approach-avoidance decision making suggests that novel modes of DBS responsive to the

neuropsychiatric functions of the nucleus could one day help alleviate neuropsychiatric symptoms in Parkinson's disease.

Title: Bayesian state-space modeling of reversal learning in fmri

Authors: ***S. ZOROWITZ**[1], A. AFZAL[2], T. DECKERSBACH[2], K. K. ELLARD[2], A. L. GILMOUR[2], D. D. DOUGHERTY[2], E. N. ESKANDAR[3], A. S. WIDGE[2];
[1]Psychiatry, Massachusetts Gen. Hosp., Charlestown, MA; [2]Psychiatry, [3]Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Background: Reversal learning is a dynamic process during which associations are undone in light of new, conflicting information. It involves a multitude of neural structures, including dorsolateral prefrontal cortex (DLPFC) and the basal ganglia. Deficits in reversal learning have been implicated in psychiatric disorders including MDD, OCD, and addictive disorders. Conventional approaches to measuring reversal learning underutilize available information, neglect important individual differences, and do not provide per-trial estimates of learning. Here we extend previous work to model per-trial reversal learning in the fMRI.
Methods: 30 healthy participants and 14 MDD/GAD patients performed an fMRI reversal learning task. We devised a Bayesian state-space model (SSM) that estimates a per-trial learning state, informed by response time and accuracy. Time-to-criterion (TTC), or the trial at which a participant achieves and maintains 80% likelihood of correct response after reversal, was calculated for each participant using their individual SSM estimates. Two fMRI models of reversal learning, one with and without the SSM estimates as regressors, were fitted per-subject and compared using paired t-tests.
Results: TTC was longer in patients than in healthy controls ($t=-2.587, p=0.015$), and TTC across participants predicted scores on the BRIEF metacognition scale ($\beta=2.20, p=0.043$) and the BIS-11 nonplanning impulsivity scale ($\beta=0.818, p=0.039$). The fMRI model with SSRE estimates

found greater activation in bilateral DLPFC, dACC, and caudate, and detected deactivation in OFC. Model comparisons show improved SNR gain in DLPFC and caudate with the SSM; OFC deactivation was not detected in the model without SSM estimates.
Conclusions: The SSM model captured variability in reversal learning that is clinically useful, and facilitates more robust detection of activation during reversal learning in the fMRI. The SSM model has great utility in understanding the domain of reversal learning.

Abstract: Modulating psychiatric state along stable therapeutic paths has long been stably driven through counseling and therapy and pharmaceutical approaches. As a supplement to these approaches, we are exploring the use of neural stimulation to tap into and subtly modify how humans respond in one particular psychological domain: emotion regulation. Using a standardized task to sample emotion regulation, the Emotion Conflict Resolution (ECR) task, we both identify the brain regions which are active during the task as well as examine now neural stimulation alters both the behavioral and physiological dynamics during the task. We examine neural activity in the form of local field potentials (LFPs) from a range of brain areas routinely recorded with implanted electrodes during prototypical clinical evaluation of patients with intractable epilepsy (N=9 patients). First, we could correlate ECR task-relevant behavior to the

LFP voltage signal in the dorsolateral prefrontal cortex (dlFPC), the dorsomedial prefrontal cortex (dmPFC), the temporal cortex, the rostral anterior cingulate cortex (rACC) and the orbitofrontal cortex (OFC) ($p<0.001$, N=9, Wilcoxon signed rank test). These same regions exhibited power changes in theta (4-8 Hz) and high gamma (65-200 Hz), with across-patient consistencies such as increased activity in the left hemisphere. Finally, we introduce stimulation in brain regions which were either predicted to be involved in emotion regulation in the fMRI domain or were shown to be active during the task (N=9 patients). We found that 1) left hemisphere stimulation induced the most significant changes in task-relevant behavior ($p<0.0044$, N=9, Wilcoxon signed rank test); 2) stimulation in the amygdala, dmPFC, and dorsal anterior cingulate induced trial-specific behavioral changes across patients; 3) we found a longer term effect of stimulation that altered the LFP responsiveness of specific brain regions to the task which we hypothesize to be dose-dependent (ANOVA, $p<0.000001$). These results point to a measured approach that when and where we stimulate could play a major role in modulating emotional responses to psychologically relevant tasks, with the hope that we can use this information to close the loop between neural activity, neural stimulation, and behavior along therapeutic means.

Title: A biophysical model of electrical stimulation evoked responses in cortical and subcortical brain regions of the human and non human primate

Authors: ***I. BASU**[1], A. C. PAULK[1], K. FARNES[1], M. M. ROBERTSON[1], B. CROCKER[2], D. I. VALLEJO-LOPEZ[2], D. D. DOUGHERTY[3], S. S. CASH[2], E. N. ESKANDAR[1], M. KRAMER[4], A. S. WIDGE[3];

Abstract: Deep brain stimulation (DBS) is used to treat drug resistant pathologies such as movement disorders, epilepsy, and pain and has potential for managing psychiatric disorders. This works for pathologies affecting a well localized brain region, but is inadequate to treat complex neuro-psychiatric disorders, which are characterized by network-wide alterations and a higher variability across patients. Experimental opportunities with human subjects are too limited to fully understand the complex interactions that arise in the brain network due to stimulation, which has limited the design of new stimulation approaches. To address this challenge, we developed a biophysically relevant model of the cortical and subcortical local field potentials that can be easily parameterized from a limited dataset to computationally explore the impact of stimulation parameters on a patient's brain activity. We used the Jansen-Rit model of single and coupled cortical columns to simulate the effect of electrical stimulation at different frequencies (10-160 Hz) on the local field potential. Each column was modeled as a population of pyramidal cells receiving inhibitory and excitatory feedback from local interneurons and excitatory input from neighboring or distant columns. An additive input to all the populations simulated electrical stimulation. We recorded stimulation-evoked potentials from human subjects undergoing monitoring for epilepsy surgery, then determined a subset of the model parameters by optimizing the correlation between the actual and model response. We also used a dataset recorded from a non-human primate to fit the model and then use data recorded over a period of 2 weeks to test how well the model could predict this data. We found that using a single column model, the simulated evoked responses could model low, but not high frequency stimulation. Including a second coupled column increased the correlation between the simulated and recorded high frequency stimulation evoked responses, especially for sub-cortical regions. The model could also predict evoked responses over a period of a week before it required re-parameterization. This modeling framework can potentially help overcome the inherent drawback in human brain stimulation studies that necessitate a narrow subset of stimulation parameters. By using the model to explore a wide range of stimulation settings, an optimal stimulation strategy for a given patient can be proposed and tested. This has applications in designing DBS-based neurophysiology experiments and in the creation of model-driven closed-loop neuro-stimulation algorithms.

Abstract: Closed-loop Deep Brain Stimulation (DBS) may offer a promising alternative therapy for intractable neuropsychiatric illness, including depression, post-traumatic stress disorder, bipolar disorder, attention deficit disorder, substance abuse, and anxiety. However, the neural features of neuropsychiatric illness required to optimally drive stimulation parameters and effectively 'close the loop' remain obscure. The dorsal Anterior Cingulate Cortex (dACC) is associated with cognitive control, attention, and reward-based decision making. Dysfunction in the dACC is prevalent in neuropsychiatric illness, and its associated network is a primary focus for treatment of neuropsychiatric illness with closed-loop DBS. Knowledge of healthy and impaired network connectivity dynamics during periods of high cognitive demand will aid in the development of closed-loop feature classification. In the present study, local field potentials (LFP) were recorded from multi-sensor depth electrodes in epilepsy patients performing the Multi-Source Interference Task (MSIT). The MSIT task is proven to reliably activate the dACC in healthy controls. Canonical correlation and coherence analyses were performed to identify functional connectivity dynamics between pre-identified regions of interest before and during the MSIT task, differentiate between trial types based on functional connectivity, and analyze the effect of in-task DBS on the identified networks. We have found significant differences between MSIT task state and resting state networks, where connectivity during task tends to be greater than during rest. We present preliminary results on how stimulation of cortical and subcortical targets changes MSIT task network dynamics.

Title: An exploration of stimulation effects in the non-human primate brain

Authors: M. M. ROBERTSON[1], A. C. PAULK[1], I. BASU[1], J. CHENG[5], C. MARTINEZ-RUBIO[1], *J.-B. EICHENLAUB[2], D. DOUGHERTY[3], S. S. CASH[4], A. S. WIDGE[3], E. N. ESKANDAR[1];

Abstract: Neuropsychiatric disorders are notoriously difficult to treat, due in part to the complexity of heterogeneous networks in the brain. For many years, treatment of mental illness focused on identifying and correcting chemical imbalances across the brain, though such treatments are successful in a limited number of patients and, even then, the side effects can be devastating. Neuromodulation through electrical stimulation may provide an opportunity to finely tailor treatments toward an individual's needs. Recent studies have found success in treating refractory psychiatric illness through deep brain stimulation (DBS), confirming its practicality for treatment. However, traditional DBS methods are limited in that stimulation is constant and often at high frequencies (~130 Hz) regardless of active mental state. Instead, we propose the use of a closed-loop device that will monitor brain activity and stimulate focally in both location and time to alleviate symptoms and shift neural activity in therapeutically relevant directions. Towards this, we examine how single-site and multi-site stimulation at different frequencies and amplitudes alters neural activity in the non-human primate (NHP, N=2) brain. Using chronically implanted miniDBS electrodes that target cortical and subcortical brain regions and an ECoG array placed over the dorsolateral prefrontal cortex (dlPFC), we observe differential effects of stimulation in the ventromedial prefrontal cortex (vmPFC), the dorsal anterior cingulate cortex (dACC), and the nucleus accumbens (NAcc). Each of these targeted regions have been associated with neuropsychiatric disorders, including depression, posttraumatic stress disorder, and addiction. We show that high frequency stimulation in the vmPFC induced changes to the evoked potentials in both the NAcc and the dACC, and also induced a post-stimulation increase in gamma (30-55 Hz) power and suppressed delta (0-4 Hz) power across multiple days (n=5 days). In contrast, dACC stimulation at the same frequencies induced little change in voltage and power. The effects of NAcc stimulation were more complex,

as lower frequency stimulation had comparatively stronger effects on gamma, but this depended on the level of current used. Finally, we examined stimulation-induced changes in coherence across these regions. Taken together, these methods allow us to understand the stimulus space for inducing targeted changes in neural activity. Additionally, we are able to assess the consistency of stimulation across days and months, which is necessary for understanding clinically relevant changes in the effectiveness of DBS in treating neuropsychiatric disorders.

Title: Characterizing stimulation-evoked synchrony in brain networks

Authors: ***A. YOUSEFI**[1], A. C. PAULK[1], I. BASU[1], B. NAZARI[4], K. B. FARNES[1], M. M. ROBERTSON[1], B. CROCKER[2], S. S. CASH[2], D. D. DOUGHERTY[3], A. S. WIDGE[3], E. N. ESKANDAR[1], U. T. EDEN[5];

Abstract: Brain synchrony underlies the formation of functional neuronal networks and mediates their associated functions. Various cognitive and mental brain disorders are related to dysregulated brain synchrony. A major goal in both clinical and basic neuroscience is to characterize dynamics of brain networks and utilize neural stimulation to regularize brain synchrony. Here, we propose a mathematical framework to model synchrony of brain networks. We then use the model to study role of neural stimulation in controlling brain oscillations. State-space methods have been successfully used to model dynamical features of the neural signals. Here, we utilize the state-space framework to describe the dynamics of synchronous activity between two brain areas. We define a state variable that represents the degree of synchrony between two brain areas, and a set of observation processes that characterize the likelihood of measured neural activity in these brain areas as a function of the synchrony state

variable. We also define a state transition process that governs the temporal dynamics of the synchrony state. The neural signals we consider have non-normal distributions, and their relationship with the state variable can be highly non-linear; thus, established state-space algorithms are not able to track state dynamics and estimate model parameters. We develop a new adaptive filter and estimation procedure to track the level of instantaneous synchrony at each instant, while simultaneously estimating the parameters of our model. The algorithm consists of: 1) a filter-smoother procedure, and 2) a Variational-Bayes algorithm, which sequentially estimates model free parameters and the state variable to maximize the likelihood of the observed neural data. We then extend the dynamical model by including additional variables related to neural stimulation. Using this extended model, we are able to characterize the effect of neural stimulation on brain synchrony.
We illustrate this method on neural data collected from both humans and non-human primates. The ultimate goal of this research is to build a new interventional tool for the human patients suffering from brain disorders related to abnormal synchrony.

Title: Multimodal exploration of decision-making in the human subthalamic nucleus

Authors: ***S. R. PATEL**, T. HERRINGTON, S. SHETH, M. MIAN, S. BOURNE, S. ZOROWITZ, A. AFZAL, T. DECKERSBACH, A. WIDGE, D. DOUGHERTY, E. ESKANDAR;

Abstract: Deep brain stimulation (DBS) is being explored for the treatment of neuropsychiatric disease such as Obsessive-Compulsive Disorder and Major Depression. However, the continuously-on motif of first-generation DBS systems may prove to be inefficient in treating more complex and distributed cognitive functions associated with psychiatric disease. We demonstrate closed-loop control of cognitive behavior. In three separate studies, we collected

functional imaging (25 healthy control), single-neuronal recordings from the subthalamic nuclues (STN) undergoing DBS (7 patients), and intermittent STN stimulation behavior (11 patients). For each of these modalities, subjects were engaged in a probabilistic decision-making task. During high-demand trials, we found BOLD activity selectively in the left STN that predicted whether subjects would place a high or low wager ($p < 0.001$; small volume correction). Interestingly, we found that single-neuronal activity in the left STN also predicted high or low wagers during a 500 ms window on a trial-by-trial basis ($F(9,1450) = 2.55$, $p = 0.02$; ANOVA). Finally, we applied intermittent stimulation during this window, selectively on high-demand trials, and found that we were able to make subjects more conservative ($F(2,28) = 2.93$, $p = 0.05$; ANOVA). In this study, we demonstrated that neuronal activity in the STN predicts decisions under uncertainty on a trial-by-trial basis. We then showed that we could apply intermittent electrical stimulation through the implanted deep brain stimulation electrode to bias the decision signal and ultimately alter subject behavior, resulting in less impulsive choices.

Title: Oscillatory synchronization enables dynamic information processing to resolve reward seeking vs. risk avoidance conflict

Authors: *T. A. SITNIKOVA[1], S. ZOROWITZ[3], A. AFZAL[3], A. L. GILMOUR[3], K. K. ELLARD[1], T. M. HERRINGTON[1], S. PATEL[1], A. C. PAULK[1], M. HAMALAINEN[2], S. STUFFLEBEAM[2], A. S. WIDGE[1], D. D. DOUGHERTY[1], E. N. ESKANDAR[1], T. DECKERSBACH[1];

Abstract: Optimal cost-benefit analysis is at the core of living a productive and enjoyable life. Deciding to seek a rewarding experience often depends on assessing the involved risks. To understand the neural mechanisms of resolving an approach-avoidance conflict, we concurrently

recorded magneto- and electro-encephalographic (M/EEG) data while healthy subjects (age mean=31, sd=7) decided whether to take varying risk levels of an aversive stimulus in pursuit of varying amounts of a monetary reward. Each trial started with a risk offer (10-90% probability of electric shock to the ankle), which was followed, 1 sec later, with a reward offer (5-95 cents). The risk levels accepted by each subject were median split into low and high perceived-risk conditions. We found evidence that oscillatory synchronization of source localized M/EEG activity reflected differences in information processing between the low and high perceived-risk trials. On the low risk trials, an optimal strategy was to take risk regardless of reward - similar to taking everyday risks of driving a car, regardless of reward value of the trip destination. In contrast, on the high risk trials, it was efficient to postpone the decision until both risk and reward could be considered together - similar to ascertaining the reward value before considering a dicey car drive in a blizzard. We observed that synchrony in the beta rhythm (15-30Hz), previously found to facilitate forming neural ensembles to represent information, was increased, between the ventrolateral prefrontal cortex (VLPFC) and the orbitofrontal cortex (OFC), immediately after the low risk offer, but not until after the reward offer on the high risk trials. Thus, beta synchrony in this circuit, believed to support evaluation of salient information in relation to behavioral choices, may establish neural ensembles to represent the risk, reward, and/or choice information. In addition, synchrony in the alpha rhythm (8-15Hz), previously suggested to suppress irrelevant information, was increased, between VLPFC/OFC and a cognitive control structure, the dorsolateral prefrontal cortex (DLPFC), immediately after the high risk offer, but not until after the reward offer on the low risk trials. This suggested that alpha synchrony may inhibit salient but currently-irrelevant inputs, when the decision is postponed or already made. Individual differences in these temporal patterns of beta and alpha synchrony predicted self-reported abilities to regulate response to emotional stimuli to sustain goal-directed behavior. Synchrony may regulate dynamic representation of the risk, reward, and behavioral choice information during a cost-benefit analysis.

Hosp., Boston, MA; [5]Dept. of Radiology, [6]MGH/HST Martinos Ctr. for Biomed. Imaging, Boston, MA

Abstract: Decision making depends on how humans adapt to social and environmental challenges. The neural correlates of flexibility in the face of these challenges has been associated with activity in the cingulo-frontal-parietal cognitive/ attention network (CFP) along with the detection and resolution of emotional conflicts by the salience network. Yet, the intersection of decision and resolving emotional conflict remain largely unknown on the level of populations of neurons, such as what is sampled by local field potentials (LFPs). Using standardized tasks to sample emotion regulation and cognitive flexibility, the Emotion Conflict Resolution (ECR) task and the Multi-Source Interference (MSIT) task, we both identify the brain regions which are active during the tasks through various levels of conflict and correlate these neural dynamics with behavior. We examine LFP from a range of brain areas routinely recorded by implanted electrodes during prototypical clinical evaluation of patients with intractable epilepsy (N=9 patients). First, ECR task-relevant behavior is significantly correlated to the LFP voltage signal in the dorsolateral prefrontal cortex (dlFPC), the dorsomedial prefrontal cortex (dmPFC), the temporal lobe, the rostral anterior cingulate cortex (rACC) and the orbitofrontal cortex (OFC) ($p<0.001$, N=9). Relative to MSIT, ECR induces significantly larger voltage deflections in prefrontal cortical (PFC) and rACC activity across patients ($p<0.001$, Wilcoxon signed rank test). These same regions exhibit power changes in theta (4-8 Hz) and high gamma (65-200 Hz), with increases in activity in the left hemisphere in ECR versus MSIT. In terms of network dynamics, we observe a decrease in coherence between the amygdala and PFC during ECR with a concurrent increase in dACC and PFC coherence during MSIT. We correlate these changes in behavior and physiology to standard psychiatric self-report measures of emotional regulation (ERS, DERS) and cognitive flexibility (BRIEF). These results suggest a wide realm of cortical and subcortical structures are involved in modulating emotional responses in addition to decision making. Yet, specific neural structures, namely the dlPFC, OFC, and rACC, may represent key nodes in differentiating the salience network from the CFP network. We hypothesize how differential network dynamics can explain compensatory neural activation in patients with challenges in emotion regulation or cognitive flexibility. These investigations of spatiotemporal dynamics could help to better understand the processes within psychiatric pathophysiology, informing future clinical innovations in diagnosis and treatment.

Title: The control of firing patterns of midbrain periaqueductal gray neurons *In vivo*

Authors: *H. H. SUBRAMANIAN, P. A. SILBURN;
The Univ. of Queensland, Brisbane, Australia

Abstract: The midbrain periaqueductal gray (PAG) functions as the critical relay of the limbic brain and functions to mediate environmental challenges (flight or freezing) or emotional expression (vocalization, fear, stress or anxiety). In this context, the PAG maintains critical circuitries that control respiration, vocalization, cardiovascular system, pain and analgesia, micturition and, lordosis (Subramanian and Holstege, 2014). However it is not known what type of activity patterns the PAG neurons express in vivo. Using a combination of precollicular decerebrated and, urethane-anesthetized, spontaneously breathing rats the PAG was mapped for extracellular neuronal activity within its various subregions. Drugs were applied by direct microiontophoresis into the PAG to activate silent cells and test their drug sensitivity. Forebrain regions, the anterior cingulate cortex (ACC), hippocampus and amygdala were chemically stimulated to examine their effects on PAG neuronal function. Respiratory, laryngeal and cardiovascular system parameters were monitored during central interventions. Overall the PAG was found to be predominantly quiescent in the resting state. Nonfiring PAG cells could be activated by iontophoresis of the excitatory amino acid glutamate and ceased activity when glutamate ejection was terminated. Few sporadically firing cells were found in the dorsal PAG. These cells fired in a slow, irregular pattern. Robust spontaneoulsy active cells were very few, restricted to the lateral and ventrolateral PAG region. These were either non-bursting cells with a near normal distribution around 200 to 250 msec, or burst-firing cells typically showing a bimodal distribution. However activation of the anterior cingulate cortex, the hippocampus or the amygdala caused immediate activation of PAG neurons. In such instances, PAG cells showed two distinct types of of activity patterns; 1) single spike firing and burst firing, phasic or tonic. The functional implications of PAG neuronal activity are thus discussed in terms of inherent function, inputs from forebrain structures and its impact on descending motor and autonomic control during limbic triggered emotional expression.

Title: Optogenetic stimulation of the excitatory parabrachial projections to central amygdala induces anxiety- and depression-like behaviors in rats

Authors: Y.-Q. CAI, *Z. Z. PAN;
Anesthesiol. and Pain Med., UT-MD Anderson Cancer Ctr., Houston, TX

Abstract: The amygdala is an important brain area that is involved in integration and modulation of aversive and motivational emotion behaviors including those of affective pain, but the underlying cellular circuitry remains largely unclear. The spinoparabrachial pathway and the projection from the parabrachial (PB) nucleus to the lateral division of central nucleus of amygdala (CeAI) have been characterized as an important cellular circuit that relays pain signal from the spinal cord to the corticolimbic brain for pain processing; however, it is still unknown how the pain signal from this neuronal circuit is perceived and processed to influence integrated emotion behaviors in brain response to pain. In this study, we injected AAV-CaMKII-ChR2-EGFP virus into the PB nucleus to transfect glutamatergic PB neurons and their excitatory projections including those to CeAl. We show here that there are strong direct projections from the glutamatergic PB neurons to CeA and mostly to CeAl. In contrast, no significant PB projection to the neighboring basolateral amygdala is present. In normal rats after PB injection of the virus, photostimulation of the excitatory PB-CeAl projections in CeAI induces significant anxiety- and depression-like behaviors, as measured in the open field test and the forced swimming test, respectively. Interestingly, this photostimulation has no effect on the behaviors of sensory pain in either thermal or mechanical pain test. These findings may suggest that the pain-driven activation of CeAl neurons alone is sufficient to induce negative emotion behaviors of affective pain, an emotion-modulating process that does not influence the perception of sensory pain in acute conditions.

Abstract: Anxiety disorders plague up to 28% of adults at some point in their lifetimes, yet existing therapies are burdened with side-effects and can result in increased tolerance and dependence over time with repeated use. We have previously identified the basolateral amygdala (BLA) projection to the ventral hippocampus (vHPC) as a robust pathway that can bidirectionally control anxiety-related behavior upon acute optogenetic manipulation. Given our proven ability to robustly alter synaptic transmission in an acute manner, we next investigated whether we could induce plasticity in such a manner that anxiety-related behavior would be altered in a lasting way. By injecting an anterogradely-traveling viral vector allowing for expression of the stabilized step-function opsin (SSFO) in a cre-dependent manner into the BLA and injecting a retrogradely-traveling viral vector into the vHPC carrying cre-recombinase, we

selectively expressed SSFO in BLA-vHPC neurons. Following 5 days of photostimulation, we observed a decrease in anxiety-related behaviors as measured by the elevated plus maze and open field test at all of the time points we tested, which included 12 hrs, 7 days, 30 days and 90 days following the last optogenetic manipulation. We are now exploring the cellular and synaptic mechanisms underlying this behavioral phenomenon.

Title: Negative over positive: unidirectional inhibitory interaction among amygdala projection neurons

Authors: ***G. G. CALHOON**, A. BEYELER, P. NAMBURI, G. GLOBER, K. M. TYE; Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: The ability to anticipate the presence of threats and the availability of natural rewards, and then to use that foresight to select appropriate behaviors is central to survival. The basolateral amygdala (BLA) is a nucleus poised to decipher the predictive value of environmental events, as individual populations of neurons there have been shown to encode cues predicting aversive or appetitive outcomes. We recently identified two largely non-overlapping, projection-target defined populations of BLA neurons which oppositely encode

positive and negative emotional valence. Nucleus accumbens projecting BLA neurons (NAc projectors) undergo synaptic strengthening following reward learning and show a reduction in synaptic strength following fear conditioning, whereas BLA neurons projecting to the centromedial nucleus of the amygdala (CeM projectors) undergo a reduction in synaptic strength following reward learning and enhancement of synaptic strength following fear conditioning. In behaving animals, NAc projectors preferentially encode sucrose predictive cues, whereas CeM projectors preferentially encode aversive quinine predictive cues. However, it is yet unknown how these populations of neurons interact within the BLA. Based upon the opposing roles of these populations in encoding positive and negative valence, we hypothesized that NAc and CeM projectors mutually inhibit each other. To test this hypothesis, we performed targeted whole-cell patch-clamp recordings in BLA projection neurons, identified by the presence of retrogradely travelling fluorescent beads (retrobeads). We then evaluated the impact of photostimulation of the opposing population upon synaptic currents and firing rate in retrobead-positive cells. We found that photoactivation of either population of projectors evokes monosynaptic, glutamatergic currents as well as GABAergic inhibitory currents in the opposing population. Surprisingly, however, we found that photostimulation of NAc projectors *increases* the firing rate of CeM projectors, whereas photostimulation of CeM projectors *inhibits* firing in NAc projectors. These findings suggest that although lateral inhibition exists between both populations, CeM projectors are capable of suppressing activity in the opposing pathway whereas NAc projectors are not. Considered in the context of the individual contributions of these two populations to valence encoding, our present findings provide a potential mechanism allowing fear and escape related behaviors to supersede reward seeking in the presence of threat.

Abstract: Observational learning is a powerful survival tool, allowing an individual to learn about environmental stimuli that predict specific threats without direct experience. This ability has been conserved from rodents to humans, and has been linked to the anterior cingulate cortex (ACC) and the basolateral amygdala (BLA). However, little is known about the processes that occur within this circuit, and the degree of specificity to observational learning. To investigate how information is encoded and transmitted through this network, we performed electrophysiological recordings from neurons identified as part of the ACC-BLA network by optogenetic-mediated phototagging to reveal that this network encodes information obtained through observational learning. We also demonstrate that selective inhibition of the ACC-BLA projection impairs observational fear conditioning and other social behaviors, but not classical fear conditioning and that inhibition of ACC input to the BLA alters the amygdalar representation of a cue that predicts shock to another mouse. Lastly, we utilize calcium imaging to assess how ACC neurons involved in observational learning play a role in other social behaviors. Altogether, we show that transfer of cue information from the ACC to the BLA plays a causal role in enabling observational learning and that this same input is needed for general social behavior.

Title: Transcranial alternating current stimulation reduced negative emotions and functional integration of anterior cingulate cortex

Authors: *K. ONODA, T. KAWAGOE, H. ZHENG, S. YAMAGUCHI;
Shimane Univ., Izumo, Japan

Abstract: Transcranial alternating current stimulation (tACS) is a novel, non-invasive bran stimulation technique. Studies have demonstrated that tACS modulated cortical neural activity affecting perceptual/cognitive performance. However, it is unclear whether effects of tACS reached deep brain areas. We hypothesized that 6 Hz tACS on the frontal area would alter connectivity and network properties of anterior cingulate cortex, based on evidence from frontal theta waves and monitoring responses (error-related, or feedback-related negativity) generated by the anterior cingulate cortex. Resting-state functional MRI (10 min) and emotional state (Positive and Negative Affect Schedule) were assessed before and after tACS (6 Hz, 1000 mA, 10 min). Healthy young voluntary participants (N =22, Mean age = 23.4 ± 3.5 years) were randomly assigned to a real or sham stimulation group. The active electrodes of the tACS were centered around electrode positions F3 and F4 in the 10-20 system. Resting-state functional MRI data were preprocessed by Statistical Parametric Mapping 12 (slice timing correction, realignment, normalization, and smoothing). Effects of white matter, cerebrospinal fluid, and head movements were regressed out from functional data. The whole brain data were divided into 312 regions of interest based on a subdivided automated anatomical labelling template, and mean time courses of BOLD signals were extracted in each region. Functional connectivity matrix for each individual was calculated from correlation coefficients between all pairs of time courses. Measures of functional integration and segregation were computed for each region by applying graph theory to the connectivity matrix. Results indicated that degree and nodal efficiency of the anterior cingulate cortex, which might reflect the level of functional integration, decreased in real, compared to the sham tACS group. Moreover, negative emotion score in real tACS group decreased significantly, whereas positive emotion score decreased in shame tACS group. Importantly, the decreased functional integration of anterior cingulate cortex was significantly correlated with decreased positive emotion scores in the real tACS group. These results suggest that 6Hz tACS on frontal area modulated network properties of anterior cingulate cortex, and caused changes in emotion states.

Title: The neural basis of the human affective startle modulation - evidence from two independent studies using parallel EMG-fMRI

Authors: *M. KUHN[1], J. WENDT[2], R. SJOUWERMAN[1], M. MÖLLER[1], C. BÜCHEL[1], T. B. LONSDORF[1];
[1]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Dept. of Psychology, Univ. of Greifswald, Greifswald, Germany

Abstract: Administration of a brief burst of white noise ("startle probe") elicits a defensive reflex cascade which can be measured as whole body startle in rodents and in humans by facial electromyography (EMG) of the orbicularis oculi muscle as a blink reflex. Thereby, response magnitude is modulated by the affective state which manifests as response inhibition in positive and potentiation in negative states.
The neural pathway underlying affective startle modulation has been extensively delineated in rodents and critically involves the nucleus reticularis pontis caudalis and the central nucleus of the amygdala. In humans, this pathway has not been investigated so far even though the startle reflex is widely employed in human emotion ("affective startle modulation") and fear conditioning experiments ("fear-potentiated startle").
For the first time, we provide converging evidence for a similar neural network in humans and rodents by reporting results of parallel facial EMG recordings and fMRI in a fear conditioning experiment (study 1, fear-potentiated startle) as well as an affective startle modulation study using high-resolution brainstem/amygdala fMRI (study 2). We show a relationship between EMG strength and central amygdala activation as well as an affective modulation of the central amygdala and reticular areas of the brainstem. In line with the neurobiological model of affective startle modulation, we further report an increased functional crosstalk between these implicated areas during fear-associated and emotionally negative states. This work has potential impact for translating findings from the vast literature of affective startle modulation in rodents to humans as well as for a more mechanistic investigation of behavioral results on a neural level.

Title: Beta noradrenergic blockade in the basolateral amygdala, but not the medial prefrontal cortex, rescues the immediate extinction deficit

Authors: ***T. F. GIUSTINO**[1], J. R. SEEMANN[2], G. M. ACCA[2], T. D. GOODE[2], P. J. FITZGERALD[2], S. MAREN[2];
[1]Inst. For Neurosci., College Station, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Early intervention strategies such as psychological debriefing and exposure therapy are widely practiced following a traumatic experience. These therapies are aimed at reducing the development of stress and trauma-related disorders (e.g., anxiety, phobias, and posttraumatic stress disorder) and are thought to rely on extinction like-processes. However, animal models and human research suggest extinction training often fails to reduce fear long term when administered soon (minutes to hours) after trauma. This is likely due to high levels of psychological stress in the wake of trauma, yielding an immediate extinction deficit (IED). We have previously shown that systemic beta-adrenoceptor blockade (propranolol, 10 mg/kg, i.p.) delivered immediately after fear conditioning (and 30 min prior to immediate extinction training) rescues the IED. In contrast, propranolol administered 30 min prior to delayed extinction (24 hrs post conditioning) produced retrieval deficits. The neural substrates underlying these effects remain largely unknown. Here animals underwent a standard auditory fear conditioning procedure and then received either immediate (30 min after conditioning) or delayed (24 hrs after conditioning) extinction training. We used intracranial infusions of propranolol prior to immediate or delayed extinction targeting either the infralimbic (IL) subdivision of the medial prefrontal cortex or the basolateral amygdala (BLA) to examine the effects of beta adrenoceptor blockade on extinction learning. Interestingly, intra-BLA, but not intra-IL, propranolol rescued the IED; that is, animals receiving intra-BLA propranolol prior to immediate extinction showed less spontaneous recovery of fear during extinction retrieval. In contrast, neither intra-BLA nor intra-IL propranolol modulated delayed extinction learning. Overall, these data contribute to a growing literature suggesting dissociable roles for key nodes in the fear extinction circuit depending on the timing of extinction relative to conditioning. These data suggest heightened noradrenergic activity in the BLA underlies extinction deficits during high psychological stress. Propranolol may be a useful adjunct to therapeutic interventions in recently traumatized individuals who are at risk for developing trauma-related disorders. Supported by NIH grant R01MH065961.

Title: Single neurons in the medial prefrontal cortex of freely moving rats signal fear renewal.

Authors: *P. J. FITZGERALD, T. F. GIUSTINO, S. MAREN;
Dept. of Psychology, Texas A&M Univ., College Station, TX

Abstract: In Pavlovian fear conditioning experiments, rodents are typically trained to fear a previously behaviorally neutral conditioned stimulus (CS), such as an auditory tone, by pairing it with a footshock. Fear can subsequently be extinguished by presenting the CS repeatedly without shock. Extinction memories are labile and limited to the context in which extinction learning occurred; that is, fear returns when the CS is encountered outside the extinction context (fear renewal). Previous studies suggest the ventral hippocampus plays a critical role in the contextual regulation of fear renewal. However, the role of medial prefrontal cortex (mPFC), a key node in fear modulation, is not well understood in renewal. Here we performed *in vivo* recordings in mPFC of freely moving rats, to investigate single neuron firing patterns during extinction retrieval and fear renewal. In six Long-Evans rats, a microelectrode array was implanted in the right hemisphere, spanning both the prelimbic (PL) and infralimbic (IL) subdivisions of mPFC, to allow for recordings across a five day, modified renewal protocol. Rats were fear conditioned on Day 1 (context A), extinguished (45 tones) in a different context on both Days 2 and 3 (context B), given an unsignaled reminder shock in the conditioning context on Day 4, and finally given a dual retrieval-renewal session, in which the order of these two tests was counterbalanced across animals, on Day 5 (retrieval: context B, renewal: context C). In this design, the same neurons were recorded during both the retrieval (low fear) and renewal (high fear) sessions. Recordings revealed little difference in spontaneous firing between the retrieval and renewal sessions, but the CS-evoked response in IL was lower in renewal than in retrieval. In contrast, PL CS-evoked responses were slightly elevated during renewal. Importantly, individual units showed context-dependent firing to the CS, with 35% of neurons in IL and 28% of neurons in PL showing preferential firing to the CS presented in the retrieval and renewal contexts, respectively. Collectively, these findings suggest that CS-evoked responses in mPFC during renewal convey task-related contextual information. Future recordings in mPFC, combined with chemogenetics, are planned to address potential interactions with ventral hippocampus in transmitting contextual information during fear renewal. Supported by NIH grant R01MH065961.

Title: Opposing inhibition in prelimbic prefrontal neurons impairs active avoidance

Authors: *M. M. DIEHL, G. J. QUIRK;
Psychiatry, Univ. of Puerto Rico, Sch. of Med., San Juan, PR

Abstract: It has been previously demonstrated that pharmacological inactivation of prelimbic prefrontal cortex (PL) with muscimol prevents the expression of platform-mediated avoidance in response to a conditioned tone (Bravo-Rivera, et al., 2014). Last year, we reported that optogenetically silencing PL using Archaerhodopsin (Arch) during the tone delayed but did not prevent avoidance (Diehl et al., 2015 SFN abstract). A possible reason for this discrepancy is that muscimol inactivates all cell types, whereas Arch containing the CaMKIIa promoter preferentially targets glutamatergic neurons. PL neurons recorded during this task showed both excitatory and inhibitory responses to the tone, but only inhibitory responses were correlated with avoidance (Bravo-Rivera, et al., 2014 SFN abstract). PL neurons exhibiting inhibitory tone responses in avoidance were classified as excitatory neurons, based on low baseline firing rate (<15 Hz) and broad spike width (>225 μs; Sotres-Bayon, et al, 2012). This suggests that inhibition of PL glutamatergic neurons may be key for avoidance responses. To test this hypothesis, we used channelrhodopsin (AAV-CaMkII-hChR2(H134R)-eYFP) to prevent tone-induced inhibition of glutamatergic neurons in PL. We stimulated during the tone at a rate of 4Hz, which is the average spontaneous firing rate of PL neurons (Burgos-Robles, et al., 2009). Photoactivation of rostral PL neurons blocked avoidance throughout the tone compared to eYFP controls (rPL-ChR2=17.5% time on platform n=5, eYFP=89.9% n=6, $p<0.01$). In contrast, photoactivation of caudal PL neurons had no effect on avoidance (cPL-ChR2=86.5% n=3, eYFP=89.9% n=6, $p=0.38$). The present findings suggest that inhibitory tone responses in rostral PL are essential for the expression of platform-mediated avoidance. Inhibition of PL glutamatergic neurons could serve to disinhibit neurons in striatum to drive avoidance, similar to disinhibition of basolateral amygdala SOM^+ cells during fear conditioning (Wolff et al, 2014).

Title: Hippocampal-prefrontal projection mediates contextual fear memory retrieval

Authors: *J. JIN[1], T. GOODE[1], Q. WANG[2], S. MAREN[1];
[1]Inst. for Neuroscience; Dept. of Psychology, Texas A&M Univ., College Station, TX; [2]Dept. of Biology, Texas A&M Univ., College Station, TX

Abstract: Extinguished fear to a conditioned stimulus (CS) 'renews' outside of the context in which extinction training occurred. The hippocampus has a critical role in fear extinction, but how it contributes to the context-dependence of extinction memories is not clear. Here we examine the hypothesis that projections from the ventral hippocampus (VH) to the infralimbic region (IL) of the medial prefrontal cortex mediates fear renewal via feed-forward inhibition. In experiment 1, we used 'designer receptors exclusively activated by designer drugs' (DREADDs) to either selectively inhibit or activate VH neurons projecting to IL in different test contexts after extinction. Virus either expressing an inhibitory (AAV8-hSyn-DIO-hM4D[Gi]-mCherry) or an excitatory (AAV5-hSyn-DIO-hM3D[Gq]-mCherry) DREADD was infused into VH, and Cre-expressing virus (CAV2-Cre or AAV5-Cre-eGFP) was infused in the IL to enable DREADD expression in VH neurons projecting to IL. Four weeks later, rats underwent ABA renewal in a counterbalanced within-subjects design. Rats infused with inhibitory DREADD were tested to the CS outside of the extinction context on CNO (1 mg/kg, i.p.). As predicted, DREADD-mediated inactivation of VH neurons projecting to IL disrupted fear renewal as compared to control animals. Moreover, activation of VH neurons projecting to IL by excitatory DREADD led to renewal of fear in the extinction context on CNO (2 mg/kg, i.p.). These data suggest that VH projections to the IL can bidirectionally control fear relapse after extinction. In experiment 2, the hypothesis was further tested by microinfusion of GABA receptor antagonists into the IL during fear renewal. Rats were implanted with a bilateral cannula aimed at IL. A week later, rats underwent ABA renewal in a between-subjects design with microinfusion of $GABA_A$ antagonist picrotoxin, $GABA_B$ antagonist CGP55845, cocktail of two drugs or saline into the IL before renewal test. Consistent with VH-IL circuit manipulation, microinfusions of picrotoxin, CGP55845 or cocktail of two all disrupt fear renewal. These data together suggest that contextual control of fear is mediated by VH-IL circuit via feed-forward inhibition.

Title: Reversible inactivation of the bed nucleus of the stria terminalis disrupts the expression of fear to unpredictable threats

Authors: *T. D. GOODE, G. M. ACCA, S. MAREN;
Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: The bed nucleus of the stria terminalis (BNST) is thought to control conditioned fear responses to contexts but not short-duration cues. However, a conditioned context may inevitably differ from a discrete cue in terms of when the animal expects an aversive event to occur during presentation of the stimulus. The current experiments sought to examine whether US predictability is a factor in the recruitment of the BNST, independent of CS duration. First, to establish a strong vs. weak predictor of footshock, rats underwent either forward (i.e., CS-then-US) or backward (i.e., US-then-CS) fear conditioning. Specifically, we hypothesized that the expression of fear to the less predictable (backward) CS would be mediated by the BNST, whereas expression of a forward-trained CS would not. In Experiment 1, rats received twelve forward CS (10 sec, 2 kHz, 80 dB auditory cue)-then-US (2 sec, 1.0 mA footshock) pairings ('FW') or twelve backward US-then-CS pairings ('BW') in Context A (60-sec intertrial intervals, ITIs). Freezing served as the dependent measure of fear. The next day, rats underwent 1 hr of context extinction in the conditioning context or equivalent exposure to a novel context (Context B). 24 hrs later, rats were tested to the auditory CS (eight CS-only trials; 60-sec ITIs) in a separate novel context (Context C). Both forward and backward conditioning resulted in robust fear; fear to the BW but not FW CS was susceptible to extinction of the conditioning context. In Exp. 2, naïve rats were implanted with cannulae targeting the BNST. 1 week after surgery, rats were trained to a FW or BW CS as in Exp. 1, with another group receiving 5 FW conditioning trials instead of 12. 24 hrs after conditioning, rats were infused with the AMPA receptor antagonist, NBQX, or vehicle immediately prior to 12 CS-only testing trials (60-sec ITIs) in a novel context. Intra-BNST infusions of NBQX blocked fear expression to the BW CS, but did not significantly alter fear expression to the 5- or 12-training trials FW CS. A third experiment demonstrated that BNST inactivation disrupted fear expression to a previously conditioned context in which shock (2 sec, 1 mA) was experienced long after placement in the chamber (9 min, 'unpredictable') compared to a context within which shock was experienced soon after

placement (1 min, 'predictable'). These results suggest that fear evoked by unpredictable CSs, whether contexts or cues or long- or short-duration stimuli, are mediated by the BNST.

Title: Nucleus reuniens mediates the encoding of extinction memories.

Authors: *K. R. RAMANATHAN[1,2], J. JIN[3], S. MAREN[3];
[2]Dept. of Psychology, [3]Dept. of Psychology and Texas A&M Inst. for neurosciences, [1]Texas A&M Univ., College Station, TX

Abstract: The hippocampus (HPC) and medial prefrontal cortex (mPFC) are two brain areas that have an important role in the extinction of fear memories. Inactivation of the dorsal (Corcoran et al., 2005) or ventral (Sierra-Mercado et al., 2011) hippocampus or the infralimbic cortex (Sierra-Mercado et al., 2011) impairs the acquisition of fear extinction. The anatomy of this circuit suggests that unidirectional, monosynaptic projections from the HPC to the mPFC supports extinction learning. However, the mPFC is positioned to influence information processing in the HPC via indirect projections through the thalamic nucleus reuniens (RE); it is not known how the RE or mPFC->RE projections contribute to extinction learning or retrieval. To address these questions, we first examined whether muscimol inactivation of RE would affect extinction learning. Animals were implanted with a single cannula targeting RE. After recovering from surgery, rats were subjected to 5 tone (CS)-footshock (US) pairings in context A. Twenty-four hours later, they were infused with either muscimol ($GABA_A$ agonist) or saline in RE 10 mins before they received extinction session wherein they received 45 CS-alone trials in context B. This was then followed a day later by retrieval tests in the extinction context (B) and the conditioning context (A). RE inactivation attenuated both within-session extinction, as well as fear suppression in the extinction context the following day; the renewal of fear in the conditioning context was not affected by RE inactivation. To determine if extinction deficits subsequent to RE inactivation are due to blocking PFC input to the RE (and presumably the

HPC), we selectively silenced RE projecting neurons in the mPFC. Rats were first injected with a Cre-dependent inhibitory DREADD (AAV8-hSyn-DIO-hM4D(Gi)-mCherry) in the mPFC and AAV5-CMV-Cre-eGFP in RE to retrogradely transduce DREADD expression in RE projectors in the mPFC. Four weeks later, the rats received the behavioral protocol used in the first experiment. We found that silencing RE projectors in the mPFC reproduced the extinction deficits we observed after muscimol inactivation of RE. Interestingly, there was also stronger renewal in rats extinguished under mPFC->RE inactivation. These results suggest that prefrontal->hippocampal communication is required for fear extinction and the RE is a critical relay to enable this interaction.

Title: TRPV1 receptors modulate aversive responses and social behavior in rodentes

Authors: ***A. B. TERZIAN**, L. RESSTEL;
Pharmacol., Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: TRPV1 receptor (rTRPV1; transient receptor potential vanilloid type 1) is widely distributed in the central nervous system (CNS), on areas involved with modulation of emotional responses such as midbrain and prefrontal cortex. Pharmacological or genetic inhibition of this receptor reduces neuronal activity, resulting in decreased fear and anxiety levels. However few studies investigated the role of rTRPV1 on acquired fear and social behavior, which are highly related to species survival and several psychiatric disorders. Therefore, this study aimed to investigate the role of rTRPV1 in different phases of cued fear conditioned (CFC) and social investigation (SInv) in wild-type (WT) and rTRPV1 knockout mice ($TRPV1^{-/-}$). Mice (C57bl/6 background; 8-12 weeks) submitted to the SInv protocol, were allowed to explore the empty 3-

chamber box (Habituation) for five minutes. On the following phase (Phase 1), animals were either exposed to an empty cage or to one containing a mouse, located in each extreme of the box. Later (Phase 2; 1h or 24h interval), a new mouse was introduced into the empty cage. The time exploring the cages in each phase was evaluated. The CFC protocol was performed in 3 days - on the first day (d0), animals received foot-shock associated with an auditory cue in context A [5 shocks, 0,65mA, 1s; paired with a tone (30s, 1kHz, 70dB)]. Twenty-four hours later (d1), animals were placed in a different context B, where the auditory cue was presented without the foot-shock. On the third day (d2), animals were submitted to the same conditions as in d1. The acquisition (d0), extinction (d1) and extinction learning (d2) were evaluated based on the level of freezing behavior. As a result on SInv, both WT and TRPV1$^{-/-}$ showed preference for the cage containing a mouse on Phase 1, also, both groups spent more time investigating the new mouse on Phase 2 after 1h delay. Interestingly, when Phase 2 was delayed 24h, TRPV1$^{-/-}$ did not exhibit preference for the new mouse. On CFC protocol, the cued fear acquisition was similar for both groups. Nonetheless, on the following days (d1-d2) TRPV1$^{-/-}$ showed reduced freezing behavior, resulting in improved extinction learning when compared to control. In conclusion, our results suggest rTRPV1 involvement in the modulation of learned behaviors with emotional content, suggesting a new approach to future treatment for psychiatric disorders.

Title: TRPV1 receptor of the ventral portion of medial prefrontal cortex modulates conditioned emotional response: involvement of local glutamatergic and nitrergic system.

Authors: ***D. L. ULIANA**, L. S. ANTERO, S. F. LISBOA, L. B. M. RESSTEL;
Pharmacol. Departament, Sch. of Med. of Ribeirão Preto - USP, Ribeirão Preto, Brazil

Abstract: Transient Potential Vanilloid Type 1 receptor (TRPV1) present in the ventral portion of medial pre-frontal cortex (vMPFC) modulates the conditioned emotional response (CER), in

contextual fear conditioning (CFC). TRPV1 receptor activation has been related with increase behavior and cardiovascular response during contextual re-exposure. Furthermore, the vMPFC NMDA glutamate receptor and neuronal nitric oxide synthase (nNOS) are involved with CER modulation. Possibly, the response induced by TRPV1 involves modulation of glutamate release and NO production. Therefore, this study tests the hypothesis that TRPV1 receptor modulates CER through NMDA activation and NO production. Male Wistar rats (250-270g) with bilateral guide cannula targeted to the vMPFC were first exposed to a chamber during 10 min (habituation). In a second exposure to the same chamber, they received 3 electrical footshocks (0.85 mA, 2 s). 24h later, a polyethylene catheter was implanted in the femoral artery for cardiovascular recordings. After additional 24h, the behavioral and autonomic responses (mean arterial pressure - MAP, heart rate - HR and cutaneous temperature - CT) were continuously assessed during the 10 minutes of the re-exposition to the same chamber with no footshocks (test session). Vehicle (Saline or DMSO10%) or/and the TRPV1 agonist (capsaicin; 0.1, 1, 10nmol); NMDA antagonist (LY 2 nmol) or nNOS inhibitor (NPLA; 0.04 nmol) were administered in the vMPFC 10 min before the test session. The Institution's Animal Ethics Committee approved housing conditions and experimental procedures (process number: 171/2014). TRPV1 agonist receptor in the dose of 1nmol increased the time spent in freezing behavior ($F_{3,21}$=11,66; p<0,05, ANOVA, Tukey pos-hoc), and also induced an enhancement of the rise in MAP ($F_{3,21}$=16,64, p<0.05, ANOVA, Tukey pos-hoc), HR ($F_{3,21}$=9,84, p<0.05, ANOVA, Tukey pos-hoc) and the CT decrease ($F_{3,21}$=3,81, p<0.05, ANOVA, Tukey pos-hoc) during the re-exposure. LY and NPLA, were not able to change either freezing behavior (p>0.05) or autonomic response (MAP, p>0.05; HR, p>0.05; CT, p>0.05). However, when administrated previously to the TRPV1 agonist, capsaicin 1nmol, prevented the CER enhancement. The present data demonstrate that the TRPV1 agonist, capsaicin, changed freezing behavior and autonomic response in the re-exposure session, suggesting that TRPV1 receptor in vMPFC modulate CER, in CFC model. And also, this response seems to be dependent NMDA activation and NO production.

Title: The expression of contextual fear conditioning involves ACh release and activation of M1-M3 muscarinic receptors/NO/cGMP pathway in the dorsal hippocampus of rats.

Authors: *L. ANTERO, D. L. ULIANA, L. B. RESSTEL;
Pharmacol., Ribeirão Preto Med. Sch. - USP, Ribeirão Preto, Brazil

Abstract: Contextual fear is evoked by re-exposing an animal to an environment previously paired with an aversive stimulus, followed by alterations in behavioral and cardiovascular parameters controlled by the central nervous system. Several studies provide evidence for the involvement of dorsal hippocampus (DH) in contextual fear conditioning. In addition, the cholinergic system in the rats' hippocampus controls conditioning-related behavior, where an increase in acetylcholine (ACh) is associated with defensive behavior retrieval in contextual conditioning. One of the targets of ACh in the DH is the muscarinic receptors, including M1 and M3 receptors subtypes. These receptors facilitate autonomic and behavioral responses associated to threatening situations. Moreover, evidence shows that activation of cholinergic receptors promotes release of nitric oxide (NO) and cyclic guanosine monophosphate (cGMP) in the DH, which can modulate behavioral responses during aversive situations. Therefore, the present study investigated the involvement of ACh, muscarinic receptors and the NO/cGMP pathway in the DH, on contextual fear conditioning expression.
Methods: Male Wistar rats (200-250g), implanted with bilateral guide cannulas direct to the DH, were submitted to contextual fear conditioning (3 electric footshocks, 0.85 mA, 2s). After 24 h, a polyethylene catheter was implanted in the femoral artery for cardiovascular recordings. On the following day, drugs were administered in the DH 10 min before re-exposure to the conditioning chamber. Drugs used were the acetylcholinesterase enzyme inhibitor, neostigmine (0.1 - 3.0 nmol/500nL); M1 and M3 muscarinic antagonist, fumarate (6.0 nmol/500nL); M1 muscarinic antagonist, pirenzepine (6.0 nmol/500nL); NO synthase inhibitor, NPLA (0.01 nmol/500nL); NO scavenger, cPTIO (0.2 nmol/500nL); and soluble guanylate cyclase inhibitor (sGC), ODQ (0.1 nmol/500nL. Freezing and autonomic responses were recorded for 10 min.
Results: The higher doses of neostigmine increased the expression of a conditioned emotional response. This response was prevented by an M1-M3 muscarinic antagonist, NPLA, cPTIO and ODQ. However, pretreatment with the M1 antagonist only prevented the increased autonomic response induced by neostigmine. Moreover, neostigmine produced an increase in NO release in the DH.
Conclusion: Our results show the involvement of the hippocampal cholinergic system in the expression of contextual fear conditioning, via the M1-M3/NO/sGC pathway. Furthermore, our results suggest that DH muscarinic receptors have different roles on the conditioned emotional response.

Title: Subcortical projection-specific control of innate anxiety and learned fear by the ventral hippocampus

Authors: *J. C. JIMENEZ[1], A. GOLDBERG[3], G. ORDEK[2], V. M. LUNA[2], K. SU[2], S. PENA[2], L. ZWEIFEL[4], R. HEN[2], M. KHEIRBEK[3];
[1]Columbia Univ., New York, CA; [2]Columbia Univ., New York, NY; [3]Univ. of California, San Francisco, San Francisco, CA; [4]Univ. of Washington, Seattle, WA

Abstract: The ventral hippocampus (vHPC) has become appreciated for its role in anxiety-related behaviors, serving as a circuit hub that connects cognitive association regions with subcortical structures that directly regulate mood. Although some studies have observed vHPC activity changes in anxiety-related tasks, it is still not understood how diverse vHPC limbic output streams differentially contribute to emotional behaviors. To understand the mechanisms by which distinct vHPC output streams differentially contribute to anxiety-related behaviors, we first determined whether there existed dedicated output streams from vHPC to different subcortical nuclei. Anterograde tracing studies revealed dense terminal innervation of the Basomedial Amygdala (BMA) and Lateral Hypothalamus (LHA), two regions implicated in anxiety, fear, and behavioral responses to stress. Retrograde tracing techniques revealed that vHPC outputs to the LHA and BMA are segregated into two non-overlapping cell populations within vHPC, with distinct laminar organization within the vCA1 subregion. We next determined how these segregated outputs may differentially modulate anxiety-related behavior, employing optogenetic techniques in downstream terminal fields in BMA and LHA. Optical modulation of vHPC-LHA terminals produced aversion and acutely increased anxiety-related behavior without impacting the encoding or retrieval of contextual fear memories. Conversely, vHPC-BMA

terminal modulation impaired the encoding and retrieval of contextual fear memories without altering innate anxiety-related behavior. To understand the mechanisms by which distinct vHPC output streams could contribute to these behaviors, we used miniaturized microscopes to perform cell-type specific calcium imaging *in vivo* in freely behaving mice. This allowed us to visualize vHPC whole-population and projection-specific activity during anxiety-related and learned fear tasks. We found that, at the population level, vHPC activity increased during exploration of innately anxiogenic environments, including the center of the Open Field test and the open arms of the Elevated Plus Maze and Zero Maze, but not to exploration of a novel object. Alternatively, in CFC, re-exposure to a previously conditioned environment did not impact overall rate of transients, rather, increased correlated activity within vHPC and stabilized the ensemble representations of context. Ongoing imaging studies are aimed at determining if the specific vHPC-BMA and vHPC-LHA cell populations are differentially recruited during innate anxiety and learned fear tasks.

Title: Differential role of the hippocampal & basolateral amygdalar endocannabinoid neurotransmission in the modulation of fear memory retrieval in rats

Authors: B. RUBINO, M. CARLUCCI, E. SANTI, P. RATANO, *P. CAMPOLONGO; Dept. Physiol. and Pharmacol., Sapienza Univ. of Rome, Roma, Italy

Abstract: To date, the understanding of the relative contribution of the principal endocannabinoids, anandamide and 2-arachidonoylglycerol (2-AG), in the regulation of memory retrieval of stressful experiences is still limited. To address this issue, we investigated the effects induced by pharmacological manipulation of the endocannabinoid signaling in the dorsal hippocampus or in the basolateral complex of the amygdala (BLA). Adult male Sprague Dawley rats were trained in a Contextual or Auditory Fear Conditioning task (CFC and AFC,

respectively). They were bilaterally infused, 60 minutes before retrieval, into the BLA or into the dorsal hippocampal with the FAAH inhibitor, URB597, or the MAGL inhibitor, KML29, respectively increasing endogenous levels of anandamide and 2-AG. In a first experiment, URB597 (3-30 ng/0.2 µl/side) or KML29 (2-200 ng/0.2 µl/side) were infused into the BLA of rats trained in the CFC task. We found that increasing anandamide or 2-AG signalling in the BLA did not influence the retrieval of fear memories. Conversely, infusion of URB597 (10 ng/0.2 µl) into the BLA of rats trained in the auditory version of the task induced an impairing effect on memory retrieval. In a second experiment, URB597 (3-30 ng/0.5 µl/side) or KML29 (2-200 ng/0.5 µl/side) were infused into the CA1 field of the hippocampus; we found that the infusion of KML29 (2 ng/0.5 µl) impaired retrieval of aversive memory in the CFC, but Intra-CA1 infusions of URB597 or of both URB597 and KLM29 in the AFC task did not influence memory retrieval. The cannabinoid receptor antagonist AM251 blocked the impairing effects induced by URB597 on retrieval of cued fear memory or by KML29 on retrieval of contextual fear memory, thus demonstrating that increasing anandamide levels in the BLA or 2-AG levels in the CA1 region of the hippocampus negatively modulates fear memory retrieval through a CB1 receptor dependent mechanism. Our results suggest that the endocannabinoid system is crucially involved in the regulation of retrieval of memory for stressful experiences and it might represent a new therapeutic target for the treatment of neuropsychiatric disorders, such as the Post-Traumatic Stress Disorder.

Title: Effects of intra-amygdaloid injection of the D1 antagonist SCH23390 on the fear/anxiety induced by the exposure to a living cat in rats.

Authors: *E. N. LEVARIO RAMÍREZ, M. CRESPO RAMÍREZ, M. PÉREZ DE LA MORA; Cognitive Neurosci., UNAM, Mexico, D.F., Mexico

Abstract: Amygdaloid DA system participates in the modulation of conditioned and non-conditioned fear. Behaviorally, the intra-amygdaloid infusion of DA D1 agonists and antagonists elicits anxiogenic and anxiolytic effects respectively on conditioned and non-conditioned models of fear/anxiety suggesting an anxiogenic role for the amygdaloid DA D1 receptors. However, these studies have been restricted to relatively simple and ethologically-poor models. The aim of this study was to evaluate the role of amygdaloid DA D1 receptors on fear/anxiety exposing rats to a living adult cat, a real threatening and ethologically relevant model to rodents. Adult male Wistar rats were exposed to a cat in a rectangular plexiglass box having a safe and a danger zone relative to either the presence or absence of the cat separated by a narrow tunnel. The testing procedure consisted of three 10 min video-recorded phases. At the first phase (habituation) rats were allowed to explore the box for 4 days in the absence of any cat. Behavior at the fourth day of habituation was taken as baseline. At the second phase (acquisition), rats received a bilateral intra-amygdaloid injection of either SCH23390 (40 or 120 ng/side), a D1 antagonist or vehicle (saline) and were immediately placed in the safe zone of the box allowing them to explore the whole device, including the danger zone where the cat was already present. At the third phase (retrieval), one day after cat exposure animals were placed into the box but without any cat. Results showed that saline treated rats avoid exploring the danger zone of the box (avoidance behavior) when they are exposed to the cat. SCH23390 infusion into the amygdala has no effects on the time spent by the rats in the danger zone during the acquisition of the avoidance behavior but selectively increased the time spent in this zone following retrieval of the behavior 24 hrs after the exposure to the cat. Our results suggest that amygdaloid DA D1 receptor mechanisms may have a role in the aversive behavior that rats experience in the presence of its predator.

Title: A central amygdala to BNST circuit that regulates anxiety

Authors: *S. AHRENS, B. LI;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The expression of fear and anxiety are evolutionary conserved behaviors that are important for survival as they allow adaptation to a harmful environment by minimizing

exposure to potential threats. The central amygdala (CeA) and the bed nucleus of the stria terminalis (BNST) are important structures in mediating different aspects of fear and anxiety related behaviors and they are highly interconnected. While the amygdala is thought to mediate immediate responses to threat, the BNST is considered to be involved in sustained fear responses.
States of sustained fear often result from an immediate threat; however, how and where this transition occurs is still unclear.
In previous studies we found that cued fear conditioning in mice induces changes in synaptic transmission in the central lateral amygdala (CeL): While the glutamatergic transmission onto Somatostatin positive (SOM+) neurons was increased, the transmission onto Somatostatin negative (SOM-) cells was reduced and this plasticity change was crucial for fear memory. Recently, we found that genetic deletion of the receptor tyrosine kinase ErbB4 in SOM+ neurons causes the same change in synaptic transmission in the CeL and is associated with increased expression of conditioned fear as well as increased anxiety measured in the open field and elevated plus maze. Interestingly, these SOM/ErbB4 mutant mice also display a strongly elevated expression of c-fos of neurons in the oval nucleus of the BNST (ovBNST), a region that receives substantial projections from the CeL and that has been shown to be anxiogenic when activated. An increase in c-fos expression in the ovBNST was also observed in wildtype mice 24h after fear conditioning. This makes the SOM/ErbB4 mutant mice to an attractive model to study the circuits between CeL and ovBNST in fear and anxiety behaviors.
Normalizing the synaptic transmission onto the SOM+ cells in the CeL of ErbB4 mutant mice not only normalizes the expression of conditioned fear, but also reduces the anxiety phenotype and decreases c-fos expression in the ovBNST, suggesting a modulation of ovBNST activity through the CeL.
Electrophysiological recordings in the ovBNST of SOM/ErbB4 mutant mice revealed changes in GABAergic transmission that might provide the underlying mechanism for the increased activity of ovBNST.
Taken together, we propose a model involving a CeL to ovBNST circuit that mediates the transition from an immediate threat response to a sustained fear response, which is important for the animal's behavioral adaptation of risk taking behavior after encountering threatening situations. Disturbances in this circuit are potentially involved in anxiety disorders.

Title: Netrin-G1 regulates fear and anxiety in dissociable neural circuits

Authors: *Q. ZHANG, S. ITOHARA;
Riken, Wako/Saitama, Japan

Abstract: Netrin-G1 is a glycosyl-phosphatidylinositol-anchored synaptic adhesion molecule whose deficiency results in impaired fear and reduced anxiety under specific circumstance as well. To understand the cell type and circuit specificity of these responses, we generated netrin-G1 conditional knockout mice with loss of expression in cortical excitatory neurons, inhibitory neurons, or thalamic neurons, zona incerta neurons. Genetic deletion of netrin-G1 in cortical excitatory neurons resulted in altered anxiety, but intact fear, whereas loss of netrin-G1 in inhibitory neurons resulted in attenuated fear, but intact anxiety. These data indicate a remarkable double dissociation of fear and anxiety involving netrin-G1 in excitatory and inhibitory neurons, respectively. Our findings support a crucial role for netrin-G1 in dissociable neural circuits for the modulation of emotion, and provide genetic models for investigating the mechanisms underlying the dissociation. The results also suggest the involvement of glycosyl-phosphatidylinositol-anchored synaptic adhesion molecules in the pathogenesis of emotion-related mental disorders.

Title: Social buffering during fear memory extinction involves medial prefrontal cortex

Authors: *T. GORKIEWICZ, K. ROKOSZ, K. MEYZA, E. KNAPSKA;
Nencki Inst., Warsaw, Poland

Abstract: Social buffering is a phenomenon that has been found in many social species, including humans. It has been observed that presence of a conspecific lowers stress level of

previously stressed animals. Though the behavioral expressions of social buffering are relatively well recognized, little is known on its neuronal underpinnings. Thus, we have developed a model of social buffering in rats that allow for studying neuronal basis of social modulation of fear and its extinction. In this model rats are kept in pairs in home cages for at least two weeks prior to onset of the experiment (to allow them to create stable social bounds). During the first phase of behavioral testing animals are separately fear conditioned. During the next three days one rat from each pair undergoes fear extinction procedure consisting of three sessions a day. The second rat from each pair is at that time only exposed to experimental cage. On the last day of experiment, both animals are tested together. They are placed in the experimental cage, in separate compartments, and presented to conditioned tones. The level of fear (measured as freezing) is compared to the animals treated in the same way but tested alone or rats that were subjected to fear extinction and then tested together. We observed a clear difference in the level of freezing between the rats that were not fear extinguished and tested separately or with a partner. Testing rats together resulted in much lower freezing response than testing them separately, with social exposure as effective in reducing fear as fear extinction. To investigate whether the mechanisms underlying social buffering effect we observed are similar to the ones involved in fear extinction, we compared activation of the prefrontal cortex and amygdala, the structures critical for extinction of conditioned fear. We found lower activation of the anterior cingulate cortex, and prelimbic and infralimbic parts of the prefrontal cortex in animals tested together, whereas no differences were observed in the basolateral and central amygdala. The inhibition of the anterior cingulate and prelimbic cortices resembles the pattern of activation observed in rats subjected to fear extinction; however activation of the infralimbic cortex related to low level of fear after fear extinction was not observed here. Taken together, these results suggest that the mechanisms of social buffering of conditioned fear can only partially rely on the neuronal circuits involved in fear extinction.

Title: Role of dopaminergic D2 receptors of globus pallidus in anxiety response in rat

Authors: G. AVILA[1], E. CHUC-MEZA[2], O. PICAZO[4], *M. GARCIA-RAMIREZ[3]; [1]ENCB-IPN, México, Mexico; [2]ENCB-IPN, Mexico, Mexico; [3]ENCB-IPN, DF, Mexico, Mexico; [4]ESM-IPN, Mexico, Mexico

Abstract: Globus pallidus (GP) is an important nucleus in control of movement. This GABAergic nucleus shows D1 and D2 dopamine receptors and receives dopaminergic innervation from substantia nigra pars compacta (SNc) (Anaya-Martínez et al, 2006; Dejean et al, 2011; Caravaggio et al 2014). In rodents, partial dopaminergic lesion by 6-hidroxydopamine (6-OHDA) in SNc produce anxiety and depression responses (Drui et al, 2014). Additionally, appetitive or aversive stimuli raise dopamine release in GP (Fuchs y Hauber, 2005) suggesting that dopaminergic innervation of GP is also involved in emotive process. In this sense, present work explores participation of dopaminergic innervation of GP in anxiety response of rat. Dopaminergic lesion in GP was made by local administration in both GP with 6-OHDA (500 nL of 6-OHDA, 15 μg/μL). Behavioral tests, elevated plus maze (EPM), burying behavior (BB) and social interaction (SI) and spontaneous motor activity (MA) were performed 30 days after lesion. Results shown reduced time spent in open arms in EPM, increased burying time in BB and decreased social interaction time (SI) without effect in MA. Others groups of rats were implanted with unilateral guide cannula for local administration of 500nL of vehicle, haloperidol (200μM), PD168077 (200μM), amphetamine (90μM) or haloperidol+PD168077. Haloperidol shown similar effects than bilateral lesion with 6-OHDA and were reverted by co-administration of agonist PD168077. In other hand, PD168077 or amphetamine increased time in open arm in EPM and reduced burying time in BB, without change in social interaction time respect of control group. In all cases motor activity was not affected. These results suggest the dopamine innervation in GP, could modulate anxiety behavior acting in D2 receptors. Chuc-Meza and García-Ramírez are COFAA fellow

Abstract: Recent discoveries demonstrated that recruitment of alternative brain circuits permits compensation of memory impairments following damage to brain regions specialized in integrating and/or storing specific memories, including both dorsal hippocampus and basolateral amygdala (BLA). Here, we first report that the integrity of the brain histaminergic system is necessary for long-term, but not for short-term memory of step-down inhibitory avoidance (IA). Second, we found that phosphorylation of cyclic adenosine monophosphate (cAMP) responsive-element-binding protein, a crucial mediator in long-term memory formation, correlated anatomically and temporally with histamine-induced memory retrieval, showing the active involvement of histamine function in CA1 and BLA in different phases of memory consolidation. Third, we found that exogenous application of histamine in either hippocampal CA1 or BLA of brain histamine-depleted rats, hence amnesic, restored long-term memory; however, the time frame of memory rescue was different for the two brain structures, short lived (immediately posttraining) for BLA, long lasting (up to 6 h) for the CA1. Moreover, long-term memory was formed immediately after training restoring of histamine transmission only in the BLA. These findings reveal the essential role of histaminergic neurotransmission to provide the brain with the plasticity necessary to ensure memorization of emotionally salient events, through recruitment of alternative circuits. Hence, our findings indicate that the histaminergic system comprises parallel, coordinated pathways that provide compensatory plasticity when one brain structure is compromised.

Title: Cortical drive to the extended amygdala modulates stress-induced behavior in mice

Authors: *K. S. GIRVEN, D. SPARTA;
Anat. and Neurobio. Dept, Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: The ventral bed nucleus of the stria terminalis (vBNST) is a portion of the extended amygdala that has been implicated as a key structure involved in the modulation of fear, stress, and negative affect (Davis, 2010). Although the vBNST receives input from many brain regions, input from the insular cortex (IC) is particularly interesting in relation to stress; being that the IC is a locus for autonomic responses to emotional stimuli (Moraga-Amaro, 2012). We hypothesized that glutamatergic drive from the IC onto vBNST neurons modulate anxiety-like behavior. First, we injected retrograde tracers into the vBNST, and found a dense projection from the caudal portion of the IC. To determine if the IC to vBNST projection promotes aversion and/or anxiety-like behavior we used optogenetics to photostimulate IC terminals in the vBNST during behavior tasks. We then used pharmacogenetics to inhibit IC terminals within the vBNST during a foot-shock stressor. Results implicate this IC-vBNST projection to be critical in the modulation of anxiety-like behavior. Alterations of this circuit may ultimately be important in furthering the modeling of stress related circuitry in the brain.

NSERC 06106-2015

Title: Neuronal correlates for neuroendocrine adaptation to repeated stress.

Authors: *S. MATOVIC[1], E. W. SALTER[2], X. WANG[2], W. INOUE[1];
[1]Neurosciences, [2]Robarts Res. Inst., London, ON, Canada

Abstract: Activation of the hypothalamic-pituitary-adrenal (HPA) axis, which results in the increased systemic release of glucocorticoids, is a hallmark of the stress response. The apex of this neuroendocrine response is formed by a group of neurons that synthesize corticotropin-releasing-hormone (CRH) in the paraventricular nucleus of the hypothalamus (PVN). Importantly, this stress response is honed with experience: for example, repeated exposure to a stressor decreases the responsiveness of the HPA axis to that same stressor. Despite its

importance in stress physiopathology, the neuronal plasticity that underlies the adaptation of the HPA axis is poorly understood. Here, we report a neuronal correlate for the adaptation of the HPA axis during repeated stress. We used a CRH-reporter mouse line that expresses red fluorescent protein (TdTomato) in CRH neurons. We challenged these mice (8-12 weeks) with a daily 1h restraint stress for 21 consecutive days. On the 22nd day, repeated restraint mice and control (stress naive) mice received a 1h restraint before dissection. By using immunohistochemistry, we found that stress-induced cFos (a neuronal activation marker) expression in CRH neurons was robustly attenuated in the repeated restraint group compared to control mice, verifying that stress habituation occurs at the level of CRH neurons. In a separate set of mice, we conducted whole-cell, patch clamp electrophysiology from identified PVN CRH neurons and found that repeated restraint stress decreased the intrinsic excitability of CRH neurons. Specifically, we found two mechanistically dissociable changes: 1) the time to elicit an action potential in response to depolarizing current injections was significantly delayed in stressed mice compared to controls; 2) the frequency of repetitive firing during long-duration current injections was decreased by repeated stress. The stress induced change in the delay to first spike was reversed by an A-type potassium channel blocker: 4-aminopyridine (4-AP, 5mM), but was insensitive to a Ca^{2+} chelator (BAPTA, 10mM) included in the internal solution. By contrast, the decrease in repetitive action potential firing was insensitive to 4-AP but was rescued by intracellular dialysis of BAPTA, indicating roles for postsynaptic Ca^{2+} signaling curtaining the excitability of CRH neurons during repetitive firing. Understanding how the HPA axis adapts, or fails to adapt to chronic stress will advance our knowledge about stress resilience, and may lead to the development of new therapeutics, prevention and diagnosis of stress-related disorders.

Title: C-Fos activation mapping of the bed nucleus of the stria terminalis in response to multimodal stress-inducing stimuli

Authors: ***X. LIN**[1], K. SAMI[1], M. LI[1], F. BERTON[2], W. FRANCESCONI[2], X. XU[1]; [1]Univ. of California Irvine, Irvine, CA; [2]The Scripps Res. Inst., La Jolla, CA

Abstract: The bed nucleus of the stria terminalis (BNST) is an important part of the extended amygdala circuitry, and has been implicated in regulation of acute and chronic stress responses. Given that modern life stresses are often multidimensional and involve multiple concurrent psychological, social and physical aspects, it is of much interest to characterize the pattern of BNST neural activation in the animal model in response to combined or multimodal stress-induced stimuli with concurrent hours-long light, loud noise, jostling and restraint. We also tested the hypothesis that the multimodal stress (MMS) causes strong BNST circuit responses comparable to acute stress with prolonged electrical foot shocks (EFS). In this study, we have assessed neural activation by tracking the expression of the immediate early gene c-Fos in control and stressed mice exposed to either electrical foot shocks (60 shocks within 30 minutes) or multimodal stress (3 hours) at 30-60 minutes, 24 hours, and 1 week following the stress treatment. At each time point, blood samples were collected for plasma corticosterone measurements, and the brains were perfused and sectioned for c-Fos immunostaining. For both stressed groups, we found that c-Fos expression in the BNST regions was abundant at 30-60 minutes following MMS and EFS, and rapidly decreased at 24 hours after the stress treatment. The c-Fos activation one week after was similar to the control level. The stress hormone corticosterone in the blood showed a stress-induced profile temporally correlated to the c-Fos activation strength in the brain. For the MMS group, dorsomedial BNST and ventral BNST regions appeared to have higher densities of c-Fos activated neurons (30-60 minutes: 425 ± 27 /mm^2 and 404 ± 91 /mm^2) than that of dorsolateral BNST (213.93 ± 39.57 /mm^2). For the EFS group, the densities of c-Fos activated neurons for dorsomedial BNST, ventral BNST and dorsolateral BNST regions were 739 ± 34 /mm^2, 515 ± 67 /mm^2 and 302 ± 23 /mm^2, respectively. Both MMS and EFS also caused high concentrations of acute c-Fos expression in other brain regions including the prefrontal cortex, olfactory cortex, thalamus, paraventricular nucleus of hypothalamus, and central amygdala. Taken together, our data support that the BNST is critically involved with acute stress responses including MMS and EFS, and that MMS appears to be as effective as EFS in stress induction.

Title: Distinct neural projections from the anteroventral bed nuclei of the stria terminalis modulate the endocrine and behavioral stress responses

Authors: *S. B. JOHNSON[1], R. M. ANDERSON[1], E. B. EMMONS[2], S. A. ROMIG-MARTIN[1], N. S. NARAYANAN[2], R. T. LALUMIERE[1], J. J. RADLEY[1];
[1]Psychology, [2]Neurol., Univ. of Iowa, Iowa City, IA

Abstract: The bed nuclei of the stria terminalis (BST) are critically important for integrating stress-related signals between the limbic forebrain to hypothalamo-pituitary-adrenal (HPA) effector neurons in the paraventricular nucleus of the hypothalamus (PVH). Nevertheless, the circuitry underlying BST control over the HPA axis and stress-related behaviors has remained obscure. To better understand these functions, we employed optogenetic techniques to manipulate activity in the somata and terminal fields of the anteroventral (av) BST. Adult rats received bilateral microinjections, into avBST, of adeno-associated viruses expressing channelrhodopsin (ChR2[E123A]-eYFP; ChR2), archaerhodopsin (eArch3.0-eYFP; Arch), or a control virus (YFP) under the synapsin promoter. Photoexcitation of avBST cell bodies during 10 min tail suspension abrogated HPA output (by 25% corticosterone [CORT], 10 min after stress onset; $p < 0.05$), while photoinhibition augmented ACTH abd CORT levels (by XX% and 30%, respectively, 30 min after stress onset; $p < 0.05$ for each) and increased immobility (by 32%; $p < 0.05$). Subsequent experiments interrogated terminal fields emanating from the avBST to account for the endocrine and behavioral functions subserved by this cell group. These experiments identified that the PVH and ventrolateral periaqueductal gray (vlPAG) as recipients of functionally distinct GABAergic avBST outputs capable of restraining stress-induced HPA activation and behavioral coping, respectively, during stress exposure. Specifically, photoinhibition of avBST terminals in PVH augmented HPA output (both ACTH and CORT at 30 and 60 min after stress onset; $p < 0.05$ for each) without affecting immobility behavior. Conversely, photoinhibition of the avBST-vlPAG pathway had no effect on HPA output, but significantly augmented immobility in both the tail suspension and forced swim tests (by 150% and 51%, respectively; $p < 0.05$ for each). These results direct attention to the avBST as a region important for the adaptive coordination of endocrine and behavioral output, identifying a novel circuit wherein impairment could account for core features of stress-related mood disorders.

Title: Topographic gene expression analysis of the nucleus accumbens shell and ventral tegmental area yields novel therapeutic target possibilities for anxiety, depression, and drug addiction

Authors: *E. J. CROFTON, Y. ZHANG, S. KOSHY, T. A. GREEN;
Pharmacol. and Toxicology, Ctr. for Addiction Res., Univ. of Texas Med. Br., Galveston, TX

Abstract: Psychiatric disorders such as addiction have proven difficult to treat and the available pharmacotherapies for anxiety and depression are not effective for all individuals or have unwanted side effects. Novel target identification strategies are therefore necessary to develop effective pharmacotherapeutics for these disorders, especially with minimal side effects. One strategy is to select targets based on gene expression patterns. Genes have evolved to be expressed to a large degree only in the specific cells they are needed. We hypothesized that genes with specific topographical expression patterns in the reward circuitry, specifically the nucleus accumbens shell (NAcSh) and the ventral tegmental area (VTA), would provide novel targets/pathways that would control behavior. Therefore we conducted a topographic gene expression analysis of with the Anatomic Gene Expression Atlas (AGEA) from the Allen Brain Atlas. Gene expression lists for the VTA and NAcSh were then analyzed for pathway relationships with Ingenuity Pathway Analysis. Some genes with expression restricted to the NAcSh are fatty acid binding protein 5 (FABP5), cocaine and amphetamine regulated transcript preopropeptide (CARTPT), cytochrome P450 family 26b polypeptide 1 (CYP26B1), and activating transcription factor 3 (ATF3), for which we and others have validated in addiction and depression studies. In addition to the expected pathways Glutamate Receptor Signaling and cAMP-mediated Signaling, novel pathways in the NAcSh included Cardiac Beta-adrenergic Signaling, Relaxin Signaling, and tRNA Splicing. Top upstream regulators in the NAcSh included cAMP responsive element binding protein 1 (CREB1), huntingtin, and L-dopa. Genes identified with specific expression in the VTA included dopa decarboxylase (DDC), tyrosine hydroxylase (TH), alpha synuclein (SNCA), and neuron-derived neurotrophic factor (NDNF). Top canonical pathways identified in the VTA included Glutamate Receptor Signaling and Dopamine Receptor Signaling but also Cholesterol Biosynthesis, Flavin Biosynthesis, and LXR/RXR Activation. Top upstream regulators included histone deacetylase 4 and brain derived neurotrophic factor (BDNF). MicroRNAs previously found to be altered in the blood of depressed patients were also identified as upstream regulators in the NAcSh (miR-17-5p) and the VTA (miR-34a-5p). Through a topographic gene expression analysis we have identified novel targets in the VTA and NAcSh, some of which have been validated. Therefore novel target possibilities for developing therapeutics for depression and addiction can be identified with topographic analysis of gene expression patterns.

Title: Modulation of the endocannabinoid system within the nucleus accumbens shell elicits anxiolytic-like effects in rats

Authors: *T. PARDO, N. YUSIF, C. S. MALDONADO;
Biol., Univ. of Puerto Rico - Rio Piedras Campus, San Juan, PR

Abstract: At the moment, the functional role of the co-localization of the cannabinoid type-1 (CB1) and the transient receptor potential vanilloid type-1 (TRPV1) receptors within the Nucleus Accumbens shell (NAc shell) on anxiety states has not been studied. Thus, the present study seeks to elucidate the effects of this receptor interaction within the NAc shell on anxiety states. We hypothesized that blocking TRPV1 and the fatty acid amide hydrolase (FAAH) within the NAc shell would elicit an anxiolytic response in rats. In the present experiment, male Sprague Dawley rats were implanted with bilateral brain cannula aimed at the NAc shell. Following recovery from surgery, rats received pre-treatment of microinfusions (0, 0.125, 0.5 nmol/0.4 µl) of N-arachidonoyl-serotonin (AA-5-HT), a dual blocker of FAAH and TRPV1, within the NAc shell. After treatment, rats were tested in an elevated plus maze paradigm for a period of 5 minutes. Behavioral parameters measured were: time spent in open arms, time spent in closed arms, rearing, flatback and grooming. At the end of the experiment, rats were euthanized and their brains collected for histological and western blot analysis. Results showed that pre-treatment with both doses of the antagonist significantly increased the time spent in the open arms and decreased the time spent in the closed arms when compared to vehicle injections ($p < 0.0001$ for both doses and parameters). Furthermore, western blot analysis of rats pre-treated with 0.5 nmol/0.4 µl of AA-5-HT revealed CB1 receptor downregulation in the NAc shell. The present findings suggest that the endocannabinoid system modulates anxiety within the NAc shell, giving this area a more important role in the regulation of anxiety than previously thought.

Title: The anxiolytic effect of elevated 2-Arachidonoylglycerol signalling in the basolateral amygdala is mitigated by heightened levels of emotional arousal

Authors: *K. LEITL[1], M. MORENA[1], H. VECCHIARELLI[1], M. GRAY[1,2], P. CAMPOLONGO[2], M. HILL[1];
[1]Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada; [2]Sapienza, Rome, Italy

Abstract: Endocannabinoid (eCB) system manipulation can induce distinct and often opposite effects on anxiety, cognition depending on the stress level and the aversiveness of the environmental context. The basolateral complex of the amygdala (BLA) represents an important structure for the ability of eCB signaling to modulate emotional behavior, and the target of brainstem projections that modulate arousal. We recently reported that high levels of emotional arousal were associated with an impairment in the anxiolytic effects of elevating anandamide (AEA) signaling in the BLA. To extend these findings, we examined the impact of 2-arachydonoylglycerol (2-AG) manipulations within the BLA on anxiety-like behavior and determined if these effects were sensitive to changes in the animals' arousal state. Male adult Sprague-Dawley rats were tested for anxiety behavior in an Elevated Plus Maze (EPM) for 5 min under low or high arousal conditions. The low arousal (LA) group was extensively handled and habituated to the experimental room and tested under red light condition, the high arousal (HA) group was not handled or habituated and tested under high light condition. We have previously found increased AEA levels in the amygdala, selectively under LA conditions and a positive correlation between increased AEA levels and anxiolytic-like behavior shown during the EPM. Moreover, pharmacologically-induced elevation of AEA signaling locally in the BLA further reduced anxiety in LA animals through the activation of cannabinoid type 1 (CB1) receptors, without being effective in the mitigation of the arousal-induced anxiety response in the HA group. With regard to 2-AG, we found that neither of the two different arousal conditions altered 2-AG levels in the amygdala, however we surprisingly found that 2-AG levels positively correlated with higher levels of anxiety. In the second part of this study we evaluated the effects of intra-BLA infusion of the 2-AG hydrolysis inhibitor KML29 and the CB1 receptor antagonist AM251 on anxiety behavior. HA and LA rats were given bilateral intra-BLA administration of KML29 (200 ng/side) or its vehicle alone or together with a non-altering behavioral dose of AM251 (1 ng/side) 30 min prior to the EPM test. Similar to what was found with AEA signaling, we found that KML29 was able to selectively decrease the anxiety response in LA rats through a CB1-mediated mechanism, without affecting emotional behavior in the HA group. Together,

these findings suggest that, depending on the arousal state, the eCB system is differentially activated to regulate the anxiety response in the amygdala and help to understand the state-dependency of many interventions on anxiety.

Title: ASIC1a in ASIC4-positive neurons is important for innate fear and anxiety phenotypes.

Authors: *Y.-C. CHIEN[1], S.-H. LIN[2], C.-C. CHEN[3];
[1]Academia Sinica/Institute of Biomed. Sci., Taipei, Taiwan; [2]Inst. of Biomed. Sciences, Academia Sinica, Taipei, Taiwan; [3]Taiwan Mouse Clinic, Natl. Comprehensive Mouse Phenotyping and Drug Testing Center, Academia Sinica, Taipei, Taiwan

Abstract: ASIC4 is a member of acid-sensing ion channels and widely expressed in many nuclei in the CNS. However, the physiological function of ASIC4 is still unclear. To probe the role of ASIC4, we generated an ASIC4-knockout/Cre-ERT2-knockin mouse line. Compared with wild-type littermates, ASIC4 knockouts showed higher levels of fear response (freezing) to the presence of 2,4,5-trimethylthiazoline (TMT), a component of fox urine; ASIC4 knockouts also demonstrated higher levels of anxiety-like behaviors in the open field (OF) and elevated plus maze (EPM) task. These phenotypes were opposite to the ASIC1a knockout mice, which showed lower levels of TMT-induced fear and less anxiety-like behaviors in these two mouse anxiety tasks. Based on genetic mapping results, we hypothesized that ASIC4 in the CR/VIP-positive cortical interneurons (or the NG2-positive glia) might modulate innate fear and anxiety state by counteracting the membrane expression and thus the activity of ASIC1a. To test this working hypothesis, we first generated $ASIC4^{CreERT2/+}$::$ASIC1a^{f/f}$ conditional knockouts and screened the phenotypes in the TMT, OF and EPM task. Results indicated that $ASIC4^{CreERT2/+}$::$ASIC1a^{f/f}$ conditional knockouts showed ASIC1a-like phenotypes in the innate fear and anxiety tests. We further examined whether ASIC4 KO affects the ASIC1a protein expression in specific brain areas. Interestingly, we found ASIC1a membrane protein expression is increased in ASIC4 KO in PAG, BNST, pituitary gland, VPM/VPL, amygdala and cerebellum as compared with wildtype control. Our results supported that ASIC1a in ASIC4-positive neurons is responsible for the fear/anxiety phenotypes.

Title: Circuit-specific plasticity of inhibitory synapses on VTA dopamine neurons

Authors: ***K. BARCOMB**, A. M. POLTER, A. C. TSUDA, J. A. KAUER;
Brown Univ., Providence, RI

Abstract: GABAergic synapses are crucial regulators of the excitability of VTA dopaminergic neurons. Our previous work has shown that these synapses undergo nitric-oxide dependent long-term potentiation (LTP_{GABA}) that is sensitive to both drugs of abuse and stress (Polter and Kauer, EJN, 2014). It remains unknown, however, whether this phenomenon is specific to certain circuits within the complex structure of the VTA. GABAergic synapses in the VTA arise from both local neurons and from long-range projections from the rostromedial tegmental nucleus (RMTg), and nucleus accumbens (NAc), among others. Furthermore, dopaminergic neurons within the VTA are heterogeneous, with distinct populations projecting to the NAc and the prefrontal cortex. While this region has been highly studied, plasticity and cell-type specific properties of its inhibitory circuitry are still not well understood. Given the importance of VTA function in disorders such as substance abuse and depression, a better understanding of plasticity within inhibitory subcircuits of the VTA and how it is modulated by stress may reveal circuit-level mechanisms of stress-linked diseases.

Here, we use viral-mediated expression of channelrhodopsin and retrograde microbead labeling to test the circuit specificity of LTP_{GABA} induced by the nitric oxide donor, SNAP. We find that synapses arising from local VTA GABAergic neurons express LTP_{GABA}. Synapses from local GABA neurons on both putatively dopaminergic (Ih+) and non-dopaminergic (Ih-) neurons displayed similar average magnitudes of LTP_{GABA} (LTP magnitude, Ih+: 130 ±9% of baseline, n=15; Ih-: 126 ±11% of baseline, n=12). However, a smaller proportion of Ih- cells than Ih+ cells exhibited potentiation (Ih+: 80% potentiated, Ih-: 38% potentiated). These data suggest that local

GABA neurons are capable of exhibiting LTP_{GABA} on most cells in the VTA but that local inputs onto certain subtypes of Ih- neurons may not express LTP_{GABA}In contrast, inhibitory synapses arising from the RMTg do not express LTP in either Ih+ or Ih- cells (LTP magnitude, Ih+: 107 ±15% of baseline, n=7; Ih-: 90 ±7% of baseline, n=4). In addition, we investigated whether dopamine neurons projecting to specific target regions were capable of expressing LTP_{GABA}. We find that NAc-projecting dopamine neurons exhibit SNAP-induced LTP_{GABA} (LTP magnitude, 125 ±7% of baseline, n=6). Taken together, our studies indicate that subcircuits within the VTA differ in their expression of LTP at inhibitorysynapses, allowing differential modulation of these inputs by experience.

Title: Sex-specific phenotypes in a rat model of post-traumatic stress disorder (PTSD)

Authors: ***A. POOLEY**, A. J. ROBISON, M. S. MAZEI-ROBISON, A. L. EAGLE, S. M. BREEDLOVE, C. L. JORDAN;
Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Men and women respond differently to traumatic stress, but the neurobiological basis for this is not understood. Diagnoses and treatment of post-traumatic stress disorder (PTSD) would likely benefit by understanding these sex differences. Women are twice as likely as men to develop symptoms of PTSD following a traumatic experience. They are also affected longer, and tend to re-experience trauma more than men through flashbacks, nightmares, and intrusive memories. Clinical studies indicate that women with PTSD are more likely to show an internalizing phenotype (associated with comorbid anxiety and depression) whereas men are more likely to show an externalizing phenotype (associated with comorbid aggression, substance abuse and impulsivity). Our data begin to shed light on the neurobiological reasons why men and women respond differently to traumatic stress. The single prolonged stress (SPS) paradigm is a well-validated rat model for PTSD, recapitulating clinical symptoms of the disorder in male rats—enhanced startle, dysregulation of the hormonal stress response, and changes in corticolimbic activation. However, we are the first to compare the effects of SPS in male and female rats at the behavioral, physiological, and cellular levels. We found the acoustic startle response to be exaggerated in males following SPS, as expected, but SPS did not affect the

startle response of females. However, based on the dexamethasone suppression test (DST) and neuronal activation in the prefrontal cortex, females are in fact affected by SPS. We are the first to show a behavioral effect of SPS in females where females, but not males, showed a depressive-like anhedonic effect on sucrose intake following SPS. Given this striking sex difference, we then sought to determine whether normal sex differences in adult gonadal hormones mediate these responses. We find that removing testicular hormones eliminates the difference in the acoustic startle response between stress-exposed and control males, reflecting a loss in the anxiolytic effect of endogenous androgens in males. On the other hand, the effect of SPS on sucrose intake in females may be independent of ovarian hormones. Taken together, these data begin to uncover novel neurobiological mechanisms underlying sex-specific responses to trauma that may pave the way for the development of new sex-specific diagnostic tools and treatments for men and women with PTSD.

Title: Vagus nerve stimulation reverses extinction impairments and alters PTSD symptoms in the SPS animal model

Authors: *L. J. NOBLE, I. J. GONZALEZ, V. B. MERUVA, A. K. HUTCHINSON, T.-A. DAM, S. K. THOMAS, E. MEYERS, M. P. KILGARD, C. K. MCINTYRE;
Univ. of Texas At Dallas, Dallas, TX

Abstract: Posttraumatic stress disorder (PTSD) can develop following a traumatic event. Symptoms of PTSD include hypervigilance, avoidance, and increased anxiety. Exposure therapy is a form of cognitive behavioral therapy that is commonly used to treat these symptoms. During exposure therapy, patients are repeatedly exposed to cues that remind them of the trauma until they learn healthier responses to those cues. However, PTSD patients show impairments in

extinction learning, which may increase nonresponse rates and dropout rates. Adjuncts to exposure therapy could be utilized to increase the effectiveness by promoting successful extinction learning, this could lead to decreases in nonresponse and dropout rates. Vagus nerve stimulation (VNS) is an FDA-approved treatment for the prevention of seizures. VNS shows promise as an adjunct for exposure therapy because previous research indicates that it enhances memory consolidation in rats and in humans, and we recently found that pairing VNS with unreinforced exposures to a conditioned stimulus can enhance extinction learning and protect against relapse in the single prolonged stressor (SPS) rat model of PTSD that shows resistance to extinction. The current studies are designed to test the hypothesis that extinction impairments contribute to general symptoms of PTSD and, therefore, treatments that promote successful extinction should produce benefits that reach beyond the cue-induced fear. SPS and control rats were fear conditioned for two days, then given daily extinction training with VNS or sham stimulation. One week, and six weeks later, rats were given tests of hypervigilance (startle), avoidance (conditioned place avoidance), and general anxiety (elevated plus maze). We hypothesize that reversing extinction impairments in SPS-treated animals with VNS will decrease anxiety, avoidance, and hypervigilance. Results indicate that VNS pairing with extinction training brought fear expression in SPS-treated rats to control levels, and increased time spent in the open arms of an elevated plus maze (versus sham-treated SPS rats) one week after extinction training. These results suggest that VNS enhancement of extinction also provides benefits for additional PTSD symptoms seen in the SPS model.

Title: A preclinical mouse model of traumatic memory storage- implications for PTSD

Authors: *S. SILLIVAN, N. JOSEPH, C. MILLER;
The Scripps Res. Institute-Florida, Jupiter, FL

Abstract: How does the brain stably maintain memories for a lifetime? Understanding how the brain maintains a memory has significant implications for disorders perpetuated by lasting, pathogenic memories, such as post-traumatic stress disorder (PTSD). Despite the clinical importance of this memory process, mechanisms of long-lasting ("remote") memory are understudied and remarkably elusive. PTSD is precipitated by an individual experiencing or witnessing a traumatic event that later leads to substantial dysfunction in fear processing, including hyperactivation of the amygdala (AMY) upon exposure to fearful stimuli and generalization of fearful responses to nonfearful stimuli. The AMY is the brain's emotional memory center and, unlike hippocampus-dependent memories, which shift to the cortex over time, AMY-dependent memories continue to rely on the AMY weeks after learning. In rodents, a "normal" fear memory can be converted to a traumatic memory by pre-exposure to stress. Subsequent fear conditioning (FC) results in a fear memory that displays greater resistance to extinction than one formed in the absence of prior stress (stress enhanced fear learning; SEFL). We have fine-tuned an SEFL paradigm that combines restraint stress with FC to precipitate traumatic memories in male mice. Characterization of this SEFL paradigm revealed strong face validity to PTSD: (1) extinction resistance, (2) generalization of fear (3) differential vulnerability (stress-resilient and -susceptible phenotypes arise), (4) persistence of elevated fear for more than 30 days and (5) a dose-dependent response of the stressor. Given that the prevalence of PTSD is nearly twice as high in the female population, we also performed the SEFL paradigm in female mice. Gender specific differences in fear extinction and retention were observed in female mice compared to their male counterparts, suggesting that female mice are more sensitive to the stress component of this paradigm. To identify molecular components that contribute to traumatic memory storage, RNA sequencing was performed on AMY tissue from SEFL male mice that did not undergo extinction, 30 days after FC shock training. Bioinformatic analysis of genes changed in 'PTSD-like', stress-susceptible mice indicated that this paradigm recruits major neurotransmitter systems and pathways involved in critical neuronal processes, such as CREB signaling, cAMP-mediated signaling, corticotropin releasing hormone signaling, and protein kinase A signaling. This preclinical PTSD model represents a valuable tool for studying long-lasting memory mechanisms, which has significant therapeutic implications for those suffering from PTSD.

Title: PTSD-like behavioral profile of mice with full 5-HT2C receptor editing: response to paroxetine treatment.

Authors: M. RÈGUE[1], C. POILBOUT[1], *L. LANFUMEY[1], R. MONGEAU[2];
[1]INSERM 894 Ctr. of Psychiatry and Neurosciences, Paris, France; [2]Pharmacol. Dept., Univ. Paris Descartes, Paris, France

Abstract: Post-traumatic stress disorder (PTSD) is a stress-related disorder caused by exposure to a psychological trauma. No pharmacological treatment demonstrated a wide efficacy and there are only few preclinical PTSD models that meet face and predictive validity. PTSD is characterized by a deregulation of fear responses, including fear extinction deficits and generalization. Serotonin 2C receptor (5-HT2CR) editing impacts anxiety-like behaviors, and we recently demonstrated in the fear conditioning paradigm, that mice expressing only the fully edited 5-HT2CR isoform (VGV mice) display increased innate fear behaviors as well as fear extinction deficits and context generalization. Interestingly, 5-HT2CR inactivation has been shown to alter the expression of the brain-derived neurotrophic factor BDNF, known to regulate memory, and proposed to play a central role in PTSD. In this context, VGV mice were characterized as an animal model for PTSD. Wild-type (WT) and VGV adult C57Bl/6 mice were used to assess fear-related behaviors (ultrasound test and fear conditioning), memory and flexibility (Barnes maze). WT and VGV mice also received either paroxetine (delivered in drinking water; ~5.5 mg/kg/day) or tap water during 28 days. Then cue fear conditioning (6 x 2.5 kHz CS, 0.5 mA foot-shocks) was conducted to evaluate fear extinction (40 x CS alone). Fear behavior was also assessed in reaction to an innately aversive ultrasonic stimulus. Brains were dissected for qRT-PCR analyses of *Bdnf* gene expression. Data were analyzed using the Student's t-test and the two-way ANOVA. Chronic paroxetine treatment in VGV mice reduced freezing in both fear conditioning and ultrasound-induced fear paradigms and partially reversed contextual fear generalization. However, as previously reported, chronic paroxetine impaired rather than improved the extinction process in WT mice. Furthermore, this treatment normalized *Bdnf* mRNA dysregulations in the hippocampus and the amygdala of VGV mice. Interestingly, VGV mice displayed no alteration of spatial learning and no impairment of cognitive flexibility. Our data showed that, while presenting no general cognitive impairment, VGV mice displayed severe fear memory dysregulations, similar to those of PTSD patients, which could be partially prevented by paroxetine. Our results also provided further evidence that BDNF may be a factor underlying PTSD-like behaviors. VGV mice are thus a relevant animal model to design new pharmacological strategies for PTSD.

Abstract: Kynurenic acid (KYNA) is a metabolite of tryptophan degradation and acts as an antagonist of both NMDA glutamate and alpha-7 nicotinic acetylcholine receptors. Prior work has shown that endogenous KYNA modulates dopamine levels in the rodent brain. For example, the well-established and purportedly adaptive increase in dopamine levels in the medial prefrontal cortex following an acute restraint stress is abolished in rats after adrenalectomy (ADX), and this effect is secondary to an abnormal increase in extracellular KYNA. As the response to stress is abnormal in several major psychiatric diseases, we hypothesized that there may be a link between stress-induced changes in KYNA and behavior, especially in pathological situations. Here we tested the behavioral relevance of this stress-induced increase in KYNA by training ADX rats (or sham-operated controls) in a fear discrimination procedure. One set of rats in each group was exposed to a 2-hour restraint stress while the others remained in the home cage (ie, a 2X2 experimental design). Immediately thereafter, all rats underwent fear conditioning in which one auditory conditioned stimulus (CS+) was paired with mild foot shock and a second auditory cue (CS-) was not paired with shock (three trials of each, intermixed over a 6-min session). Forty-eight hours later, rats were tested for conditioned fear to each cue by re-exposing them to the auditory stimuli in a novel context without any shocks delivered. Sham-operated control rats exhibited more conditioned fear (freezing behavior) to the CS+ than the CS-, regardless of whether they underwent restraint stress. Similarly, ADX rats that were not restrained exhibited more fear to the CS+ than the CS-. In contrast, ADX rats exposed to 2 hours of restraint stress exhibited high levels of fear to both stimuli, reminiscent of impairments in fear learning exhibited by persons with post-traumatic stress disorder (PTSD). Ongoing studies are testing the specific role of KYNA in mediating these behavioral effects.

Title: Influence of estrous stage on the behavioral response of female rats to a predator-based psychosocial stress model of PTSD

Authors: ***E. D. EISENMANN**, R. M. ROSE, M. E. FRY, B. L. JOHNSON, M. R. HUNTLEY, M. E. HEIKKILA, B. A. KOHLS, P. R. ZOLADZ;

Abstract: Although females are more likely to develop post-traumatic stress disorder (PTSD), a female animal model of PTSD is still non-existent. Here, we have examined the effects of an animal model of PTSD, previously validated in male rats, on female rats and how estrous stage might influence any effects. Female Sprague-Dawley rats were exposed to psychosocial stress or control conditions for 31 days; vaginal smears were collected on days 1, 11 and 32 to determine estrous stage. Stressed rats were given two cat exposures, separated by 10 days, and subjected to daily social instability throughout the paradigm. Control rats were handled daily. Rats were tested on the elevated plus maze (EPM) on day 32 and in an open field on day 33. Results indicated that estrous stage during testing interacted with stress to affect behavior. Specifically, stressed females in estrus spent less time in the open arms of the EPM than controls. Additionally, stressed females in estrus or diestrus were less mobile and made fewer rearing episodes in the open field than controls. This work provides preliminary evidence for an interaction between female hormones and chronic stress and could be useful for understanding susceptibility factors for PTSD in females.

Title: Clonidine prevents the anxiogenic, but not cardiovascular, consequences of a predator-based psychosocial stress model of PTSD

Authors: *M. E. FRY[1], E. D. EISENMANN[1], R. M. ROSE[1], B. L. JOHNSON[1], M. R. HUNTLEY[1], M. E. HEIKKILA[1], K. L. ROBINSON[1], B. R. RORABAUGH[2], P. R. ZOLADZ[1]; [1]Psychology, Sociology, & Criminal Justice, [2]Pharmaceut. & Biomed. Sci., Ohio Northern Univ., Ada, OH

Abstract: Individuals with PTSD are at increased risk for cardiovascular disease. We previously reported that a predator-based psychosocial stress model of PTSD led to greater myocardial sensitivity to ischemic injury. Here, we examined whether chronic administration of the noradrenergic antagonist clonidine would prevent such effects. Male Sprague-Dawley rats were exposed to psychosocial stress or control conditions for 31 days. Stressed rats were given two cat exposures, separated by 10 days, and subjected to daily social instability throughout the paradigm. Control rats were handled daily. Beginning on day 2, rats received daily injections of 0.05 mg/kg clonidine or vehicle (saline), continuing through day 32. Rats were tested on the elevated plus maze (EPM) on day 32, and on day 33, rat hearts were isolated and subjected to 20 min ischemia and 2 hr reperfusion on a Langendorff isolated heart system. Consistent with previous work, clonidine blocked the development of anxiety-like behavior in stressed animals. However, clonidine was ineffective at preventing the stress-induced increase of myocardial sensitivity to ischemic injury. Stressed rats, overall, exhibited larger infarct sizes and reduced post-ischemic recovery of contractile function relative to controls. These findings suggest a potential dissociation between the anxiogenic and cardiovascular effects of this chronic psychosocial stress paradigm.

Title: Decreased voluntary ethanol consumption in a predator-based psychosocial stress model of PTSD

Authors: *R. M. ROSE, E. D. EISENMANN, B. L. JOHNSON, M. E. FRY, M. E. HEIKKILA, M. R. HUNTLEY, P. R. ZOLADZ;
Psychology, Sociology, & Criminal Justice, Ohio Northern Univ., Ada, OH

Abstract: Individuals with post-traumatic stress disorder (PTSD) exhibit high rates of substance abuse, which may be due to self-medication. Here, we have examined whether a well-established animal model of PTSD would influence voluntary ethanol intake in rats. Male Sprague-Dawley rats were exposed to psychosocial stress or control conditions for 31 days. Stressed rats were given two cat exposures, separated by 10 days, and subjected to daily social instability throughout the paradigm. Control rats were handled daily. Beginning on day 32, rats were given access to either ethanol (10% EtOH + 1% sucrose) or water (1% sucrose) in 12-hr cycles (1930-0730 every night) using a two bottle, free choice paradigm for 21 days. Results revealed that stressed rats consumed less ethanol than control rats throughout the 21 days of ethanol exposure. It is possible that stressed rats consumed less ethanol because they exhibited a greater aversion to the novel stimulus, or the chronic stress paradigm altered drug sensitivity such that the stressed rats required less ethanol to induce the desired effect. Follow-up studies are currently in progress to delineate such possibilities.

Title: Adolescent trauma results in distinct behavioral covariates and neural activation patterns in habenula associated brain regions

Authors: *G. I. ELMER[1], J. R. SCHANK[2], J. MITCHELL[3], R. DAMAZDIC[2], C. L. MAYO[1], D. BRADY[1], A. PINCUS[2], C. KING[2], M. HEILIG[2], J. D. TAPOCIK[2];
[1]Psychiatry, Maryland Psychiatric Res. Ctr., Baltimore, MD; [2]Lab. of Clin. and Translational Studies,, NIAAA, NIH, Bethesda, MD; [3]Psychology, Colby, Waterville, ME

Abstract: The consequences of trauma, especially early life trauma, infiltrate psychiatric illness across a range of diagnoses including major depressive disorder, generalized anxiety and substance abuse making trauma exposure a highly penetrable, life-changing event. Unfortunately, the neurobiology underlying the consequences of trauma exposure is poorly understood and effective models and treatment interventions are slow in development.
The majority of currently used animal models rely on acute physical stress or exposure to predator scent to mimic trauma. While these paradigms produce stress-related phenotypes, physical and odor-induced stress are not directly life-threatening and may not induce the neural events necessary for a robust animal model. We have developed an animal model that directly exposes the subject in close contact with a live predator (LPE) yet prevents physical harm. In the model, male Wistar rats are exposed a rat snake (60-100cm long) for 10 min at post-natal days (PND) 31, 46 and 61 by placing rats in a perforated restrainer tube within a larger arena that holds the live snake. Twelve days following the last snake exposure rats are assessed in a battery of behavioral tests. In the current experiment, rats were perfused and tissue prepared for cFOS analysis in six brain regions.
LPE produces robust behavioral and neurobiological consequences. Exposed rats had significantly blunted corticosterone response following the third snake exposure, decreased exploratory behavior and increased defecation in open field, decreased open arm entries in elevated plus maze, decreased saccharin preference, increased conditioned fear and increased rates of learned helplessness. cFOS analysis revealed significant increased expression in the lateral habenula (LHb) and dorsal raphe following repeated LPE. Analysis of a correlation matrix across brain regions revealed a change in strength of regional associations following LPE as measured by cFOS covariance. In particular, LPE resulted in a significant correlation between lateral LHb and RMTg cFOS expression that survived multiple comparisons correction. In addition, there was a strong correlation (short of multiple corrections threshold) between the nucleus incertus and medial LHb and dorsal raphe brain regions.
Further investigation is required to determine if the association between regions is causal or merely reflects co-activation. The combination of roles hypothesized to be involved in LHb and RMTg-associated circuitry place this network in an ideal situation to mediate core symptom constructs altered by trauma exposure that cross diagnostic borders.

Title: Susceptibility to traumatic stress predicts elevations in cocaine self-administration and the dopaminergic response to cocaine.

Authors: *Z. D. BRODNIK[1], M. CLARK[2], K. KORNSEY[2], R. A. ESPAÑA, 19129[2];

Abstract: Patients with post-traumatic stress disorder have a heightened vulnerability to developing substance use disorders. Despite clear clinical evidence for this vulnerability, preclinical studies of prior stress experience on cocaine self-administration behavior have produced inconsistent results. We used the predator order stress model of post-traumatic stress disorder with segregation of subjects as susceptible or resilient based on elevated plus maze behavior and context avoidance. We then determined behavioral and neurochemical differences across susceptible, resilient, and control populations using cocaine self-administration, in vivo microdialysis, and ex vivo fast scan cyclic voltammetry. Susceptible subjects showed an increased propensity to self-administer cocaine, which corresponded with increased basal levels of nucleus accumbens dopamine, and increased dopamine responses to cocaine. Resilient subjects did not show changes in cocaine self-administration or in vivo dopamine signaling. Nonetheless, we found increases in both the dopamine release-promoting effects of cocaine and dopamine autoreceptor sensitivity ex vivo. Our results suggest that traumatic stress results in alterations to dopamine systems that drive an increase in the propensity for susceptible subjects to self-administer cocaine. In contrast, traumatic stress results in both active and passive forms of resilience that function to prevent gross changes in cocaine self-administration for resilient subjects.

Title: Awake resting-state fMRI in a post-traumatic stress disorder rat model

Authors: *P. D. PEREZ, D. DOPFEL, L. ANTINORI, J. RUDDY, N. ZHANG;
Biomed. Engin., Pennsylvania State Univ., University Park, PA

Abstract: A stress response occurs when an individual perceives a threat to its safety that can potentially exceed its coping resources. Psychophysiological responses are directed towards adaptation. In the event of maladaptation, strong traumatic stimuli may produce chronic stress disorders that can develop into excessive anxiety, phobias and post-traumatic stress disorder (PTSD). The mechanisms of PTSD are poorly understood since most studies in humans focused on populations that had already been exposed to a wide variety of different traumatic experiences such as war veterans and victims of accidents or crime. Using animal models allows for investigating the development of PTSD at different points in time. This includes the stage before the exposure to stress which is very difficult to observe in humans. We present a rat model of PTSD where we exposed rats to a single-episode traumatic event in the form of predator odor. Our study investigates the neuroplasticity changes at the circuit level to a single life threatening situation using awake resting-state functional magnetic resonance imaging (rsfMRI). By using awake imaging, we can avoid the confounding factors that usually accompany the use of anesthetics. Behavior techniques are also used to evaluate the efficacy of stress trauma. Furthermore, we explore how fear conditioning and extinction mechanisms are modulated by the traumatic event. These learning processes and their dysregulation are believed to be at the core of chronic stress disorders. We present a longitudinal group of experiments with multiple goals. First, the impact of single-episode trauma and the onset of chronic stress disorders are studied. We then investigate their effects in fear conditioning and later fear extinction processes. Our study allows us to look for vulnerability markers to PTSD at the circuit level with non-invasive techniques thus segregating the exposed rats in resilient and vulnerable populations. The understanding and detection of vulnerability to PTSD is of great importance in the prevention and treatment, opening the way to extending this knowledge to humans.

Title: Do opiate and hypothalamus-pituitary-adrenal gland systems affect fear, depression, and movement behaviors for posttraumatic stress disorder in rats?

Authors: *C. CHIU[1], A. C. W. HUANG[2];
[1]Dept. of psychology, Fo Guang Univ., Taiwan (R.O.C.), Taiwan; [2]Psychology, Fo Guang Univ., Yilan County, Taiwan

Abstract: Posttraumatic stress disorder (PTSD) is a severe anxiety disorder. PTSD patients often suffer from fear major symptom and some comorbidity including depression and anxiety behaviors. However, whether the opiate and hypothalamus-pituitary-adrenal gland (HPA) systems influence fear, depression, anxiety, and movement behaviors remains unclear. The aim of the present study addresses this issue. All of rats receive a saline or 10 mg/kg morphine subcutaneously injection 30 min prior to a footshock treatment. Then, rats were placed in the footshock box for 2 min and receive a footshock (3 mA, 10s) to produce a severe trauma. Next day, rats were given into 0.5 mg/kg dexamethasone (DEX) or its vehicle once a day for three days. During this period of time, situational reminder was given. With no footshock, rats were placed in the footshock box for 2 min. Fear behavior was measured. After that, rats were respectively tested depression, and movement behaviors in the forced swimming and open field tests.
The present data showed that morphine or DEX injections might decrease freezing time and significantly reduced freezing time compared with the Saline/VEH group, indicating morphine or DEX might decrease fear behavior. The combination of morphine and DEX administrations exhibited the lower freezing time than the single morphine and DEX groups. The synergism of morphine and DEX showed a highest value of swimming time, indicating the addition of morphine and DEX can effectively reduce depression. However, either morphine or DEX cannot affect movement and moreover, the addition of morphine and DEX cannot influence movement. The present data can provide clinical implications and thereby it can give us knowledge to understand how the opiate system and HPA axis involve in fear, depression, and motor functions to PTSD patients.

Title: Oxytocin attenuates stress-induced reinstatement of alcohol seeking in mice with a history of trauma

Authors: *C. KING, W. C. GRIFFIN, J. F. MCGINTY, H. C. BECKER;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Exposure to chronic stress can lead to serve psychiatric issues including post-traumatic stress disorder (PTSD), anxiety and depression, many of which are often complicated by the presence of concurrent substance or alcohol use disorder. An amassed body of evidence has recently emerged to support a role for the endogenous neuropeptide oxytocin (OXT) system in both drug-seeking and stress-related behaviors. Previous research in our laboratory has demonstrated that OXT reduces ethanol in a variety of drinking paradigms. The present study was designed to extend these findings by examining the effects of OXT on stress-induced reinstatement of alcohol seeking in mice with and without a history of repeated predator odor exposure stress. Adult C57BL/6J mice (n=48) were trained to acquire stable rates of lever responding under a fixed ratio (FR)-4 schedule for 12% ethanol in 20-min sessions. Once active lever response rates and ethanol intake had stabilized (<15% variability across 3 consecutive days), mice were injected with yohimbine (2mg/kg) or saline 15 minutes prior to exposure to predator odor (2,3,5-Trimethyl-3-thiazoline; TMT-PE) or saline (CTRL), for 5 consecutive days. Next the mice were returned to active self-administration to re-establish baseline levels of responding, followed by an extinction phase (14 days) in which no cues or alcohol reward was present. At the conclusion of the extinction phase, mice were injected with OXT (1mg/kg) or saline 30 minutes prior to 15 minute TMT exposure. Reinstatement session was immediately following TMT exposure. Results indicated mice with a history of TMT exposure showed an exacerbated stress-induced reinstatement compared to mice with history of saline exposure ($p<0.001$). Further, OXT treatment attenuated reinstatement in the TMT-PE group ($p<0.0001$).

These results implicate a role for oxytocin in decreasing stress-induced reinstatement of alcohol seeking. Additional studies are underway to examine the effects of OXT treatment of neurobiological markers of stress, as well as the mechanism through which oxytocin may be modulating stress-induced reinstatement, particularly in animals with a history of trauma. Supported by DoD/US Army Institute for Molecular Neuroscience 803-94, NIH grants P50 AA10761and U01 AA014095, and T32 AA007474, and VA Medical Research.

Title: Effects of acute immobilization stress on brain network functional connectivity and its use as a PTSD model

Authors: *D. DOPFEL[1], N. ZHANG[2];
[1]Bioengineering, Pennsylvania State Univ., State College, PA; [2]Pennsylvania State Univ., University Park, PA

Abstract: Post-traumatic stress disorder development is difficult to study in humans. It is difficult to screen patients prior to trauma and the stress response immediately after trauma is typically not studied in people. This creates a gap in our understanding of the disorder that can be filled by animal models. Work by Mitra et al. analyzed the effect of stress duration on behavioral and cellular changes in acute immobilization stress paradigm in rats. They found that acute immobilization stress (AIS) leads to morphological changes and behavioral manifestations reminiscent of anxiety. The increase in spine formation in the basolateral amygdala and behavioral manifestations of anxiety caused by a single event stressor suggest the relevance of this paradigm as a PTSD model. To explore this model further male Long-Evan rats were subjected to AIS. To further validate this model, behavioral cut-off criteria were used to determine the assignment of vulnerable or susceptible rats within the stressed group. The prevalence of vulnerable rats was found to be similar to prevalence of PTSD in people that have experienced a traumatic event. Furthermore, work by Roa et al. suggests that glucocorticoids protect against behavioral and cellular effects of stress. To better understand the role of glucocorticoids in the stress response and in a model of PTSD, serum corticosterone levels were

measured at multiple time points throughout the experiment. Baseline, stress response and post stress levels were analyzed in relation to the susceptibility of the animals and behavioral manifestations of anxiety. The separation of vulnerable and susceptible animals allows for a further study of neurological differences between individuals before and after the occurrence of the traumatic event using awake rodent resting state functional magnetic resonance imaging (rs-fMRI). rs-fMRI suggests a variation in functional connectivity patterns between the vulnerable and susceptible animals. This is novel from a similar imaging study in our lab, due to a stressor of a different modality. In fact, combining these two studies data sets will allow the study of changes in stress response caused by a variation in the stressor and a further validation of the changes of network connectivity due to stress that may form the basis of future rs-fMRI pre-diagnostic/diagnostic screening of populations (e.g. soldiers) for PTSD susceptibility. Information gained from the monitoring of glucocorticoid levels allows for a separate diagnostic measure of susceptibility and may validate glucocorticoid supplementation as a therapeutic option for those that are at an acute risk of trauma or have experienced a traumatic event.

Title: Role of alpha2-adrenergic receptors in modulating post-traumatic stress disorder-like behaviors in a novel fearful DxH congenic recombinant inbred mouse strain with a DBA/2J background

Authors: R. WICKRAMASEKARA, Y. FARHAT, S. AKKOSEOGLU, *D. M. YILMAZER-HANKE;
Biomed. Sci. Dept., Creighton Univ., Omaha, NE

Abstract: Post-traumatic stress disorder (PTSD) results from exposure to highly stressful and aversive traumatic events that lead to re-experiencing of the trauma, intrusive thoughts and flashbacks, which are often modeled in the fear-conditioning paradigm, as well as to hyperarousal and anhedonia. These symptoms can be accompanied by elevated baseline

noradrenaline levels and provocation of flashbacks and panic attacks following delivery of the alpha2-adrenergic receptor antagonist yohimbine (Yoh). We have developed a novel fearful and stress-prone C3H-like recombinant inbred (C3HLRI) mouse strain by backcrossing C3H/HeJ mice selected for a high fear-sensitized acoustic startle response (FSS) onto DBA/2J mice with a low FSS. Compared to control DBA/2J mice, the congenic C3H-like recombinant inbred (C3HLRI) mice show increased startle reactivity, depressive-like behavior in the forced swim test, enhanced basal tissue noradrenaline levels, and a poor noradrenergic response to stress as seen in PTSD patients. In the present study, we applied Yoh to test the hypothesis that fearful/stress-prone C3HLRI mice are a model for PTSD using the open field and auditory fear-conditioning tests. The alpha2-adrenergic receptor agonist clonidine (Clon) was used to reverse Yoh effects. Six week old C3HLRI and DBA/2J mice received i.p. injections of Yoh (2.5 and 5.0 mg/kg), Clon (0.06, 0.08 and 0.1 mg/kg) or saline 30 min before behavioral testing. Yoh and Clon both reduced locomotion in a dose dependent manner in the open field test. Anxiety-like measures assessed in the open field indicated increased anxiety levels with Yoh and reduced anxiety levels with Clon in C3HLRI mice but not control DBA/2J mice. Anxiolytic effects of Clon were blocked by Yoh when the mice were administered the antagonist Yoh shortly before Clon delivery. In fear-conditioning, Yoh induced a fear extinction deficit in both strains, however, overall freezing levels were higher in C3HLRI mice. Plasma corticosterone levels were increased 30 minutes after Clon injection in both strains, although no significant differences were observed between the two strains. In summary, Yoh provoked increased anxiety and fear levels in the open field and fear-conditioning tests in C3HLRI but not DBA/2J mice. Along with previous data on higher conditioned fear levels, depressive-like behavior, enhanced stress reactivity, and noradrenergic changes in C3HLRI mice compared to DBA/2J mice, the present findings support the hypothesis that C3HLRI mice may serve as a PTSD model.

Title: Single prolonged stress-induced deficits in fear extinction recall are affected by exposure to functional modulators of astrocytic glutamate transport

Authors: T. S. COTRONE[1], *B. S. JORTNER[2], M. F. EHRICH[1], B. G. KLEIN[1];
[1]Biomed. Sci. and Pathobiology, Virginia Tech, Col. of Vet. Med., Blacksburg, VA; [2]VA-MD Regional Col. Vet Med., Blacksburg, VA

Abstract: Persistence of intrusive fear memories in Post-Traumatic Stress Disorder (PTSD) may be more attributable to a trauma-induced, pre-frontal cortex (PFC) -mediated dysfunction of fear extinction memory compared with an amygdala-mediated dysfunction of fear memory formation. There is also evidence that stimulating extrasynaptic NMDA glutamate receptors impairs long-term potentiation at glutamatergic synapses. We are exploring the hypothesis that a PTSD-related situational trauma impairs astrocyte-mediated glutamate reuptake in PFC, leading to increased extrasynaptic NMDA receptor activation, resulting in impairment of PFC-mediated fear extinction memory. We employed the Single Prolonged Stress (SPS) protocol as a rat model of PTSD in a 2 trauma (SPS; No SPS) x 3 drug (ceftriaxone; dihydrokainate; saline) factorial design. Ceftriaxone (CEF) was used to increase glutamate astrocytic transporter (GLT-1) concentration, dihydrokainate (DHK) was used to block GLT-1, and saline was used as a sham treatment. 7 days after SPS or No SPS, all rats were exposed to a light-cued fear conditioning paradigm, followed 24 hrs later by an extinction session, followed 24 hrs later by an identical extinction session to assess fear extinction memory. Rats were sacrificed after the second extinction session and the hippocampus, amygdala, and prefrontal cortex were removed for Western blot of glucocorticoid receptor (GR) and GLT-1. For saline-treated rats, SPS exposure resulted in significantly poorer fear extinction recall compared to the No SPS group. Treatment with CEF, intended to increase GLT-1-mediated uptake of glutamate and reduce extrasynaptic NMDA receptor stimulation in PFC, eliminated this SPS-induced impairment in fear extinction recall. However, DHK treatment, intended to block GLT-1-mediated uptake of glutamate and increase extrasynaptic NMDA receptor stimulation in PFC, also eliminated this SPS-induced impairment. In addition to these results for fear extinction recall, analyses revealed effective fear acquisition and fear extinction in all experimental groups, with magnitudes unaffected by trauma condition or drug treatment. Western blot analysis confirmed, in our SPS rats, the previously-reported increase in hippocampal GR. It also confirmed, in No SPS rats, that our CEF treatment was increasing GLT-1 protein concentration equally in PFC and amygdala. These results suggest that modulation of astrocytic glutamate reuptake can affect fear extinction recall deficits in rats exposed to a situational trauma analog of PTSD, but the specific mechanisms are not clear at this time. Title: Animal models of post traumatic stress disorder: behavioral characterization and pharmacological validation

Authors: *I. MORGANSTERN, Q. CHANG, A. CHOO, L. THIEDE, K. HOMA, E. SABATH, W. ALVINS, J. SUTPHEN, M. LANG, S. DAVIS, T. HANANIA;
Behavioral Pharmacol., Psychogenics, Tarrytown, NY

Abstract: Posttraumatic stress disorder (PTSD) is a common anxiety disorder characterized by hyper-arousal, disturbing flashbacks and numbing or avoidance of memories of a traumatic event or experience (DSM V, 2013). In order to fill the current gap in PTSD treatment research and increase our understanding of the underlying neurobiological and pathophysiological mechanisms, the development and validation of robust preclinical models with high face and construct validity is absolutely necessary. The current series of studies present findings from two animal models of PTSD, namely the mouse chronic social defeat (CSDS) model (Berton et al., 2006; Golden et al., 2011) recently developed in collaboration with Dr. Eric Nestler and also the fear-conditioned, Wistar- Kyoto (WKY) rat model (DaSilva et al., 2011; 2013). Specifically, our data with the CSDS model suggests that animals most susceptible to social stress after going through the 10-day social defeat paradigm exhibit increased social avoidance behavior, anhedonia and potentiated fear responding to sound cues. Most interesting are the findings with our proprietary algorithm-based behavioral SmartCube ® system, which measures whole animal behavior. These analyses demonstrated very unique and specific behaviors related to anxiety and fear of the susceptible versus control mice that progressed over time and were evident as long as 6 weeks after the social defeat stress. In a separate series of experiments, we characterized the extinction profile of fear-conditioned WKY rats (0.6mA shock, 6 shocks over 8 min). The findings suggest that compared to their outbred counterparts (Wistar), this stress-sensitive rat strain (WKY) exhibits deficits in fear extinction that are pronounced and long lasting. Pharmacological data with acute or intermittent ketamine treatment as well as compounds targeting more traditional mechanisms related to 5-HT or adrenergic signaling will also be presented for these models. Collectively, the data gathered from these two preclinical models offers a dynamic portfolio of PTSD-relevant behavioral profiles (anxiety, social avoidance, abnormal fear regulation) that can potentially be utilized as a tool to screen novel drug compounds. Our pharmacological evidence demonstrates the predictive validity of these models and further supports the use of CSDS mouse model and WKY rat model in future PTSD drug testing.

Title: Acetylcholinesterase (AChE) heterozygous mice present with a postraumatic stress disorder-like phenotype

Authors: *K. SMITH[1,2], R. M. RODRIGUIZ[3], J. S. COLVIN[2], M. W. PEASE[2], N.-L. NGUYEN[2], C. KIM[2], J. J. WILKINS[2], D. E. WILLIAMSON[2], W. C. WETSEL[3,2,4,5]; [1]Neurosci., UT Hlth. Sci. Ctr. San Antonio, Durham, NC; [2]Psychiatry and Behavioral Sci., [3]Mouse Behavioral and Neuroendocrine Analysis Core Facility, [4]Neurobio., [5]Cell Biol., Duke Univ., Durham, NC

Abstract: The neurotransmitter, acetylcholine (ACh), is inactivated primarily by the enzyme acetylcholinesterase (AChE). Blockade of AChE has been implicated in anxiety-like behaviors in both rodents and humans. Here, heterozygous (HET) AChE mice were behaviorally assessed in tests for anxiety, hyperarousal, and fear learning and extinction. These behaviors were assessed also following treatment with fluoxetine, a selective serotonin reuptake inhibitor, and diazepam, an anxiolytic. Compared to their wild-type (WT) littermates, HET mice spent less time in the open areas of the elevated zero maze and they showed augmented startle responses to white noise stimuli (80-120dB). Although diazepam exerted no effect on zero-maze behaviors, acute fluoxetine treatment dose-dependently alleviated both the zero-maze and the hyperarousal behaviors. Following auditory fear conditioning, HET mice exhibited enhanced freezing behaviors to both context and cued testing compared to their WT controls. During extinction, HET mice demonstrated a significant delay in reducing their freezing responses to the

conditioned stimulus when tested over 8 days. Separate groups of mice were subjected to fear conditioning and then were treated for 15 days with the vehicle or fluoxetine. Examinging for contextual and cued fear conditioning, freezing responses were reduced in the fluoxetine-treated HET mice relative to the HET vehicle controls and their responses were not differentiated from those of their WT littermates. These findings show that AChE-deficient mice present with heightened anxiety- and posttraumatic stress disorder- like behaviors and these responses can be alleviated with fluoxetine. Together, our results suggest that the AChE HET mice may represent a useful animal model to examine the biological mechanisms that may underlie these abnormal behaviors.

Title: Acute nicotine enhances spontaneous recovery of contextual fear and changes c-fos early gene expression in infralimbic cortex, hippocampus, and amygdala

Authors: *J. TUMOLO[1], B. GARRETT[2], M. G. KUTLU[2], E. HOLLIDAY[2], T. J. GOULD[2]; [1]Psychology, [2]Temple Univ., Philadelphia, PA

Abstract: Post-traumatic stress disorder (PTSD) is a devastating disorder with a lifetime prevalence of approximately 7% in adult Americans. Exposure therapy, which attempts to extinguish cues and contexts that trigger fear responses, is an effective treatment to reduce fear-related symptoms of PTSD. However, relapse of these symptoms following successful exposure therapy is fairly common. In rodents, spontaneous recovery (SR), where extinguished fear response resurfaces following extinction treatment, is used as a model of fear relapse. Previous studies from our lab identified nicotine as a strong mediator of fear extinction but the nicotinic modulation of fear relapse is unknown. Therefore, in the present study, we investigated the effects of acute nicotine administration on spontaneous recovery of contextual fear in C57BL6/J mice. In Experiment 1, mice were trained in contextual fear, given extinction, and one week later tested for SR immediately following administration of either acute nicotine (0.18 mg/kg) or

saline. Mice given nicotine showed significantly higher levels of SR than those given saline. In Experiment 2, in order to test whether acute nicotine's effects are specific to the retrieval of extinction memories, we trained mice using the same procedure but this time subjects did not receive extinction treatment. Again, mice were given either acute nicotine (0.18 mg/kg) or saline prior to memory recall test 12 days later. Our results demonstrated that mice administered acute nicotine showed comparable freezing levels to those administered saline, suggesting that acute nicotine selectively modulates retrieval of extinction memories. Finally, we employed a *c-fos* immunohistochemistry experiment in order to identify the brain regions responsible for the enhancing effects of acute nicotine on SR. The results of this experiment showed that *c-fos* immunoreactivity cells were significantly increased in the ventral hippocampus and basolateral amygdala and significantly decreased in the infralimbic cortex compared to saline-treated mice. Overall, our results show that acute nicotine may negatively affect retrieval of extinction memories and therefore augment fear relapse by altering the activation patterns of key brain regions in the fear extinction circuitry.

Title: mGluR5 mediates both resilience to traumatic stress and relapse to cocaine seeking.

Authors: *J. SHALLCROSS, L. KNACKSTEDT, M. SCHWENDT;
Univ. of Florida, Gainesville, FL

Abstract: Post-traumatic stress disorder (PTSD) develops in a subset of people exposed to trauma. Complicating successful treatment of PTSD is comorbidity with substance use disorder. In this study we utilized a novel rodent model of comorbid PTSD-cocaine addiction that separates rats into trauma-resilient (RES) and susceptible (SUS) cohorts prior to cocaine exposure. First, rats underwent a single 10 minute exposure to the predator odor 2,4,5-trimethylthiazoline (TMT) and were then classified as RES or SUS using cut-off behavioral criteria based on behavior in both the elevated plus maze (EPM) and acoustic startle response (ASR) tasks. SUS, RES, and controls rats went through cocaine self-administration followed by

extinction training and a cue-primed reinstatement test. We found that drug-taking behavior did not differ among groups, however SUS animals showed delayed extinction learning and significantly higher reinstatement than both RES and control animals. In a subset of animals that experienced only TMT exposure, we performed RT-PCR analysis of amygdala and PFC mGlu5 receptor mRNA and found significantly higher expression in RES as compared to both SUS and control rats, suggesting a potential role of increased mGlu5 in encoding resilience to trauma. We then assessed the efficacy of compounds to enhance extinction of both operant responding and conditioned fear and to reduce cocaine-seeking in a reinstatement test. Rats underwent daily extinction of both the TMT context and the operant response and were treated with vehicle CDPPB, a positive allosteric modulator (PAM) of mGlu5, during the first five days of extinction. During the last 5 days of extinction, rats received either vehicle or ceftriaxone, an antibiotic reliably shown to reduce cocaine relapse, immediately after the extinction session. CDPPB enhanced operant extinction learning in SUS rats. Ceftriaxone alone (without CDPPB) significantly reduced lever pressing during a cue-primed reinstatement test in both Ctrl and RES, but only in SUS rats that had received CDPPB previously. Preliminary analysis of fear response during extinction shows significantly reduced freezing in SUS rats treated with CDPPB compared to vehicle. Characterization of specific mGlu5 mediated circuitry involved in resilience may aid in the development of precise pharmacological interventions for individuals with trauma and stressor related disorders. Title: Effects of single prolonged stress, a ptsd model, on adult hippocampal neurogenesis and extinction-retention

Authors: *E. RODRIGUEZ[1], I. LIBERZON[2];
[2]Psychiatry, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Functionally, posttraumatic stress disorder (PTSD) has been linked to impairments in fear extinction retention and contextual processing, dependent on intact prefrontal cortex-

hippocampus circuitry. Hippocampus is critical for processing of contextual information, and fear extinction depends on the context. Interestingly, PTSD patients have been reported to have hippocampus functional and volumetric abnormalities. At the cellular level, adult hippocampal neurogenesis plays a role in key hippocampal functions. Furthermore, neurogenesis is sensitive to stress suggesting a link between traumatic stress, hippocampal neurogenesis and deficits in contextual processing. Here we investigate if our PTSD model- single prolonged stress- affects adult hippocampal neurogenesis and how it relates to context-dependent fear processing. Experiment 1- all rats were injected with BrdU twice per day for four days, then left undisturbed for 21 days. Rats were then assigned to either Controls or SPS. SPS consists of two hours of restraint, immediately followed by 20min force swim, 15min rest, exposure to ether until loss of consciousness, then seven days undisturbed. After, all rats are fear conditioned (FC) to a tone in context A , the next day they are exposed to the tone until fear is extinguished (FE) in context B, following day they are tested for recall (ER) by exposing to the same tone in context B. Experiment 2- In addition to procedures from Experiment 1, rats were given access to environmental enrichment for seven days following SPS, followed by FC, FE and ER during the next three days. Experiment 3- Rats were given access to locked or unlocked running wheels for 24days, exposed to either SPS or undisturbed, injected with BrdU for four days, followed by FC, FE and ER during the next three days. Brains were fixed and processed for immunohistochemistry using DAB or fluorescence for BrdU alone or co-labeling with NeuN. SPS decreased the number of BrdU+ cells in the dentate gyrus of the hippocampus. Results of the effects of environmental enrichment or voluntary exercise are pending. These results suggest that SPS exposure may lead to a decrease in hippocampal neurogenesis and that the degree to which it is reduced may play a direct role in fear extinction learning.

Abstract: Recent epidemiological studies have reported high comorbidity rates of post-traumatic stress disorder (PTSD) and substance use disorders (SUD), however the underlying neuronal mechanism(s) contributing to this relationship remains largely unknown. Chronic substance abuse has been linked to neural modifications in reward pathways, particularly the mesolimbic dopaminergic pathway, resulting in profound alterations in the incentive value of rewarding stimuli. Single prolonged stress (SPS) is a validated preclinical model of PTSD in rats. The objective of the current study was to assess the effects of SPS on behavioral alterations linked with the dopaminergic system. To investigate this, male Sprague-Dawley rats were exposed to SPS or no stress and then assessed at least one week later for locomotor activity, novel object exploration (NOE) and pre-pulse inhibition (PPI) with or without *d*-amphetamine (AMP) (0.5 mg/kg) administration. Results showed that AMP-induced hyperactivity was significantly increased in rats previously exposed to SPS. In addition, in the NOE paradigm, SPS rats spent significantly more time in the center of the arena, had a higher number of entries into the center, and had a higher center-periphery ratio. Rats treated with AMP spent more time exploring the novel object, an effect enhanced by previous SPS exposure. Together, these findings suggest enhanced exploratory and novelty seeking behavior in rats previously exposed to SPS which may be indicative of greater impulsivity. In addition, these findings also suggest a cross sensitization between AMP and SPS which may have implications for the relationship between PTSD and SUD.

Title: Post-stress glucose eliminates PTSD-like symptoms following traumatic stress in rats: Temporal constraints

Authors: *N. SMITH, M. A. CONOSCENTI, T. R. MINOR;
UCLA, Los Angeles, CA

Abstract: Exposure to uncontrollable traumatic stress in the learned helplessness procedure results in PTSD-like symptoms during later testing, including exaggerated fearfulness to a mild stressor and a transition to an unresponsive state termed *conservation-withdrawal*. Symptoms are eliminated when stressed rats are given access to a concentrated glucose solution following the trauma. Rats had access to glucose for 18 hours after traumatic stress in the original study of glucose prophylaxis (Minor & Saade, 1996). Three experiments are reported that assessed any temporal constraints on the benefits of post-stress glucose ingestion.
Experiment 1 assessed temporal differences in fluid consumption in stressed and nonstressed rats during the 18 hours following stress induction. Rats were exposed to 100, 1.0 mA inescapable tail shocks (S) or simple restraint (R) in tubes during a 1.83 hours stress-induction session. Rats in each of the stress condition had 18 hours free access to glucose (G: 40% w/v) or water (W) in their drinking bottles to complete a 2x2 factorial design. Contacts were recorded when a circuit was completed between the water spout and the grounded floor of a rat's metal cage. Rats were exposed to 5, five-sec fixed duration footshocks in a shuttlebox 24 hours after stress induction. Unconditioned shuttle crossing to the shocks and intertrial behavioral freezing (a measure of fear) were scored during the test.
Peak fluid consumption occurred at the onset of darkness in all groups. However, S and R groups ingested significantly more fluid in the glucose condition during the first three hours following stress than did their water-control counterparts. Total fluid intake for the 18-hour post-stress period did not differ significantly among groups. Post-stress glucose ingestion eliminated the exaggerated fearfulness that normally occurs following traumatic stress, and eliminated the transition to conservation-withdrawal as measured by unconditioned shuttle crossings.
Experiment 2 varied time (1, 3, 6, or 18 hours) that glucose or water was available immediately following shock or restraint. Test performance improved in all groups given at least 3 hours access to glucose. Experiment 3 assessed how long after stress access to glucose could be delayed to prevent performance deficits. Groups that received access to glucose within 3 hours of trauma improved test performance compared to 6 hours after trauma.
These experiments provide additional evidence that post-stress glucose is a simple and effective method of preventing behavioral pathology following traumatic stress and identify important constraints when the manipulation is likely to be beneficial.

Title: IGFBP2 induces resilience to stress in rats via a novel non-IGF1 or AMPA receptor dependent mechanism

Authors: *J. S. BURGDORF[1], E. M. COLECHIO[2], N. GHOREISHI-HAACK[2], A. L. GROSS[2], X.-L. ZHANG[3], P. L. STANTON[4], R. L. KROES[2], J. R. MOSKAL[1,2];
[1]Falk Ctr. for Mol. Therapeutics, McCormick Sch. of Engin., Northwestern Univ., Evanston, IL; [2]Aptinyx Inc., Evanston, IL; [3]New York Med. Col., Valhalla, NY; [4]New York Med. Col., Evanston, IL

Abstract: Growth factors play an important role in both resilience to stress and positive affect. Insulin-like growth factor 1 (IGF1) is the only growth factor that has shown antidepressant properties in human clinical trials and is associated with positive affect. In animal studies, Insulin-like growth factor binding protein 2 (IGFBP2) has been shown to have both IGF1-dependent and IGF1-independent effects and is upregulated by positive affect induced by rough-and-tumble play in rats. We evaluated the ability of IGFBP2 to reverse stress-induced behavioral deficits using a rat chronic unpredictable stress paradigm. We tested the dependence of IGFBP2 effects on IGF1- and AMPA receptor activation using specific receptor antagonists. In addition, we measured dendritic spine morphology in the hippocampal dentate gyrus and medial prefrontal cortex 24 hrs after *in vivo* dosing. IGFBP2 (0.3-10 µg/kg i.v.) was 100 times more potent than IGF1 at reducing immobility in the Porsolt forced swim test. Unlike IGF1, the behavioral effects of IGFBP2 were not blocked by the IGF1-receptor antagonist JB1, or by the AMPA-receptor antagonist NBQX. A single dose of IGFBP2 (1 µg/kg IV) reversed stress induced deficits in Porsolt, novelty induced hypophagia, sucrose preference, and ultrasonic vocalization assays. Both IGF1 and IGFBP2 increased the density of mature dendritic spines in both medial prefrontal cortex and hippocampus 24 hrs post-dosing. Taken together, these data suggest that IGFBP2 induces resilience to stress via a novel IGF1 receptor-independent mechanism, and that IGFBP2 mimetics may have therapeutic potential for the treatment of neuropsychiatric disorders associated with chronic stress.

Title: The role of Akt signaling in persistent fear expression in a rodent model of post traumatic stress disorder

Authors: *D. K. KNOX, T. DEPIETRO, J. STAIB, M. CHAMNESS, E. MOULTON; Psychology, Univ. of Delaware, Newark, DE

Abstract: Single prolonged stress (SPS) exposure results in extinction retention deficits in rodents and is often used to model post traumatic stress disorder in humans. Recent research we have conducted suggests SPS-enhancements in fear memory could contribute to extinction retention deficits in the SPS paradigm. Previous studies have found that SPS increases baseline levels of Akt in the hippocampus. Furthermore, Akt signaling modulates fear memory formation. These findings raise the possibility that SPS could enhance fear memory by enhancing Akt signaling in emotional circuits in the brain. In turn, this enhancement in fear memory could lead to extinction retention deficits in the SPS model. To test this hypothesis, we looked at the effects of SPS on the Akt signaling in emotional circuits by examining levels of phospho and pan PDK and Akt in SPS and control rats at baseline and after fear conditioning. After removal from the housing colony or after the end of Pavlovian fear conditioning, rats were euthanized and brains extracted and stored at -80 ºC. The medial prefrontal cortex (mPFC), amygdala (AMY), ventral

hippocampus (vHipp), and dorsal hippocampus (dHipp) were then dissected from whole brains and western blot used to determine protein levels in all brain regions. While the study is ongoing, preliminary findings suggest that SPS enhances phosphorylated PDK levels in the mPFC and dHipp after fear conditioning. The initial results are consistent with the hypothesis that Akt signaling has a role in mediating extinction retention deficits in the SPS paradigm, which raises the possibility that enhanced Akt signaling after stress exposure could contribute to persistent fear memory expression.

Title: Effects of glucose on learned helplessness behavior with a novel control condition

Authors: *N. C. CHRISTIE[1], M. A. CONOSCENTI[2], T. R. MINOR[2];
[1]Psychology, UCLA, Woodland Hills, CA; [2]Psychology, UCLA, Los Angeles, CA

Abstract: PTSD is a disorder that affects a wide range of people worldwide. A major contributing factor to the onset of PTSD is the inability of the hippocampus to consolidate the traumatic memory properly. Our intervention aimed to reinstate the consolidatory properties of the hippocampus by bringing it back "online." This memory can then be specified to the context of the trauma, leading to a reduction in the overgeneralization of fear to other contexts. In this experiment, 32 adult male Sprague-Dawley rats were separated into four groups of eight. The control group received no shock and had access to only water. The other three groups received either 18 hours of access to water, fructose, or glucose immediately following an acute stressor in the form of an uncontrollable tail shock administered over a time period of two hours. Fructose was used as a placebo control to determine that it is the unique properties of glucose that reduce learned helplessness behaviors and not simply a sweet tasting solution post-trauma. The shock glucose group received the same acute stressor of an uncontrollable tail shock administered over a time period of two hours, with 18 hours of access time to glucose immediately after trauma. The results of the post-trauma behavioral task show that there is no significant difference between the shock-fructose and shock-water groups. Both demonstrated the same levels of learned helplessness behavior in the shuttle box task. Consistent with previous

research in the lab, the shock-glucose and restraint-water groups group demonstrated significantly better learning in the post-trauma escapable shock shuttle box test.

Title: Establishing a modified model of PTSD in adolescent rats

Authors: ***A. L. GARRISON**, E. N. WALSH, J. M. SMITH, T. E. KOELTZOW;
Bradley Univ., Peoria, IL

Abstract: New diagnostic criteria for Posttraumatic Stress Disorder (PTSD) in children and adolescents highlight the need to better understand the neurophysiological adaptations that trauma might elicit during development. The single prolonged stress (SPS) rat model of PTSD reliably produces an enhanced fear response to traumatic cues and disrupted cortisol regulation similar to that typically observed in humans with PTSD (Wang et al., 2008; Knox et al., 2012). In addition, SPS has been shown to influence the response of rats to cocaine (Eagle et al., 2015), a finding that is relevant to reports of co-morbidity of PTSD with substance abuse disorders (Jacobsen et al., 2001). The current study aimed to investigate the possible long-term effects of exposure to a modification of the SPS model (two hours of restraint stress followed by 20 minutes of forced swim) during adolescent development (Postnatal Day 32-35 at time of induction). Dependent variables included spontaneous locomotor activity as well as responses to a black/white chamber and an open field. Data indicate that the modified SPS procedure failed to elicit robust alterations in the behavior of SPS adult rats compared to controls. In contrast, exposure of SPS to adolescent rats tended to decrease spontaneous locomotor activity, measured as total distance travelled during a one hour test (t (21) = 1.39, p = 0.09; Cohen's d = 0.59), compared to controls. Similar effects were observed when rats were tested 4 weeks later (t (21) = 1.68, p = 0.05; Cohen's d = 0.66). The results of the behavioral anxiety data were more complex. For example, total crosses in the open field tended to be lower among SPS rats (t (20) = 1.53, p = 0.07; Cohen's d = 0.45) when test two weeks after SPS, but this trend was absent when tested 4

weeks later (t (21) = 0.26, n.s.). By contrast, no statistically significant differences were observed in the black/white chamber two weeks after SPS (BW crosses: (t (21) = 0.62, n.s.), though SPS-exposed rats exhibited a statistically significant decrease in exploration of the black/white chamber when tested 4 weeks later (t (21) = 1.91, $p < 0.05$; Cohen's d = 0.81). Finally, although SPS-exposed adolescent rats tended to exhibit hypoactivity in a variety of measures, there were no statistically significant differences in response to a cocaine challenge (F (1,21) = 0.15, n.s.). Taken together, data results indicate that adolescent rats may be more sensitive to stress compared to adult rats. On-going research aims to identify factors that may correspond to vulnerable vs. resilient individual responses to trauma.

Title: Combined single prolonged stress (SPS) and CO_2 inhalation as a novel model of comorbid post-traumatic stress disorder (PTSD) and panic disorder associated behaviors in mice

Authors: *K. M. MCMURRAY[1,2,3], J. D. SCHURDAK[2,3], L. L. VOLLMER[2], R. SAH[2,3]; [1]Psychiatry, Univ. of Cincinnati- Reading Campus, Cincinnati, OH; [2]Psychiatry, Univ. of Cincinnati, CIncinnati, OH; [3]Cincinnati VA, Cincinnati, OH

Abstract: Post-Traumatic Stress Disorder (**PTSD**) and Panic Disorder (**PD**) are highly comorbid and debilitating psychiatric disorders. PTSD and PD have a lifetime prevalence of ~8% and ~5% in civilian populations, respectively, while the incidence is higher in combat veterans (PTSD ~13%; PD ~8%). Primary treatments for both disorders are limited by high abuse potential (benzodiazepines), delayed onset (SSRI/SNRI) and a lack of effect in a large proportion of patients. Additionally, comorbid PD and PTSD is associated with worse patient outcomes pointing to a need for understanding the underlying pathophysiology in order to develop novel pharmacotherapies and improve treatment outcomes. Despite a high prevalence and debilitating effects, the neurobiology and underlying mechanisms of comorbid panic-PTSD is largely unknown. Development of translational models simulating comorbid panic and PTSD-like behaviors is urgently needed. Low dose CO_2 inhalation selectively induces panic attacks in PD

subjects compared to healthy controls. Further, prior sensitivity to CO_2 is associated with worse PTSD symptoms, suggesting potential for common vulnerability factors. Previous studies in our lab have used rodent models of CO_2-inhalation evoked freezing (panic-like) and traumatic stress evoked startle and fear conditioning (PTSD-like) behaviors (Vollmer et al 2016; McGuire et al 2010; Schmeltzer et al, 2015). The current study investigated the emergence of panic- and PTSD-relevant behaviors in a conjunction CO_2-inhalation-single prolonged stress (SPS) model. We hypothesized enhanced fear and panic associated behaviors in mice exposed to both stress and CO_2 inhalation. Male BALB/C mice were exposed to SPS (restraint for 2 hr, 10 min forced swim and exposure to ether until losing consciousness) or were undisturbed. One week later, all mice were exposed to air or 5% CO_2 for 10 min and freezing behavior was scored. Following one week of recovery PTSD-like behaviors were assessed (acoustic startle and context fear conditioning). Prior SPS exposure altered CO_2 evoked fear-like behaviors and induced deficits in fear-extinction learning in a subgroup of SPS treated animals. Freezing to CO_2 was correlated with freezing during fear conditioning only within SPS treated mice, suggesting SPS exposure may interact with CO_2 inhalation to impact PTSD-relevant behaviors. Ongoing studies are further investigating potential sub-populations representing susceptibility or resistance in a larger cohort. Collectively, development of this novel model will advance our understanding of comorbid PTSD and PD.

Title: Chronic 'PTSD-like' effects (after 6months) in a mouse model of comorbid traumatic stress and repetitive mTBI

Authors: *M. ALGAMAL[1], J. O. OJO[1,2], M. OWENS[1], M. MULLAN[1,2], D. DIAMOND[3,4], F. CRAWFORD[1,2,3];
[1]Roskamp Inst., Sarasota, FL; [2]The Open Univ., Milton Keynes, United Kingdom; [3]James A. Haley Veterans' Hosp., Tampa, FL; [4]Univ. of South Florida, Tampa, FL

Abstract: Background: Comorbid mTBI and PTSD can be clinically challenging to diagnose in humans, due primarily to the heterogeneity and clinical overlap shared by both conditions. This emphasizes the critical need to develop a relevant animal model whereby many variables can be effectively controlled. This work aimed to investigate the behavioral and neurobiological interrelationship between mTBI and traumatic stress in a mouse model.
Methods: Four groups of animals were examined in this study – sham, stress, repetitive-mTBI (r-mTBI) and stress+rmTBI. Briefly our Two separate cohorts were used in this study. Cohort (I) received chronic stress and/or r- chronic stress paradigm involved 21 days of unpredictable repetitive exposures to: danger-related predator odor (Fox urine, TMT) whilst under restraint, a daily social stressor involving unstable social housing with an alternate congener, and physical trauma in the form of five repeated inescapable footshocks on separate days. Animals receiving r-mTBI and stresssors were exposed to five closed head injuries 1hr after each inescapable footshocks. mTBI paradigm once at 3 months of age, while cohort (II) received this twice, at 3 and 5 months of age. A battery of behavioral tests for fear, anxiety, depression and spatial memory was conducted, in addition to molecular profiling of brain and plasma samples.
Results: Behavioral analyses at 2 weeks, 3months and 6 months post-exposure showed that stressed mice in both cohorts demonstrated significant weight loss, recall of traumatic memories, anxiety and depressive-like behavior when compared to sham mice. Interestingly repeated mTBI abrogated the stress related phenotype in the fear memory, and depression tests. Neuroendocrine studies implicate the noradrenergic system and the HPA axis as contributory factors for the observed differences between stress and sham mice.
Conclusion: Our results show that animals exposed to stressful trauma alone demonstrate some similar traits with the human condition as defined by DSM-V. Distinct and overlapping traits were observed between the mTBI and stress groups. We anticipate that our model will be a good platform to explore targeted biomarkers and treatment strategies in PTSD and repetitive mTBI.

Title: Relationship between methamphetamine use, reinforcement and seeking in mice with high genotype-dependent methamphetamine intake.

Authors: *S. SHABANI[1], E. I. MOJICA[1], L. HELLMUTH[1], S. HOULTON[1], T. J. PHILLIPS[2,3];
[1]Biol., Minot State Univ., Minot, ND; [2]Behavioral Neurosci., Methamphetamine Abuse Res. Center, Oregon Hlth. & Sci. Univ., Portland, OR; [3]Veterans Affairs Portland Hlth. Care Syst., Portland, OR

Abstract: Based on data for cocaine addiction, pattern of drug use in the form of binge/abstinence cycles is thought to influence drug seeking, i.e. craving, and vice versa. General cocaine use pattern in humans, however, is different from methamphetamine (MA) use pattern. We have developed a genetic mouse model for which genetic factors associated with pattern of MA use also influence other addiction relevant traits such as sensitivity to the rewarding, reinforcing and aversive effects of MA. The genetic model is comprised of mouse lines generated via selective breeding for higher (MAHDR) and lower (MALDR) amounts of MA intake in a two-bottle choice (water vs. MA dissolved in water) drinking procedure. In the current study, male and female MAHDR mice and their higher MA intake progenitor strain, DBA/2J (D2) mice, were used to explore the influence of binge/abstinence MA use on MA seeking and taking. Mice first engaged in an operant oral self-administration procedure in which MA was gradually faded in and saccharin gradually faded out and MA concentration was increased to 80 mg/l. Then a multiple bottle choice procedure was used in which half of the animals were given access to a 3:1 ratio of MA:water bottles and half were controls given access to 4 water bottles only. The MA access period was for an 18h period daily; water was available 24h per day. During the multiple bottle choice procedure, MA concentration was increased every 4d from 20 to 40 and then 80 mg/l, and then animals were given access every other day for another 5 trials. Between days of acute withdrawals from voluntary drinking, animals resumed operant oral self-administration for 5 trials that were paired with both discrete and contextual cues. Finally, an extinction phase in the operant procedure lasted 16 days followed by a cue-induced reinstatement test. In MAHDR mice, MA reinforcement behavior in females was significantly lower than in males; however, female MAHDR mice had higher MA intake than males during subsequent voluntary MA drinking. Sex had no significant effect in D2 mice. MA reinforcement behavior was significantly higher in MAHDR than D2 mice. Prior exposure in an operant procedure had minimal effect on subsequent voluntary drinking in MAHDR mice, but substantially attenuated voluntary MA intake in D2 mice. Compared to water controls, voluntary MA drinking did not influence MA reinforcement behavior during acute withdrawal or MA seeking in a cue-induced reinstatement test in either genotype. Our results indicate that genotype and sex play important roles in MA use patterns, reinforcement and seeking traits, and the impact of MA experience on subsequent MA intake.

Title: Context-independent effects of footshock on drug-seeking

Authors: *C. PIZZIMENTI[1,2], T. NAVIS[2], K. M. LATTAL[2];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Fear-related disorders and substance use disorders are highly comorbid. Even following long periods of abstinence, comorbid individuals have high rates of relapse to drugs of abuse, especially in response to cues previously paired with drug. Previous attempts to characterize the role of fear on reinstatement have administered both the drug and the stressor within the same environment. Therefore, little is known about how fearful experiences in a specific context cause persistent changes in drug-seeking behavior in other contexts. To address this we examined the effects of massive footshock in one context on cue-induced drug-seeking for methamphetamine in another context. In Experiment 1, animals were trained to self-administer methamphetamine in Context A. On day 8 of self-administration (16 total sessions) animals received either a battery of footshocks in Context B or exposure to that context only, and were then allowed to continue daily self-administration sessions in Context A. Animals that received shock reinstated significantly more than controls to drug-associated cues and took significantly longer to extinguish lever pressing following reinstatement. In Experiment 2 the battery of footshocks were administered in Context B before acquisition of self-administration in Context A. Animals that received footshock showed significantly elevated responding during cue-induced reinstatement. In a separate group of animals corticosterone (CORT) levels were measured once per week for two weeks prior to footshock, immediately following footshock, and once per week for five weeks after footshock. These time points were chosen because it was at approximately five weeks following footshock that enhancements in cued-reinstatement were observed in Experiments 1 and 2. Animals also underwent a dexamethasone (DEX) test to assess the response of glucocorticoid receptors. CORT was significantly elevated immediately following footshock relative to controls, but there were no persistent differences between groups, and there was no reliable difference between groups in response to DEX. Taken together, these

results suggest that this novel, translatable model replicates the human condition in which exposure to a massive stressor in a specific context produces long-term changes in drug-seeking behavior in non-fear associated contexts. These data also suggest these changes are not due to long-term alterations to the HPA axis itself, but are likely due to changes at the neurobiological or circuit level.

Title: Examination of sex dependent neural substrates correlated with meth triggered reinstatement in rats

Authors: *S. T. PITTENGER[1], S. CHOU[2], S. T. BARRETT[1], O. D. LOH[1], R. A. BEVINS[1]; [1]Univ. of Nebraska-Lincoln, Lincoln, NE; [2]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Methamphetamine (meth) use results in a heavy economic and societal burden, costing the United States an estimated 23 billion dollars annually. Meth dependence is often characterized by persistent and chronic relapse to drug use. A relapse can occur weeks or even months after the last drug use, often resulting in periods of sustained meth use. Relapse after long periods of abstinence remains a major impediment to the treatment of meth use and drug addiction. Notably, nearly 45% of individuals that do seek treatment for meth addiction are women. Given the high rates of meth addiction in women, the role of sex in meth relapse remains understudied. The limited animal research that has investigated sex differences on meth-taking has illuminated notable differences between the sexes. Preliminary work in our lab investigating sex-differences in meth reinstatement has shown that females show greater reinstatement induced by a meth priming injection. This study identified sex-dependent neural substrates correlated with meth-triggered reinstatement using immunohistochemistry. Male and female Sprague-Dawley rats were surgically implanted with indwelling jugular catheters. Half of the rats were then trained to self-administer meth; the other half self-administered saline infusions during 21 daily sessions (2h). Rats were then given 12 extinction sessions. Twenty-four hours after the last extinction session, rats received reinstatement testing. Half of the rats received a meth-prime (0.3 mg/kg, SC) injection and half of the rats received a saline injection.

This design resulted in 4 separate groups for each sex (SalSA/SalT, SalSA/MethT, MethSA/SalT, MethSA/MethT) allowing for careful investigation of brain regions correlated with meth-triggered reinstatement. Brains were harvested following the reinstatement session and cFos immunoreactivity was measured in 20 brain regions. Meth triggered reinstatement in both sexes and this effect was more robust in females compared to males. Fos activation was significantly increased following meth-primed reinstatement in the cingulate cortex area 1, lateral orbitofrontal cortex, prelimbic cortex, caudate putamen, nucleus accumbens core and shell, central nucleus of the amygdala. Significant sex differences were also found with females showing greater cFos immunoreactivity. These sex differences were found to be greatest in rats that received a meth-prime following meth self-administration (MethSA/MethT) and in brain regions associated with drug addiction (e.g., cingulate cortex area 1, lateral orbitofrontal cortex, caudate putamen, nucleus accumbens core).

Title: Cue-induced relapse to methamphetamine seeking in compulsive methamphetamine takers and abstinent rats

Authors: *I. N. KRASNOVA, N. TERRY, M. MCCOY, B. LADENHEIM, J. CADET;
Mol. Neuropsychiatry Res. Br., NIDA, NIH, DHHS, Baltimore, MD

Abstract: The treatment of methamphetamine (METH) addiction is associated with a high rate of relapse to drug use even after long periods of abstinence. The high degree of recidivism is probably related to METH-induced neuroadaptations in the brain. Here, we studied differences in cue-induced relapse in rats that continue to self-administer METH compulsively and those that became abstinent in the presence of contingent footshocks. We trained rats to self-administer METH (0.1 mg/kg/ infusion) for 9 h/day for 20 days. Subsequently, 50% of the METH infusions were punished by mild electric foot-shocks (0.18 ->0.36 mA, 0.5 sec) for 10 days. A control group of rats self-administered saline. During training, rats showed binge patterns of METH self-administration, with the first hour intake gradually escalating over time. Total METH intake also

escalated over time. During shock phase, approximately 55% of animals reduced METH self-administration to about 20% of pre-shock level (shock-sensitive rats), whereas the remaining animals continued to self-administer the drug (>50% of pre-shock level) in spite of electric foot-shocks (shock-resistant rats). Importantly, we did not find significant differences in drug intake during self-administration training between the shock-resistant and shock-sensitive rats. Next, we conducted extinction tests on withdrawal days 2 and 30 in the presence of METH-associated cues. We found increases in cue-induced reward seeking on withdrawal day 30 in comparison to withdrawal day 2 in both, shock-resistant and shock-sensitive rats. However, shock-resistant rats showed significantly higher METH seeking than shock-sensitive animals. Our results show that escalation of METH intake occurs in rats that become compulsive drug takers and in those that develop abstinence in the presence of adverse consequences. These observations are consistent with clinical literature. Our findings also revealed that compulsive METH takers showed a greater relapse to drug seeking than abstinent rats.

Title: Effects of Ro5-4864 on methamphetamine self-administration in male and female rats

Authors: ***G. F. GUERIN**[1], S. M. HAROLD[1], S. R. PORTER[1], C. D. SCHMOUTZ[1], G. LI[2], J. M. COOK[2], N. E. GOEDERS[1];
[1]LSUHSC-S, Shreveport, LA; [2]Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Methamphetamine abuse continues to be a serious and growing problem with no approved treatment. We have previously demonstrated differential effects of benzodiazepines on various methamphetamine-related behaviors based upon their relative affinities for either the "central" benzodiazepine (BZD) binding site associated with the $GABA_A$ receptor or the "peripheral" BZD binding site associated with the translocator protein of 18kDa (TSPO). Specifically, oxazepam, which binds to both receptors, decreases methamphetamine self-

administration, conditioned place preference and drug discrimination. In contrast, alprazolam, which binds only to the central BZD binding site, augments the effects of methamphetamine at certain dose combinations. The current experiment was designed to investigate the effects of Ro5-4864 on methamphetamine self-administration in rats. Ro5-4864 is a potent selective ligand for TSPO that does not bind to the $GABA_A$ receptor complex and lacks typical "central" benzodiazepine-like effects. Male and female Wistar rats were trained to self-administer methamphetamine (0.05 mg/kg/infusion) during daily two-hour sessions. After responding stabilized, several doses of Ro5-4864 were administered intraperitoneally 30 minutes before the start of the sessions. Self-administration was dose dependently decreased in both males and females; however, female rats were more sensitive to these effects. The TSPO receptor has an integral role in the ability of certain benzodiazepines to decrease methamphetamine self-administration and could be important in developing novel treatments for stimulant addiction.

Title: Differential effects of ratio requirement on reinforcing efficacy of synthetic cathinone analogs of MDMA

Authors: *S. B. DOLAN, M. GATCH;
Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Novel psychoactive substances have been established as a prominent fixture in global drug culture, with synthetic cathinones being amongst the most prevalent of these substances. Although initially used as semi-legal alternatives to illicit recreational drugs, many synthetic cathinones have been diverted into "ecstasy" formulations *in lieu* of MDMA. The current study aimed to investigate the reinforcing effects of MDMA along with three synthetic cathinone analogs of MDMA with propyl-, butyl-, or pentylamine side-chains: methylone, butylone, and pentylone, respectively. Two separate groups of adult, male Sprague-Dawley rats were trained to

self-administer 0.05 mg/kg/infusion methamphetamine under a FR1 or FR10 schedule of reinforcement. Rats trained on the FR1 schedule underwent substitution testing under an FR1, whereas rats trained on the FR10 underwent substitution testing under a progressive ratio. Each test compound was robustly self-administered at similar rates under the FR1 schedule. Conversely, under the progressive ratio, there were substantial differences in reinforcing efficacy among the compounds. Methylone and butylone produced greater self-administration than vehicle controls, but less than methamphetamine controls; however, pentylone produced self-administration comparable to methamphetamine. MDMA, on the other hand, was not self-administered at a greater rate than the vehicle control. These results indicate that each of the test compounds serves as a reinforcer under a continuous schedule of reinforcement, but when the behavioral cost of reinforcement is increased under the progressive ratio, the reinforcing efficacy of these synthetic cathinones is positively associated with its side-chain length. Additionally, these data indicate that the cathinone analogs of MDMA may serve as more efficacious reinforcers than MDMA. Translationally, these data suggest that MDMA and the synthetic cathinone analogs are equally efficacious as substitutes for methamphetamine when access is unhindered, but when increased costs are imposed, synthetic cathinones with longer side-chains may be used as substitutes for psychostimulant-maintained behavior. Furthermore, the prevalence of these synthetic cathinone analogs of MDMA in “ecstasy” formulations may result in increased compulsive “ecstasy” use in turn leading to complications arising from acute intoxication as well as increased likelihood for chronic use not typically seen with MDMA.

Title: Effects of oxytocin following traumatic stress on methamphetamine seeking in female rats.

Authors: *C. E. O'NEILL, R. J. NEWSOM, J. F. MCGINTY;
Inst. of Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Previous research has shown a strong link between posttraumatic stress disorder (PTSD) and substance use disorders (SUD). Stimulants, such as methamphetamine (METH), are

among the most highly abused by those with comorbid PTSD, and these patients typically exhibit a longer history of use and poorer overall treatment outcomes in comparison with individuals diagnosed with a SUD alone. Previous work from our lab has shown that male rats exposed to 5 days of TMT(2,4,5-dihydro-2,5-trimehylthiazoline) exhibit exacerbated levels of TMT-induced reinstatement (RST), but that 10 days of systemic oxytocin (OXT) administration prior to initiation of METH self-administration blocks RST only in TMT pre-exposed rats (Ferland et al., 2016). The goal of the present study was to determine whether these effects are similar in female rats. Thus, we exposed female rats to TMT or saline for 5 days followed by 10 days of OXT (1.0 mg/kg, i.p.) or saline. Plasma corticosterone (CORT) was significantly elevated and animals displayed increased anxiety in the open field following 15 min of TMT exposure on both the 1st and 5th day, with no evidence of habituation to the stressor. Plasma OXT levels were elevated following the 1st day of TMT exposure, but returned to baseline levels by the 5th day. Similar to males, TMT pre-exposed female rats injected with saline for 10 days prior to METH SA exhibited significantly increased stress-induced RST than saline pre-exposed rats injected with saline prior to METH SA. In contrast, female rats pre-exposed to saline followed by 10 days of OXT showed a significant decrease in stress-induced METH seeking compared to saline pre-exposed rats injected with saline prior to the initiation of SA. The same pattern was observed in cue-induced RST, indicating that OXT treatment following either TMT or saline pre-exposure suppressed METH seeking. Tissue collected following TMT-induced RST is currently being processed for alterations in mRNA expression for genes related to OXT and stress signaling in several brain regions.

Title: Rearing condition alters the ability of ceftriaxone to attenuate cue and amphetamine reinstatement

Authors: *E. J. GARCIA, D. L. ARNDT, M. E. CAIN;
Dept. of Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: The glutamate homeostasis hypothesis of addiction proposes that excessive synaptic and extracellular glutamate levels promote drug reinstatement after extinction. After chronic psychostimulant self-administration, glutamate homeostasis is reduced by decreasing cysteine-glutamate exchanger (xCT) and primary glial glutamate transporter 1 (GLT1) expression. Ceftriaxone (CTX) restores glutamate homeostasis by upregulating xCT and GLT1, thereby reducing reinstatement. Rodents reared in an enriched condition (EC) show faster extinction learning and less drug-induced reinstatement when compared to rats reared in isolated (IC) or standard conditions (SC). The effect of rearing condition on glutamate homeostasis during reinstatement is not understood. To understand how rearing condition alters the function of GLT1 and determine how GLT1 is implicated in AMP reinstatement, rats were randomly assigned to vehicle (VEH) or CTX treatment after a 30 day rearing period in EC, IC, or SC conditions. Rats were then implanted with indwelling jugular catheters and allowed to self-administer AMP (0.1 mg/kg/infusion) on a FR1 schedule of reinforcement during 60-min sessions. AMP reinforcement was paired with a tone/light stimulus. After stable responding was achieved, rats were trained under extinction conditions such that active lever responding no longer presented AMP reinforcement or the tone/light stimulus. Beginning on the 6th extinction day, differentially reared rats were randomly assigned to receive daily injections of VEH or CTX (200 mg/kg ip) that continued through the last reinstatement test. After responding on the active lever was significantly reduced, rats were tested in a cue-induced reinstatement test where active lever responding resulted in the tone/light stimulus. Rats were trained in extinction and responding was reduced again prior to the AMP-induced (0.25 mg/kg s.c.) reinstatement test. During the AMP-induced reinstatement test active lever responding resulted in no programmed consequence. Results indicated that EC rats had a faster rate of extinction but CTX administration did not affect extinction learning. The cue-induced reinstatement test revealed that EC rats had less responding than IC or SC rats. Notably, CTX treatment reduced EC responding and increased IC responding in the first 10 minutes of the cue-induced reinstatement test. During the AMP-induced reinstatement test, CTX significantly reduced responding in SC rats but not EC or IC rats. These results demonstrate EC rearing protects against cue-induced reinstatement and that rearing condition changes the ability of CTX to restore glutamate homeostasis.

Title: Self-administration of psychstimulants via vapor inhalation in rats

Authors: *M. A. TAFFE[1], J. D. NGUYEN[2], S. A. VANDEWATER[2], M. COLE[3];
[1]Cmte Neurobio. of Addictive Disorders, [2]The Scripps Res. Inst., La Jolla, CA; [3]La Jolla Alcohol Research, Inc, La Jolla, CA

Abstract: Addiction to methamphetamine (MA), cocaine and increasingly the cathinone derivative psychostimulants ("bath salts", "plant food", "flakka"), interferes with many aspects of personal health, vocational performance, interpersonal relationships and financial well-being. The consequences of stimulant addiction also strain legal and emergency medical resources throughout the US, making it a significant public health problem. Despite higher rates of treatment admissions for smoked versus other routes of cocaine administration and increasing proportions of MA users who smoke, there are no convenient models of inhalation self-administration available for rodent research. We have developed an e-cigarette based technology that can deliver locomotor stimulant doses of MA, 4-methylmethcathinone (mephedrone), 3,4-methylenedioxypyrovalerone (MDPV) or α-Pyrrolidinopentiophenone (alpha-PVP) to rats via inhalation. This study determined if inhaled psychomotor stimulants serve to reinforce operant behavior. Groups of rats were trained to nose poke for 2-min epochs of exposure to vaporized MA, MDPV, mephedrone, alpha-PVP or the propylene glycol (PG) vehicle. Stable or gradually increasing numbers of stimulant vapor epochs were obtained while responding for the PG vehicle alone gradually decreased across sessions. Responses on the drug-associated hole increased relative to the alternate hole, with 89% selectivity observed in some groups. Pretreatment with the dopamine D1-like receptor antagonist SCH23390 decreased responding for MA vapor. This study shows that rats will make nose poke responses to obtain access to psychostimulant vapor. This establishes a new model of intrapulmonary self-administration of drugs in rats which uses a technology (e-cigarette) that is increasingly being adapted in human users for non-nicotine drug use.

Title: Sufficiency of dopamine receptor stimulation in the reinstatement of methamphetamine seeking

Authors: T. A. LARSON[1], M. C. WINKLER[1], *R. K. BACHTELL[2];
[2]Dept. of Psychology & Neurosci., [1]Univ. of Colorado, Boulder, CO

Abstract: Methamphetamine (METH) continues to be a widely used psychostimulant, however the neurobiological mechanisms underlying it's seeking and relapse are still unclear. Previous data has shown that antagonism of dopamine receptor subtypes differentially affect METH reinforcement and relapse. Using a common rodent model of relapse, we assessed whether stimulation of dopamine receptor subtypes (D1, D2, and D3) are sufficient to induce METH seeking. Rats were trained to self-administer METH via lever press during daily 2-hr sessions on a fixed-ratio 1 schedule for 10 consecutive days. Extinction procedures commenced after 1 day of abstinence and lever pressing was extinguished throughout the 6 consecutive extinction sessions. The following pharmacologically developed agonists were administered via systemic intraperitoneal injection or directly into the nucleus accumbens core (NAc) prior to a reinstatement test session: SKF 81297 (D1 agonist), quinpirole (D2-like agonist), and 7-OH-DPAT (D3 agonist). Systemic administration of SKF 81297 produced a dose-dependent modest reinstatement of METH seeking. Systemic quinpirole produced a robust dose dependent reinstatement of METH seeking. Intra-NAc administration of SKF 81297 produced robust reinstatement, while quinpirole and 7-OH-DPAT were ineffective. These findings demonstrate distinct reinstatement patterns that is dependent on the route of administration and may aid in assessing the involvement of specific dopamine receptor subtypes in methamphetamine seeking.

Title: The 5-HT_{1B} receptor agonists, CP 94,253 and zolmitriptan, attenuate the reinforcing and motivational effects of methamphetamine.

Authors: *R. GARCIA[1], A. R. COTTER[2], K. LESLIE[2], K. ENNIS[2], T. BENSON[2], M. F. OLIVE[3], J. L. NEISEWANDER[2];
[1]Interdisciplinary Grad. Program in Neurosci., [2]Sch. of Life Sci., [3]Psychology Dept., Arizona State Univ., Tempe, AZ

Abstract: We previously found that the selective 5-HT_{1B} receptor (5-HT_{1B}R) agonist, CP 94,253, enhances cocaine self-administration (SA) during initial training but attenuates SA after 3 weeks of abstinence from cocaine. Here we examined if CP 94,253 and the mixed 5-$HT_{1B/1D}$R agonist, zolmitriptan, produce similar abstinence-dependent effects on methamphetamine (meth) SA. Male Sprague-Dawley rats were tested for the effects of CP 94,253 on meth reinforcement rates on both fixed and variable ratio (VR) 5 schedules and on a progressive ratio (PR) schedule of reinforcement. Similarly, we tested for the effects of zolmitriptan on meth reinforcement on a VR5 schedule. We found the typical inverted U-shaped meth SA dose-response function when rats were pretreated with vehicle on both low ratio schedules. CP 94,253 produced a downward shift of the descending limb of the dose-response function prior to abstinence. Post-abstinence, CP 94,253 produced a downward shift of the entire dose-response function. CP 94,253 also attenuated reinforcers obtained and breakpoints on the PR schedule compared to vehicle pretreatment both pre- and post-abstinence. Importantly, administration of SB 224,289, a selective 5-HT_{1B} receptor antagonist, blocked the attenuating effects of CP 94,253 on meth SA. The decreases in SA measures were not likely due to motor impairments, as CP 94,253 had no effect on locomotor activity. Interestingly, acute treatment of zolmitriptan attenuated meth SA pre- and post-abstinence similar to the effects of CP 94,253. In addition, the attenuating effects of zolmitriptan on meth SA following a period of abstinence were sustained after each of 3 more treatments given every 2-3 days during the resumption of meth SA. Thus, unlike the abstinence-dependent modulatory effect of CP 94,253 on cocaine SA, this study found that both CP 94,253 and zolmitriptan inhibit meth SA regardless of abstinence. These findings suggest that 5-HT_{1B}R agonists may have clinical efficacy as treatments for psychostimulant use disorders.

Title: Rewarding effects of a methamphetamine and morphine speedball as assessed by ultrasonic vocalizations in rats

Authors: ***T. T. TOWNER**, A. ROCHA, K. A. TRUJILLO;
California State Univ. San Marcos, San Marcos, CA

Abstract: The combination of a stimulant and opiate is commonly known as a "speedball". The traditional speedball is a combination of cocaine and heroin, and became newsworthy for contributing to the deaths of notable celebrities, including John Belushi and Chris Farley. However, with other opioids and psychomotor stimulants gaining popularity, including methamphetamine (METH) and morphine (MOR), non-traditional speedball combinations have the potential to be increasingly abused. The current study assessed the behavioral effects of a METH/MOR speedball. Animals were tested in two behavioral paradigms: locomotor activity and ultrasonic vocalizations (USVs) since increases in locomotor behavior and 50 kHz USVs reflect increases in reward. Animals received saline (control), METH (0.3mg/kg), MOR (5.0 mg/kg), or a combination of METH and MOR (speedball). METH-treated animals had immediate and long-lasting increases in locomotor behavior, representing stimulating properties of the drug. MOR-treated animals showed a biphasic locomotor response, with an initial mild depression of movement followed by an increase. Activity in the speedball group was much greater than either drug alone, suggestive of a synergistic effect. When assessing USVs, METH produced a rapid increase in vocalizations, reflecting its powerful rewarding effects. Similar to past work, MOR did not induce 50 kHz vocalizations. In contrast to locomotor behavior, the speedball group did not show an increase in USVs; in fact, it appeared that MOR inhibited METH-induced USVs. The ability of MOR to inhibit METH-induced USVs suggests that opioids may play an active role in suppressing vocalizations. In this regard, evidence suggests that the nucleus ambiguus, a brainstem region populated with mu opioid receptors, is essential in

USV production. Thus, opioid activity in the nucleus ambiguus may inhibit the motor output pathway for the production of reward related USVs. The results replicate earlier work demonstrating synergistic interactions between METH and MOR in locomotor behavior, and suggest that 50 kHz USVs are not useful for assessing rewarding effects of opioids, alone or in combination with other drugs.

Title: Complex behavioral interactions between dissociative drugs and methamphetamine

Authors: *A. ESCOBEDO, K. A. TRUJILLO;
California State Univ. San Marcos, San Marcos, CA

Abstract: Dissociative drugs such as phencyclidine (PCP, Angel's Dust) and ketamine (KET, Special K) are abused in the dance club and rave scene for their complex behavioral effects including hallucinations, delusions, excitement and reward. Similarly, methamphetamine (METH) is a powerful and highly addicting psychomotor stimulant that is used at dance clubs and raves. Because these drugs are use in the same settings, there is the potential for these drugs to be used simultaneously. Indeed, studies show that psychomotor stimulants, such as METH, are the drugs most likely to be used with dissociatives in dance club settings. Drug users often combine drugs of abuse to potentiate rewarding effects. This effect is most notable with a cocaine/heroin combination, known as a "speedball." Another reason for combining drugs is that one drug will reduce negative side-effects of the other. The present studies examined the behavioral effects of combining a dissociative drug with METH in Sprague-Dawley rats. The locomotor effects of KET (10.0 mg/kg s.c), PCP (1.0 mg/kg s.c), or MK-801 (0.1 mg/kg s.c), were assessed alone or in combination with METH (1.0 mg/kg s.c). It was hypothesized that a combination of METH with a dissociative would produce a greater stimulant effect than either drug alone. The doses of the dissociatives were selected because they are the lowest that produce a stimulant response. The dissociative was administered 15 minutes before METH and the

locomotor response was assessed in a Kinder Scientific Motor Monitor. Interestingly, although KET reduced METH-induced hyperlocomotion, the opposite was found for PCP and MK-801 - these drugs enhanced the locomotor response to METH. The results illustrate the complex effects of combinations of dissociatives with METH, and suggest that KET is unique in its ability to suppress METH-induced locomotor behavior. Moreover, the results raise questions as to why individuals abuse combinations of KET and METH. Whereas PCP or MK-801 enhances the response to METH, perhaps leading to increased reward, KET appears to reduce the rewarding effects of METH. Future research should explore the neural mechanisms that mediate these differing interactions and that explain the unique effects of KET in combination with METH.

Title: Altered effort expenditure and intact reward sensitivity for non-drug rewards in protracted drug withdrawal

Authors: *A. B. THOMPSON[1], J. GERSON[1], A. STOLYAROVA[1], A. BUGARIN[1], Z. GUTTMAN[1], J. JENTSCH[2], A. IZQUIERDO[1];
[1]Psychology, UCLA, Los Angeles, CA; [2]Psychology, Binghamton Univ., Binghamton, NY

Abstract: Humans and experimental animals exposed to drugs of abuse exhibit altered reward-seeking behavior that persists long after drug taking has ceased. We previously reported increased voluntary running behavior and increased effort for larger magnitude food rewards in rats withdrawn from methamphetamine, mAMPH (Thompson et al. 2015, Stolyarova et al. 2015). Here we set out to further investigate reward-seeking behavior in prolonged withdrawal. First we assessed reward sensitivity in Long-Evans rats that had undergone withdrawal from mAMPH or that were previously treated with saline (SAL). Following an escalating regimen of

exposure followed by 7-10 days of withdrawal, rats were given a choice between plain water and sucrose solutions of increasing concentrations (1, 2, 4, 8, 16, 32%). mAMPH- and SAL-pretreated animals preferred and consumed sucrose to the same extent. Similarly, when given free choice between lab chow and sugar pellets, all animals preferred the sugar pellets equivalently. We conclude from this that reward sensitivity and choice behavior are intact in protracted withdrawal when options have equal effort requirements. We then assessed willingness to exert effort in a progressive ratio task involving freely available chow as a competing reinforcer (Randall et al. 2012). Animals were pretrained on progressive ratio for 2-5 days prior to introduction of the chow. When trained to stable performance, mAMPH-withdrawn rats pressed the lever significantly less than SAL animals, though they consumed the same quantity of food. In order to assess the contribution of dopamine D2-containing medium spiny neurons (MSNs) to choice behavior, we administered the selective A2A agonist CGS 21680. Excitatory A2A receptors are selectively expressed on D2 MSNs, therefore this agonist mimics the effect of a phasic decrease in dopamine concentration. Whereas systemic administration of CGS 21680 resulted in a significant decrease in both lever pressing and chow consumption, microinfusions of CGS 21680 in the nucleus accumbens selectively reduced lever pressing while leaving chow consumption unaffected, suggesting that alterations in this striatal population contribute to the observed behavior. This reduced lever pressing was exhibited by both mAMPH and SAL-pretreated rats. mAMPH has previously been reported to decrease D2 function in the striatum (Jentsch et al., 2014), which may render the indirect pathway resistant to dopaminergic inhibition. Ongoing experiments are aimed at uncovering and reversing the mechanism by which mAMPH-withdrawn rats show reduced thresholds for action directed at the freely-available chow over the preferred, more costly option.

Title: Recovery effects on behavior and development during abstinence after chronic methylphenidate treatment

Authors: *D. FRICKE[1], A. VIJAYASHANTHAR[1], C. F. LOWINGER[1], L. B. JERMYN[1], L. S. ROBISON[2], M. HADJIARGYROU[4], D. E. KOMATSU[3], P. K. THANOS[1];

Abstract: Methylphenidate (MP) has been prescribed for the treatment of Attention Deficit Hyperactivity Disorder. According to the International Narcotics Control Board, MP was dispensed at a record 2.4 billion doses in 2013. Most psychotropic drugs, show sudden and even extreme reversible effects after cessation of treatment. A previously established dual-dose drinking paradigm was used to mimic clinical drug delivery. Using an 8-hour-limited-access-drinking-paradigm, male Sprague-Dawley rats received MP solutions at 4 mg/kg MP (LD) or 30 mg/kg MP (HD) during the first hour, and 10 mg/kg MP (LD) or 60 mg/kg MP (HD) for the remaining 7 hours. This dosing paradigm produced peak serum concentrations at 8 ng/ml for the LD group and 30 ng/ml for the HD group. Chronic behavioral and physiological effects of these dual-dosages were assessed throughout three months of treatment and one month of abstinence, beginning in adolescence. Results have shown significant effects on food intake, body weight, locomotor activity, circadian rhythm activity, and anxiety/exploratory behavior during the 13 weeks of treatment. MP dose-dependently decreased body weight and food intake. HD MP resulted in hyperactivity limited during the dark cycle, decreased exploratory behavior, and increased anxiolytic behavior. During this abstinence, the average weight of HD MP remained the lowest but the rate at which it increased rose to that of the control group. Consumption for both treatment groups had returned to baseline. Therefore, MP's effect on body weight, consumption behaviors and appetite were reversible. The significant anxiolytic, exploratory and locomotor effects seen in HD MP during treatment, decreased and returned mostly to baseline with the cessation of MP treatment; once again suggesting that the effects of chronic MP administration are reversible. A decrease in total circadian locomotor activity, limited to the active (dark) cycle in HD MP was seen. This decrease brought the activity of HD MP down to control, even showing hypolocomotor behavior at certain time points, while the LD MP group remained hyper active during similar time points and similar percentages as when they were on treatment. Analysis for novel object recognition, social interaction and forced swim test are still in progress. Comparison to the female test group under the same conditions is also in progress.

Title: Separating the agony from ecstasy: prosocial effects and neurotoxicity of R(-)-3,4-methylenedioxymethamphetamine in mice

Authors: *D. W. CURRY[1], L. L. HOWELL[2];
[1]Neurosci. Grad. Program, [2]Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA

Abstract: (+/–)-3,4-methylenedioxymethamphetamine ((+/–)MDMA) is an amphetamine derivative that became popular as a recreational drug (ecstasy) and therapeutic tool during the 1970's and early 1980's. Escalating use led to its prohibition but scientific interest in the drug has persisted due to its unique prosocial effects. Under clinical observation, volunteers report that (+/–)MDMA increases feelings of closeness towards others, empathy, and gregariousness. In addition to these acute effects, there is evidence of enduring therapeutic effects such as improved interpersonal functioning and significant symptom reduction in PTSD patients. An ongoing clinical trial is now investigating its potential as a treatment for autism. However, serious limitations remain to wider clinical use of (+/–)MDMA, including its abuse liability and suspected neurotoxicity. There is thus significant impetus to isolate the prosocial mechanisms of (+/–)MDMA from the neurotoxic and abuse related effects. We investigated the hypothesis that the left handed enantiomer of (+/–)MDMA, (–)MDMA, may retain the prosocial effects of racemic MDMA but lack neurotoxicity. We found that both (+/–)MDMA (7.8 mg/kg) and (–)MDMA (17 mg/kg) significantly increased murine social interaction, but only (+/–)MDMA produced stimulant-like side effects. Furthermore, unlike racemic MDMA, (–)MDMA did not induce hyperthermia or neuronal markers of toxicity such as reactive gliosis or decreased brain monoamine content. These results indicate that the prosocial effects of (+/–)MDMA are separable from the neurotoxic and locomotor stimulant effects. (–)MDMA has prosocial effects similar to racemic MDMA but does not increase locomotor behavior or induce markers of neurotoxicity in mice. Further evaluation of (–)MDMA is needed in other species, but these results suggest that it may be a more viable therapeutic than racemic MDMA.

Title: Effect of sigma 1 receptor antagonist PD 144418 on methamphetamine self administration in rats

Authors: *M. TAPIA, J. LEE, G. GEREAU, D. MILLER, M. WILL;
Univ. of Missouri., Columbia, MO

Abstract: Use of illicit drugs, such as methamphetamine is a growing health concern across the United States. A recent national survey of drug use and health by the National Institute on Drug Abuse found that approximately 5% of Americans 26 or older use methamphetamine. Methamphetamine, a psychostimulant, works by elevating extracellular monoamine neurotransmitters, including dopamine, via multiple pathways. One way is by increasing intracellular calcium levels via IP_3. In addition to its effects on dopamine, methamphetamine can also elicit effects via sigma receptors. Multiple studies have shown that its effects maybe partially mediated by sigma 1 receptors (σ1). σ1 receptor antagonists however can reduce these effects. For example, our lab has shown that locomotor induced activity of methamphetamine can be reduced with the administration of a σ1 antagonist PD-14418. The purpose of this study is to further investigate the role of σ1 receptor antagonist PD-144418, specifically on methamphetamine self-administration in rats. Rats were first food trained to familiarize them with the task via a fixed ratio schedule. Once the criterion for the fixed ratio was met, rats were implanted with intravenous catheters. Self-administration training of methamphetamine occurred on a fixed ratio (0.05 mg/infusion; 2-hour sessions 6 days per week). Active lever presses were recorded but not reinforced. When the criteria for FR2 was met, animals were given a single injection of PD-144418 and placed back into the operant chamber and allowed to self-administer methamphetamine. We predict that administration of PD-144418 will decrease the acquisition and maintenance of methamphetamine self-administration in rats by reducing the reinforcing nature of methamphetamine.

Title: The effects of enriched environment on the response to methamphetamine in adolescent and adult mice

Authors: A. M. DAHLY, E. P. BAKER, E. C. MAGNUSON, *J. H. WEISS, *J. A. SIEGEL; Psychology and Neurosci., The Univ. of St. Thomas, Saint Paul, MN

Abstract: Methamphetamine (MA) has neurotoxic effects on the adult human brain that can lead to deficits in behavior and cognition. Long-term exposure to MA also alters the stress response and hypothalamus-pituitary-adrenal axis function. The rising rates of adolescent MA use make it imperative that we understand the long-term effects of MA exposure on the adolescent brain and how these effects may differ from those seen in adults. Rearing in an enriched environment reduces MA seeking behavior, MA self-administration, and MA cue-induced reinstatement in adult rodents. However, relatively little research has examined the effects of MA on adolescent behavior and how housing environment might alter the behavioral response to MA in adolescence. In order to assess age differences in the response to MA and the possible effect of housing environment on the response to MA, this research examines the long-term effects of MA exposure during adolescence or adulthood on behavior and plasma corticosterone levels in male C57BL/6J mice housed singly in standard housing conditions or housed in groups in enriched environments. Current experiments are ongoing to study the effects of adolescent or adult MA exposure and housing environment on behavior in the open field test, the Porsolt forced swim test, and the social interaction test to evaluate locomotor activity and risk-taking behavior, depression-like behavior, and social interaction behaviors, respectively. Plasma corticosterone levels will be measured following behavioral testing. Based on previous data, we expect adolescent and adult MA exposure to increase risk-taking behavior, increase depression-like behavior, decrease social behaviors, and decrease plasma corticosterone levels. Because the adolescent brain is still developing, we expect that the MA-induced behavioral and corticosterone alterations in adulthood will be less severe than those observed in adolescence. Furthermore, we predict that housing in an enriched environment will mitigate the effects of MA in both age groups, but that this effect will be more pronounced in the adolescent mice. These findings will contribute to a greater understanding of how MA alters behavior in an age group that has been relatively understudied and how an enriched environment might alter the response to MA.

Title: Systemic administration of the GABAA receptor antagonist bicuculline prevents the effects of the administration of the 5-HT1A receptor agonist 8-OH-DPAT on the discriminative signal of amphetamine in a conditioned taste aversion procedure

Authors: *F. MIRANDA-HERRERA, A. SANDOVAL-SÁNCHEZ, L. N. CEDILLO, J. C. JIMENEZ, A. I. BARRIENTOS-NORIEGA, R. I. RUIZ-GARCIA;
Univ. Nacional Autonoma De Mexico, Tlanepantla, Edo Mex, Mexico

Abstract: The mesolimbic dopamine (DA) system, specifically the projection from the ventral tegmental area (VTA) to the nucleus accumbens (nAcc), is an important locus for the production of the locomotor, reinforcing, rewarding, and discriminative stimulus effects of cocaine and amphetamine (AMPH). Evidence suggests that serotonin (5-HT) may regulate some of the behavioral effects of psychostimulants. Several studies indicate that 5-HT1A receptor subtype might play an important role in modulating some behavioral effects of AMPH. It has been reported that low doses of 8-OH-DPAT (DPAT), which preferentially stimulates 5-HT1A somatodendritic autoreceptors, reduces cocaine-induced locomotor activity. We demonstrated that the systemic administration of a low dose of DPAT (0.03 mg/kg) reduces the discriminative signal of AMPH. This effect may be due to the fact that DPAT administration stimulates somatodendritic 5-HT1A autoreceptors in the raphe nucleus to decrease the activities of serotonin neurons that project to the GABAergic interneurons in the VTA. Consequently, the decrease in the stimulation of 5-HT1B receptors, located on the presynaptic terminals of GABAergic interneurons that synapse with DAergic neurons, increases the GABA levels in the VTA and decreases the DA levels in the nAcc. If this suggestion is true, then the effect reported previously should be preventable if the GABAA receptors are blocked via the administration of a GABAA receptor antagonist. This study was designed to examine the effects of the systemic administration of the GABAA receptor antagonist bicuculline on the AMPH-induced discriminative signal using a conditioned taste aversion procedure. Additionally, the GABA levels in the VTA and the DA levels in the nAcc were also evaluated using an *in vivo*

microdialysis. After a group of rats learned AMPH-saline discrimination, AMPH was substituted with different doses of DPAT (0.003, 0.01 and 0.03 mg/kg), bicuculline (0.5, 1.0 and 3.0 mg/kg) or combinations of DPAT (0.03 mg/kg) + AMPH (1.0 mg/kg) or bicuculline (3.0 mg/kg) + DPAT (0.03 mg/kg) + AMPH (1.0 mg/kg). In separate groups of rats, the GABA and DA levels in the VTA and nAcc, respectively, were evaluated using *in vivo* microdialysis technique. We observed that DPAT did not substitute for AMPH, but when DPAT was administered in combination with AMPH, a dose-dependent decrease was observed in the AMPH cue. This effect was reversed by the administration of bicuculline. We also observed that DPAT increased the GABA levels in the VTA and decreased the DA levels in the nAcc. These data suggest that 5-HT1A somatodendritic autoreceptors might play a regulatory role in the discriminative AMPH cue.

Title: Apomorphine induced post-trial increases or decreases in dopaminergic activation can reverse or enhance catalepsy conditioning induced by haloperidol

Authors: *M. P. CARRERA[1], R. J. CAREY[2], F. R. C. DIAS[1], L. R. OLIVEIRA[1], B. G. SANTOS[1], J. L. L. SILVA[1];
[1]State Univ. of North Fluminense, Campos dos Goytacazes, Brazil; [2]SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Haloperidol reduces behavioral activity and can induce catalepsy that can be conditioned as well as sensitized to contextual cues. Post-trial drug treatments can induce potent conditioned responses indicative of the efficacy of trace conditioning of drug effects. The present study determined the impact of post-trial low and high dose apomorphine treatments on conditioned catalepsy. A paired/unpaired Pavlovian conditioning protocol was used, where groups of rats were given 10 daily administrations of vehicle or haloperidol (1.0 mg/kg) either

paired or unpaired to catalepsy testing. Ten min. after the treatments, the rats were placed on a horizontal bar and catalepsy duration was recorded during a maximum period of 10 min. This was termed the haloperidol sensitization phase. After the end of this phase, a saline test was conducted to assess for conditioned catalepsy (conditioned catalepsy test 1). As expected, repeated haloperidol treatments induced sensitization and conditioning of a catalepsy response selectively in the paired group. On the next day, there was a haloperidol re-induction treatment. On the following day, conditioned catalepsy test 2 was carried out followed by immediate post-trial treatments, in which the groups were subdivided into 3 vehicle groups, 3 unpaired haloperidol groups and 3 paired haloperidol groups and were given one of three post-trial treatments (vehicle, 0.05 mg/kg apomorphine or 2.0 mg/kg apomorphine). On the next day, the conditioned catalepsy test 3 was performed. On the following day, a haloperidol challenge test was carried out. The high dose apomorphine post-trial treatment eliminated conditioned catalepsy and counteracted not only the sensitized catalepsy response but also the initial acute catalepsy response to haloperidol, whereas the low dose apomorphine post-trial treatment enhanced conditioned catalepsy and the haloperidol induced a sensitized catalepsy response. The same post-trial apomorphine treatments given to vehicle and unpaired groups were equivalent to post-trial vehicle treatments. These results demonstrated that the immediate post-trial interval even for a conditioned drug inhibitory association is malleable and that the conditioning can be modified by increases/decreases in activity of the dopamine system.

Title: Attentional effects on network dynamics in local field potentials of primate lateral prefrontal cortex

Authors: *M. ABBASS[1], L. DUONG[1], A. SACHS[2], J. MARTINEZ-TRUJILLO[1];
[1]Univ. of Western Ontario, London, ON, Canada; [2]The Ottawa Hosp., Ottawa, ON, Canada

Abstract: Recent studies have investigated the brain's structural and functional connectivity networks, largely by using graph theory. Complex networks have been unveiled at the microscopic cellular level as well as at the whole-brain level through the use of neuroimaging. In particular, small world networks have been found across these scales. These are networks in which there is a high level of local clustering among nodes, with short paths that globally connect all the nodes in the network. Here, we investigate the presence small world networks among channels in a microelectrode array (MEA), representing small clusters of neurons. Two male macaque monkeys (*macaca Fascicularis*) were trained to attend to one of four stimuli presented in the different visual field quadrants. Local field potentials (LFPs) were recorded from a 96-channel MEA in the left lateral prefrontal cortex (Area 8A). Spectral power was obtained by complex wavelet convolutions for 34 frequencies, ranging from 4Hz to 250Hz. Mean power data in 200ms intervals from -400ms to 800ms around the cue were calculated for each frequency. Pearson's correlation was calculated between 32 channels of the MEA. Significant correlations ($p<0.05$) were used to obtain a clustering coefficient and path length. These parameters were used to quantify the small world property of the network. Significance was assessed with permutation testing. Higher clustering coefficients were observed in lower frequencies compared to higher frequencies during attention tasks. However, small world networks were observed in the higher frequency bands, during or shortly following the presentation of the cue. The most prominent small world network found across all trials was observed in the frequency band centered at 147Hz, 200-400ms following the cue (3.192, $p<0.001$). These results suggest that LFP high frequency oscillators within the LPFC have a small network architecture. This may reflect the intrinsic connectivity between neurons between cortical columns within the area.

Title: Partially-segregated neuronal populations in the lateral prefrontal cortex encode attended and memorized visual features

Authors: *D. MENDOZA-HALLIDAY[1], J. MARTINEZ-TRUJILLO[2];
[1]MIT, Cambridge, MA; [2]Robarts Res. Inst., Western Univ., London, ON, Canada

Abstract: Visual attention and working memory are interrelated but separable cognitive functions known to depend on the lateral prefrontal cortex (LPFC). Whether they are subserved by the same or different neurons within this area remains controversial. To investigate this, we recorded LPFC neuronal activity in two macaques during two conditions: while they attended to the motion direction of a stimulus that remained visible during the entire trial, and while they maintained in working memory the direction of a stimulus after it disappeared. We found that some neurons mainly encoded the attended direction, others mainly encoded the memorized direction, and others encoded both to different extents. This form of mixed selectivity enabled a machine-learning algorithm to decode from the population activity, on a single-trial basis, the stimulus' direction and whether it was attended or memorized. Our results indicate that in LPFC, the neuronal populations encoding attended and memorized visual features do not fully overlap, but are instead partially segregated, providing a mechanism for the brain to distinguish between sensory and mnemonic representations.

Title: Chemogenetic inhibition of prefrontal projection neurons and attentional capacities in forebrain trkA-suppressed rats

Authors: *V. V. PARIKH, M. G. KUTLU, S. JOSHI, B. YEGLA;
Psychology & Neurosci., Temple Univ., Philadelphia, PA

Abstract: The basal forebrain (BF) cholinergic system mediates essential aspects of attentional information processing and cholinergic atrophy is reported in Alzheimer's disease (AD). The prefrontal cortex (PFC) is a key area involved in top-down control of attention and cholinergic signaling. Additionally, disrupted prefrontal activity may be more detrimental in cholinergic pathology. Here, we utilized a chemogenetic approach involving DREADD (Designer Receptors Exclusively Activated by Designer Drugs) to study the consequences of prefrontal inhibition on attentional capacities in young rats with a normal or compromised cholinergic system. Because nerve growth factor signaling via tropomyosin kinase A (trkA) receptors is critical for cholinergic function, and this mechanism is disrupted in AD, cholinergic hypofunction was produced by BF trkA suppression. Wistar rats were trained in an operant sustained attention task (SAT) that consists of a random sequence of signal and non-signal trials divided into 3 blocks. Animals trained to criterion (≥70% correct responses), received bilateral infusions of AAV vector expressing trkA shRNA into the BF. Another cohort of animals received BF injections of a control AAV vector. Both groups of rats simultaneously received bilateral infusions of HA-tagged hM4D(Gi) under CaMKIIa promoter into the medial PFC. Following post-surgery recovery, the animals were kept on task for 4-weeks and then tested for performance in a distractor session (dSAT; flashing house light in the 2nd block). 45-min prior to the onset of testing session, the animals received an injection of clozapine-N-oxide (CNO; 1mg/kg i.p.) to inhibit the activity of prefrontal projection neurons. For control conditions, animals received the injection of a vehicle. TrkA knockdown *per se* did not affect the performance in the pre-distractor block but produced moderate impairments in the post-distractor block indicating disruption in cholinergic modulation of PFC activity. CNO injection did not affect the dSAT scores in rats with intact trkA receptors. However, contrary to our predictions, CNO-mediated Gi activation of CaMKII-positive neurons in the PFC reversed the detrimental effects of trkA suppression on performance under attentionally-taxing conditions. Together these data illustrate that prefrontal inhibition of subcortical and other cortical regions via projection neurons may

exert beneficial effects on attentional processes under conditions of cholinergic hypoactivity. Moreover, a balanced activity rather than hyperactivity of prefrontal projection neurons may be desirable to maintain cognitive performance in AD.

Title: Real-time tagging of visual, saccadic, spatial memory and attention prefrontal representations

Authors: ***S. BEN HAMED**[1], C. WARDAK[2], E. ASTRAND[3];
[1]Inst. des Sci. Cognitives Marc Jeannerod, Bron Cedex, France; [2]Cognitive Neurosciences, Inst. des Sci. Cognitives Marc Jeannerod, Bron, France; [3]Mälardalen Univ., Mälardalen, Sweden

Abstract: Seminal studies on the neurophysiology of the frontal eye fields (FEF) describe the existence, in this prefrontal cortical region, of visuo-motor neurons that respond both to a visual stimulus presented within their visual receptive field and to an eye movement executed towards that same spatial position. A high proportion of these visuo-motor cells also respond during the memory delay of a memory-guided saccade towards these same preferred spatial locations. As a result, these cells are proposed to subserve the prefrontal populational representations of spatial visual, oculomotor, memory and attentional information thanks to a *common* spatial code. In the present study, we use Brain-Machine Interface and machine-learning methods to quantify cortical spatial population information on single behavioral trials, to tag, with a high temporal resolution, these different neuronal processes and infer their corresponding population neuronal codes.The real-time decoding is performed onto simultaneous invasive multi-unit activity (MUA) recordings in the FEF, bilaterally (using two 24-contact linear multi-electrodes, one in each FEF), in two monkeys, while they are engaged in three different behavioral tasks. Task 1 is

a memory-guided saccade task designed to dissociate in time between visual-, memory/attention- and oculomotor-related processing. Task 2 is a manual response peripherally cued-target detection task, designed to dissociate in time between visual and spatial attention processing, in the absence of any eye movement. Task 3 is the same as task 2, except that the cue is a central cue. We show that prefrontal spatial information can be accessed through a simple linear decoding approach, suggesting a neural basis function encoding schema for this information. However, we also show that the neuronal population codes for visual, saccadic and memory signals are not identical, though strongly overlapping, indicating that the neuronal population codes are more complex than the sum of individual neuronal codes and are dynamically updated as a function of the ongoing behavior. We show that the neuronal population codes differ between spatial attention and spatial memory information, suggesting that these two functional processes are operated by distinct though overlapping neuronal populations. Last, we show that the neuronal population codes of spatial attention are very similar whether the cue is presented centrally or peripherally. These observations are discussed in the context of the spatial functions of the FEF.

Title: Reward strengthens the representation of task-relevant information in the prefrontal cortex during learning

Authors: ***B. MASSI**[1], C. H. DONAHUE[2], D. LEE[1];
[1]Neurosci., Yale Univ., New Haven, CT; [2]Gladstone Inst., UCSF, San Francisco, CA

Abstract: How an animal's behavior should be influenced by previous experience depends on environmental uncertainty. Previous studies have identified that neurons throughout the brain exhibit activity related to past events, but how environmental uncertainty affects these signals is unknown. To study this, we trained rhesus monkeys to perform a probabilistic reversal learning task in which the stability of the reward probabilities was manipulated. To initiate each trial, the

animals fixated a small square for 0.5s before two peripheral targets were presented. One target was associated with a high reward probability (80%), and the other with a low reward probability (20%). Following an additional 0.5s of fixation, a number of yellow dots surrounded the targets indicating the magnitude of potential reward available from each target. After a variable delay (0.5 ~ 1.2s), the animal was required to select one of the two targets. The stability of the reward probabilities was manipulated across blocks of trials. During volatile blocks, a red and green target were presented and underwent periodic uncued reversals in reward probability. During stable blocks, a cyan or diamond target always had an 80% reward probability, whereas an orange or square target was always associated with a 20% reward probability. Thus, the animals had to use recent outcome history to identify the target with the high reward probability in the volatile block, but not during the stable block. We analyzed single-unit activity from the dorsolateral prefrontal cortex (DLPFC), the orbitofrontal cortex (OFC), and the anterior cingulate cortex (ACC). In each region, we found that the outcome of the previous trial was more strongly represented in the volatile block than the stable block. Moreover, the current location of the target color chosen in the previous trial was most strongly represented in the DLPFC following rewarded trials in the volatile block. This indicates that reward strengthens the representation of task-related signals. Indeed, task-irrelevant signals related to the previously chosen location were present in the DLPFC, but unaffected by previous outcomes. We also found that signals related to the switch in target colors chosen in successive trials were present in all three regions and were also modulated by reward. Therefore, reward strengthens the representation of task-relevant information in the prefrontal cortex, providing a substrate for identifying important contingencies during reinforcement learning.

Title: Micro- and macro-circuit components of a putative attention filter

Authors: ***M. G. WHITE**, M. PANICKER, B. M. ROBERTS, B. N. MATHUR;
Pharmacol., Univ. of Maryland, Sch. of Med., Baltimore, MD

Abstract: The claustrum has broad cortical interconnectivity and transiently responds to salient stimuli. This enigmatic forebrain structure is therefore proposed to enable the intercortical communication necessary for attentional allocation (Mathur 2014). Using neuronal tract tracers we explore the connectivity profile of the mouse claustrum with cortical areas implicated in attention. We find that the claustrum displays dense interconnectivity with the anterior cingulate cortex (ACC) in particular, which is functionally implicated in attentional control in rodents. To examine the responsivity of claustrum neurons to ACC input, we use whole-cell patch clamp electrophysiology and optogenetics in acute mouse brain slices. We find that claustral spiny projection neurons faithfully fire in response to ACC afferent stimulation and that inhibitory claustral microcircuits provide feedforward and feedback inhibition, thus sculpting the ACC-mediated drive of claustrum projection neurons. Our results suggest that the claustrum is organized to filter and propagate incoming frontal cortical signals.

Title: Prefrontal neurons fulfill criteria for solving the credit assignment problem

Authors: ***W. F. ASAAD**[1], J. PERGE[2], E. N. ESKANDAR[3];
[1]Neurosurg., [2]Neurosci., Brown Univ., Providence, RI; [3]Neurosurg., Massachusetts Gen. Hosp. / Harvard Med. Sch., Boston, MA

Abstract: Credit assignment is the process by which a success or failure is linked with its potential cause. Proper credit assignment is necessary for any form of associative learning, but is more challenging when the causal environmental feature or stimulus is ephemeral and no longer

present when feedback is obtained about the outcome (temporal credit assignment problem) or when multiple potentially relevant features were concurrently present (structural credit assignment problem).
We trained two nonhuman primates to perform a learning task which entailed both a structural and a temporal credit assignment problem and recorded neuronal activity in the lateral prefrontal cortex. The task required the animals to learn which cue among four, presented earlier in a trial, was associated with a correct spatial choice at the end of the trial. We found that neuronal activity fulfilled the necessary criteria for providing a solution to the credit assignment problem: First, most neurons encoded the outcome of a trial, and many simultaneously encoded the identity of the relevant cue at the time of feedback, even though that cue was no longer present. This concurrent representation is necessary in order to link the outcome with the causal cue. Second, when the same neurons were recorded in a task with identical visual and motor elements, but with a different rule that rendered the identity of the cue irrelevant for learning, the cues were no longer represented in neuronal activity, demonstrating that the cue representation was actively engaged when necessary for learning.
Third, the neuronal representation of the cues at the time of feedback were sufficiently similar to the representation of the same cues at the time of their actual presentation, earlier in the trial, such that the identity of the correct cue could be determined from ensemble activity using a decoder trained at a different time point within the trial. This stability of representation over time is necessary for linking the outcome at the end of the trial with the causal feature that had appeared earlier.
Together, these data are consistent with the notion that neurons in the lateral prefrontal cortex provide the necessary, selective and stable representation of relevant features at the time of feedback to enable credit assignment.

Title: Distractor suppression and distractor interference in the light of direct real-time access to the covert attentional spotlight from the frontal eye fields

Authors: *F. DI BELLO[1], S. BEN HADJ HASSEN[1], E. ASTRAND[2], S. BEN HAMED[1]; [1]Inst. Des Sci. Cognitives Marc Jeannerod, Bron Cedex, France; [2]Mälardalens Univ., Västerås, Sweden

Abstract: The frontal eye fields (FEF) plays a key role in top-down attentional control (Moore et al., 2003; Ekstrom et al., 2008, Ibos et al., 2013) and distractor suppression (Lennert et al., 2013, Suzuki et al., 2013). The inactivation of this brain area leads to a perturbation of visual attention processes which could be interpreted as deficits in attention shift commands (Wardak et al. 2006) and distractor suppression (Suzuki et al., 2013). Crucially, using classification methods applied to the ongoing time-resolved simultaneously recorded FEF multi-unit activity, we demonstrate direct two-dimensional (x,y) access to the spatial location of covert attention, i.e. to the attentional spotlight (Astrand et al., 2016). Surprisingly, this attentional spotlight is rarely anchored at the cued location, but moves around on the work screen. Here, we further demonstrate that overt behavior and distractor interference can only be interpreted if we take in account the precise location of this covert attentional spotlight at a given moment in the task. Specifically, we recorded bilateral neural activity from the frontal eye fields of two monkeys during a cued target detection task in which, in the half of the trials, a distractor was presented at a varying distance from the target. We reproduce the observation that the proportion of false alarm responses to a distractor decreases as the physical target-distractor distance increases. This is classically interpreted as an indication of a higher distractor interference effect at the cued location, where attention is assumed to be. We however show that this observation only holds when the attentional spotlight, as accessed from the FEF activity, is far away from both the distractor and the target. In contrast, if the attentional spotlight is either close to the target or to the distractor, distractor suppression is enhanced and fewer false alarms are produced. These observations are further supported by the fact that, at the single neuron level, distractor suppression increased as the distractor gets closer to the attentional spotlight. In summary, this work shows that the description of a central cognitive function, namely attention, remains flawed in the absence of a real-time access to its underlying covert processes as estimated from ongoing prefrontal neuronal activities and challenges our current understanding of distractor interference and suppression mechanisms.

Title: Mapping connections of prefrontal cortex using electrical microstimulation and fMRI in the macaque

Authors: *R. XU, N. P. BICHOT, P. K. WEIGAND, A. TAKAHASHI, R. DESIMONE; MIT, Cambridge, MA

Abstract: Lateral prefrontal cortex (LPFC) plays an important role in cognitive control. The architecture of LPFC remains unclear: is it comprised of distinct sub-systems with systematic differences in their functionality, or is it an integrated region in which different LPFC areas perform essentially the same computation? Determining the cortical connections of subregions of LPFC is invaluable as an anatomical constraint. Although previous tracer studies have looked at connections of LPFC, it is difficult to reach a clear and fine parcellation of this region due to the sparseness of injection sites and individual differences across animals. Moreover, the tracer results usually lack same-subject comparisons with neurophysiological observations in behaving animals. Here we mapped the connectivity of LPFC subregions *in vivo* using combined electrical microstimulation and fMRI (EM-fMRI) in the macaque.

We implanted a male macaque monkey (8 kg) with an oval-shaped chamber that covers areas anterior to the arcuate sulcus and along the principal sulcus. The animal was scanned in a 3T Siemens Trio magnet under propofol anesthesia (0.1-0.4 mg/kg/min) and with his eyes covered. We delivered 500 μA, 333 Hz charge-balanced bipolar current pulses for 210 ms every second in 30-sec blocks. The locations of stimulations sites were confirmed with T1 and T2 anatomical MRI images during each session, before and after microstimulation. At each site, we collected four runs (34 mins) of MION signals using an EPI sequence (2 mm isotropic), to balance between maximizing SNR and minimizing scanning time.

We stimulated LPFC sites close to the junction between the arcuate and principal sulci, including the frontal eye field (FEF), area 46, dorsolateral prefrontal cortex (DLPFC), and the ventral preacuate (VPA) region we recently found to play an important role in feature-based visual attention (Bichot et al., 2015). The EM-fMRI connections were in general consistent with monosynaptic connections reported in previous tracer studies. Based on the preliminary data, we found differences between the connections of ventral and dorsal regions relative to the principal sulcus. The connections of ventral sites (in VPA, ventral bank of area 46, and part of FEF) included most ventrolateral PFC (VLPFC) and few DLPFC regions. On the other hand, connections of dorsal sites (in DLPFC, dorsal bank of area 46, and part of FEF) included most DLPFC and few VLPFC regions. Most interestingly, only the ventral sites seemed strongly connected to mid-to-high visual areas and lateral intraparietal cortex.

Title: Effects of attention on neural activity of orbitofrontal cortex

Authors: *Y. XIE, C. NIE, T. YANG;
Inst. of Neurosci., Shanghai, China

Abstract: Attention can influence the responses of individual neurons throughout visual cortex. It is unknown if it also affects the responses of neurons encoding more abstract features associated with visual stimuli. Neurons in the orbitofrontal cortex (OFC) are found to encode value associated with visual stimuli. Here we investigated how visual attention may affect their responses. Two monkeys were trained to perform a passive viewing task in which they had to maintain their fixations when simple shapes were presented peripherally on a computer screen. The shapes were randomly selected from a pool of five, each associated with 0, 1, 2, 4, and 8 drops of water, respectively. When shapes were presented alone in a trial, their associated reward was delivered at the end of the trial. When two shapes were presented together, one of them was randomly selected and its associated reward was delivered. We measured monkeys' pupil dilation responses to the shapes and confirmed that they understood the value of each shape. When two shapes were presented at the same time, the dilation of pupil size mostly reflected the value of the shape that predicted a larger reward. We next recorded single unit activity in OFC. As expected, a subset of neurons encoded shape's value during the shape presentation period. When two shapes were presented together, their responses could be explained by the weight sum of their responses to the single shapes. The weight for the response to the higher valued shape dictated the neurons' responses. Next, we manipulated monkeys' attention by temporarily rotating one of the shapes for 100 ms in some two-shape trials. The rotation was not linked to the reward. We again modeled the neurons' responses with the weighted sum model and compared the weights against the weights obtained from the no-rotation trials. We found that the weight for the responses to the rotated shape increased. The latency for this weight increase was 77 ms in one monkey and 177 ms in the other. Behavior analysis suggested that the difference in the latency in two monkeys may be explained by a combination of both bottom-up and top-down attention mechanisms. Our results demonstrate how attention may affect OFC neural activities.

Title: Neuronal modulations in prefrontal cortex are associated with multiple components of visuospatial attention

Authors: *T. Z. LUO, J. H. R. MAUNSELL;
The Univ. of Chicago, Chicago, IL

Abstract: Neuronal signals related to visuospatial attention are found in widespread brain regions, and these signals are generally assumed to participate in a common mechanism of attention. However, the effects of attention on target detection can be separated into two distinct components: spatially selective shifts in either the response criterion or the perceptual sensitivity of the observer. We have previously found (Luo & Maunsell 2015) that when monkeys are trained to do a variant of the Posner attention paradigm, a task used in many single-neuron studies of attention, enhanced performance is typically associated with changes in both criterion and sensitivity. But when these two components of attention were dissociated using a specifically designed task, we found that attention-related neuronal modulations in area V4 of visual cortex corresponded to behavioral shifts in sensitivity, but not shifts in criterion.
More recently, we have been examining visual responses in prefrontal cortex (areas 45 and 46). Neurons with spatially selective visual responses were selected using a memory-guided saccade task. In contrast to responses in V4, visual responses in prefrontal cortex were modulated by behavioral changes in both criterion and sensitivity. Both increases in sensitivity (enhanced discrimination) and decreases in criterion (greater tendency to respond) increase the response of visual neurons in prefrontal cortex. During the visual stimulus period, increases in sensitivity were associated with an average of 61% increase in firing rates, and decreases in criterion were associated with a 23% increase.
These results show that attention-related neuronal modulations across prefrontal cortex and visual cortex are not associated with a single mechanism of visuospatial attention. Instead, prefrontal cortex contributes to multiple mechanisms of attention, while visual cortex is associated with one of these mechanisms. The results indicate that visuospatial attention is not a unitary process in the brain but instead consists of separable mechanisms.

[2]McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: A fundamental building block of voluntary behavior is the ability to respond to information from the environment with appropriate motor actions. While seemingly simple, this process of transforming sensory information into motor commands consists of at least two distinct steps - detecting sensory information relevant to current behavioral goals from a noisy environment and selecting appropriate motor actions based on those stimuli. While neural substrates of sensorimotor mapping and attention have been widely studied in non-human primates, many questions remain due to lack of tools that can selectively probe and manipulate neural activity, especially in a projection-specific manner. The availability of optogenetic and viral-based gene expression tools in mice enables the interrogation of cell type-specific contributions to circuit-level mechanisms underlying these cognitive phenomenon. Here, we devised a visual sustained-attention, sensorimotor task for head-fixed mice to probe the selective contribution of specific neuronal subsets. First, we used rabies viruses to identify a caudal midline prefrontal region (anterior cingulate cortex) that is anatomically poised to contribute to both attentional processing of visual stimuli, owing to its top-down projections to visual cortex,

and sensorimotor transformation, due to its feed-forward projections to superior colliculus. Mice were trained to report the spatial location of a visual stimulus by rotating a ball. We made the task attention-demanding by including a variable foreperiod that introduces uncertainty in temporal expectancy for visual stimulus onset. In the first set of experiments, we found that optogenetic inactivation of this prefrontal area compromises performance on the task. Subsequently, two-photon microscopy and projection-specific optogenetic inactivation has allowed us to probe the functional contribution of visual cortex- and superior colliculus-projecting prefrontal neurons to sustained attention and sensorimotor transformation, respectively.

Title: Comparison of the contribution from superior colliculus and frontal eye field to covert spatial attention

Authors: *A. BOLLIMUNTA, A. R. BOGADHI, R. J. KRAUZLIS;
Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: Both superior colliculus (SC) and frontal eye fields are known to contribute to covert spatial attention. Comparing their contributions by measuring the deficits caused by reversible inactivation (e.g., muscimol) is confounded by the differences in the amount of the pharmacological agent required to cause the deficit, and by differences in the size and organization of these two brain areas. Here, taking advantage of the fact that reversible inactivation also causes changes in metrics of overtly generated saccades, we measured the contribution of SC and FEF to covert spatial attention relative to their contribution to saccades. Two male macaque monkeys were trained on a visually guided saccade task and a spatial attention task. The attention task consisted of two types of trials: Foveal attention (FA) and Peripheral attention (PA). During PA trials monkeys had to maintain fixation and detect a change in the direction of motion stimulus presented in the periphery. During FA trials the motion stimulus should be ignored and monkeys had to detect changes in the luminance of the central fixation point. Blocks of FA and PA trials were interleaved. The magnitude of change in PA and FA was set at threshold level. Monkeys reported the relevant event in each type of trial by

releasing a lever to get a juice reward. Reversible inactivation of SC (n = 33) and FEF (n = 19) were done by injecting muscimol. The amount of muscimol injected ranged from 0.3 to 0.5 µl in SC and 1.5 to 3.0 µl in FEF. The efficacy of inactivation in each session was gauged by measuring the increase in latency of visually guided saccades to targets placed at the same location as the peripheral stimulus in the attention task. Performance in the attention task was measured both before and during inactivation.
The deficit in the visually guided saccade task was used as a benchmark to compare the deficit in the attention task. The increase in saccade latencies ranged from 6 to 115 ms in SC, and 28 to 140 ms in FEF. A significant deficit in the attention task was observed in 78% of SC inactivation sessions and in 26% of FEF sessions. The probability of observing a deficit in the attention task given a saccade latency deficit was estimated using the saccade latencies as predictive variables in logistic regression analysis. Results show that the probability of observing a deficit in the attention task during FEF inactivation required a saccade deficit that was about twice as large as during SC inactivation. Hence, relative to saccades, covert spatial attention appears to be more dependent on activity from the SC than from FEF.

Title: Prefrontal inter- and intra-hemispheric neuronal noise correlations depend on the ongoing behavior.

Authors: *S. BEN HADJHASSEN, E. ASTRAND, C. WARDAK, S. BEN HAMED;
Inst. Des Sci. Cognitives Marc Jeannerod, Bron cedex, France

Abstract: The frontal eye field (FEF) is a brain area involved in the control of eye movements and attention. Importantly, it is a crucial node of the default-mode network (Vincent et al., 2007), the activity of which varies as a function of the arousal and attentional state of the subject. However, the exact neuronal processes underlying the characteristic default-mode network connectivity and task-dependence is still unclear. Here, we focus onto inter- and intra-hemispheric FEF neuronal noise correlations, taken as a possible neurophysiological correlate of the functional connectivity obtained with fMRI, and we investigate how these vary as a function of the ongoing behavior. In a recent study (Astrand et al.,2016), we show that these noise correlations are significantly lower on correct trials than on incorrect trials. Increased noise

correlations can be seen from trial onset to trial end, independently from any attentional orientation, and they correlate with a degraded processing of both sensory and cognitive information. In the present study, we provide evidence to the effect that noise-correlations do not only depend on overt behavioral performance, but are dynamically tuned to the ongoing behavioral requirements of the task. To this end, we performed bilateral simultaneous multiunit activity (MUA) recordings from the right and the left FEF of two macaque monkeys, using two 24-contact multi-electrodes, while the monkeys were engaged in different types of simple tasks. In order to quantify the impact of the ongoing behavior onto the inter-and intra-hemispheric noise correlations, we calculated for specific timings in each task, four different parameters:trial-to-trial noise correlations, mean firing rates, the standard deviation around the firing rates as well as the associated Fano factor. Our analyses demonstrate a clear dependence of the inter- and intra-hemispheric noise correlations on the ongoing task as well as on the ongoing overt performance. Importantly, this change in noise correlations is independent of changes in the related overall firing rate properties. Importantly, we describe task-specific topographically organized patterns of inter-hemispheric noise correlations changes. We propose that inter- and intra-hemispheric noise correlations in the FEF dynamically adjust sensory and cognitive processes to the ongoing motivational and behavioral requirements of the task

Title: Neural network properties are dynamically modulated by attention in primate lateral prefrontal cortex

Authors: *L. DUONG[1], M. ABASS[3], A. SACHS[4], J. MARTINEZ-TRUJILLO[2];
[1]Robarts Res. Inst., London Ontario, ON, Canada; [2]Robarts Res. Inst., London, ON, Canada; [3]Med., Western Univ., London, ON, Canada; [4]The Ottawa Hosp., Ottawa, ON, Canada

Abstract: Recent studies have used graph theoretical approaches to analyze complex network activity in the brain. One seemingly ubiquitous finding is the existence of small-world network from the microscopic to macroscopic scale. These networks are characterized by nodes which are highly clustered locally, and complemented by short path lengths which globally connect each node in the network. We aimed to explore the network properties of *in vivo* neural ensembles in the prefrontal cortex, and how these networks are affected by top-down attention. We implanted multi-electrode arrays in the lateral prefrontal cortex (lPFC) of two non-human primates (*Macaca Fascicularis*) and recorded spiking activity from neurons during a task that required the animals to covertly attend towards one of four spatial targets on a computer screen. Using firing rates computed for each neuron in non-overlapping bins during each trial, we obtained Pearson's correlation matrices between units for different time points during a trial. Significant correlations ($P<0.05$) in each matrix were used to compute clustering coefficients and average path lengths for each unit. Small-world network properties were quantified using a double ratio, with the numerator being the empirical clustering coefficient divided by that of a random network, and the denominator being the observed path length divided by that of a random network. The significance of this small-world network index was assessed using a permutation test. Interestingly, we found that the small-world index increased when monkeys allocated spatial attention. We have previously shown that ensembles of neurons in this area can be used to robustly decode where in space a monkey is allocating its attention. Therefore it is possible that these dynamic network properties enable the optimal encoding of spatial information during attention.

Title: Responses of frontal eye field neurons in a visual foraging task

Authors: *K. MIRPOUR[1], Z. BOLANDNAZAR[1], J. W. BISLEY[1,2,3];
[1]Dept Neurobiol, [2]Jules Stein Eye Inst., [3]Dept. of Psychology and the Brain Res. Inst, David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract: To find an object effectively during visual search, we use strategies to look at the most probable places and to avoid unlikely places or objects that have already been looked at. The priority map hypothesis is one of the theories that explains how these strategies are formed at the neural level. We have previously shown that activity in the lateral intraparietal area (LIP) acts like a priority map, in which both pre-attentive bottom-up signals and top-down cognitive feedback are integrated to represent the attentional priority of stimuli in the visual field. This is then used to guide eye movements. Although the activity in LIP represents the behavioral importance of objects in visual field, it does not correlate directly with eye movement behavior. We previously proposed that a single additional step of divisive normalization is necessary before the information present in LIP can be used to guide eye movements and hypothesized that this occurs as information is fed forward to the Frontal Eye Field (FEF). To test this hypothesis, we recorded the responses of FEF neurons in two animals while they performed a visual foraging task. The animals searched through 5 potential targets (Ts) and 5 distractors to find a target loaded with reward. After the stimuli appeared, the animals were free to move their eyes. Stimuli were spaced such that when the animal was looking at one stimulus, another was in the FEF neuron's response field. FEF neurons that contributed to the foraging task could be placed in four functional categories: 1) Neurons that showed an increase in response to previously fixated Ts. 2) Neurons that represented the attentional priority of the visual scene in a similar way to LIP. 3) Movement neurons, which didn't differentiate the attentional priority of the objects but responded to the initiation of an eye movement. 4) Neurons that showed a late response that correlated with predicted value, consistent with downstream normalization from LIP. Many of these neurons started off responding more to previously fixated Ts, but changed their responses about 150 ms after fixation onset, a time that is consistent with feedforward normalization. We conclude that the guidance of eye movements is driven by a network in which processing occurs at each step. LIP responses, the gain of which varies as a function of set size, are biased by low-level salience and top-down cognitive feedback. We propose that post-normalized FEF responses incorporate subjective value and, we predict, will not show set size effects, allowing the decision of where to look to be made with an absolute threshold. The output of this process is represented in the responses of the movement neurons.

Title: Animal model of spatial neglect in macaque monkeys

Authors: *K. TSUJIMOTO[1,3], M. SAWADA[1], M. FUKUNAGA[2], M. YOSHIDA[1,3];
[1]Div. of Behavioral Development, Dept. of Developmental Physiol., [2]Div. of Cerebral Integration, Dept. of Cerebral Res., Natl. Inst. For Physiological Sci., Myodaiji-cho, Japan;

Abstract: Spatial neglect is a characteristic failure to explore the side of space contralateral to a brain lesion, which cannot be explained by primary sensory or motor disorders. The purpose of this study is to establish monkey model of spatial neglect. The spatial neglect of the human involves the dorsal attention network and the ventral attention network. Anatomical studies suggest that the homologous region of the ventral attention network in the human includes superior temporal gyrus (STG) in monkeys. Based on this findings, we made a lesion in the right STG of three monkeys and evaluated behavior of the monkeys after the lesion. To evaluate their behavior in the cage, we used a 'food-choice' task. In this task, a piece of apple was hidden in a well under a cover with a stripe pattern. If the monkeys selected the well with a striped pattern among the wells without patterns, the monkeys got a reward. In this task, reaction time to touch the well in the contralesional side was longer than that in the ipsilesional side for 3 month after the lesion. To evaluate their behavior on the monkey chair, we used a 'target-selection' task and a free-viewing task. The visual stimuli of the target-selection task was presented on a display with a touch panel. The visual stimuli consists of a target and nine distractors. If the monkeys touched the target within 2 sec, the monkeys got a reward. In the target-selection task, the percentage of correct response to the targets in the contralesional side was lower than that in the ipsilesional side for one month after the lesion. In the free-viewing task, fifty-six natural images in total were used as test images and were randomly presented. In the free-viewing task, gaze positions was strongly biased toward the ipsilesional side for more than one month after the lesion. Motor deficit and sensory deficit were not detected in the behavior on the cage and the chair. These results suggest that the STG lesion induced spatial neglect in the monkeys. We also evaluated the functional connectivity of the monkeys before and after the lesion using resting-state fMRI. For this purpose, we measured the BOLD activity of the monkeys under isoflurane anesthesia (1%) with a 3T MRI before 1week, and 1, 2, 3, 4 weeks after the lesion. The analysis suggests that the functional connectivity between the posterior parietal cortex and the prefrontal cortex was decreased for one week after the lesion. Since this result is consistent with findings with human spatial neglect patients, our results suggests that the neural mechanisms of behavioral deficits in monkeys are similar to those of human.

Title: Methylphenidate enhances early stage sensory signal processing within the rat during performance of a visual signal detection task

Authors: *R. L. NAVARRA[1], B. D. CLARK[2], B. D. WATERHOUSE[3];
[1]Pharmacol. and Physiol., [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA;
[3]Cell Biol., Rowan Univ. Sch. of Med., Stratford, NJ

Abstract: Abnormal processing of sensory information is a core feature of many neuropsychiatric disorders, including attention deficit hyperactivity disorder (ADHD). The psychostimulant, methylphenidate (MPH), is used clinically to treat ADHD as well as off-label as a performance enhancing drug (PED) by healthy individuals. MPH enhances catecholamine transmission via blockade of norepinephrine and dopamine reuptake transporters. However, it is not clear how these effects impact neural circuits responsible for sensory signal processing and behavioral outcomes. We have found that MPH increases both speed and strength of individual and ensemble neuronal responses to visual stimuli within the dorsal lateral geniculate nucleus (dLGN) of the rat while improving the speed to make correct responses during performance of a visual signal detection task, suggesting that enhanced sensory signal transmission may be a significant component of the action of PEDs. Here, we investigated the effects of MPH on an additional measure of early stage sensory signal processing, the visual evoked potential (VEP). VEPs are waveforms produced in response to visual stimuli that can be extracted from local field potentials within the dLGN. MPH (2 mg/kg, i.p.) reduced the latency and amplitude of P30, i.e. first positive deflection of the VEP occurring 30 msec following stimulus presentation. It is generally accepted that P30 represents first prominent indication of signal transmission within the dLGN (Meeren et al., 1998). A reduction in P30 latency suggests visual signals during task performance are being transmitted to the dLGN more quickly following MPH administration. MPH also decreased the amplitude of the P30 response. Similar effects were observed in the visual cortex of monkeys performing a cue targeting task (Sundberg et al., 2012), where selective attention decreased both the latency and the magnitude of the first deflection of the VEP to target cues. Thus, it appears MPH effects on dLGN VEP's mimic top-down influences of selective

attention on VEP's recorded from monkey visual cortex. These results are consistent with faster sensory signal processing and better visual signal detection. Furthermore, in the present study immunostaining showed that catecholaminergic innervation to the dLGN is solely noradrenergic. This work suggests that MPH, acting via noradrenergic mechanisms, can substantially impact early stage sensory signal processing and subsequent behavioral outcomes. As such, sensory enhancement may be a significant component of psychostimulant-induced performance enhancement in ADHD patients and healthy individuals.

Title: Indvidual rats choose alternate, sub-optimal strategies in a (flawed) signal detection task. An observational study, with a moral.

Authors: *B. D. CLARK[1], J. S. SHUMSKY[1], B. D. WATERHOUSE[2];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Cell Biol., Rowan Univ. Sch. of Med., Stratford, NJ

Abstract: While reviewing records of rats that had performed a signal detection task over several weeks - months, we observed instances of high-scoring individuals reverting, abruptly and permanently, to lower levels of baseline performance. Examining the sequence of trials, we discovered that these animals had switched, in part, to a win-shift, lose-stay strategy. which, due to the design of the task, was rewarded in roughly 58% of trials. This departure from desired randomness in trial type presentation order emerged from the use of a sampling-without-replacement scheme to select trial type in the controlling software. While the use of this scheme prevents drastic imbalance in trial-type totals, it does so at the cost of introducing modest predictability: once a trial's type is given (signal vs non-signal), the next trial is slightly more likely than chance to be of the other type. At a point, the animals we observed shifted to this easier but less-rewarded strategy, and thereafter they used it, accepting a lower reward rate than they could have achieved by attending to the signal light. Additional records were discovered of mid-level performers who had been using win-shift behavior throughout training. Interestingly, the animals that employed this method (~15% of tested rats) appeared to use a hybrid approach

depending on intertrial delay: for short delays, the win-shift strategy was prominent, but for the longest delays, animals used the signal detection strategy. The transition between these typically appeared at intertrial delays of 6-8 seconds. Our task design may inadvertently resemble a cognitive effort task (Cocker et al., 2012), with the easier, win-shift, lose-stay approach being adopted by "slacker" individuals. The moral: Departing from true randomness in study design can create opportunities for subjects to behave in unexpected ways.

Title: Population encoding of attentional states in the absence of visual stimulation

Authors: *A. C. SNYDER[1,3,5], B. M. YU.[3,4,5], M. A. SMITH[1,5,2,6];
[1]Dept. of Ophthalmology, [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [3]Electrical and Computer Engin., [4]Biomed. Engin., Carnegie Mellon Univ., Pittsburgh, PA; [5]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [6]Fox Ctr. for Vision Restoration, Pittsburgh, PA

Abstract: The visual world contains more information than the brain can process. Through selective attention we preferentially process relevant information at the expense of ignored items.

These processing improvements are reflected by increased firing rates and decreased response (co)-variability during visual stimulation. However, the preparatory state changes that precede and underlie these processing differences remain mysterious. In particular, evidence to date suggests attention minimally influences baseline firing rates before the stimulus is presented. In other words, the spatial locus of attention would be difficult or impossible to decode from single-neuron activity before the stimulus is presented, despite the anticipatory nature of attention. We used high-yield population recordings to test the hypothesis that anticipatory attention states are reflected in characteristic patterns of activity across the population, without a change in average population firing rate. We found, consistent with prior reports, that attention increased sustained firing rates in response to attended visual stimuli in macaque V4 neurons, but did not affect average baseline rates. When analyzing baseline activity patterns using a high-dimensional state-space approach, we found that V4 populations reliably encoded the attention state during the baseline with characteristic patterns (but not overall rates) of activity. We simultaneously recorded population activity in dorsolateral prefrontal cortex (PFC), reasoning this area implicated in executive functions might guide V4 attention states. We tested the hypothesis that the attention state as decoded from baseline PFC population activity (in high-dimensional space) predicts the response of a V4 population to a subsequent stimulus. Our results strongly support the encoding of attention state by patterns of population activity that are not visible at the level of individual neurons or pairs. Furthermore, our simultaneous recordings suggest that feedback from prefrontal cortex has an important role in generating the attention state in visual cortex.

Title: Neuronal correlates of attentional selectivity in area V4 is independent of motivational context

Authors: *S. GHOSH, J. H. R. MAUNSELL;
Dept. of Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Previous work from our lab has shown that when monkeys shift their attention to increase their behavioral sensitivity, i.e, an ability to detect a stimulus, at one visual field

location, neurons in area V4 with receptive fields in that location respond more strongly (*Luo and Maunsell, 2015*). However, in those experiments an increase in sensitivity in one hemifield was always associated with a decrease in sensitivity in the other hemifield. The observed modulation of neuronal activity could therefore depend on the absolute sensitivity at the receptive field location regardless of it's value at distant site, or it could depend on the relative sensitivity at the two locations (attentional selectivity). We therefore trained two rhesus monkeys to do an orientation change detection task in which we could keep their behavioral sensitivity constant at the receptive field location while varying at a distant location over a broad range. If neuronal responses depend only on sensitivity and not on selectivity, this manipulation would not affect their responses. Using chronically implanted multielectrode arrays, we recorded spikes from populations of neurons in area V4. We found that varying sensitivity at the distant site substantially modulated V4 responses. As the behavioral sensitivity decreased at the distant location away from receptive fields, neuronal responses became stronger, despite the fact that the animal's overall performance declined. A sensitivity change at the distant site was about half as effective in changing the firing rate of the neurons as the same change in sensitivity at the receptive field location. Thus, the responses of V4 neurons are increased not only by increases in behavioral sensitivity at the receptive field location, but also by increases in attentional selectivity for the receptive field location relative to a distant location. Changes in sensitivity and selectivity could be controlled by adjusting either the relative reward sizes associated with stimuli at the two sites, or the relative difficult of the orientation changes at the two sites. The effects of sensitivity and selectivity were the same regardless of how the changes were motivated.

Title: Dual-task interference in macaque early visual cortex

Authors: *J. POSSEL[1], M. W. SELF[1], P. R. ROELFSEMA[1,2,3];
[1]Netherlands Inst. For Neurosci., Amsterdam Zuidoost, Netherlands; [2]Dept. of Integrative Neurophysiol., Ctr. for Neurogenomics and Cognitive Res., Amsterdam, Netherlands; [3]Psychiatry Dept., Academic Med. Ctr., Amsterdam, Netherlands

Abstract: Multitasking generally leads to suboptimal performance (for example slowing of responses and/ or more mistakes). Task interference occurs when two tasks have to be performed at the same time or with a short stimulus onset asynchrony (SOA). Responses are typically slower to the second task if the SOA is within the interference range. This effect is known as the psychological refractory period (PRP). There are numerous theories that speculate on why it is not possible to perform two tasks in parallel. Some studies suggest that the sharing of a common resource between two tasks functions as a processing bottleneck and therefore causes the delayed response to the second task. Others suggest that the selection of two responses cannot happen in parallel. However, it is not clear which neural mechanisms underlie this behavioral phenomenon.
We studied how the PRP influences neural activity in different areas along the visual hierarchy (i.e. V1 and V4) in monkeys using implanted multi-electrode arrays. Task 1 was a spatial location judgment which the monkeys reported via a hand movement. Task 2 was a curve-tracing task in which the monkey mentally traced a target curve and ignored a distracter curve and made a saccade to a circle at the end of the target curve. We examined the influence of dual-task interference on the early sensory responses and the later attentional selection signals.
We found that monkeys also show a PRP effect as their RTs in the curve-tracing task (task 2) were longer at short SOAs. Previous studies have revealed attentional modulation of neuronal responses in V1 and V4 in the curve-tracing task. We found that the PRP reduced the attentional modulation in V1 and V4 and that it also increased the latency of the attentional modulation in V1. The PRP had comparatively little influence on the initial visually driven activity. We conclude that the PRP is associated with a decrease in attentional selection that is required to solve task 2. Our results thereby support theories that propose that there is a limitation of attentional processing (shared resource models) if two tasks need to be performed in close succession.

Title: Spatial summation sub-compartments in the orientation column

Authors: *X. SONG[1], M. LI[2], T. XU[3], D. W. HU[2], A. W. ROE[1], C. Y. LI[2,3];
[1]Zhejiang Univ. Interdisciplinary Inst. of, Zhejiang, China; [2]The Col. of Mechatronics and Automation, Changsha, China; [3]Univ. of Electronic Sci. and Technol. of China, Chengdu, China

Abstract: In the primary visual cortex (V1) of cats, neurons with different orientation preferences are arranged in a pinwheel-like structure with a number of iso-orientation domains (IODs) around a pinwheel center (PC). We previously found that there are clusters of neurons in V1 organized according to their spatial summation properties (surround suppressive or non-suppressive, Neuron 35:547-553, 2002). However, the spatial relationship between these two functional architectures remains unclear. In this study, using intrinsic signal optical imaging combined with local field potential (LFP) and single-unit recording methods, we found three concentric sub-regions centered on the orientation-pinwheel. The central most region contained neurons with small receptive fields and strong suppressive surrounds, while the outermost region contained neurons with larger receptive fields and weak suppressive surrounds. We hypothesize that orientation pinwheels s and surround suppression zones are orthogonally represented parameters in cat V1. These inter-related organizations may be significant for further understanding the functional organization of visual cortex and provide new bases for visual features integration.

Title: Communication between the pulvinar and the layers of Area V4 during selective visual attention

Authors: *R. LY[1], S. KASTNER[1,2];
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, Princeton Univ., Princeton, NJ

Abstract: A fundamental question in neuroscience is how large-scale networks of neurons interact to give rise to cognitive function. A recent study (Saalmann et al., 2012) suggests that the pulvinar nucleus of the thalamus influences cortical visual areas during selective visual attention in the alpha (8-15 Hz) frequency band. The laminar profile of this influence could inform network-level models of visual processing and attention, but is as yet unknown.
We simultaneously recorded laminar activity in area V4 using a linear multielectrode array, and spiking activity and local field potentials in the pulvinar using single-unit microelectrodes in a macaque monkey while the animal performed a spatial attention task. Receptive fields (RFs) overlapped across V4 layers and the pulvinar, suggesting that we recorded from an interconnected network. We computed oscillatory power and coherence within area and layer, and Granger-causal influences between the pulvinar and laminar currents in V4, at gamma and alpha/beta frequencies. We compared these measures when the animal attended to the shared RF versus when the animal attended away and when there was a stimulus in the RF versus when there was not. These effects are discussed in the context of recent evidence demonstrating gamma synchrony and Granger-causality across areas as markers of bottom-up processing and alpha/beta synchrony and Granger-causality across areas as markers of top-down processing.

Title: The attentional bias for novelty fluctuates across time

Authors: *D. VATTEROTT, J. GOTTLIEB;
Neurosci., Columbia Univ., New York, NY

Abstract: A common postulate of learning theories is that animals by default assign high salience to novel items, facilitating their ability to detect, attend to, and learn about these items (Brockmole & Henderson, 2005; Foley et al., 2014). However, psychophysical studies have produced mixed results documenting either novelty or familiarity preferences in children and adults (Hunter & Ames, 1988; Park, Shimojo, & Shimojo, 2010), suggesting that novelty biases are not fixed but depend on the task or context. To date, little is known about this dependence, and especially the role of the subjects' behavioral state. To investigate this question we designed a task where rhesus monkeys (Macaca mulatta) could express their spontaneous novelty preference during a free-viewing epoch coinciding with the inter-trial intervals of a fixation task. Two monkeys completed behavioral trials by simply fixating a central point for a juice reward. Following reward delivery, the monkeys were presented groups of 4 images (colored fractal patterns), the fixation point was extinguished and the monkeys were allowed to freely view the fractal patterns. The images remained on the screen for a 2 second period until they were extinguished and the next trial started. Groups of 4 fractals were randomly selected and presented over several daily sessions (several hundreds of trials), familiarizing the monkeys with the individual images and their contextual grouping. In 20% of trials, a randomly selected familiar image was replaced by a novel, trial-unique item. Both monkeys showed a novelty bias, fixating the novel items more frequently than they fixated the familiar ones, and this bias grew as the monkey gained exposure to the familiar patterns. Importantly, the bias was not constant but showed slow fluctuations, waxing or waning over stretches of ~100 trials during a session. The fluctuations were independent of the visual salience of the novel patterns (measured with a canonical salience model (Walther & Koch, 2006) and were also independent of fluctuations in instrumental performance, which had a shorter time scale. The results suggest that this paradigm can reliably elicit state-dependent novelty biases, paving the way to investigating their neuronal correlates.

Title: Superior colliculus inactivation with functional imaging reveals novel nodes in the control of spatial attention

Authors: *A. R. BOGADHI[1], A. BOLLIMUNTA[1], D. A. LEOPOLD[2], R. J. KRAUZLIS[1]; [1]Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: We recently showed that inactivation of the superior colliculus (SC) leads to attention deficits in a behavioral task despite normal attention-related neuronal modulation in visual cortex (Zenon & Krauzlis, 2012). This finding suggests that SC inactivation might affect brain regions downstream to visual cortex, leading to the observed spatial attention deficits. To identify these potential brain regions, we employed fMRI with and without SC inactivation in two monkeys trained to perform a spatial attention task in a vertical scanner.

The stimulus sequence on each imaging run (~480s) consisted of three different blocks: Baseline (B), Foveal Attention (FA) and Peripheral Attention (PA) blocks. B blocks (~10s long) were interleaved between FA and PA blocks, each 20s long. In B block trials, the relevant stimulus was a central fixation point that dimmed at randomized times. FA block trials were similar to B block trials but added a peripheral motion-change stimulus as an irrelevant distracter. In PA block trials, the fixation point did not dim and the peripheral motion change was the relevant stimulus. The task of the monkey was to maintain central fixation and report the relevant stimulus change (fixation dimming in B & FA blocks, peripheral motion change in PA blocks) by releasing a lever to get a juice reward.

A total of 225 runs from 16 control sessions and 220 runs from 18 inactivation sessions in 2 monkeys were included. Eye movements were recorded during each imaging run. For our preliminary analysis, we identified several cortical (MT,FST,LIP,FEF) and sub-cortical (SC,Caudate,Pulvinar) clusters in the control dataset that showed attention-related modulation by contrasting PA and FA conditions (t-scores > 3.39). The effect of SC inactivation on BOLD responses in these clusters was quantified as a t-score comparing the attention-related increase in BOLD during control and inactivation.

During SC inactivation, the monkey's behavioral performance was significantly impaired for stimulus changes in the contralateral hemifield. During the same blocks, we observed a significant drop in the attention-related BOLD modulation in fronto-parietal areas implicated in the control of spatial attention. However, the biggest reduction in the attention-related BOLD modulation was observed in area FST in the superior temporal sulcus. At the same time, several sub-cortical areas (pulvinar, caudate) showed a significant reduction in attentional modulation on the side of the injection. These results identify area FST as a potentially important node in the cortical and sub-cortical network for the control of spatial attention.

Title: How configural is the configural superiority effect? a neuroimaging investigation of configurality in visual cortex

Authors: O. M. FOX, *A. HAREL, K. B. BENNETT;
Psychology, Wright State Univ., Dayton, OH

Abstract: Many regions in occipito-temporal cortex (OTC) are sensitive to the organization of elements in the visual field. When stimulus features are perceptually well-organized, one often observes an improvement in behavioral performance, a phenomenon known as the Configural Superiority Effect (CSE). Prior neuroimaging work on CSE regards it as an "all or none" phenomenon, focusing on the contrast between configural and non-configural stimuli. However, it is still not clear whether CSE emerges also in response to deviations from these two endpoints. The current study examined the extent to which behavioral and neuroimaging markers of CSE are responsive to the degree of configurality in visual displays. Subjects were tasked with reporting the anomalous quadrant in a visual search task while being scanned. Degree of configurality was manipulated by incrementally varying the rotational angle of the features within the stimulus arrays. Behaviorally, we observed faster response times with increasing levels of configurality. These behavioral changes were accompanied by increases in response magnitude across multiple visual areas in OTC, including early visual cortex as well as object-selective cortex. Our findings suggest that the neural correlates of CSE can be observed even in the absence of "perfect" configurations, and demonstrate that configural information is already present at early stages of the visual hierarchy.

Title: The role of cacna1c in cognitive functioning

Authors: *Z. R. DARUWALLA, D. FISCHER, A. RAJADHYAKSHA;
Pediatric Neurology, Weill Cornell Med. Col., New York, NY

Abstract: Genome-wide association studies have identified several single nucleotide polymorphisms (SNPs) in the *CACNA1C* gene that have been associated with neuropsychiatric disorders including schizophrenia, bipolar disorder, autism spectrum disorder and attention deficit hyperactivity disorder. Common to these neuropsychiatric disorders are impairments in cognitive functioning. Utilizing a forebrain-specific *cacna1c* conditional knockout mouse in which there is a loss of *cacna1c* in the CamK2-expressing glutamatergic cells of the forebrain we have identified deficits in social behavior together with deficits in PFC-specific learning and memory tasks. Indeed, targeted knockdown of *cacna1c* specifically in the adult PFC recapitulated the deficit in social behavior but not in learning and memory suggesting a developmental role of *cacna1c* in learning and memory. Through electrophysiological recordings and biochemical techniques we are currently studying the neurobiology underlying these cognitive deficits in the PFC of forebrain-specific *cacna1c* knockout mice in comparison to the PFC-specific adult *cacna1c* knockdown mice. The idea is to identify the common or diverging pathophysiology in the PFC that may be mediating the social deficits observed in both these mouse models. We are also working towards identifying a pharmacological reversal of the behavioral deficits, specifically the social impairments that we observed in the forebrain-specific *cacna1c* knockout mice and the PFC-specific adult *cacna1c* knockdown mice. Overall, this study has identified a novel role of *cacna1c* in PFC-driven cognitive functioning and will highlight the anatomical and neurobiological mechanisms mediating these behaviors in an effort to provide better therapeutic strategies for treating cognitive impairments in neuropsychiatric patients.

Title: Altered markers of synaptic development and learning and memory deficits in the cereblon knockout mouse model of intellectual disability

Authors: D. K. FISCHER, C. C. BAVLEY, *A. M. RAJADHYAKSHA;
Joan and Sanford I Weill Med. Col. of Cornell Univ., New York, NY

Abstract: *Cereblon* (*CRBN*), the human gene on chromosome 3p26.2, has been found to be associated with a non-syndromic, autosomal recessive type of mild mental retardation/intellectual disability (ID). Previous work from our lab using male *Crbn* knockout (*Crbn*$^{-/-}$) mice has shown deficits in hippocampal learning and memory using the Morris water maze, Y-maze, and fear conditioning behavior tests. These behavioral findings using the *Crbn*$^{-/-}$ animal model mirror the human condition, suggesting that this model is an effective tool for investigating the molecular mechanisms associated with hippocampal deficits in intellectual disability.

Hippocampal circuitry in mice is formed during critical periods of development, particularly postnatal days 0-21 (P0-P21). It is during this period that both excitatory (E) and inhibitory (I) synapses are meticulously formed and pruned, thereby shaping the functionality of the hippocampus necessary for learning and memory. Notably, imbalance in E/I synaptic activity has been directly implicated in neurodevelopment disorders with deficits in learning and memory. To begin to examine altered synaptic development during the critical growth period of *Crbn*$^{-/-}$ mice, we examined synaptic protein levels in P7 hippocampal tissue. Examination of excitatory and inhibitory synaptic markers revealed significantly higher levels of VGLUT2 protein levels in P7 *Crbn*$^{-/-}$ mice compared to wildtype littermates with no difference in VGLUT1 or the inhibitory marker, VGAT. Examination of markers of synapse number revealed higher levels of presynaptic marker synaptophysin but not of the postsynaptic marker PSD-95. We also examined postsynaptic synaptic adhesion molecules, neuroligin (NLGN) 1-4, critical for synaptogenesis, in P7 *Crbn*$^{-/-}$ mice hippocampal tissue. Interestingly, only the inhibitory synapse, NLGN-2 levels was altered, with significantly higher levels in *Crbn*$^{-/-}$ mice compared to wildtype littermates. Ongoing studies are investigating molecular mechanisms of altered synaptic markers, as an abundance of synapses may cause abnormalities in neurodevelopment and mediate the learning and memory deficits observed in *Crbn*$^{-/-}$ *mice.*

Abstract: Mutations in the X-linked *MECP2* gene cause Rett syndrome (RTT), an autism spectrum disorder characterized by impaired social interactions, motor abnormalities, cognitive defects and a high risk of epilepsy. Because decreases in cholinergic markers are correlated with increases in clinical severity for patients with RTT, we hypothesized that dysfunction in cholinergic function is involved in RTT. Here, we showed that conditional deletion of Mecp2 in cholinergic neurons caused part of RTT-like phenotypes, which could be rescued by re-expressing Mecp2 in the basal forebrain (BF) cholinergic neurons rather than in the caudate putamen (CPu) of conditional knockout (*Chat-Mecp2*$^{-/y}$) mice. We also found that choline acetyltransferase (ChAT) expression was decreased in the BF and that α7 nicotine acetylcholine receptor (nAChR) signaling was strongly impaired in the hippocampus of *Chat-Mecp2*$^{-/y}$ mice to an extent sufficient to produce neuronal hyperexcitation and increase seizure susceptibility. Application of PNU282987 or nicotine in the hippocampus rescued these phenotypes in *Chat-Mecp2*$^{-/y}$ mice. Taken together, our findings suggest that Mecp2 is critical for normal function of cholinergic neurons and dysfunction of cholinergic neurons can contribute to numerous neuropsychiatric phenotypes.Mutations in the X-linked *MECP2* gene cause Rett syndrome (RTT), an autism spectrum disorder characterized by impaired social interactions, motor abnormalities, cognitive defects and a high risk of epilepsy. Title: Effect of the sigma-1 receptor selective compound LS-1-137 on the DOI-induced head twitch response in mice

Authors: *R. R. LUEDTKE, Ph.D.[1], M. MALIK[2], C. RANGEL-BARAJAS[3], R. H. MACH[4]; [1]Dept Pharmacol & Neurosci, Univ. North Texas Hlth. Sci. Cter, Fort Worth, TX; [2]Ctr. for Neurosci. Discovery, Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [3]Dept. of Psychological & Brain Sci., Indiana Univ. Bloomington, Bloomington, IN; [4]Radiochemistry Laboratory, Dept. of Neurol., Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Several receptor mediated pathways have been shown to modulate the murine head twitch response (HTR). However, the role of sigma receptors in the murine (±)-2,5-dimethoxy-4-iodoamphetamine (DOI)-induced HTR has not been previously investigated. We examined the ability of LS-1-137, a novel sigma-1 vs. sigma-2 receptor selective phenylacetamide, to modulate the DOI-induced HTR in DBA/2J mice. We also assessed the *in vivo* efficacy of reference sigma-1 receptor antagonists and agonists PRE-084 and PPCC. The effect of the sigma-2 receptor selective antagonist RHM-1-86 was also examined. Rotarod analysis was performed to monitor motor coordination after LS-1-137 administration. Radioligand binding techniques were used to determine the affinity of LS-1-137 at 5-HT2A and 5-HT2C receptors. LS-1-137 and the sigma-1 receptor antagonists haloperidol and BD 1047 were able to attenuate a DOI-induced HTR, indicating that LS-1-137 was acting *in vivo* as a sigma-1 receptor antagonist.

LS-1-137 did not compromise rotarod performance within a dose range capable of attenuating the effects of DOI. Radioligand binding studies indicate that LS-1-137 exhibits low affinity binding at both 5-HT2A and 5-HT2C receptors. Based upon the results from these and our previous studies, LS-1-137 is a neuroprotective agent that attenuates the murine DOI-induced HTR independent of activity at 5-HT2 receptor subtypes, D2-like dopamine receptors, sigma-2 receptors and NMDA receptors. LS-1-137 appears to act as a sigma-1 receptor antagonist to inhibit the DOI-induced HTR. Therefore, the DOI-induced HTR can be used to assess the *in vivo* efficacy of sigma-1 receptor selective compounds.

Abstract: Neurodevelopmental disorders, including autism spectrum disorders (ASD), are highly male biased, but the underpinnings of this are unknown. Striatal dysfunction has been strongly implicated in the pathophysiology of neurodevelopmental disorders, raising the question of whether there are sex differences in how the striatum is impacted by genetic risk factors linked to neurodevelopmental disorders. Here, we report male-specific deficits in striatal function

important to reward learning in a mouse model of 16p11.2 hemideletion, a genetic mutation that is strongly associated with risk of neurodevelopmental disorders, particularly autism and ADHD. We find that male, but not female, 16p11.2 deletion animals show impairments in reward-directed learning and maintaining motivation to work for rewards. Male, but not female, deletion animals overexpress mRNA for dopamine receptor 2 and adenosine receptor 2a in the striatum, markers of medium spiny neurons signaling via the indirect pathway, associated with behavioral inhibition. Despite equivalent effects in males and females on the mRNA levels of genes located within the 16p11.2 region in the striatum, including the kinase ERK1, hemideletion males show *increased* activation in the striatum for ERK1 at baseline and in response to sucrose, a signaling change associated with decreased striatal plasticity. In contrast, we find that hemideletion females show increased protein for ERK1 as well as the related kinase ERK2, and no change in phosphorylation either at baseline or in response to sucrose. These data indicate male-specific vulnerability in the mechanisms regulating intracellular signaling in the brain as a result of a genetic lesion.

Title: Cortical GluN2B contribution to reversal learning in Prenatal Alcohol Exposure

Authors: *K. L. MARQUARDT[1], J. CAVANAGH[2], K. CALDWELL[1], J. BRIGMAN[1,3]; [2]Dept. of Psychology, [1]Univ. of New Mexico, Albuquerque, NM; [3]New Mexico Alcohol Res. Ctr., UNM Hlth. Sci. Ctr., Albuquerque, NM

Abstract: With a prevalence rate of 2-5%, Fetal Alcohol Spectrum Disorders (FASD) are a leading cause of preventable developmental disability in the U.S. FASD has a high societal cost, with estimates that as many as 46% of adolescents with FASD end up incarcerated, and 29% end

up being treated for alcohol and drug abuse by the age of 21. These outcomes are the consequence of individuals being unable to alter actions appropriately, leading to repetitive maladaptive behaviors. We have demonstrated that mice given prenatal alcohol exposure (PAE; daily maternal BAC ~85 mg/dL) have impaired behavioral flexibility, but not learning, demonstrated by an increase in perseverate responses on a touch-screen discrimination-reversal paradigm. Interestingly, conditional cortico-hippocampal knockout of the GluN2B (GluN2B^{CxNULL}) subunit of the N-methyl-D-aspartate (NMDA) receptor also results in selective disruption of reversal, but not learning. It is well known that ethanol can directly inhibit NMDA receptors and that GluN2B is highly expressed during gestation, where it may be modulated by PAE. Optimal behavioral flexibility requires both the dorsal striatum (dS) for formation of stimuli-reward associations, and the orbital frontal cortex (OFC) for reversal. We show that PAE reduces the expression of GluN2B in the OFC, but not in other subdomains of the frontal cortex, suggesting a unique role for GluN2B subunits in reversal learning. To further characterize the role of GluN2B subunits in behavioral flexibility we utilized dual region *in vivo* electrophysiology to record in both the OFC and dS during learning and reversal stages of a discrimination-reversal touch-screen paradigm in both PAE and GluN2B^{CxNULL} mice and controls. Analysis of local field potential oscillations revealed differences in phase coherence in both OFC and dS for PAE animals, but only in dS for GluN2B^{CxNULL}. Suggesting changes in modulation of the dS by the OFC during reversal in both models that is GluN2B subunit dependent. Inter site phase synchrony, a measure of functional connectivity, showed decreased connectivity in PAE animals, but delayed connectivity in GluN2B^{CxNULL}. Our data suggest that PAE deficits may be at least partially due to loss of GluN2B levels in the cortex, but it is selective to loss in the OFC which drives the deficit. By understanding the cause of deficits in PAE, and by utilizing translatable touch screen tasks, we will be able to develop better treatment tools for FASD.

Title: Alcohol induced mGluR2 deficit in the prefrontal cortex leads to behavioral inflexibility in rats

Authors: *S. PFARR[1], M. L. KLEE[1], M. W. MEINHARDT[1], N. MEIER[3], O. VON BOHLEN UND HALBACH[3], M. SCHNEIDER[1], R. L. BELL[4], K. SCHÖNIG[2], W. H. SOMMER[1]; [1]Psychopharmacology, [2]Molecula Biol., Central Inst. of Mental Hlth., Mannheim, Germany; [3]Inst. für Anatomie und Zellbiologie, Universitätsmedizin, Greifswald, Germany; [4]Inst. of Psychiatric Res., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: The medial prefrontal cortex (mPFC) is critically involved in cognitive flexibility and top down control over behavior. Both, in humans and animals, excessive alcohol use causes damage in the prefrontal cortex. In a previous study we found that alcohol dependent rats lost control over their alcohol seeking behavior, which was mediated by a metabotropic glutamate receptor 2 (mGluR2) deficit in the infralimbic (IL) – Nucleus Accumbens (NAc) Shell projection [1]. An open question is whether this molecular mGluR2 deficit has also functional consequences on executive functions.

Here, we used chronic intermittent alcohol vapor exposure (CIE) to induce alcohol dependence in adult Wistar rats. Investigations were done after a period of prolonged abstinence (3 weeks), where animals show persistent neuronal and behavioral adaptations here referred to as 'post-dependent' state (PD) [2]. First we demonstrate a distinct profile of structural changes in the mPFC – NAc circuit in PD rats characterized by significantly increased spine density in mPFC sub regions, but decreased spine density in the NAc. Further, in an Attentional Set Shifting Task (ASST) PD rats showed significant impairments compared to control animals, when the rules of the test were changed. This inability to change their strategy indicates a reduced cognitive flexibility of the PD rats. The deficit in ASST performance was partially reversed after re-establishing mGluR2 expression in the IL of PD rats by viral vector mediated gene transfer, while overexpression of mGluR2 in control rats had no behavioral consequence. On the other hand no deficit in ASST performance was found in a functional mGluR2 knockout line, the Indiana Alcohol preferring rats (Indiana P rats), compared to their respective control strain (Indiana NP rats). This indicates a possible functional compensation of the genetic mGluR2 deficit. Furthermore, first experiments using a viral mGluR2 knockdown approach in the IL did not produce a deficit on ASST in Wistar rats.

These data further establish the long lasting impact of a history of alcohol dependence on mPFC function, especially on cognitive flexibility. mGluR2 deficit in the IL emerges as a molecular mechanism mediating alcohol induced cognitive impairments. However, mGluR2 deficit alone does not seem to be sufficient to induce this pathology, but likely requires interaction with other, so far unknown alcohol induced molecular alterations.

Title: Modeling exposure therapy in rats: fear extinction-induced infralimbic protein synthesis underlies reversal of chronic stress-induced cognitive inflexibility

Authors: *E. A. FUCICH[1], D. PAREDES[2], D. A. MORILAK[2];
[1]Pharmacol., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX; [2]Dept. of Pharmacology, Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Stress-related psychiatric disorders, like depression or post-traumatic stress disorder, are prevalent yet poorly treated. These disorders share cognitive flexibility deficits associated with medial prefrontal cortex (mPFC) dysfunction. Psychotherapies invoking cognitive flexibility can be efficacious even in pharmacotherapy-resistant patients, although, as with pharmacotherapies, response to psychotherapy can be incomplete, some patients do not respond, and relapse remains an issue. Thus, understanding the neurobiological mechanisms underlying its efficacy could inform more rapid, efficacious, or long-lasting behavioral therapies, or could inform the development of adjunct treatment strategies designed to improve its effect. Pre-clinically, we have shown that chronic unpredictable stress (CUS) causes deficits in mPFC-mediated cognitive flexibility on the attentional set-shifting test (AST). We have shown that fear extinction learning, which engages mPFC cognitive flexibility and conceptually resembles exposure therapy for PTSD in humans, can model exposure therapy in rats by improving set-shifting performance in the AST that has been compromised by chronic stress (SfN Abstract 468.07, 2014). This study tested whether extinction-induced mPFC protein translation was necessary for the reversal of stress-compromised set-shifting by extinction therapy. After 2 weeks of CUS or control treatment, rats received microinjections of the protein synthesis inhibitor anisomycin or saline vehicle in the ventral mPFC (i.e., the infralimbic region, IL) followed by fear extinction training or control treatment. They were tested on AST 24h later. Anisomycin delivered to IL cortex blocked the rescue of mPFC-mediated cognitive flexibility by extinction in stressed rats. By contrast, control injections of anisomycin into the PrL subregion of

mPFC dorsal to the IL did not attenuate the beneficial effects of extinction. Ongoing studies are examining changes in plasticity-related proteins in IL tissue of rats following fear extinction. These results suggest that fear extinction-induced protein translation underlies the therapeutic effect of fear extinction. Such processes may be important to the beneficial effects on cognition that have been compromised by chronic stress, and may suggest targets for the development of adjunct pharmacological tools to enhance the efficacy of behavioral therapy.

Title: Modeling exposure therapy in rats: fear extinction-induced infralimbic activity underlies reversal of chronic stress-induced shift towards passive coping

Authors: *D. A. MORILAK, E. FUCICH, M. SAUNDERS;
Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Stress-related psychiatric disorders, like depression or post-traumatic stress disorder, are highly prevalent yet poorly treated. These disorders share many dimensions, including maladaptive avoidant coping strategies, thought to be modulated by medial prefrontal cortex (mPFC) activity. Psychotherapies invoking mPFC activity can be efficacious even in pharmacotherapy-resistant patients, although, as with pharmacotherapies, patient response and relapse remain issues. Identifying the neurobiological mechanisms underlying psychotherapy's

efficacy could lead to more rapid, efficacious, or long-lasting treatments. Pre-clinically, chronic unpredictable stress (CUS) induces a shift towards passive coping behavior in rats, similar to avoidant coping behaviors seen in patients with stress-related psychiatric illness. We have previously shown that fear extinction, which engages mPFC and closely resembles exposure therapy for PTSD, can model psychotherapy in rats by restoring active coping in the shock probe defensive burying (SPDB) test after chronic stress (SfN Abstract 468.07, 2014). In this study, we tested the hypothesis that mPFC activity during extinction is necessary for its beneficial effect in reversing CUS-compromised coping behavior in the SPDB test. To test the necessity of mPFC glutamatergic cell activity during extinction for its therapeutic impact, rats received AAV microinjections into the ventral mPFC (infralimbic cortex, IL) to express the Gi-coupled designer receptor exclusively activated by designer drug (DREADD) hM4Di or control GFP protein, driven by a CaMKII promoter. After four weeks of viral expression, including 2 weeks of CUS or control treatment, rats received an IP injection of the designer drug clozapine-n-oxide (CNO, 1mg/kg) followed by extinction or control treatment 30 min later. They were tested on SPDB 24h later. Immunohistochemical analyses of IL cortex showed that >60% of extinction-induced cFos was colocalized with CaMKII. In rats expressing the inhibitory hM4Di receptors in CaMKII+ neurons in IL, CNO reduced extinction-induced cFos expression by >60%. CNO also blocked the rescue of active coping by extinction in the SPDB test in stressed animals expressing hM4Di. These results suggest that mPFC activity underlies the effect of extinction on mPFC-modulated coping behavior. This study further shows that fear extinction is a useful model of exposure therapy, allowing us to investigate neural mechanisms responsible for its therapeutic effects.

Title: Alter neuronal ensembles in a neuronal overproduction mouse model of autism

Authors: *W. FANG, R. YUSTE;
Columbia Univ., New York, NY

Abstract: The variability in brain connectivity likely underlies individual differences in brain function. However, the causal link between variability in brain development and function remains poorly understood. In particular, it is not known how the brain regulates neuronal production and/or compensates if fewer or more neurons are generated. This is not an academic question since there are significant differences in brain size and neuron numbers across individuals. In addition, pathologies such as autism or mental retardation are associated with abnormal neuron numbers. We investigated a new mouse model of autism with overproduction of neurons in the neocortex and explored how surplus of neurons leads to differences in functional connectivity. We focused on neuronal ensembles, which are composed of specific groups of functionally related neurons and could represent building blocks of cortical function. To map neuronal ensembles and identify their spatiotemporal layouts in vivo, we performed two-photon calcium imaging of populations of primary visual cortical neurons. We find more and larger neuronal ensembles in the neocortex of autism mouse model brains. In addition, coactive neurons in these ensembles are more localized. These findings suggest that increased number of neurons generates more local functional modules, and agree with clinical studies showing stronger functional connectivity in autistic patients. Our work thus reveals that, in a mouse model of autism, neuronal overproduction leads to altered functional connectivity in the neocortex, providing developmental insights into the pathophysiology of autism.

Title: Methamphetamine rescues latency of reward collection in TAT transgenic mice while not affecting probabilistic learning, motivation, or exploratory behavior compared to controls.

Authors: *M. B. MILIENNE-PETIOT[1,3], D. S. DEBEN[3], J. W. YOUNG[1], A. MINASSIAN[1], T. TMARC[2];
[1]Psychiatry, [2]UCSD, La Jolla, CA; [3]Pharmacol., Utrecht Univ., Utrecht, Netherlands

Abstract: Introduction - Human Immunodeficiency Virus (HIV) is a worldwide problem with a prevalence of 0.8%. Due to the chronic nature of the disease, it can lead to HIV-associated neurocognitive disorders (HAND). HIV sufferers often abuse methamphetamine (METH), with claims of alleviation of symptoms by users. One important protein of HIV and HAND is the Transactivator of Transcription (TAT) as it can be expressed in the brain. Importantly, both TAT and METH inhibit dopamine transporter (DAT) function, and so may exert synergistic effects on behaviors relevant to HIV risk transmission such as reward-seeking and motivation. Confirmation of synergistic effects require testing in experimental animals, and can be conducted in inducible TAT mice. Methods - 59 male transgenic mice (30 wildtype (WT); 29 TAT+) were tested in the Probabilistic Learning (PL) task, Progressive Ratio Breakpoint (PRB) task, and in the Behavioral Pattern Monitor (BPM). Mice were treated with an increasing dose METH regimen (or vehicle) for 4 weeks before receiving 7 days of doxycycline injections to induce TAT expression. Results - Neither genotype, METH, or their interactions affected BPM measures, effortful motivation, or PLT accuracy. A main effect of METH on Mean Reward Latency (MRL) in the PRB was observed [$F_{(1,46)}=4.9$, $p<0.05$], but no interaction with genotype ($F<1$, ns). In the PL task, there was an interaction between genotype and METH for MRL [$F_{(1,49)}=4.6$, $p<0.05$]. Vehicle-treated TAT expressing mice exhibited significantly higher MRL compared to WT mice ($p<0.01$), an effect not observed after METH treatment (ns). Conclusion - TAT protein expression in mice slowed the collection of rewards, without affecting choice latency. Pretreatment with METH however, rescued the latency to collect rewards. These data may relate to HIV sufferers seeking METH to alleviate reward apathy. No other interactive effects were observed however, in probabilistic learning, effortful motivation, or exploratory behavior. Future studies should further evaluate the effects of concomitant HIV and drug use on other types of behavior.

Title: Pavlovian and dopaminergic influences on the development and escalation of 'compulsive' checking behaviour in rats: implications for models of obsessive compulsive disorder (OCD).

Authors: *D. M. EAGLE[1], C. SCHEPISI[1], S. CHUGH[1], S. DESAI[1], S. HAN[1], T. HUANG[1], J. LEE[2], C. SOBALA[1], W. YE[1], T. W. ROBBINS[1];

Abstract: Compulsive checking is a common, debilitating symptom of OCD. For healthy people, checking is a functional, appropriate behaviour, and it is not clear how this behaviour develops into the excessive/compulsive checking that is found in OCD. We propose that prior Pavlovian-conditioned links between checking and positive outcomes might influence the subsequent development of high levels of checking behaviour.
In previous studies, quinpirole (dopamine D2/3R agonist) increased checking responses of rats (in behavioural tests including the Observing Response Task (ORT)). In the ORT, rats use a lever (checking response) to access information about which of two other levers gives food reward. In the current study, prior to ORT training, 24 rats received Pavlovian Autoshaping training (Pav), to develop an association between the checking response lever and 'reward' pellets (24 rats received Control (Con) training). When treated with quinpirole (QNP; 0.5 mg/kg, 10 sessions) on the ORT, Pav rats significantly increased checking, whereas Con rats' checking was not increased by QNP. The interaction between Pav and QNP increased checking both during the QNP treatment phase and during 10 non-treatment days post-QNP, showing potential long-term effects of this treatment interaction. Functional checking (responses to turn the light on) was affected to a greater extent than dysfunctional checking (checking responses while the light was illuminated and having no further consequence).
OCD checking may also be influenced by uncertainty. When uncertainty was increased in the

ORT, previously Pav-trained rats selectively escalated dysfunctional checking compared with Con rats. Further investigation showed that rats defined by published criteria as 'sign-tracking' escalated dysfunctional checking to a far greater extent than 'goal-tracking' rats (which made no more dysfunctional checking responses than Con rats).
These results support our hypothesis that Pavlovian conditioned links between checking and positive outcomes affect:
i) dopaminergic mechanisms controlling checking;
ii) uncertainty-induced escalation of dysfunctional checking, especially for 'sign-trackers'.
These findings give us insight into how checking might transform from functional behaviour to excessive and dysfunctional behaviour in OCD.

Title: Cortico-striatal regions of the rat and checking-like behaviour: Dissociable effects of lesions to the orbitofrontal cortex, medial prefrontal cortex, nucleus accumbens core and dorsal striatum in an operant observing response task

Authors: *L.-S. D'ANGELO[1,2], D. M. EAGLE[1,2], C. M. COMAN[3], T. W. ROBBINS[1,2];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Behavioural and Clin. Neurosci. Inst., Cambridge, United Kingdom; [3]Univ. Paris-Saclay, Paris, France

Abstract: Excessive checking is a common, debilitating symptom of obsessive-compulsive disorder (OCD). To further examine cognitive processes underpinning checking behaviour, and clarify how and why checking develops, we designed a novel operant paradigm for rats, the observing response task (ORT) (Eagle et al., 2014). In the present study, the ORT was used was used to investigate the functional role that brain regions implicated in a neuroanatomical circuit of OCD may play in compulsive checking behaviour. There is evidence that OCD is related to dysfunction of cortical-basal ganglia systems (Graybiel & Rauch 2000; Menzies et al. 2008). The experimental approach involved excitotoxic lesions of the orbital frontal cortex (OFC), medial prefrontal cortex (mPFC), nucleus accumbens core (NAcbC) and dorsal striatum (DStr), brain

regions considered to be of relevance to OCD. In the ORT, rats pressed an 'observing' lever for information about the location of an 'active' lever that provided food reinforcement. OFC lesions had no effect on observing but did impair instrumental choice behaviour in a pattern of deficits suggesting that OFC lesions disrupted the ability to use information from observing appropriately. mPFC lesions selectively increased functional observing without affecting other task measures. Rats with NAcbC lesions made significantly more observing responses than control shams, both for functional observing lever presses and non-functional observing lever presses. DStr lesions had no effect on observing, but reduced both active and inactive lever presses. These results provide novel information about the role of cortico-striatal regions in checking-related behaviour and accordingly provide insight into possible pathophysiology that underlies the development of compulsive checking observed in OCD.

Title: Effects of cola nitida acetone extract on brain sodium-potassium adenosine triphosphatase activity, spatial memory in healthy and streptozotocine induced diabetic female wistar rats

Authors: *A. O. IMAMFULANI, K. O. SANUSI, B. V. OWOYELE;
Physiol., Univ. of Ilorin, Ilorin, Nigeria

Abstract: Background: Individuals with type 1 diabetes have been reported to show modest deficit on wide range of neuropsychological tests compared with nondiabetic subjects. This study was carried out to investigate the effects of acetone extract of Cola nitida on brain Na+/K+ ATPase activity and spatial memory of STZ induced diabetic Wistar rats.
Methods: Female Wistar rats were used for this study and were randomly distributed into six (6) groups with seven animals in each group. Animals in group 1 were control and administered normal saline; Group 2 animals were diabetic group and Group 3 were diabetic animals and administered 50mg/kg of kola nut extract per day; Group 4 were diabetic animals and administered 100mg/kg of kola nut extract per day; Group 5 were healthy animals and administered 50mg/kg of kola nut extract per day; Group 6 were healthy animals and administered 100mg/kg of kola nut extract per day. After three (3) weeks of administration, the spatial memory and Na+/K+ ATPase activity were analysed.

Results: The result of the experiment shows a significant increase in Na+/K+ ATPase activity of groups 3 and 4 administered 50mg/kg and 100mg/kg of kola nut extract respectively when compared with group 2
($p<0.05$), and a significant increase ($p<0.05$) in Na+/K+ ATPase activity of groups 5 and 6 administered 50mg/kg and 100mg/kg of kola nut extract respectively when compared with group 1 ($p<0.05$).
Conclusion: this study shows that kola nut extract has positive effect on brain Na+/K+ ATPase activities and spatial memory of STZ-induced diabetic Wistar rats.

Title: Behavioral and physiological effects of excitatory DREADD expression in the rat medial prefrontal cortex: Lack of evidence for neuronal activation with clozapine-N-oxide

Authors: *K. ISHIWARI[1], A. M. GEORGE[1], C. D. MARTIN[1,2], K. A. HAUSKNECHT[1], R.-Y. SHEN[1], S. HAJ-DAHMANE[1], J. B. RICHARDS[1];
[1]Res. Inst. on Addictions, [2]Psychology, Univ. at Buffalo, Buffalo, NY

Abstract: Habituation of reinforcer effectiveness (HRE) may be a fundamental property of reinforcing stimuli. Abnormal HRE due to genetic and/or environmental factors may play a role in dysfunctional behavioral regulation seen in such disease states as ADHD, autism, obesity, and drug abuse. We have previously shown that operant responding for a visual sensory stimulus (light onset) rapidly habituates in rats[1]. Electrophysiological evidence indicates that novel sensory stimuli increase burst firing of midbrain dopaminergic (DA) neurons, which rapidly decreases with repeated presentation of the stimulus[2]. The medial prefrontal cortex (mPFC) modulates the activity of midbrain DA neurons through multiple pathways, exerting both excitatory and inhibitory influences. To elucidate the role of the mPFC in HRE, the present study attempted to examine effects of chemogenetic neuronal activation of the mPFC using a designer receptor exclusively activated by designer drugs (DREADD) on HRE of a light stimulus. Three groups of male rats were tested for snout poke responding for light onset in six 18-min daily sessions. One group of rats (n = 12) expressed the excitatory DREADD (AAV5-CaMKIIα-

hM3Dq-mCherry) in the mPFC and were injected with clozapine-N-oxide (CNO; 3 mg/kg, i.p.) 30 min before each of the six light reinforcement sessions. A second group (n = 10) also expressed hM3Dq in the mPFC but received saline vehicle. A third group (n = 7) had sham surgery in the mPFC and received CNO. The hM3Dq/CNO rats displayed larger degrees of both between- and within-session habituation in responding for the light relative to the hM3Dq/saline rats. However, the sham-operated rats receiving CNO also habituated to the same degree as the hM3Dq/CNO rats. Moreover, whole-cell patch-clamp recordings in brain slices showed that bath application of CNO (10-30 μM) did not significantly increase the excitability of layer V mPFC pyramidal neurons expressing hM3Dq/mCherry (n = 6 cells). Taken together, our results suggest that CNO, or its metabolites, had attenuating effects on responding for the light that were not DREADD-mediated.

Title: Timing and temporal discounting in a model of aging-related parkinsonism

Authors: ***M. BUHUSI**[1], A. MANJUNATH[2], A. R. MATTHEWS[1], K. OLSEN[1], J. CARLSON[1], J. YANG[3], C. V. BUHUSI[1];
[1]Dept. Psychology, [2]Dept. Engin., Utah State Univ., Logan, UT; [3]Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Parkinson's Disease, the most common neurodegenerative movement disorder, is also associated with deficits in timing, planning, working memory and inhibitory control, suggestive of frontal executive dysfunction due to alterations in dopaminergic circuits. Glial-derived neurotrophic factor (GDNF) is essential for regulating DA release in the basal ganglia and the survival of DA neurons, and GDNF-deficient mice are considered an animal model for aging-

related Parkinsonism. Therefore, we assessed interval timing in the peak-interval (PI) procedure and decision making in the temporal discounting (TD) task as measures of executive function in GDNF-heterozygous (HET) mice, having a partial reduction of GDNF levels, and their wild-type littermate controls (WT). As expected, relative to WT controls, a significant impairment in timing was found in aged, but not in adult presymptomatic GDNF-HET mice. Also, adult presymptomatic GDNF-HET showed no deficits in TD relative to their WT controls. However, following chronic unpredictable stress, adult GDNF-HET mice showed increased impulsive choice indexed by a reduction in percent larger-later choices and a reduction in area under the TD curve. Moreover, adult stressed GDNF-HET mice, but not their WT controls, showed decreased neuronal activation (number of cFos positive neurons) in the orbitofrontal cortex and nucleus accumbens, suggestive of maladaptive response to stress, in accord with recent reports linking GDNF to resilience to stress. Interestingly, impulsivity (indexed by area under the TD curve) negatively correlated with activation of the nucleus accumbens core and shell, but not with orbitofrontal activity. Taken together, these results support interval timing and temporal discounting as markers of cognitive impairment in animal models of Parkinsonism, and identify GDNF-deficient mice as a double-hit (gene x environment) model of stress-related cognitive impairment.

Title: Increased hippocampal neurogenesis is associated with worse contextual memory.

Authors: *J. JORDAN[1], S. SCHWARTZ[3], I. VORONINA[4], K. LIN[5], C. HARDING[5,2,1], C. PYTTE[1,3,2], A. WINTER[6];
[1]Biol., [2]Psychology, Grad. Center, The City Univ. of New York, New York, NY; [3]Psychology, Queens College, The City Univ. of New York, Flushing, NY; [4]Chem., [5]Psychology, Hunter College, The City Univ. of New York, New York, NY; [6]Paul D Schreiber High Sch., Port Washington, NY

Abstract: The hippocampus is essential for the formation of new spatial and contextual memories and is a site of adult neurogenesis. Exactly how newborn neurons contribute to hippocampal-dependent memory has been widely debated. Evidence has shown that ablating neurogenesis impairs contextual memory, a hippocampal-dependent form of memory, and it is often assumed that increased neurogenesis improves hippocampal memory. To investigate the relationship between new neurons and strength of contextual memories, we injected mice with the mitotic marker BrdU (2 times per day for 4 days). Two weeks later, mice were fear-conditioned to a particular context, then re-exposed to the fearful context both at a 30-minute and at a 24-hour delay. We subtracted movement during the recall sessions from baseline movement measured before shock was delivered during the training session; a larger difference between these two values indicates better contextual memory. We sacrificed mice 4.5 weeks after the last BrdU injection and used IHC to label BrdU and NeuN, a marker of mature neurons, throughout the dorsomedial dentate gyrus. In separate sections, we labeled doublecortin (DCX), a marker of immature neurons. Surprisingly, we found that numbers of BrdU+ neurons were negatively correlated with contextual memory, both 30 minutes and 24 hours after training. The more new neurons, the worse the mouse's memory. These findings were the same when analyzing new neuron densities across the entire dentate gyrus, as well as specifically in the subgranular zone, the site within the dentate gyrus where new neurons are born. We found no significant correlations between DCX+ neuron density and recall at either time point. No significant correlations were found between DCX+ or BrdU+/NeuN+ neurons and baseline movement before fear conditioning or with auditory fear memory. Although other work has shown that new neurons are needed for new contextual memories, too many may interfere with hippocampal processing. Alternatively, mice that were able to form better memories may have fewer new neurons surviving to maturity. Though we cannot determine causality, a higher density of mature new neurons was associated with worse contextual memory.

Title: Depletion of adult neurogenesis compromises hippocampal feedback inhibition.

Authors: *C. L. HOLLANDS[1], S. KERNIE[2], O. LAZAROV[1];
[1]The Univ. of Illinois at Chicago, Chicago, IL; [2]Columbia Univ., New York, NY

Abstract: Hippocampal adult neurogenesis is thought to play an essential role in hippocampal plasticity, but the mechanism is not fully elucidated. Here we show that ablation of neurogenesis in the adult brain compromises recognition memory. Ablation of neurogenesis was achieved by treating nestin-δ-HSV-TK mice with valganciclovir. To assess the impact of loss of neurogenesis on the activity of the hippocampal circuitry we examined the expression of the immediate early gene *Egr-1* (*zif268*), as an indicator of neuronal activation following learning. For this purpose, nestin-δ-HSV-TK mice were trained in the pattern separation task, probed for long-term memory and immediately examined for *Egr-1* expression in the hippocampus. We show a significant increase in the number of *Egr-1* expressing neurons in both the CA3 and CA1 regions in nestin-δ-HSV-TK mice with ablated neurogenesis compared to nestin-δ-HSV-TK mice with intact neurogenesis. These results suggest that neurogenesis plays an important role in regulation of feedback inhibition, and that interference with inhibitory hippocampal circuitry following depleted neurogenesis leads to neuronal over activation. This data suggests that deficits in adult neurogenesis may induce deficits in learning and memory.

Title: Analysis of gender and strain differences in basal hippocampal neurogenesis in adult rats

Authors: A. M. FORMICA, F. E. GRIFFEY, A. R. DIXON, *D. M. HAYES;
Psychology, Radford Univ., Radford, VA

Abstract: A comprehensive body of research now indicates that neurogenesis occurs throughout adulthood in a variety of species. This process, by which new neurons are born and ultimately become integrated into existing brain circuitry takes place in four stages: cell proliferation, differentiation, maturation, and survival. One of the two primary regions where neurogenesis occurs is the hippocampus, which plays an extensive role in learning and memory. Though investigators have analyzed how various experimental interventions might affect neurogenesis in this brain region, studies have been primarily conducted in male Sprague-Dawley rats despite known differences between the genders as well as rat strain. For instance, androgens have been shown to enhance cell proliferation while estrogens have been shown to ultimately suppress proliferation. Additionally, female rats have been shown to be more susceptible to stress when compared to male rats with stress having been found to inhibit neurogenesis. Furthermore, Long-Evans rats have generally outperformed Sprague-Dawley rats on several hippocampal-dependent learning tasks, such as the Morris Water Maze, where better performance is generally thought to correlate with higher levels of neurogenesis. The current study was therefore designed to investigate baseline levels of neurogenesis using rats of both genders from two separate strains. To that end, adult male and female Sprague-Dawley and Long-Evans rats were perfused without exposure to experimental manipulations. Brains were collected, sliced, and stained for Ki67 immunoreactivity, an endogenous indicator of cell proliferation. Though it was predicted that Long-Evans rats and male rats would show significantly higher levels of neurogenesis than their respective counterparts, preliminary analyses failed to reveal an effect of either strain or gender on the number of Ki67-positive cells found in the hippocampus. Furthermore, there was not a significant interaction between gender and strain on Ki67-positive cell numbers. However, the data does show a trend toward Long-Evans animals displaying increased cell proliferation compared to Sprague-Dawley animals, which may become statistically significant with increased statistical power. Results from this study will extend findings that suggest a need for researchers to take into account various strains and both genders in future studies in order to increase the generalizability of research intended to model human conditions.

Title: Lentiviral overexpression of interleukin-1β in the hippocampus induces neurogenesis-associated cognitive deficits in touchscreen learning paradigms

Authors: *C. M. HUESTON, J. F. CRYAN, Y. M. NOLAN;
Univ. Col. Cork, Cork, Ireland

Abstract: Adult neurogenesis within the subgranular zone of the dentate gyrus of the hippocampus is integral for normal cognitive function, and is especially important for spatial memory tasks and pattern separation tasks. Previous studies have demonstrated that acutely elevated levels of the pro-inflammatory cytokine interleukin-1β (IL-1β) in the hippocampus has detrimental effects on some aspects of memory and cognitive function, as well as a negative impact on the proliferation and survival of newly born neurons. Touchscreen-based platforms for testing cognitive function have been developed that allow several different types of memory and learning to be assessed, including pattern separation which can be tested using the location discrimination paradigm. The current study aimed to assess whether long-term increased expression of IL-1β through lentiviral-mediated overexpression of the protein would alter performance in pattern separation using the touchscreen location discrimination test. To accomplish this, adult male Sprague-Dawley rats were first trained to use the touchscreen testing apparatus, and to perform intermediate-separation location discrimination. Once all animals had passed criteria, a lentivirus overexpressing IL-1β and the fluorophore mCherry, or a control virus expressing only mCherry was bilaterally injected into the dorsal dentate gyri of rats, and they were allowed to recover. Two weeks after injection, rats were re-tested on the intermediate location discrimination task to check post-surgical performance. Rats were then introduced to the large and small separation aspects of the pattern separation task. IL-1β overexpression in the dorsal hippocampus resulted in impaired performance in the large, but not the small location discrimination task. Additionally, IL-1β overexpression resulted in a reduction in the number of proliferating new cells within the dentate gyrus as measured by Ki67 expression. The survival and numbers of newly born neurons will also be measured by immunohistochemical analysis using antibodies against DCX and BrdU/NeuN. Together, the results from the current experiment suggest that chronic overexpression of IL-1β in the hippocampus induces a deficit in pattern separation, a hippocampal neurogenesis-dependent cognitive behaviour.

Title: Exercise-induced changes in NGF are critical for the rescue of spatial working memory and septohippocampal functioning

Authors: *J. M. HALL[1], F. GOMEZ-PINILLA[2], L. Z. YING[2], L. M. SAVAGE[1]; [1]Psychology, Binghamton Univ., Binghamton, NY; [2]UCLA, Los Angeles, CA

Abstract: Exercise has shown robust capabilities at improving and rescuing cognitive function in both humans and rodents, which has been assumed to directly involve increases in hippocampal neurotrophins and hippocampal neurogenesis. Our laboratory has recently shown that exercise with an adaption period leads to: 1) a rescue of spatial working memory, 2) a restoration of septohippocampal cholinergic functioning and 3) a selective re-emergence of the Nestin+ cholinergic phenotype (Hall & Savage, 2016). Thus, our aim was to investigate which neurotrophin, brain-derived neurotrophic factor (BDNF), or nerve growth factor (NGF), was responsible for this cholinergic-based recovery. To do so, PTD and control rats were infused with fluorescent latex microspheres into the dorsal hippocampus that were coated with either TrkA-IgG or TrkB-IgG, to sequester free NGF and BDNF (respectively) during exercise. Rats also received ventral hippocampal cannulations for assessment of acetylcholine release during spontaneous alternation. Results indicated that sequestering NGF, but not BDNF, abolished the exercise-induced recovery of spatial working memory and acetylcholine release. Thus, exercise-induced changes in NGF within the septohippocampal pathway represent another avenue for recovery of function for disorders of memory and cognition.

Title: Seizures originating in different brain regions have differential effects on fear memory and the functional integration of seizure-generated granule neurons

Authors: *N. NOGOVITSYN[1], J. J. BOTTERILL[2], H. J. CARUNCHO[3], L. E. KALYNCHUK[4];

Abstract: Temporal lobe epilepsy is associated with impaired cognition, but the mechanisms by which this occurs remain unclear. Here, we investigated whether seizures that originate in different brain regions have differential effects on hippocampal-dependent learning and memory and the recruitment of adult-generated neurons into memory networks. To accomplish this, we used the kindling model of epilepsy, in which daily brief electrical stimulation of a discrete brain region instigates the gradual development and intensification of motor seizures. We subjected rats to 99 kindling stimulations of limbic (basolateral amygdala and dorsal hippocampus) or non-limbic (caudate nucleus) brain regions. To evaluate the effects of seizures on hippocampal neurogenesis and the integration of adult-generated neurons into memory networks, we performed BrdU pulse-chasing experiments (3 i.p. injections; 24 hours apart) 4-weeks prior to the cessation of kindling. Upon the completion of kindling, rats were subjected to a 4-day hippocampal dependent trace fear conditioning paradigm comprising habituation, training, and memory testing (tone and context, respectively). Approximately 1 hr after the final contextual fear memory retrieval test (day 4), all rats were sacrificed and their brains were prepared for immunohistochemistry. We found that kindling had no effect on the acquisition of hippocampal-dependent fear conditioning; however, limbic-kindled, but not non-limbic kindled, rats showed impaired retrieval of fear memories. Interestingly, impaired memory retrieval in limbic-kindled rats coincided with reduced expression of the neural activity markers Fos and Arc throughout the dentate gyrus. We also found that limbic-kindled rats had increased hippocampal neurogenesis as measured by BrdU cell counting, but almost none of these new neurons co-localized with Fos or Arc. In contrast, approximately 10% of mature adult-generated neurons co-localized with Fos in control and caudate-kindled rats. Collectively, our findings suggest that limbic, but not non-limbic kindling prevents the recruitment of mature adult-generated neurons into memory networks. These observations may help explain the cognitive impairments that are most commonly associated with limbic seizures.

Title: Could changes in hippocampal neuron cytoarchitecture explain the depressive behavior of CB1 knockout mice?

Authors: ***H. A. BRUSCO**, D. SORIANO, F. CONDE, L. CALTANA;
IBCN (UBA-CONICET) Facultad De Medicina UBA, Buenos Aires, Argentina

Abstract: Cannabinoid receptors are expressed in the hippocampus. CB1R is preferentially expressed in pyramidal neurons and astrocytic processes, while CB2R is expressed in microglial, astroglial and endothelial cells.
CB1-receptor-knockout mice are used as an animal model of depression, although the morphological substrate of this behavior is not completely understood yet. And, as the hippocampus is an important area of the central nervous system involved in behavior, the aim of this work was to characterize hippocampal neurons in CB1-receptor-knockout mice.
The study was performed through immunofluorescence, Golgi, Western blot and electron microscopy techniques, focusing on the dentate gyrus and CA1 areas. The genetic ablation of CB1R produces an increase in the expression of CB2R, which suggests a compensatory regulation in the endocannabinoid system.
CB1-receptor-knockout mice evidenced a lower number of undifferentiated neuronal cells precursors (Nestin+ cells) and migrating neuroblasts (doublecortin+ cells). These data suggest that CB1-receptor-knockout mice suffer alterations in adult neurogenesis in the in dentate gyrus.
CB1-receptor-knockout mice also presented cytoskeletal alterations in hippocampal neurons, as evidenced by lower expression of Neurofilaments of 160Kda and 200Kda, as well as lower expression of MAP-2 protein. These results indicate that these neurons have scarce dendritic arborization and cannot correctly connect with their targets neurons.

The number of synaptic contacts studied by Golgi technique and electron microscopy did not show significant differences between CB1-receptor-knockout mice and wild type mice; however, synaptophysin expression was lower in CB1-receptor-knockout mice, probably suggesting alterations in synapse efficiency.
Taken together, these results could explain the behavior alterations in CB1-receptor-knockout mice.

Title: Imaging the functional integration of adult-born hippocampal granule cells into the dentate gyrus network

Authors: ***S. N. TUNCDEMIR**[1], G. TURI[2], G. ORDEK[1], A. LOSONCZY[2], R. HEN, 10016[3]; [1]Integrative Neurosci., RFMH Columbia Univ., New York, NY; [2]Neurosci., [3]Psychiatry, Neuroscience, Pharmacol., Columbia Univ., New York, NY

Abstract: The ability to discriminate among similar experiences is an important feature of episodic memory. The dentate gyrus of the hippocampus and its ability to incorporate newborn granule cells throughout life is crucial for the neural computation that generates spatial and contextual discrimination behaviors. In particular, preferential activation of 1-2-month old adult born granule cells (abGCs) within the predominantly silent dentate network, is hypothesized to allow abGCs to actively participate in these behaviors. Our lab has recently shown that abGCs exhibit higher firing rate and reduced spatial tuning with similar degree of spatial remapping between contexts compared to the mature GCs (mGCs) *in vivo* (Danielson NB. et al, 2016), suggesting that abGCs indirectly modulate the activity of the mGCs by recruiting local inhibitory networks (Drew LJ. et al, 2015). Nevertheless, circuit interactions of abGCs that contribute to information processing within the dentate gyrus during discrimination behaviors are poorly understood. To this end, we will use two-photon calcium imaging in awake behaving mice to monitor the activity of abGCs and mGCs over the 4-week period during which abGCs

functionally integrate into the dentate gyrus circuits. This preparation will highlight the emergence of spatiotemporal activity of abGCs during encoding of contextual information and will allow us to test how manipulating their activity affects the circuit dynamics of mGCs.

Title: The role of adult neurogenesis in visuo-spatial learning and memory is dependent on stress during training and sex.

Authors: ***T. P. O'LEARY**, D. ESPINUEVA, D. R. M. SEIB, J. S. SNYDER;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Adult neurogenesis in the hippocampus is involved in visuo-spatial learning and memory, and also regulation of the hypothamic-pituitary-adrenal axis and stress-related behaviour. It is not yet clear, however, if the role of adult-born neurons in learning and memory is dependent on stress levels during the learning episode. To address this possibility, we used a transgenic rat that expresses the herpes simplex virus thymidine kinase, under the glial fibrillary acidic protein promoter (GFAP-TK). Administration of the anti-viral drug valganciclovir leads to death of mitotic neural precursor cells in the GFAP-TK rat. Beginning at 6 weeks of age, GFAP-TK rats were given valganciclovir orally for 6 weeks (twice per week), leading to a near-complete ablation of adult neurogenesis in the dentate gyrus. To assess the role of adult neurogenesis in learning and memory under stress, we tested GFAP-TK (N=96) and wild-type long-evans (N=103) rats in the Morris water maze using either cold 16°C water (high stress) or warm 25°C water (low to moderate stress). Rats completed acquisition training for 3 days (4 trials per day) with a probe trial (60 sec) on the following day to assess memory for the escape platform location. Both male and female rats were used, given that sex differences are found in behavioural responses to stress, and because few studies have examined sex differences in the role of adult neurogenesis. When trained in 16°C water, sex-dependent effects on learning were

found. In males, WT rats found the escape platform faster and travelled a shorter distance than GFAP-TK rats. The opposite result was found in females, as GFAP-TK rats located the escape platform faster and traveled a shorter distance than WT rats. These differences between genotypes were not found in 25°C water, and were not due to differences in swim-speed. In the probe trial, there was a trend for better memory performance in male WT rats than GFAP-TK rats, but only at the colder 16°C water. Overall sex differences in performance were found at 25°C but not 16°C, where male rats showed superior learning and memory, and slower swim speed compared to females. These results suggest that in males, adult neurogenesis is involved to a greater extent in visuo-spatial learning and memory during stressful learning episodes. The learning and memory performance of females, however, appears to be spared or even enhanced when neurogenesis is ablated. These results suggest a novel sex difference in the role of hippocampal adult-born neurons in visuo-spatial learning and memory, and underscore the importance of using both sexes when investigating the function of adult-born neurons.

Title: Inhibition of adult neurogenesis impairs learning of spatiotemporal regularities

Authors: *R. YU, J. ZHAO, J. S. SNYDER;
The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The hippocampus is an important brain structure for learning in humans and other animals. Hippocampal neurogenesis is thought to play a critical role in pattern separation. Previous research has focused on the role of hippocampal neurogenesis in spatial learning, by training rodents to discriminate spatial contexts or locations. It is currently unknown what role hippocampal neurogenesis plays in the learning of regularities. Here, we examined how the inhibition of neurogenesis impacts learning of spatiotemporal regularities. Transgenic GFAP-TK

rats were used whose hippocampal neurogenesis was inhibited selectively in adulthood by valganciclovir. The GFAP-TK rats were compared with intact wild-type littermates. Rats were trained in a spatial water maze task where they were required to find a hidden escape platform in a tank of opaque water. The platform appeared in one of two possible locations. The rats were randomly assigned to and remained in one of the three conditions throughout training: the platform appeared repeatedly in the same location for all trials on a given day (simple regularities condition), alternated between the two locations on a trial-by-trial basis (complex regularities condition), or randomly appeared between the two locations on a trial-by-trial basis (no regularities condition). The swim trajectory and the latency to reach the platform were recorded for each trial and compared between the GFAP-TK rats (lacking neurogenesis) and the wild type rats (with neurogenesis). We found that when the platform location alternated on each trial, the GFAP-TK rats performed reliably worse than wild type rats, both in terms of latency to reach the platform and swim trajectory. However, when the platform appeared repeatedly in the same location, or randomly appeared between locations, the GFAP-TK rats were not different from wild type rats. These results suggest that neurogenesis is critical for learning of complex but not simple spatiotemporal regularities.

Title: The effects of amygdala kindling on hippocampal neurogenesis and pattern separation.

Authors: ***J. K. CARR**, H. LEHMANN, N. M. FOURNIER;
Trent Univ., Peterborough, ON, Canada

Abstract: Pattern separation is a neural computational process involving the dentate gyrus (DG), which is thought to underlie critical aspects of memory retention such as maintaining independence of different memory representations. Recent evidence has indicated that young adult-generated dentate granule cells (GCs) mediate pattern separation (i.e. behavioural indices of pattern separation are impaired by down-regulation of neurogenesis and enhanced by up-regulation). In addition, hippocampal neurogenesis is also substantially altered by amygdala kindling, and these alterations are thought to underlie the progressive development of hyper-

excitable circuitry and chronic seizures seen in temporal lobe epilepsy. Specifically, amygdala kindling causes a dramatic increase in the rate of neurogenesis in the short-term, followed by a long-term suppression of neurogenesis which often falls below baseline levels. These changes in the rate of cell proliferation also coincide with aberrant changes in the migration, excitability, and functional integration of these young GCs into existing hippocampal circuits. These two lines of evidence converge on an interesting question: What impact does amygdala kindling have on pattern separation? The aim of our study was to characterize alterations in pattern separation in rats following short- (30 stimulations) and long-term amygdala kindling (99 stimulations) using a context discrimination task, which relies on pattern separation and is sensitive to manipulations of hippocampal neurogenesis. Bromodeoxyuridine (BrdU) was injected in short-term and long-term kindled rats 2-weeks prior to behavioral testing in order to label proliferating neurons, and post-mortem analysis was conducted on the brains using BrdU and IEGs (c-Fos and zif268) immunohistochemistry in order to examine the recruitment of young GCs into the network supporting pattern separation. Our findings suggest that chronic seizures may disrupt the participation of adult-born neurons in hippocampal networks involved in cognitive and mnemonic function. Support: NSERC Theme and Topic 1. Title: Modulation of glutamatergic neurons in the medial septum in the freely moving mouse

Authors: *J. ROBINSON[1,2], F. MANSEAU[1,2], S. WILLIAMS[1,2];
[1]Inst. Universitaire En Santé Mentale Douglas, Verdun, QC, Canada; [2]McGill Univ., Montreal, QC, Canada

Abstract: Neurons in the medial septum diagonal band of Broca (MS-DBB) provide important connections to the hippocampus and are critical for spatial learning and memory. Three main

neuronal populations have been identified in this region: cholinergic, GABAergic and glutamatergic. It has previously been reported that glutamatergic neurons provide connections within the MS-DBB onto both GABAergic and cholinergic neurons as well as providing sparse connections to the hippocampus. In addition, it was recently shown that optogenetic activation of glutamatergic neurons can powerfully drive CA1 hippocampal theta rhythms and initiate locomotion. To further explore the role of MS-DBB glutamatergic cells we have used optogenetics to specifically modulate this population in the freely moving mouse. Here, glutamatergic MS-DBB neurons were targeted through injection of a Cre-dependent AAV viruses containing the light-sensitive proteins, ChETA or ArchT constructs, that were used to activate or suppress glutamatergic neurons in a VGLUT2-CRE mouse line. Using this model we aim to determine how modulation of glutamatergic neurons from the MS-DBB affects theta rhythms across the hippocampus and influence animal behavior. In the freely moving mouse, we have observed that activation of these neurons drive theta rhythms across the hippocampal formation. In contrast, suppression of these glutamatergic neurons has little influence on theta power or frequency. Finally, we will examine the effects of activation and suppression of this population on exploration in an open field setting. These experiments will help to determine the role glutamatergic MS-DBB neurons play in freely behaving mice.

Title: Calcium imaging of medial septal neurons in freely-behaving mice

Authors: ***J.-B. BOTT**, S. WILLIAMS;
Dept of Pyschiatry, McGill University, Douglas Ins, Verdun, QC, Canada

Abstract: Medial septal neuronal population are GABAergic, glutamatergic and cholinergic. The medial septum is known for modulating the activity in the hippocampal formation, but the contribution of glutamatergic and cholinergic neurons remain poorly understood. More specifically the spontaneous activity pattern of those neuronal populations during behavior has not been well characterized as recording identified neuronal subpopulation in vivo in freely-moving mice is challenging.

Using calcium imaging, our objective is to characterize the spontaneous activity of cholinergic and glutamatergic neurons during various behavior in freely-moving mice. VGLUT2-Cre and ChAT-Cre mice were injected with 0.5µl of the Cre-dependent *AAV2/9-Syn-Flex-GcAMP6f* virus. Three weeks later, mice were implanted with a chronic imaging device and subjected to different behavioral tasks.
The activity pattern of glutamatergic and cholinergic neurons from the medial septum differed and appeared highly specific to different behavioral aspects of the task. More specifically, the glutamatergic neurons elicited a locomotion-related behavior whereas cholinergic cells displayed a pattern of activity that suggested a memory-encoding involvement.
Those results suggest that medial septum glutamatergic and cholinergic subpopulations contribute differentially to hippocampal-dependent cognition. Moreover, calcium imaging appears particularly adapted to extract sub-population specific activity patterns in relation to the animal behavior.

Title: Spatial reference memory impairments are associated with abolished CA1 theta-gamma cross-frequency coupling in freely behaving J20 APP mice

Authors: *G. ETTER[1,2], S. WILLIAMS[1,2];
[1]Douglas Mental Hlth. Inst., Verdun, QC, Canada; [2]McGill Univ., Montreal, QC, Canada

Abstract: Alzheimer's disease (AD) has been associated with amyloid beta (Ab) aggregation, subsequent hippocampal neurodegeneration and memory defects. The exact nature and chronology of these pathological events remains largely unknown. Theta-gamma cross-frequency coupling (CFC), a physiological phenomenon that has been associated with memory encoding and retrieval, has been previously shown to be decreased in complete hippocampus preparations from 3 weeks old transgenic AD mice model. Several authors have proposed to segregate gamma band oscillations into slow (30-60 Hz), and fast (60-120 Hz) clusters that may rely on CA3 and medial entorhinal cortex inputs, respectively. In the present study, we have monitored CA1 local field potentials in the freely behaving J20 AD mice model (PDGF-APPSw,

Ind) trained to seek a reward on a modified appetitive version of the Barnes maze as well as during REM sleep. At 6 months of age, J20 mice display more spatial errors as well as non-targeted exploration during the probe trial compared to non-transgenic (NTg) counterparts. Using a standardized measure of CFC, we show that theta-gamma CFC is significantly reduced during REM sleep, while it is abolished (not significantly different from a random distribution) when mice actively explore the Barnes maze. When isolating gamma oscillations using wavelet convolution, we show that NTg mice display dynamics (predominant fast gamma before reaching the target, followed by predominant slow gamma) that are abolished in J20 mice. This study suggests that circuits underlying cross-frequency coupling are affected very early in AD mice models and might underlie the spatial memory defects and suggests that the CFC may be an early biomarker of AD.

Title: Deep Brain Stimulation to improve memory function in an animal model of Alzheimer Disease

Authors: *E. VICO VARELA, S. WILLIAMS;
McGill Univ. -Douglas Mental Hlth. Uni. Inst., Montreal, QC, Canada

Abstract: Deep Brain Stimulation (DBS) is a therapeutic approach being evaluated for the treatment of Alzheimer Disease (AD). AD is a neurodegenerative disorder, presenting a dysfunction in the 'memory network': structures implicated in memory, such as the hippocampus and entorhinal cortex, are affected earliest and most severely. The current study aims to identify memory-facilitation mechanisms of fornix DBS in a transgenic mice model of AD (J20) by examining electrophysiological recordings of the CA1 hippocampal region. Recordings of the CA1 region were collected in 3 months old mice during REM, before and 24 hours after the Passive Avoidance task and while they were exploring objects during a Novel Place Object task. We show that transgenic positive mice display significant impairment in memory performance in

the Passive Avoidance task as measured by the latency to enter the dark chamber and Novel Place Object, assessed by the Recognition Index. Applying chronic Theta-Burst fornix DBS during the 24 hours after the initial learning of Passive Avoidance and during 3.5 hours after the Novel Place Object first exposure to the objects had a rescuing effect on the memory impairment. We intend to examine the relationship between the stimulation, behaviour and theta oscillations in the hippocampus to elucidate the modulatory effect of fornix DBS on the memory network.

Title: Altered prefronto-hippocampal neural network dynamics in a murine model of Down syndrome during memory processing

Authors: M. ALEMANY, T. GENER, *M. PUIG;
IMIM -Hospital del Mar Med. Res. Inst., Barcelona, Spain

Abstract: Alterations in neural activity in the prefrontal cortex (PFC) and hippocampus (HPC) have been postulated as pathophysiological mechanisms underlying learning and memory deficits in mental disorders. However, it is still unclear if PFC-HPC miscommunication is behind cognitive impairment in intellectual disability. Down Syndrome (DS) is the most common genetic cause of intellectual disability and is modeled in Ts65Dn mice by a partial trisomy of the murine equivalent of human chromosome 21. Ts65Dn mice exhibit dendritic and synaptic abnormalities in the PFC and HPC and severe cognitive impairments in PFC- and HPC-dependent tasks. However, whether these cellular alterations affect neural network activity and PFC-HPC communication is still unknown. Interestingly, most of these DS phenotypes are rescued both in DS human subjects and Ts65Dn mice by Epigallocatechin-3-gallate (EGCG), the main component of green tea and potent inhibitor of DYRK1A, a serine/threonine kinase whose gene is triplicated in trisomy 21. Thus, it is of high translational value to understand the cellular

mechanisms underlying EGCG-mediated cognitive amelioration. To tackle this question, we have recorded neural network activity in the PFC and HPC of Ts65Dn mice performing the Novel Object Recognition (NOR) task before and after treatment with EGCG.
METHODS: Local field potentials were recorded in the PFC and HPC of freely-moving mice via tungsten stereotrodes with the Open Ephys data acquisition system during quiet wake, open field exploration, and the performance of the NOR task that evaluates short- (1h) and long-term (24h) memory. Ts65Dn mice and their wild-type littermates were treated orally with EGCG for one month and neural activity was recorded before, during and after the treatment.
RESULTS: Our preliminary results indicate that Ts65Dn mice show alterations in neural network dynamics affecting several frequency bands in both PFC and HPC and in PFC-HPC synchrony compared to controls. Particularly, Ts65Dn mice show decreased theta oscillations in the PFC but increased theta and gamma in the HPC. Moreover, PFC-HPC synchrony is increased at theta but decreased at beta and gamma frequencies. Importantly, one month of treatment with EGCG partly rescued these oscillatory alterations in the Ts65Dn mice, especially in the HPC. Ongoing analyses will determine the relevance of these effects for memory.
CONCLUSIONS: Our findings suggest that alterations in neural network dynamics in PFC and HPC and in PFC-HPC synchrony may underlie cognitive impairment in Ts65Dn mice. EGCG may ameliorate cognitive deficits both in DS subjects and Ts65Dn mice via its effect on the PFC-HPC neural network.

Title: Serotonin 5-HT1A and 5-HT2A receptors and antipsychotics modulate gamma and theta rhythms and prefronto-hippocampal connectivity in behaving mice

Authors: *T. A. GENER, M. ALEMANY, M. PUIG;
Integrative Pharmacol. and Systems Neurosci., IMIM -Hospital Del Mar Med. Res. Inst., Barcelona, Spain

Abstract: Patients with schizophrenia (SCZ) display cognitive impairment that correlates with alterations in brain oscillations. For example, gamma oscillations in frontal areas are reduced in SCZ patients relative to healthy subjects during the performance of executive tasks. Moreover, genetic murine models of SCZ suggest that an abnormal synchrony between the prefrontal cortex (PFC) and the hippocampus (HPC) may also account for the observed cognitive impairment. The main goal of this study is to determine the neural substrates of cognitive amelioration mediated by atypical antipsychotic drugs. Specifically, we have investigated the role of the serotonin system in the beneficial actions of atypical vs. typical antipsychotics on cognition. To do so, we have recorded neural oscillatory activity in the PFC and HPC of freely-moving mice performing a memory test while administering pharmacological agents and antipsychotics that activate or inhibit serotonin 5-HT1AR and 5-HT2AR. We report drug actions on PFC-HPC oscillatory activity and how this may account for memory amelioration mediated by atypical antipsychotic drugs.
METHODS: Local field potentials were recorded in the PFC and HPC of freely-moving mice via tungsten stereotrodes with the Open Ephys data acquisition system during 1) the exploration of an open field and 2) the performance of the novel object recognition test that evaluates short- (1h) and long-term (24h) memory. The following serotonin and antipsychotic drugs were administered i.p.: 5-HT1AR agonist 8-OH-DPAT, antagonist WAY100635; 5-HT2AR agonist DOI, antagonist M100907; atypical antipsychotics clozapine, risperidone; typical antipsychotic haloperidol.
RESULTS: Our results show that 5-HT1AR activation with 8-OH-DPAT markedly reduces theta and gamma oscillations in the PFC and HPC, an effect reversed by WAY100635. Similar results were observed with clozapine, risperidone and haloperidol along with an exacerbation of delta waves; however, this was not reversed by WAY100635. This suggests that antipsychotic actions on PFC-HPC oscillations may not be mediated by 5-HT1AR during alert states, a result unexpected for clozapine. Moreover, 8-OH-DPAT increased PFC-HPC functional connectivity (Pearson´s correlation) at gamma ranges. M100907 also reduced theta and gamma PFC-HPC oscillations and exacerbated delta waves. Ongoing analyses will determine the relevance of these effects for memory.
CONCLUSIONS: 5-HT1AR and 5-HT2AR in the PFC and HPC exert strong influences on gamma and theta oscillations and PFC-HPC connectivity. However, their involvement in antipsychotic-mediated effects needs further elucidation.

Title: Quantitative EEG as a tool for monitoring efficacy of putative cognitive enhancers: Preclinical investigation

Authors: *S. DARIPELLI, V. BENADE, G. AYYANKI, V. KAMUJU, G. BHYRAPUNENI, R. NIROGI;
DMPK, Suven Life Sci. Ltd, Hyderabad, India

Abstract: Quantitative electroencephalography (qEEG) is an important tool in quantifying changes in the brain activity. In animal models of cognition, synchronous EEG activity observed in a frequency range of 4 to 8 Hz (Theta) and 30 to 50 Hz (gamma) has been associated with cognitive enhancement. Neurological diseases such as Alzheimer's disease (AD) often affect the complex neuronal network by degeneration of neurons, resulting in a "slowing" of the EEG signal which corresponds to increase of low-frequency spectral power bands and a decrease of higher-frequency bands. If these theta and gamma oscillations are associated with mnemonic or cognitive function, qEEG can be used a potential biomarker for the cognition-enhancing drugs regardless of their primary biological target.
Theta modulation studies were conducted in urethane anesthetized rats and mice. Electrical stimulations were applied to the nucleus pontis oralis and power of oscillatory activity was measured in hippocampus CA1 region. Modulation in oscillatory gamma activity in freely moving animals was measured using telemetric device (Data Sciences International). In the current study, we evaluated several drugs that were shown to have effect on the cognition in preclinical behavioral models.
Acetylcholinesterase inhibitor, donepezil, and muscarinic receptor selective positive allosteric modulator induced increases in the low frequency bands like theta in anesthetized animals and gamma oscillatory power in freely moving animals. The nonselective muscarinic acetylcholine receptor antagonist, scopolamine decreased the power of theta and the gamma oscillatory power in anesthetized and freely moving animals, respectively.
These results support that qEEG could be an effective biomarker for the evaluation of potential putative cognitive enhancers in the treatment of Alzheimer's disease.

Title: Impairments in spatial memory representations in freely moving 3xTg mice

Authors: *A. J. MABLY, D. T. JONES, B. J. GEREKE, L. L. COLGIN;
Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

Abstract: Spatial memory impairments are both a clinical feature of Alzheimer's disease (AD) and a characteristic common to many mouse models of AD. The hippocampal formation, and particularly hippocampal place cells, are thought to be essential for correct cognitive representation of spatial information. Consequently, it could be speculated that improper formation of place cells' spatial receptive fields (place fields), or instability of these fields over time contributes to the spatial memory impairments seen in AD. To assess whether place cell activity was aberrant in an AD mouse model, we recorded from hippocampal subfield CA1 of 3xTg and wildtype (Wt) mice whilst they traversed a familiar circular track. Mice ran three 10 minute sessions a day and place fields were compared across trials within each day. Place field locations and firing rates were significantly less stable across sessions in 3xTg mice compared to Wt mice. In addition, place cells in 3xTg had lower spatial information content than those of Wt mice. Furthermore, rhythmic coordination of place cell spiking was altered in 3xTg mice. These results indicate a disruption in the cognitive representation of space in an AD mouse model and, with further investigation, may provide insights into the cellular mechanisms of spatial memory impairments in AD.

Title: Experience-dependent trends in the CA1 cross spectrum revealed by a generalized additive mixed model

Authors: *B. J. GEREKE[1], A. J. MABLY[2], L. L. COLGIN[2];
[1]Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX; [2]Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: Understanding how coordinated interactions among neurons represent information that supports learning, memory, and behavior is a central goal of neuroscience. Insight into these interactions can be gained by studying both spiking neurons as well as the local field potential (LFP), which is usually taken as a signature of neuronal population activity. Spiking data is commonly studied using multivariate regression methods, such as the generalized linear model (GLM). These models have had success identifying the relative importance of covariates associated with spiking such as sensory stimuli, animal behavior, intrinsic neuronal properties, and the spiking of other neurons. Despite their popularity with spike train data, however, applications of multivariate regression methods to LFP data remain surprisingly scarce. Here, we employ a generalized additive mixed model (GAMM), a nonparametric extension of the GLM, to study the LFP cross spectrum of hippocampal area CA1. The model is optimized for large data sets, typical of LFP data, and successfully identifies the relative importance of documented frequency-specific covariate effects (e.g., running speed, theta phase, etc.), along with their second-order interactions, while accounting for “random effects” that may be attributed to a particular animal and/or recording session. The GAMM framework also supports the investigation of temporal trends, which can be difficult to study using univariate methods. We identify how such trends change in a frequency-specific manner with a rodent’s experience running on a 1-dimensional track. Recordings were obtained as animals ran on the track three sessions per day for ~5-7 days. During the first few minutes of the second and third sessions of

each day, theta (6-12 Hz), slow gamma (25-55 Hz), and fast gamma (55-100 Hz) rhythms were all transiently elevated. However, in the first session of each day, this increase in slow gamma did not occur, whereas the increase in theta was stronger than in other sessions. Such experience-dependent changes in the LFP may have interesting implications for place field backward expansion, which displays similar trends (Mehta et al., PNAS, 94, 1997), as well as for memory in general.

Title: The correlation between gamma frequency and running speed in the dentate gyrus and CA2 of freely behaving rats

Authors: *C. ZHENG[1,2], Y.-T. HSIAO[1,2], L. L. COLGIN[1,2];
[1]Ctr. for Learning and Memory, [2]Dept. of Neurosci., Univ. of Texas At Austin, Austin, TX

Abstract: Slow (~25-55 Hz) and fast (~60-100 Hz) gamma rhythms are thought to represent distinct network processing states in the entorhinal-hippocampal network. Although gamma is maximal in the dentate gyrus (DG) region (Bragin et al., *J Neurosci* 1995), few to no studies have investigated slow and fast gamma rhythms in DG. Moreover, recent studies of place cells in CA2 (e.g., Mankin et al., *Neuron* 2015) have emphasized the importance of analyzing electrophysiological signals from CA2 separately from CA3 and CA1. Although little to nothing is known about gamma rhythms in CA2, a reasonable hypothesis is that gamma in CA2 resembles gamma in CA3, considering that CA3 projects to CA2. Here, we examined slow and fast gamma rhythms in DG (n = 4 rats) and CA2 (n = 3 rats). We focused our investigation on the relationship between running speed and gamma frequency in DG and CA2. Previous work has shown that frequencies of slow and fast gamma rhythms in hippocampal subfields CA1 and CA3 show different correlations with running speed (Zheng et al., *Hippocampus* 2015). Slow gamma frequencies do not change much with running speed, whereas fast gamma frequencies increase significantly as a function of running speed. New results from DG were similar to

previous CA3 results. Specifically, DG slow gamma power was maximal at relatively low running speeds, and slow gamma frequencies did not change much with running speed. Also, as in CA3, DG fast gamma frequencies increased with increasing running speed, and DG fast gamma power was low when rats ran at speeds exceeding ~25 cm/s. As was the case in other hippocampal subfields, CA2 slow gamma power was maximal at relatively low running speeds, and CA2 slow gamma frequencies were not strongly affected by running speed. However, in contrast to DG and CA3, CA2 power in the fast gamma range strongly increased at running speeds greater than ~25 cm/s. These results suggest that slow and fast gamma in DG and CA3 may be functionally similar and additionally reveal another electrophysiological feature that distinguishes CA2 from other hippocampal subfields.

Title: Social investigation of conspecifics and robots: oscillatory neural dynamics

Authors: *E. J. LEONARDIS[1], S. HEATH[2], J. WILES[2], A. A. CHIBA[1], L. K. QUINN[1]; [1]Cognitive Sci., UC San Diego, San Diego, CA; [2]Univ. of Queensland, Brisbane, Australia

Abstract: Social interactions are a critical feature of most animals' lives, and are key to learning and survival. Rodents show many types of social behaviors including following, mirroring, wrestling, and sniffing. Rats reliably show selectivity in social behavior, behaving differently toward novel or familiar conspecifics. Recent studies have shown that rats will also engage in complex social behaviors with robotic social partners. Here we attempt to shed light on the brain signatures underlying social recognition, whether to a conspecific or a robot. Social recognition is a complex chemosensory process that can be empirically studied by habituation-dishabituation paradigms. These paradigms have reliably shown that rats will persistently investigate a novel conspecific for longer periods of time than a familiar conspecific. After being habituated to a conspecific, each rat was presented with two enclosures containing either a familiar conspecific

or a novel one. A second condition included repeating the task, using novel and familiar robots. A control condition included an additional repetition of the task using novel and familiar objects. Local field potentials were recorded from an anatomical circuit in the rat that is critical for social processing: main olfactory bulb (MOB), CA2 subregion of the hippocampus, and medial amygdala (meA). These regions have been associated with social recognition, predator identification, sexual behavior, and processing odor signals. Our recordings investigated oscillatory phase coupling in this circuit during social investigation, as a means of understanding the circuit dynamics that support social recognition. Characteristic patterns emerged, indicating that engaging in the social recognition task recruits the circuit. For example, theta phase coupled gamma oscillations in MOB show a significant increase in amplitude during novel social investigation. There are also identifiable differences of phase coherence between theta oscillations in MOB, meA, and CA2 during social investigation of conspecific, robot, and object. In addition to the primary findings, this study demonstrates how robots can be used as a feasible control to help isolate socially relevant neural dynamics.

Title: Transformation of independent oscillatory inputs into temporally precise rate codes.

Authors: ***D. A. NITZ**[1], D. TINGLEY[2], A. ALEXANDER[3], L. QUINN[3], A. CHIBA[3];
[1]Univ. of California San Diego, La Jolla, CA; [2]Neurosci., New York Univ., New York, NY;
[3]Cognitive Sci., UCSD, La Jolla, CA

Abstract: The basal forebrain's afferent and efferent structure suggests a capacity for mediating temporal coordination of activity in functionally distinct brain regions during the execution of complex behavioral sequences. To examine the role of basal forebrain (BF) in such a process, we recorded local field potentials and multiple single neuron spiking activity in the ventral pallidal and substantia innominata sub-regions of basal forebrain during performance of a selective attention task. Local field potentials provided a measure of the temporal organization of basal forebrain inputs while spiking activity patterns among basal forebrain ensembles provided a

measure of its output. Both types of neural signals were examined for their dynamics across the full set of task epochs. In addition, analyses specifically addressed the relationships between local field potential and spiking dynamics in order to detect potential input/output transformations of the basal forebrain. BF field potentials were dominated by four amplitude-independent oscillations. The higher frequency oscillations, beta (20-35 Hz), gamma (45-65 Hz), and hi-gamma (80-150 Hz) occurred as transient events and were temporally organized by the phase of the slowest, a theta rhythm (5-9 Hz). The latter finding strongly suggests that the BF theta rhythm may be responsible for sequencing higher frequency transients through time. Both features of the local field potential are consistent with time-division and frequency-division models for decoding incoming multiplexed signals. Finally, oscillations in each frequency range exhibited robust changes in amplitude as a function of task epoch. Spiking activity for a large sub-population of BF neurons was robustly phase locked to one or more of the observed LFP frequency bands. As shown in prior work, spike rates for individual neurons were strongly correlated to one or more specific task epochs and the population as a whole produce a ensemble firing rate vector for each task epoch. Trial-to-trial variation in oscillatory amplitudes were strongly correlated to spike rates of individual neurons identifying a mechanism by which oscillatory inputs can be transformed into spike rate codes. Finally, similar to observations for hippocampal place cells, spiking activity across task epochs precessed in phase against the ongoing theta-frequency local field potential oscillation. Together, the findings reveal a process by which associative brain regions such as BF can integrate independent oscillatory inputs and transform them into sequence-specific, rate-coded outputs that are adaptive to the pace with which organisms interact with their environment.

Title: Small conduction delays induce global synchrony in sparsely but strongly connected inhibitory networks.

Authors: *C. C. CANAVIER[1], R. A. TIKIDJI-HAMBURYAN[2];
[1]Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [2]George Washington Univ., Washington, DC

Abstract: Inhibitory interneuronal networks have been shown to mediate gamma oscillations that in turn are hypothesized to underlie many cognitive functions. We simulated an inhibitory network of 300 Hodgkin-Huxley neurons using the simulation package NEURON to successfully test the predictions of phase resetting theory under the assumption that the coupling is pulsatile but not necessarily weak. We extended our previous analysis of synchrony and antiphase in two neuron networks with conduction delays to global synchrony and a two-cluster mode in large all-to-all coupled networks. We generated the phase resetting curve (PRC) of a single self-connected neuron with delayed feedback equal to half the connections in the network, and using a perturbation equal to the IPSP received from the other half of the connections in the network. Using these PRCs, we analyzed a two-cluster analog of the network and show that in cases of bistability between global synchrony and a two-cluster mode, phase resetting theory under pulsatile coupling assumptions can predict the basins of attraction that determine which mode is dominant. The results are valid even in cases in which the individual interneurons are not spontaneous pacemakers, but display post-inhibitory rebound (PIR) that supports a network oscillation that is self-sustaining once it has been initiated by a strong inhibitory input. Strong inhibition that induces PIR generally results in a monotonically increasing PRC with a sharp discontinuity at phases of 0 and 1. This discontinuity destabilizes global synchrony at zero delay, but small delays stabilize synchrony as long as the slope of the PRC is less than one. These delays also tend to prevent cluster solutions; we present the criteria for the minimum delay that guarantees global synchrony for this PRC shape. We further extend these methods from all-to-all to sparsely coupled networks by reducing the strength of the self-connection and the PRC-generating perturbation in the two neuron analog of the network. We then show that in the presence of the jitter in spike timing introduced by sparse connectivity, attractors must have a minimum width in the parameter space of conduction delays in order to be robustly observed.

Title: Mechanisms of spike timing in a detailed computer model of a medial entorhinal cortical stellate cell

Authors: *M. J. BEZAIRE, M. E. HASSELMO;
Psychological & Brain Sci., Boston Univ., Boston, MA

Abstract: Stellate cells of the rat medial entorhinal cortex are known to exhibit distinct spike timing in response to patterned inputs, a characteristic likely important for coding position in putative grid cells. For example, when receiving input sufficient to observe the membrane potential theta-ramp oscillation associated with spatial navigation, the spike timing appears more consistently related to the theta phase of membrane potential oscillation than the voltage at which the spike is initiated (Domnisoru et al, 2013, Figure 4a). The extent to which this spike timing is influenced by intrinsic properties of the stellate cell versus phasic network inputs is unknown. Here we explore, using a detailed, biologically constrained computational model of a medial entorhinal cortical stellate cell, the extent to which various intrinsic properties and afferent inputs can influence the timing of stellate cell spikes during the theta-ramp regime. Our stellate cell model contains several ion channel types including HCN current, as well as detailed dendritic morphology and realistic synaptic inputs (Giocomo and Hasselmo, 2008; Heys et al, 2010, 2012; Pastoll et al 2012; Tsuno et al, 2015; Shay et al, 2015; Ferrante et al, 2016). We first validate our stellate cell model, showing its relevance to biological stellate cells in a variety of conditions, before systematically manipulating the stellate cell model to determine the dominant mechanisms that control its spike timing. The results of the simulations suggest an important role for subthreshold, intrinsic currents in setting the spike timing of stellate cells during spatial navigation. These results may guide future in vitro and in vivo experiments and can also inform future computational network models of grid cell formation.

Title: State dependence of directional interactions between basal forebrain and visual cortex in theta and gamma band local field potentials

Authors: *A.-L. KLAASSEN[1], J. NAIR[1], J. POIROT[1], A. VYSSOTSKI[2], B. RASCH[1], G. RAINER[1];
[1]Univ. of Fribourg, Fribourg, Switzerland; [2]Univ. of Zurich, Zurich, Switzerland

Abstract: The basal forebrain (BF) is an important regulator of cortical excitability and responsivity to sensory stimuli, and plays a major role in wake-sleep regulation. While the influence of the BF on EEG or LFP signals in the cortex has been extensively documented, relatively little is known about local field potential (LFP) activations within the BF.
Here we describe endogenous LFP oscillations in the basal forebrain during wakefulness, REM and SWS states that were recorded using a miniature wireless device during these different behavioral states while animals were in their home cage. Based on bilateral recordings from BF and the visual cortex (VC), we performed coherence and Granger causality analyses to study behavioral state dependent directional influences between the BF and visual cortex (VC).
We found robust gamma activity particularly during wakefulness, as well as to a lesser extent during SWS and REM. In each of the behavioral states there were robust peaks in the gamma band, each with a distinct peak oscillation frequency. Whereas gamma band directional impact of VC on the BF was negligable, we observed a pronounced directional influence of BF on the VC during wakefulness and SWS. The opposite was the case in the theta band, where we observed bidirectional influence between the two brain regions with a predominant component from VC onto the BF during REM and wakefulness.
Our evidence suggests that while gamma band effects were regulated specifically within each brain hemisphere, theta band activations were coordinated globally across both hemispheres. We report novel aspects of endogenous BF LFP oscillations and their relationship to cortical LFP signals during sleep and wakefulness. We link our findings to known aspects of the heterogeneous BF networks underlying the LFP activations, show that the Granger causality analyses can faithfully recapitulate many known attributes of these networks.

Abstract: Decoding mental content from brain activity is one of the challenging goals in neuroscience. In this study, we attempted to decode recalled color imagery using ECoG signals in the macaque cerebral cortex. We implanted 128- and 64-channel ECoG electrode arrays with a 2.5-mm spaced grid configuration on the inferior temporal and prefrontal cortices (ITC and PFC), respectively, which are known to be important for memory recall. Two monkeys were trained to perform a color recall task. In the task, an achromatic cue stimulus was presented, and after an interval, 1-2 colored shapes were sequentially presented as choice stimuli. The monkeys were required to release a lever upon the presentation of correctly colored choice that was associated with the cue, to receive a reward. We used two different types of cues: (1) scene images, and (2) Fourier descriptors. The monkeys were supposed to recall and maintain the color imagery until the choice behavior. Using the spectral powers of ECoG signals in different frequency bands as input features, we constructed a linear support vector machine classifier to predict the presented cue on a trial-by-trial basis. We found that the classifiers successfully predicted the cue from ECoG powers either in the ITC or PFC. Theta-band (4-8 Hz) powers provided the best classification performance. Next, to examine the classifier performance for recalled color imagery, but not for cue information, we calculated the generalization performance of classifiers across tasks using different cues: we trained a classifier on the data set from tasks using one type of cues (scene images) and tested them on a data set from tasks using another type of cues (Fourier descriptors) and vice versa. The result showed that even across tasks using different cues, the classifiers, constructed from theta-band powers in the PFC during or just after the cue presentation, successfully predicted the monkey's color choice. However, the classifiers

from ECoG signals in the ITC failed to predict the color choice. Because the successful classification from ECoG signals in the PFC was enabled prior to the monkey's choice behavior, this classification should be based on the pattern of ECoG signals specific to the recalled color imagery. A cortical surface-based searchlight decoding approach revealed that the channels with higher classification performance in the theta-band powers were localized in the focal regions in the PFC. Our results demonstrated that ECoG recoding potentially provides a method to read out memory content.

Title: Fimbria fornix stimulation parameters determine oscillations coupling of the prefrontal cortex and hippocampus

Authors: ***V. LUO**, M. L. SHAPIRO;
Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Specific patterns of neural oscillations are associated with many cognitive processes, including learning and memory, and the synchrony of oscillations among different brain regions may represent signaling and communication between those regions. Alterations in oscillations in the theta and gamma frequency bands have been linked to memory impairment and dysfunction in brain diseases and disorders such as Alzheimer's and schizophrenia. Different studies report conflicting results, so that the same electrical stimulation protocol can either improve or impair memory performance in people and animal models including rats. We hypothesized that stimulation parameters even within the same operationally defined category, e.g. theta burst stimulation, alter oscillation patterns across structures that ultimately determine their functional effects. To test this hypothesis, we varied the magnitude and temporal patterning of fimbria fornix (FFx) electrical stimulation in behaving rats. Stimulation electrodes were implanted in the FFx and recording electrodes were placed in both the medial prefrontal cortex (mPFC) and hippocampus. We varied the duration, frequency, and amplitude of current delivery and analyzed

local field potentials (LFPs) before, during, and after stimulation using custom-written Matlab (MathWorks) code and the Chronux toolbox (www.chronux.org). Preliminary results show that FFx stimulation modulated the amplitude and phase relationship of theta LFPs (4-12 Hz) in CA1 and mPFC, and that they varied with stimulus type, duration, and magnitude. Strong theta burst stimulation (>300 uV) increased the synchrony and reduced the phase differences between mPFC and hippocampal theta LFPs. Future experiments will vary patterned stimulation to determine how different stimulation parameters alter cognitive performance in memory tasks.

Title: Learning stages in a rule switching task affects theta-gamma couplings in rat hippocampus

Authors: *T. NAKAZONO[1,3], S. TAKAHASHI[2], Y. SAKURAI[1];
[1]Lab. of Neural Information, [2]Lab. of Neural Circuitry, Grad. Sch. of Brain Science, Doshisha Univers, Kyoto, Japan; [3]Dept. of Psychology, Kyoto Univ., Kyoto, Japan

Abstract: Hippocampal oscillations, particularly theta (6-12 Hz) and gamma (30-100 Hz) bands, play important roles in several cognitive functions. Theta and gamma oscillations show cross-frequency coupling (CFC), and the theta rhythm phase can modulate the amplitude of gamma oscillations. This phase-amplitude modulation is thought to have several cognitive roles, e.g., sensory signal detection, attention and memory processes. Previous studies found that the strength of CFC correlated with task performance during learning. To explore this correlation in more detail, we recorded local field potentials from the hippocampus of rats while they were performing a rule-switching task. In the task, rats had to choose a correct hole by using presented cues. Two types of cues (light and tone) were presented at the same time, however only one type of the cues was valid, and the other was distractor. The cue type indicating correct holes was

fixed through a session and we call such valid cue type "rule" in this task. Once the rats had learned the rule and their performance reached the criterion, the rule was changed to the other and the rats should learn the new one. The modulation index (MI), an index of the strength of CFC, showed event related changes during the rats was performing in learning trials. However these changes did not appear in control (no learning) trials. This result suggests that the coupling between theta and gamma bands in the hippocampus is engaged in rule learning. Next, we examined changes of MI through stages of learning. Our data suggested that the coupling between theta and high-gamma oscillations increased in early learning stage, but such change did not occur in late learning stage. Furthermore, the coupling between theta and low-gamma oscillations did not show these changes. These results suggest that high-gamma and low-gamma oscillations play different roles in rule switching, and process of trial and error affects the coupling between theta and high-gamma oscillations.

Title: Hippocampal theta across its areal axis: predicting, preparing or manipulating future locomotor speed?

Authors: *L. L. LONG[1], I. H. STEVENSON[1,2], M. A. ESCABI[2,3], J. J. CHROBAK[1]; [1]Psychology, [2]Biomed. Engin., [3]Electrical and Computer Engin., Univ. of Connecticut, Storrs, CT

Abstract: The hippocampal theta rhythm is a model system for understanding the temporal organization of neuronal discharge and ensemble communication within and across brain structures. While there have been significant advances in understanding the underlying neurobiology of this rhythm, the relationship of theta to emergent function continues to present a challenge. The present study exposed rodents to environments hypothesized to produce polarized locomotor-theta correlations and we examined dynamic changes in the relationship between theta amplitude and locomotor speed along the longitudinal axis of the hippocampus, as well as the entorhinal cortex. Using cross-correlation analyses between instantaneous theta amplitude and locomotor speed, we demonstrate that during open field navigation septal hippocampal theta

is instantaneously related to locomotor speed. In contrast, during navigation in a linear track, septal and entorhinal cortical theta was highly prospective and preceded changes in overt behavior by hundreds of milliseconds. Further, this time lag relationship systematically decreased across the long axis of the hippocampus. Changing open field task demands, which required linear track-like behavioral output, systematically increased the time lag between speed and theta over days. These results indicate that behavioral output as dictated by prediction of food reward location can strongly modulate speed-theta dynamics allowing the hippocampus and entorhinal cortex to engage in predictive or instantaneous integration of sensorimotor information. The results are interpreted with respect to models of hippocampal function emphasizing neuronal network dynamics that allow for the integration of incoming sensory experience with neural predictions of future sensorimotor experience.

Title: Diffusion-mapped delay coordinates characterize attractor clustering in hippocampal network dynamics during spatial navigation

Authors: *D. G. MCHAIL[1], T. BERRY[2], J. R. CRESSMAN[3], T. C. DUMAS[4];
[1]Dept. of Mol. Neuroscience, Krasnow Inst. for Advanced Study, [2]Dept. of Mathematical Sci., [3]Dept. of Physics and Astronomy, [4]Mol. Neurosci. Dept., George Mason Univ., Fairfax, VA

Abstract: The hippocampus resides within a cortical neural network that provides a geometric reference frame for spatial navigation. In rodents, hippocampal pyramidal cells code for specific locations in a testing environment, termed place cells. Place cell activity can be decoded to reliably predict animal position and intended path. Therefore, much attention has focused on spiking activity in place cell networks. While the animal is immobile, transient discharge events during sharp-wave ripples (SWRs, 100-250 Hz) code for the most recently taken route or prospectively map the next intended path, termed "trajectory events." During mobile execution of the intended trajectory, place cell spiking precedes the animal's movement, termed "look ahead." Trajectory events and look ahead are coordinated by hippocampal population oscillations

in the slow gamma (25-50 Hz) and theta (4-12 Hz) bands, respectively. These bands are typically analyzed in isolation. However, an understanding of additional relationships between theta, gamma, and SWRs during spatial navigation behaviors may provide greater insight into how patterned discharge events that relate to past or future behaviors emerge. Diffusion mapped delay coordinates (DMDC) is an algorithm for reconstructing dynamical attractors from data using time-delay embedding and diffusion maps. By estimating the most stable component of the dynamics of high dimensional time series data the algorithm can be used to discriminate and quantify distinct dynamical states. It is therefore well suited for identifying dynamics in local field potentials (LFPs). In this work, Long Evans rats were implanted at postnatal day (P) 14 with bipolar stereotrodes terminating in the radiatum of hippocampal area CA1. LFP activity was recorded in synchrony with overhead video at P24 as the animals engaged in spontaneous alternation behavior in a Y-maze. Analysis of LFP data using DMDC revealed distinct dynamical states that were related to specific maze behaviors. Closer investigation of these states allowed characterization of attractor dimension. The dimension quickly converged for epochs corresponding to deliberation at a choice point, while grooming epochs took an additional order of magnitude to converge. On average, a higher dimension attractor was found during center deliberation behavior vs. grooming. Continuing analyses will assess the differential dimensionality of CA1 oscillatory activities during alternation vs. non-alternation choices as well as arm exploration. As spatial navigation ability emerges around P21 in rodents, LFP dynamics just under vs. just over P21 will also be investigated.

Title: Memory-guided drawing training increases Granger causal influences from the perirhinal cortex to V1 in the blind

Authors: *L. CACCIAMANI, L. T. LIKOVA;
Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: The perirhinal cortex (PRC) is a medial temporal lobe structure that has been implicated in not only visual memory in the sighted, but also tactile memory in the blind

(Cacciamani & Likova, 2016). It has been proposed that, in the blind, the PRC may contribute to modulation of tactile memory responses that emerge in low-level "visual" area V1 as a result of training-induced cortical reorganization (Likova, 2012; 2015). While some studies in the sighted have indicated that the PRC is indeed functionally and structurally connected to the visual cortex (Clavagnier et al., 2004; Peterson et al., 2012), the PRC's direct modulation of V1 is unknown—particularly in those who lack the visual input that typically stimulates this region. In the present study, we tested Likova's PRC modulation hypothesis; specifically, we used fMRI to assess the PRC's Granger causal influence on V1 activation in the blind during a tactile memory task. To do so, we trained 8 congenital and acquired blind participants on a unique memory-guided drawing technique previously shown to result in V1 reorganization towards tactile memory representations (Likova, 2012). The tasks (20s each) included: tactile exploration of raised line drawings of faces and objects, tactile memory retrieval via drawing, and a scribble motor/memory control. FMRI before and after a week of training on these tasks revealed a significant increase in PRC-to-V1 Granger causality from pre- to post-training during the memory drawing task, but not during the motor/memory control. This increase in causal connectivity indicates that the training strengthened the top-down modulation of visual cortex from the PRC. This is the first study to demonstrate enhanced directed functional connectivity from the PRC to the visual cortex in the blind, implicating the PRC as a potential source of the reorganization towards tactile representations that occurs in V1 in the blind brain (Likova, 2012).

Title: Aerobic fitness and hippocampal subfield volume in young adults

Authors: *M. F. DUNNE[1], R. K. NAUER[2,3], K. SCHON[1,3,2];
[1]Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA; [2]Psychological and Brain Sci., [3]Ctr. for Memory and Brain, Boston Univ., Boston, MA

Abstract: Studies in both humans and rodents highlight a relationship between aerobic fitness, exercise, and hippocampal neuroplasticity. This relationship is postulated to be driven by adult neurogenesis, which occurs in the dentate gyrus (DG) subregion of the hippocampus. Animal studies have shown that aerobic exercise is a potent stimulator of cell proliferation and neurogenesis in the DG. While current limitations of neuroimaging in humans prevent directly measuring the rate of neurogenesis in the living human brain, aerobic fitness and hippocampal volume have been shown to display a positive correlation across the human lifespan. However, there is currently no evidence of an association between aerobic fitness and hippocampal subfield volume in young adults. With the use of high-resolution (0.4 x 0.4 x 2.6mm^3) T2-weighted structural magnetic resonance imaging, hippocampal subfields (subiculum, CA1, and DG/CA3) and medial temporal lobe (MTL) cortices (entorhinal, perirhinal, and parahippocampal) were manually segmented in 20 young adults (mean age 25.6 ± 4.4) of varying aerobic fitness. To determine fitness levels, participants performed a submaximal, graded incremental treadmill test following a modified Balke protocol to estimate VO_2 max, which was then converted to fitness percentile using ACSM norms based on age and gender (median 55th percentile). Hippocampal subfield and MTL cortex volumes were corrected for differences in intracranial volume, which was measured by manually traced mid-sagittal intracranial area. Based on the previous literature, we hypothesized that DG/CA3 and entorhinal cortex would both exhibit a positive correlation with fitness percentile. Preliminary results showed no correlation between entorhinal cortex volume and fitness or total hippocampal volume and fitness in contrast to previous work from our lab and others. However, as predicted at the subfield level we observed a significant positive correlation between DG/CA3 and fitness. Conversely, we found a significant negative correlation between CA1 and fitness. The opposing associations between subfields CA1 and DG/CA3 with fitness explain the lack of a relationship between fitness and total hippocampal volume. Our results extend previous work in humans to the hippocampal subfield level, and are in line with animal models showing that the DG/CA3 region selectively responds to exercise.

Title: The influence of adolescent hippocampal volume and functional connectivity on memory performance: a cross-sectional investigation from the Dev-CoG project

Authors: *D. E. WARREN[1], A. RANGEL[2], J. M. STEPHEN[3], V. D. CALHOUN[3], Y.-P. WANG[4], T. W. WILSON[1];
[1]Neurolog. Sci., Univ. of Nebraska Med. Ctr., Omaha, NE; [2]Creighton Univ., Omaha, NE; [3]The Mind Res. Network, Albuquerque, NM; [4]Biomed. Engin., Tulane Univ., New Orleans, LA

Abstract: Hippocampus is known to be necessary for normal declarative memory, but the effects of adolescence on hippocampal volume, function, and related cognitive processing are not well characterized. Although relatively little is known, adolescence is predicted to be associated with significant changes in the volume and/or functional connectivity of hippocampus because of substantial differences in declarative memory performance between children and adults. The Developmental Chronnecto-Genomics project (Dev-CoG) is an ongoing NSF-funded effort to better understand adolescent brain changes and will conduct repeated structural and functional MRI scans of the brains of 230 children (9-15 years of age). Here, we report preliminary findings from the current Dev-CoG dataset, which provide an opportunity to investigate adolescent changes in hippocampus and cognition. Based on neuroimaging and neuropsychological data collected from children and adolescents (N=60, age=9-15) for the Dev-CoG project, we performed a cross-sectional analysis of the developmental course of hippocampal volume and resting-state functional connectivity (rs-FC) as well as behavioral performance on a measure of declarative memory. The test of declarative memory was the NIH Toolbox Picture Sequence Memory Test. Hippocampal volume was measured through manual tracing of the hippocampus from T1 MRI (1×1×1 mm). These hippocampal masks were next used as seed regions for an exploratory whole-brain analysis of hippocampal rs-FC. Resting-state fMRI (rs-fMRI) data were collected using two identical multiband sequences (one eyes-open, one eyes-closed): voxel size, 3.3×3.3×3.0 mm; TR, 460 ms; TE, 29 ms; duration, 306 s (i.e., 650 measurements). Standard functional MRI preprocessing was applied to the rs-fMRI data followed by best-practices processing for rs-FC analyses (Power et al., 2014), including warping of individual data to appropriate atlas space for group analysis. We evaluated age-related changes in these measures of memory performance, hippocampal volume, and seed-based hippocampal rs-FC as well as the interrelated changes in these measures with age. The results provide evidence that adolescent brain development exerts selective effects on memory, hippocampus, and a broader network of brain regions supporting memory and depends on several factors. By evaluating the volumetric, functional, and behavioral consequences of adolescent brain development for hippocampus, this study addresses an important gap in our current understanding of how memory systems develop and further motivates the longitudinal collection of large datasets from child and adolescent populations.

Title: 3T hippocampal metabolites reflect verbal memory decline in aging

Authors: S. NIKOLOVA[1], S. STARK[1], *C. E. STARK[2];
[1]Univ. of California, Irvine, Irvine, CA; [2]Univ. of California Irvine, Irvine, CA

Abstract: The hippocampus experiences a variety of structural and functional alterations that are involved in age-related (and dementia-related) changes in memory. Here, we used short echo time magnetic resonance spectroscopy (MRS) to investigate the age-related changes in metabolite levels in 41 volunteers (20 younger, aged 20-35 and 21 older aged 59-74) and to determine whether metabolite levels correlated with performance on standard neuropsychological tests. ^{1}H spectroscopy data were acquired at the 3T Philips MRI using short echo time PRESS (TR/TE = 2000/37 ms), from a 2.5x1.5x1.0 cm^3 voxel in the left and right hippocampi of all subjects. Voxel dimensions were chosen to maximize the volume largely contained within the hippocampus of each subject. No significant age-related differences were observed bilaterally for Creatine (Cr), N-Acetyl-Asparate (NAA), a combined score for Glutamate and Glutamine (Glx), or Choline (Cho). There were clear age-related declines on cognitive assessments including the Rey-Auditory-Verbal Learning Task (RAVLT) and Trails B. In examining the relationship between metabolites and cognitive performance, an ANCOVA revealed that these two cognitive scores accounted for the variance in metabolite concentrations. Specifically, we found that there was a strong positive correlation between Glx and RAVLT in the whole population. This relationship appeared to be driven by the aged participants, however, as they showed a reliable correlation here ($p=0.06$) while young participants did not ($p=0.6$). A similar pattern, albeit less robust and showing a negative correlation, was found with left hemispheric Cho and Trails B. Furthermore, 14 of the aged adults had previous RAVLT scores from 3-5 years previously (using an alternate version of the task). In this group, we found that right hemispheric Cr and Glx correlated with the difference in RAVLT delayed recall scores over time. Glx was shown to correlate negatively with declining performance, whereas Cr showed evidence of an increase with cognitive decline. These data suggest that MRS measures may be useful in predicting age related verbal memory decline before any physical abnormalities are present.

Title: A longitudinal lifespan study of diffusivity changes in limbic tracts and decline of episodic memory in normal aging

Authors: *Z. SONG, D. C. PARK;
Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX

Abstract: Episodic memory (EM) is particularly vulnerable to aging. White matter tract integrity in the hippocampus-centered memory network is essential to maintain normal episodic memory. Here we investigated in a lifespan sample (aged 20-89, N=199) changes in the fornix and parahippocampal cingulum, two major limbic tracts connected to the hippocampus, and their relationships to EM decline. Diffusion tensor imaging (DTI) and EM performance of cognitively normal adults were studied at two time points (Time 1 & 2) spaced roughly 3.5 years apart in the Dallas Lifespan Brain Study. ROI-based DTI analyses were conducted on the fornix and parahippocampal cingulum based on the ICBM-DTI-81 white matter atlas. The major findings with respect to age-related changes in white matter were as follows: (a) radial diffusivity (RD) of the fornix increased in middle-aged adults from Time 1 to Time 2 (aged 40 to 59, N=62, t=3.20) but not in the young adults (aged 20-39, N=49). The increase was more prominent in older adults (aged 60 to 89, N=88, t=12.23); (b) RD of the parahippocampal cingulum increased in older adults (t=5.47) but not in the middle or young age; (c) axial diffusion (AD) of both tracts increased in older adults (t>3.50) but not in the middle or young age. Most important were the analyses that examined the effect of age and diffusivity changes in these two limbic tracts on EM change, for which global diffusivity change of major white matter tracts in the brain was controlled. Our results indicated that (a) within the elderly group (aged 60 to 89), there was a main effect of RD change of fornix (t=-2.43, p=0.02) and its interaction with age (t=2.00, p=0.05) because that RD change was more strongly related to EM change in the younger elderly compared to the oldest; (b) a similar main effect of AD change of the fornix (t=-2.20, p=0.03) and its marginal interaction with age (t=1.79, p=0.08); (c) for young and middle-aged adults, change in neither RD nor AD of the fornix was related to EM change; (d) change in neither RD nor AD of the parahippocampal cingulum had an effect on EM changes in any of the three age groups. In summary, we found that increases in both RD and AD of the fornix were related to EM decline in cognitively normal elderly, with the effects more pronounced in the younger elderly. Increase in RD of white matter tracts is often related to myelin destruction.

Microstructural mechanisms underlying increases in AD is more complex but possibly related to axonal loss. Therefore our data suggest that degradation of white matter tracts of the fornix in aging may compromise hippocampal connectivity in the core memory network, which then leads to episodic memory decline.

Title: Hippocampal viscoelasticity mediates the benefits of aerobic fitness on memory in healthy young adults

Authors: *H. SCHWARB[1], C. L. JOHNSON[2], A. M. DAUGHERTY[1], C. H. HILLMAN[1], A. F. KRAMER[1], N. J. COHEN[1], A. K. BARBEY[1];
[1]Univ. of Illinois, Urbana, IL; [2]Univ. of Delaware, Newark, DE

Abstract: The relationship between cardiovascular fitness and better memory performance is well-established across the lifespan. Better cardiovascular fitness appears to harbor larger hippocampal volumes among developing children and may slow age-related shrinkage to confer better memory ability. Yet, evidence of this relationship among healthy young adults, for whom the hippocampus is neither developing nor atrophying, is less consistent. Volume, however, is a gross measure of structural integrity and the neural underpinnings of memory. In fact, microstrucutral differences in hippocampal integrity may exist even among healthy young adults when volumetric differences are not diagnostic of tissue health or cognitive function. Indeed we have previously reported a strong positive relationship between relational memory performance and hippocampal viscoelasticity, an index of microstructural integrity from magnetic resonance elastography (MRE); however, very little is known about health correlates to this novel measure. In the current study, we investigated (for the first time) the relationship between hippocampal viscoelasticity and cardiovascular health, and their mutual effect on relational memory in a group of healthy young adults (N=51). We replicated our previous finding that hippocampal viscoelasticity correlates with relational memory performance. We extend this work by demonstrating that better cardiorespiratory fitness, as measured by V02 max, was associated with hippocampal viscoelasticity that mediated the benefits of fitness on memory function.

Hippocampal volume, however, did not account for individual differences in memory. Therefore, these data suggest that hippocampal viscoelasticity may provide a more sensitive measure to microstructural tissue organization and its consequences to cognition, even among health young adults.

Title: Functional MRI of language and memory lateralisation for presurgical evaluation of paediatric epilepsy

Authors: *S. M. BUCK[1], T. BALDEWEG[2], D. W. CARMICHAEL[3], R. ELWARD[2], F. VARGHA-KHADEM[2];
[2]Cognitive Neurosci. and Neuropsychiatry, [3]Developmental Imaging and Biophysics, [1]Inst. of Child Hlth., London, United Kingdom

Abstract: Most studies using functional Magnetic Resonance Imaging (fMRI) in paediatric temporal lobe epilepsy (TLE) have focused on language lateralisation and neglected to assess memory. Early onset seizures interfere with the normal process of hemispheric lateralisation and may result in reorganisation of memory and language in paediatric patients. Impairments in memory and learning are frequently reported in TLE patients which is not surprising given that the hippocampus plays a major role in both the generation and spread of temporal lobe seizures and autobiographical and episodic long term memory. Such deficits significantly impact the quality of life and educational progress of the patients. We have developed an fMRI paradigm to assess recall memory, known to be dependent on the integrity of the hippocampus, and language, in children undergoing epilepsy surgery.
Functional MRI correlates of language and memory lateralisation were acquired on a 3T Siemens system in healthy volunteers. Language laterality was assessed through verb generation, where nouns were heard one at a time (one every 4.18 sec) and participants were to overtly

generate a verb for each noun (eg. hear "animal", generate "running"). Memory laterality was assessed through cued recall, where cues were presented to guide recall of previously encoded words (from the language task). Cues consisted of two-phoneme word stems created from the words heard (for example "aen" as a cue for "animal"). The baseline tasks involved a simple counting block and a rest block.
Block-wise comparisons for the language task demonstrate activations in posterior inferior frontal gyrus (Broca's area) and in superior temporal gyrus bilaterally (including Wernicke's area) ($p<0.05$ (FWE)). Similar analyses computed for the memory task demonstrate activations in the temporal lobe, including the hippocampi ($p<0.001$).
Our findings represent predicted brain activations in the language and verbal recall networks, and confirm the feasibility of assessing lateralisation of language and memory within the same session. These brain activations represent interacting networks of language and recall memory. Using this protocol, we evaluate (a) the interdependence of language and memory lateralisation, and (b) the status of those patients who may be at risk of memory impairment after temporal lobectomy.

Title: KIBRA polymorphism and hippocampus-associated integrity in middle age: a multi-modal neuroimaging investigation

Authors: *L. E. KORTHAUER[1], N. T. NOWAK[2], H. SCHERKENBACH[1], E. A. AWE[1], M. FRAHMAND[1], I. DRISCOLL[1];
[1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Winona State Univ., Winona, MN

Abstract: A single nucleotide polymorphism (SNP) in the *KIBRA* gene (rs17070145) has previously been associated with memory performance and hippocampal volume in older adults, consistent with reports that this SNP is a risk allele for Alzheimer's disease. The purpose of the present investigation was to characterize the relationships between a genetic polymorphism in *KIBRA* and hippocampus-related brain integrity in healthy, middle-aged adults, which may serve

as potential biomarkers of cognitive decline and dementia prior to any overt impairment. Participants (age 40-60, M = 49.9, N = 150) completed the hippocampus-dependent transverse patterning discriminations task (TPDT) and underwent a multi-modal neuroimaging paradigm including T1-weighted structural imaging, diffusion tensor imaging (DTI), magnetic resonance spectroscopy (^{1}H MRS), and resting state functional MRI. Measures of brain integrity included hippocampal volume, white matter (WM) microstructural organization, hippocampal biochemistry, and functional connectivity. Consistent with the literature (Papassatiropoulos et al., 2006), T allele carriers had marginally larger volumes of the right and left hippocampus (p's < .1). In addition, T allele carriers had higher fractional anisotropy (FA), lower mean diffusivity (MD), and lower radial diffusivity (RD), indicating better WM microstructural organization, in the right anterior thalamic radiation, right uncinate fasciculus, and right fornix. These pathways connect the hippocampus with other subcortical and cortical areas. Additionally, better microstructural organization was observed in the genu and body of the corpus callosum and right superior longitudinal fasciculus. T carriers also had higher concentrations of glutamate (Glu) in the left hippocampus (p = .03), consistent with the role of this excitatory neurotransmitter in facilitating episodic memory (Rupsingh et al., 2011). Associations with functional connectivity were not significant. This pattern of better hippocampus-associated structural brain integrity and related WM pathways among T allele carriers was associated with better performance on the TPDT (p's < 0.01). Collectively, these findings suggest a relationship between *KIBRA* polymorphism and hippocampus-associated memory and structural integrity in middle age, decades before the onset of cognitive decline.

Title: Using eye movements to dissociate memory performance in normal and pathological aging

Authors: *J. K. BLUJUS, C. M. KAIVER, E. I. GRACIAN, K. J. JENNETTE, D. E. HANNULA, I. DRISCOLL;
Psychology, Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: Alzheimer's Disease (AD) is a progressive neurodegenerative disorder characterized by cognitive decline, particularly in the domains of learning and memory. Normal aging is also associated with cognitive decline, making it difficult to differentiate individuals who will age well from those at risk for developing AD. It is imperative to identify individuals at risk for pathological age-related cognitive impairment prior to the expression of clinical symptoms. Eye movement behavior is a sensitive index of learning and memory. Eye-movement-based relational memory effects emerge rapidly (within 500-750ms of stimuli onset) and precede explicit recognition decisions in healthy, cognitively intact individuals, regardless of task demands. The same effects are disrupted in patient populations. Specifically, eye-movement based relational memory effects are completely absent from the viewing patterns of patients with hippocampal amnesia. Therefore, eye movement measures may have utility in attempts to distinguish normal, age-related decline from pathological cognitive impairment. We tested healthy, community dwelling middle-aged (N=13; age 40-55) and older (N=23, age 65-80)adults and used the Montreal Cognitive Assessment to identify individuals performing in the Mild Cognitive Impairment range ("at risk"), as MCI has been a suggested prodrome of dementia. Participants then completed the Scene-Face Pair Task, comprised of an encoding phase immediately followed by a testing phase. The encoding phase consisted of three study blocks, 42 unique scene-face pairs in each block. Eye movements were recorded during testing while participants viewed 3-face displays superimposed atop previously studied scenes. Participants were asked to indicate whether the matching face (i.e. the associate of the scene) was present or absent. Middle-aged, and older participants directed viewing disproportionately to the matching face within 500-750ms of 3-face display onset whereas greater than chance viewing was not evident in "at risk" participants until 1000-1250ms. All of the participants distinguished target-present from target-absent displays, although recognition performance was decremented among "at risk" individuals. It is possible that this subtle reduction in recognition memory performance is a consequence of response mapping difficulties or general cognitive decline. Further research is needed to identify whether the delay in emergence of eye-movement-based relational memory effects may serve as a useful biomarker to identify individuals succumbing to disease prior to any overt clinical symptoms.

Title: Healthy ageing and memory consolidation

Authors: *A. WEARN, S. DILLON, H. K. ISOTALUS, D. TSIVOS, M. J. KNIGHT, B. MCCANN, R. A. KAUPPINEN, E. J. COULTHARD;
Univ. of Bristol, Bristol, United Kingdom

Abstract: Healthy humans expect to be able to remember information over days and weeks, or even longer. Episodic memory declines with age and diseases such as Alzheimer's disease (AD), and it is possible that very subtle deficits in long term memory could be the first detectible cognitive problems in AD. Clinically, delayed memory is almost never tested after 30 minutes and there is very little information about rates of forgetting over days and weeks in healthy ageing and neurodegenerative disease.

The hippocampus has a role in stabilisation of memories such that they are retained over long periods – memory consolidation. Pathologically, hippocampus is affected early in AD with CA1 and subiculum among the first subfields to lose volume. The distinct contributions of human hippocampal subfields to memory consolidation are not clear, although, in rodents, it is known that subiculum is critical for sharp wave ripples thought to underpin memory consolidation during sleep. We hypothesised that human long term memory would decline with age and particularly subiculum and CA1 volume would correlate with very long term memory ability in older people.

We tested memory consolidation in 27 healthy elderly people (11 male; mean age 69.3 ± 6.86 SD) using an adapted Hopkins Verbal Learning Test, with Immediate Recall (IR1-3) and delayed recall at 20 minutes, 24 hours, 48 hours, 7 days and 14 days. Participants also performed Montreal Cognitive Assessment (MoCA) and underwent T2-weighted MRI on 3T scanner using an in-house developed CPMG-like sequence (FOV = 184 x 218 x 58mm^3; slice thickness = 1.72mm; in-plane resolution = 0.34 x 0.34 mm^2; TR = 5500; echo spacing = 12ms; 12 echoes). Hippocampal subfields CA1, CA2, CA3, dentate gyrus, subiculum and stratum lacunosum/stratum radiatum/stratum moleculare were segmented on FSL using an in-house developed manual protocol and normalised to total brain volume.

Memory was remarkably well retained over 14 days: 100% retention in 44% of participants at 14 days. Only IR1 performance was significantly lower, as would be expected. Interestingly, memory consolidation did not show any significant correlation with age, estimated IQ or MoCA score. Females consistently scored significantly higher than males, but only reaching significance at IR3 (**P=0.0012). Preliminary analysis suggests a positive correlation between verbal recall at 48h and Left CA2 (**P=0.0013; ρ=0.971; n=6) possibly implicating this region in memory consolidation.

At present we have not confirmed our hypothesis and future work will employ a larger sample size. We also plan a harder consolidation task to reduce ceiling effects and potentially stratify individuals more widely.

Title: Does the social cognition enhancing effect of acute oxytocin persist with chronic administration?

Authors: ***D. FEIFEL**, P. D. SHILLING, G. MELENDEZ, J. TRAN, B. ROBERTS, A. AVALOS, W. THUY-UYEN, A. SRIVASTAVA, P. KISHORE, I. DAMANI;
Psychiatry, UCSD, LA Jolla, CA

Abstract: Background: Impaired social cognition is a debilitating feature of several neuropsychiatric disorders and there is a great need for effective treatments. Acute administration of oxytocin improves social cognition raising hope that OT or OT mimetics may be effective treatments for social cognition deficits. However, the extant literature consists primarily of studies that investigated the effects a single OT administration, whereas the chronic effects are more relevant to OT's potential use as a treatment. To investigate the effects of chronic OT on social cognition deficits, we administered daily subcutaneous (SC) OT to Brown Norway rats, an animal model that exhibits natural social cognition deficits. Methods: Male and female Brown Norway rats were administered either SC saline, 0.04, 0.2 or 1.0 mg/kg OT daily for 22 days. On the first and last day of OT treatment each rat's social recognition ability was tested in a social discrimination (SD) task, 40 min after their OT injection. A preference to interact with a novel con-specific over a familiar one is an indicator of intact social recognition in the SD task. In addition, animals were tested 1 day and 7 days after the last OT treatment to evaluate the enduring effects of OT on social recognition. Results: After a single injection, social recognition was exhibited by animals that received any of the OT doses, but not in those that received saline. After 22 daily treatments the magnitude of OT's effect on social recognition was reduced but not eliminated. This reduction was more prominent in males and in animals treated with the high dose. Seven days after OT treatments were stopped, rats treated with OT exhibited greater social recognition than those treated with saline. This persistent OT effect was least apparent in the high dose OT group. Discussion: This study confirms that a single peripheral administration of OT can reverse social recognition deficits. This effect persists after chronic

peripheral OT administration but produces partial tolerance. The persistence of restored social recognition, for at least seven days after cessation of treatment, indicates that chronic OT produces durable neural changes in social circuits. Although the highest dose of OT (1 mg/kg) produced the greatest social recognition improvement in both males and females, lower doses (0.2 mg/kg in males and 0.04 mg/kg in females) exhibited less tolerance and more post-treatment persistence of social recognition. These results support the possibility that OT or OT mimetics may be effective treatment for social cognitive deficits and these results should help inform dose selection in future clinical studies.

Title: Facial responses to experienced and observed affective touch

Authors: *L. M. MAYO, I. MORRISON, J. LINDÉ, H. OLAUSSON, M. HEILIG;
Ctr. for Social and Affective Neurosci., Linköping Univ., Linköping, Sweden

Abstract: Affiliative behaviors such as social touch are believed to elicit rewarding responses that enhance positive social interaction. In humans, one selective feature of social touch is speed of stroking. Stroking to the skin at 3 cm/s robustly activates unmyelinated C tactile (CT) afferents and produces positive subjective ratings of “pleasantness”. Here, we aimed to determine whether social touch also elicits positive affective responses as detected by facial muscle movement. We used facial electromyography (EMG) to assess affective responses to experienced or observed social touch in healthy adults (n=30). In one task, subjects received brush strokes to the arm and palm at 3 cm/s (optimal) or 30cm/s (non-optimal speed). In another task, subjects watched short video clips of touch to the arm, touch to the palm, or non-social touch (i.e. touch to a wooden arm) at 3 and 30 cm/s. After each stimulus, subjects rated how “Pleasant,” “Intense,” and “Relaxing” they found the stimulus. Affective responses to the stimuli were assessed in real-time via EMG recordings of the zygomatic (“smile”) and corrugator

("frown") muscles. Experienced touch at 3 cm/s elicited positive affective responses, including decreased corrugator and marginally increased zygomatic reactivity, while touch at 30 cm/s produced enhanced corrugator reactivity. In addition, participants rated 3 cm/s touch as more pleasant, less intense, and more relaxing. There were no significant differences between touch locations (arm, palm). Observed touch elicited similar patterns of differential affective responding based on velocity, with 30 cm/s videos eliciting increased corrugator reactivity as compared to 3 cm/s videos. Similarly, videos of social touch at 3 cm/s were rated as more pleasant, less intense, and more relaxing than videos of 30 cm/s. However, videos of non-social touch (to the wooden arm) were not rated as pleasant or relaxing at any velocity. We have shown that CT-optimal stroking velocities elicit positive affective responses as assessed by facial EMG. The differential affective responses based on stroking speed were consistent across modalities (felt, seen), consistent with a common coding framework between experienced and observed touch. Observed touch responses were specific to socially-relevant stimuli, indicating that the social nature of the touch rather than the visual features are relevant in eliciting affective facial EMG responses and hedonic ratings. Together, these findings broaden our understanding of affective, socially relevant touch by demonstrating that affective facial responses track stimulus factors related to the social relevance and valence of touch.

Title: Intermediate neurodynamic representations: A pathway towards quantitative measurements of teamwork

Authors: *R. STEVENS[1], T. L. GALLOWAY[1], A. WILLEMSEN-DUNLAP[2];
[1]IMMEX/UCLA, Culver City, CA; [2]JUMP Simulation and Educ. Ctr., Peoria, IL

Abstract: Teams work through coordinated large-scale information exchanges using inter-personal modalities, including speech and action-understandings such as gestures, posture and

other non-verbal communications. It is not surprising that neurophysiologic processes are the underpinnings of many of these interactions and while research is revealing the microscale details of social dynamics, the impact of these studies on team assembly, training, and evaluation has been minimal. One reason is the paucity of quantitative measures of teamwork that adequately span the micro-level social dynamics with the macro-level behavioral dynamics recognized and understood by expert raters. Our research suggests that intermediate representations of team members' EEG-derived variables can be developed that bridge this gap. We describe a symbolic neurophysiological representation that quantitatively portrays the second-by-second neurodynamics of healthcare and submarine navigation teams while they conducted realistic training in natural settings, yet also links to larger-scale behavioral dynamics identified by experts. Second-by-second symbolic representations were created of team member's electroencephalographic (EEG) power across the 1-40 Hz EEG spectrum, and quantitative estimates of the changing dynamics were calculated from the Shannon entropy of the data streams. Significant correlations were seen between the symbol streams entropy levels and ratings of team performance by observers using TeamSTEPPS® (healthcare), or Submarine Team Behavior Toolkit (submarine teams) rubrics. These results suggest that the frequency, magnitude, and / or durations of the teams' neurodynamc fluctuations might reflect performance aspects detected by expert raters. The development of quantitative neurodynamc measures of teamwork provides a first step for building an understandable bridge between the theory and practice of social coordination dynamics, and improving team performance.

Title: Preventive effect of suvorexant on night time falls in patients with cognitive impairment.

Authors: S. YAKOU[1], *T. SHIMAZU[2,3], K. TAKAHASHI[4];
[1]Psychiatry, Saitama Neuropsychiatric Inst., Saitama, Japan; [2]2-33-28, Tokyo, Japan; [3]Neurol., Saitama Neuropsychiatrc Inst., Saitama, Japan; [4]Neurol., Saitama Med. Univ., Saitama, Japan

Abstract: BACKGROUND:
Hypnotic treatment has been associated with increased risk for falls in cognitive impairment patients. Suvorexant, a novel dual orexin receptor antagonist was created as a drug for promoting physiological sleep. Unlike existent sleeping pills, it does not have lenitive and antianxiety

function. These characteristics reduce the side effects like muscular atonia, stagger, dependence on and tolerance for medicines. The authors examined the association between hypnotic treatment and falls in cognitive impairment hospitalized patients, focusing on the suvorexant.
METHODS:
This retrospective case-control study was conducted in an acute geriatric ward in Saitama Neuropsychiatric Institute. Medical records, including demographic, clinical, biochemical, and pharmacological variables, of cognitive impairment patients with falls (N = 32), admitted during a 9-Month period, were reviewed and compared with a control group (N = 63) of patients matched for age and gender and without falls.
RESULTS:
The usage rates of antipsychotics, antidepressants, mood stabilizers, and various nonpsychiatric medications were similar in the two groups, except for suvorexant (higher rates in patients without night time falls). There were no significant differences in the anticholinergic burden values, clinical dementia ratings, and comorbidity burden between the two groups.
CONCLUSIONS:
There was no accident of night time falls in cognitive impairment patients with the use of suvorexant. It suggests that suvorexant may prevent night time falls in cognitive impairment patients. In addition, suvorexant significantly improved patients' sleep experience. Further studies are needed in the future.

Title: Exploring the potential of oxytocin for enhancing interpersonal motor resonance upon direct eye gaze: a transcranial magnetic stimulation study

Authors: *J. PRINSEN, S. BRAMS, K. ALAERTS;
Dept. of Rehabil. Sci., KU Leuven, Leuven, Belgium

Abstract: Background. Among different social cues from the environment, the eyes constitute a very salient source for initiating social interaction or communication. Interestingly, previous work from our and other labs demonstrated that direct eye contact between two individuals can readily evoke an increased propensity to 'mirror' other peoples' actions. Particularly, using transcranial magnetic stimulation (TMS), we showed that mirror-motor mapping at the level of the primary motor cortex (M1), also known as "interpersonal motor resonance" (IMR), is significantly increased upon the observation of actions accompanied by direct eye contact, compared to the observation of actions accompanied by averted eye gaze.
Objectives. With the present study, we aimed to investigate the role of eye contact on IMR further, and in particular, explored whether administration of the 'prosocial' neuropeptide oxytocin (OT) can influence eye-contact induced IMR. OT is known to play an important role in promoting prosocial behavior and the perception of socially-relevant stimuli, such as eye gaze. To date however, the link between OT and IMR is less clear.
Method. Twenty neurotypical adult males (18-29y) participated in a double-blind placebo-controlled cross-over design including two sessions, separated by one week. They were randomly assigned to receive a single dose of OT (24 IU) or placebo nasal spray at the first and second session. In each session, TMS was used to measure changes in cortico-motor excitability at the level of M1 while participants observed video stimuli of an actress performing simple hand movements combined with either direct or averted gaze. Additionally, eye tracking was performed to evaluate potential changes in spontaneous viewing behavior of the participants.
Results. Preliminary results replicated previous findings indicating IMR-modulations by the gaze direction of the actor, such that IMR during movement observation was enhanced when combined with direct eye contact. These effects were tentatively more pronounced after administration of OT. Interestingly, participants that failed to display eye contact-induced IMR enhancements at baseline, were shown to significantly increase eye contact-induced IMR after a single-dose of OT.
Conclusions. Our results provide indications that a single-dose of OT can promote motor-mirroring of others' movements upon direct eye contact. OT may thus increase the saliency of social cues originating from the eye regions of others, which in turn may promote the propensity of an individual to automatically 'mirror' the actions and behaviors of surrounding others.

Title: Hedonic responses to touch from strangers depend on the perceived attractiveness of the caresser

Authors: *G. NOVEMBRE[1], R. ETZI[2], I. MORRISON[1];
[1]Linkoeping Univ., Linkoeping, Sweden; [2]Dept. of Psychology and NeuroMi, Milan Ctr. for Neurosci., Univ. of Milan-Bicocca, Milan, Italy

Abstract: Social touch is attracting increasing attention as a specific category of touch with typical psychophysical properties and neural underpinnings. Previous research has shown that a special type of C fibers, the C tactile (CT) afferents, are involved in detecting gentle, affective tactile input on the skin and conveying the information to the central nervous system, with the posterior insula as one of the crucial cortical targets. Despite building on such bottom-up information flow, the hedonic perception and the physiological consequences of affective touch are probably influenced by various sources of top-down information, which in turn results in adaptive behavioral strategies. For instance, it has been shown that the pleasantness of gentle caresses is affected by the belief about the gender of who is stroking, and various affective cross-sensory stimuli (e.g., pictures, odors) impact the hedonic quality of touch experiences. In the present study we aimed to build on this research by investigating how perception of affective touch is influenced by the attractiveness of hypothetical caressers. Thirty-five young participants (15 women) were brushed on the skin while seeing photos of more attractive and less attractive opposite-gender faces, and imagining those people being the caressers. Along with the Attractiveness factor, the factorial design included other two within-subject factors: Site (forearm, palm), and Velocity (3 cm/s, 30 cm/s). Participants were asked to rate the pleasantness of each stimulation, while electrocardiogram activity (ECG) was measured throughout the experiment. Results of the repeated-measure ANOVA showed that participants preferred touch stimuli delivered by more attractive people; a preference for the palm and for the slow velocity (3 cm/s) was also found. The degree to which slow stroking is preferred over fast critically depends on the attractiveness of the face stimuli, reflected by an interaction between Attractiveness and Velocity, with a higher difference for more attractive compared to less attractive. Furthermore, ECG data analysis showed that touch stimuli associated with more attractive faces resulted in significantly higher heart rate variability (HRV) than ones associated with less attractive faces. Overall, the present study confirms that contextual social information plays a major role in affective touch experiences, impacting not only the perceived hedonic quality of the experience but also the physiological state of the body.

Title: Associative learning of what is yours and mine

Authors: *P. L. LOCKWOOD, M. WITTMANN, M. APPS, G. HUMPHREYS, M. RUSHWORTH;
Univ. of Oxford, Oxford, United Kingdom

Abstract: How do we learn what items in the world are "mine" and how do we learn what belongs to other people? Much of our social lives require us to know what objects belong to whom. Previous studies have suggested that people have a 'self bias' in perceptual processing and memory such that they are faster to process stimuli that have been associated with themselves and they are better at remembering information related to themselves. In parallel, studies of decision-making have shown that associative learning occurs by solving a credit assignment problem where credit for an outcome is assigned to a cue rather than an alternative when a prediction is confirmed. However, the computational mechanisms that underpin how self-associations are formed, and the origins of the 'self bias', remain unknown.
Participants performed an associative learning task in which they were required to learn which stimuli belonged to themselves, their best friend or to a stranger. Behaviourally, we find that participants have faster reaction times when associating stimuli with themselves, and correctly identify which stimuli are theirs at a significantly higher proportion compared to their friend or a stranger. Using a computational model of associative learning, we find that participants have a higher learning rate when learning to associate stimuli with themselves compared to a friend or stranger. We also find that participants learn quicker from correct compared to incorrect information across conditions, supporting a credit assignment account of associative learning, but still learn faster after correctly assigning a stimulus to themselves than to a friend or stranger. The neural bases of these effects are yet to be elucidated but the ventromedial prefrontal cortex and superior temporal sulcus have previously been shown to correlate with a self-bias effect. Do these regions encode differences in the associative value of stimuli that are ours and others? and/or do they signal an 'ownership' prediction error that drives learning when feedback is unexpected? On-going work will examine these questions.

Abstract: We normally react to individuals who socially exclude us by either avoiding them or increasing our attempts to interact with them[1]. The neuropeptide oxytocin (OXT) plays a critical role in promoting social bonds and prosocial behaviors and can also reduce social conflict[2]. In the current study we therefore investigated if it facilitates more positive social responses towards individuals who exclude or include us.

In a randomized, double-blind, placebo-controlled, between-subject design 77 healthy Chinese participants (40 males) received intranasal OXT (40 IU) or placebo (PLC) before playing a modified virtual ball-tossing game (Cyberball) with three fictitious partners who either showed exclusion, inclusion or neutral behavioral interactions with them. The Cyberball game was played for~5 min and consisted of six rounds with a total of 60 throws in each one. One week after the initial Cyberball experiment subjects returned to complete a further three tasks but with no additional treatment: a surprise memory test for recognition of previous vs new players, likeability ratings for their face pictures and whether they wanted to play the game again with them.

Results showed that subjects threw the ball more often to individuals who excluded rather than included them (p<.001) or were neutral (p=.001), although OXT did not alter this or awareness/feelings of exclusion or inclusion (p>0.5 in all cases). However, when subjects returned a week later males, but not females, in the OXT group showed increased liking for, and preference for playing again with, players who previously excluded them (Likeability: OXT male: excluder=5.88±0.22, includer=5.22±0.26, p=0.001; OXT female: excluder=5.4±0.23, includer=5.46±0.27, p=0.744; % play again: Male: PLC: 31.67±3.11, OXT: 44.86±2.88, t=-3.12, p=0.003; Female: PLC:
35.65±5.5, OXT: 40.2±4.62, t=-0.64, p=0.53). In addition, this OXT effect in males was positively associated with independent orientation scores (r = 0.585, p = 0.007) on the Individualism and Collectivism scale (ICS). OXT had no significant effect on subsequent

recognition memory for includers or excluders (p>0.07).
Overall our results suggest that when males from a collectivist culture play simultaneously with individuals who socially include or exclude them, OXT treatment increases their motivation to re-establish connections with those who previously excluded them, particularly if they have a higher independent orientation.

Title: Is it me moving this? Embodiment over the virtual body is improved by active control

Authors: *V. BRUGADA-RAMENTOL[1], I. CLEMENS[2], Á. ROMÁN[2], G. G DE POLAVIEJA[2];
[1]Fundaçao Champalimaud, Lisbon, Portugal; [2]Champalimaud Res., Lisbon, Portugal

Abstract: The malleability of self-representation to introduce a foreign limb has been a widely studied process in the recent years in the area of cognitive neuroscience. It has been shown that both sense of ownership and sense of agency contribute to the modulation of embodiment over a body. In several studies, the presence of distortions in the foreign limb affected the reported sense of ownership and agency. However, few studies include active control over the fake limb's movement, which is crucial to understand sense of agency. We propose that under active control over a virtual body, sense of agency and sense of ownership should be more resistant to the addition of a discontinuity on the limb. On the other hand, affecting sense of agency through addition of noise to the movement of the virtual hand, should decrease both sense of ownership and sense of agency. In a custom made virtual environment, which allowed the participants to have full control over the virtual arm during a reaching-like task, we found no significant differences in reported sense of ownership and agency when a discontinuity is added to the limb. On another study, we show that the addition of noise in the movement causes a significant

decrease on the reported sense of ownership and agency over the virtual hand. When put together, these results suggest that sense of ownership is strongly affected by sense of agency, and that the modulation of one of these components influences the other. Unexpectedly, in the context of modulating sense of agency, when the hand is threatened, participants do not show a difference in reaction between control and noise conditions. This suggests that implicit and explicit measures of ownership could depend on different cognitive processes.

Title: Oxytocin increases tolerance of infidelity in males but decreases it in females

Authors: *L. XU, R. LUO, X. ZHENG, X. XU, Z. GAO, K. KENDRICK;
Sch. of Life Sci. and Technol., UESTC, Sichuan, China

Abstract: Previous studies have suggested that while oxytocin (OXT) may enhance fidelity towards partners in male monkeys[1] and humans[2] it can also decrease arousal in response to descriptions of partner infidelity[3]. Here, in a randomized, double-blind, between-subject, placebo (PLC) controlled design experiment, 160 participants (80 males, aged 18-27 years) received either intranasal administration of OXT (40 IU; n=80) or PLC. Forty-five minutes after intranasal treatment, participants completed a rating task. In this task, participants viewed neutral faces of 40 strangers of the opposite sex paired with sentences describing a behavior indicative of fidelity or infidelity (either emotional or sexual) he/she performed during a past relationship, and then rated their attractiveness, likability and trustworthiness and whether they would like to have a short or long-term relationship with them. The subjects were then given a surprise recognition memory test for the 40 faces and another 40 novel ones. All faces and sentences were selected and counterbalanced based on a pilot rating by 36 subjects (17 males). Results showed significant treatment*gender*fidelity interactions for attractiveness ($p<.01$) and likeability ($p<.05$). In male subjects OXT increased the attractiveness ($p<.05$) and likability ($p<.05$) of members of the opposite sex who had been unfaithful (both sexually and emotionally) in a relationship but in females their attractiveness was decreased ($p<0.05$). No significant OXT

effect was found for trustworthiness and relationship ratings. OXT also made women, but not men, less likely to remember the individuals showing infidelity (treatment*gender*fidelity interactions: $p<0.05$). Thus overall in men OXT increases the attractiveness and likability of female strangers who have previously shown emotional and sexual infidelity whereas in women it makes unfaithful male strangers both less attractive and memorable.

Title: Sensory and metacognitive processing is modulated by the mere inferred presence of another individual

Authors: *S. EREIRA[1], Z. KURTH-NELSON[1], S. FLEMING[2], R. DOLAN[1];
[1]Max Planck UCL Ctr., [2]Wellcome Trust Ctr. for Neuroimaing, Univ. Col. London, London, United Kingdom

Abstract: Social context is known to exert measurable effects on cognition and recent advances in behavioural economics and computational imaging have enabled the characterisation of specific examples of social cognition, such as conformity and collective decision-making. However, it has been challenging to isolate specific components of social cognition within an ecologically valid environment, an essential task for developing models of social cognitive deficits, such as in autism and schizophrenia. We developed a novel behavioural paradigm to address whether the mere presence of an other is sufficient to modulate sensory perception. Trios of participants played a perceptual decision making task concurrently on separate computers and simultaneously reported their confidence. On some trials, only one participant engaged in the task, and the others 'sat out'. On other trials, two or three participants independently engaged with the same stimuli. The number of participants engaged was cued to all participants on each trial. However, crucially, participants never saw each other's responses or outcomes. We found that, on trials with more than one participant engaged, the proportion of correct responses was

higher, and confidence was more correlated with difficulty. We propose that social context modulates sensory gain, leading to more accurate representations of perceptual inputs.

Title: How social coordination emerges and changes among multiple heterogeneous agents: An experimental 'human firefly' study

Authors: ***M. ZHANG**[1], J. A. S. KELSO[1,2], E. TOGNOLI[1];
[1]Ctr. for Complex Systems & Brain Sci., Florida Atlantic Univ., Boca Raton, FL; [2]Intelligent Syst. Res. Ctr., Ulster Univ., Derry~Londonderry, Ireland

Abstract: People's behavior, emotion, mental and physical health reflect the social milieu in which they are embedded. Social structures are essentially dynamic: their evolving characteristics depend on the coordinative stability between people's behavior. Dyadic social coordination has been well studied experimentally and mathematically at both component and collective levels. It uncovered metastability as an informationally-rich mix of integration and segregation that depends on coupling strength and differences between people's intrinsic behavior. Whereas the science of coordination (social, neural or physical) tends to polarize toward either systems of 2 or 3 components or systems composed of very many degrees of freedom, much of reality may lie in between. In an attempt to uncover laws and mechanisms of social coordination at this intermediate scale, we introduce a paradigm involving the coordination of rhythmic movement among 8 people. Subjects were seated in obscurity at booths around an octagonal table. Each subject signaled his/her tapping behavior to the group with a touchpad and watched others' taps via a ring of 8 LEDs. Each LED lit up when its assigned individual contacted the touchpad. Subjects were instructed to tap rhythmically to a visual metronome shown at the beginning of each trial (10 s) and to maintain that frequency throughout the following 50s, when they saw each other's tapping via the flashing LEDs. The pacing metronomes were parametrically manipulated to divide the subjects into 2 groups of 4 participants, with frequency differences $\delta f = 0$, 0.3 or 0.6Hz. We investigated whether subjects' behavior would persistently follow their initial group or if they would shift to the behavior of the

other group. Preliminary data show that subjects tended to persist within their initial frequency groups, yet cross-group switching also occurred. The analyses of phase-locking stability reveal that as the frequency difference δf decreases, the correlation between cross-group and within-group phase-locking changes gradually from negative to positive - a zero-correlation marked the critical frequency difference δf^* where original groups begin to merge into one. Our findings suggest that relevant variables to metastable coordination dynamics in dyadic situations still plays an important role in 8 people coordination, but multiagent coordination gives rise to social complexity with formation of groups at multiple scales. The present work opens a new behavioral paradigm for identifying neuromarkers of multi-agent coordination dynamics that may be relevant to clinical populations where social stability and instability are at stake.

Title: Oxytocin transiently and selectively facilitates acceptance of social advice from others but without increasing their trustworthiness

Authors: *R. LUO, L. XU, W. ZHAO, X. MA, X. XU, J. KOU, Z. GAO, B. BECKER, K. KENDRICK;
Sch. of Life Sci. and Technol., UESTC, Sichuan, China

Abstract: Research using economic game paradigms has suggested that the neuropeptide oxytocin (OXT) can increase willingness to trust others, although these findings have become increasingly controversial and may depend on the specific context. Here we investigated whether intranasal OXT influences trust in advice given on solving everyday social problems by either qualified or unqualified advisors. In a randomized, double-blind, between-subject, placebo-control design study 83 subjects (42 males) received either intranasal OXT (24IU) or placebo (PLC) treatment. On the first study day subjects provided written solutions to 60 everyday social problems. On the subsequent day they self-administered intranasal OXT or PLC. After 45 min they were given the 60 problems again, reminded of their answers and received alternative advice from 4 older advisors who were introduced as either experts (male/female psychological counselors) or non-experts (male/female landscape designers). In each case subjects were shown

a face picture and name of the advisor and were given either better or worse advice by them (randomly computer generated based on 4 top answers and ratings provided by independent groups of subjects) which they could either accept or reject. Subjects returned again one week later and answered the same 60 questions without being reminded of their previous or advised answers. Results revealed no main effects of advisor type or treatment (all p>0.39) but a treatment x advisor type x advisor gender interaction (p=0.026, η^2_p =0.06). OXT selectively increased acceptance of advice from a female (p=0.034, Cohen's d=0.49), but not from a male expert (p=0.792, Cohen's d=5.72) or the male or female non-experts (both p>0.32). Further analysis revealed a main effect of advice-type (p<0.001, η^2_p =0.49), with subjects being less accepting of worse advice from any advisor, but no interactions involving treatment x advice type, indicating OXT increased acceptance of both better and worse advice from the female Psychologist. Importantly, there was no OXT effect on ratings of advisor trustworthiness or likability (all advisors p>0.25). Furthermore, the OXT effect on advice acceptance was not maintained after a week, with subjects mainly reverting to their original solutions irrespective of previous accepted advice being better or worse (all p>0.14). These findings suggest that while OXT can increase trust behavior towards others it does so in an implicit, transient and highly selective person- and gender-specific manner. Thus OXT may have a rather limited utility in terms of making us generally more trusting of others.

Title: oxytocin facilitates emotional empathy for individuals expressing negative emotions in males and females

Authors: *Y. GENG, W. ZHAO, F. ZHOU, B. BECKER, K. KENDRICK;
Sch. of Life Sci. and Technol., UESTC, Sichuan, China

Abstract: Intranasal administration of the neuropeptide oxytocin (OXT) can enhance empathy, although whether both cognitive and emotional empathy are affected and the importance of valence is unclear. We have investigated OXT effects on cognitive and emotional empathy

evoked by viewing individuals expressing positive and negative emotions in two independent studies.
In two randomized, double-blind, placebo-controlled, between-subject design experiments (Exp 1: 60 males, OXT=28; Exp 2: 40 males, OXT=19 and 31 females, OXT =18) we investigated the effects of intranasal OXT at different doses (Exp 1: 24IU; Exp 2: 40IU) vs. placebo (PLC) treatment on cognitive and emotional empathy which were measured using an Asian version of the Multifaceted Empathy Test (MET) used in a previous study on Caucasian subjects. Starting 45 mins after the intranasal spray subjects were given the MET where they were asked to view natural scenes showing individuals expressing strong positive or negative emotions. Each of the 60 scenes was shown three times and subjects required to identify the emotion being expressed from 4 different options (cognitive empathy - CE), or to rate the strength of their feeling for the subject in the scene (direct emotional empathy - EE) or how aroused they were by the picture itself (indirect EE - EEI).
Results from ANOVA analyses showed that in both experiments there was a treatment *X valence interaction in Exp 1 (p=0.032, η^2_p =0.05) and a marginal one in Exp 2 (p=0.058, η^2_p =0.08). Post-hoc tests showed that this was due to OXT having a significant effect only for negative valence stimuli (Exp 1: p=0.025, Cohen's d=0.59; Exp 2 p=0.049, Cohen's d=0.48). Exploratory t-tests revealed that for negative valence stimuli OXT increased EE (p=0.029, Cohen's d=0.58) and EEI (p=0.037, Cohen's d=0.55) but not CE (p=0.937, Cohen's d=0.02) ratings in Exp. 1 and EE (p=0.043, Cohen's d=0.49) but not EEI (p=0.093, Cohen's d=0.40) or CE (p=0.498, Cohen's d=0.16) in Exp 2. There were no sex differences in OXT effects in Exp 2. There was also no evidence for dose-dependent OXT-effects in male subjects in the two experiments.
In summary, our results show that in both male and female Chinese subjects OXT only enhances emotional empathy for negative valence stimuli in the MET, whereas a previous experiment in male Caucasian subjects reported increases in both positive and negative valence using the same paradigm. In agreement with this latter study no OXT-effects on cognitive empathy were found.

Title: Behavioral and molecular individuality in zebrafish is controlled by a YY1/HDAC1/p300 pathway

Authors: *A. C. ROMAN[1], J. VICENTE-PAGE[2], G. GARCIA DE POLAVIEJA[2];
[1]Champalimaud Neurosci. Programme/ Collective Behaviour Lab., [2]Fundaçao Champalimaud, Lisbon, Portugal

Abstract: Behavioral individuality arises even in isogenic populations under identical environments, but its underlying mechanisms remain elusive. We found that inbred and isogenic zebrafish (*Danio rerio*) larvae showed behavioral individuality swimming freely in identical wells or in reaction to stimuli. This individuality was found to be encoded in individual histone-4 acetylation profiles of several genomic regions related to neurodevelopment. The interaction of a complex formed by YY1, HDAC1, and p300 with these regions is required for individuality in acetylation. Manipulations of this complex or its regulators, like acetyl-CoA, simultaneously modified epigenetic, transcriptional and behavioral individuality. These results and computational simulations suggest stochastic histone acetylation by the YY1/HDAC1/p300 complex in neurodevelopmental genes as primary mechanism of molecular and behavioral individuality in vertebrates. This mechanism seems to be partially conserved in other species like humans.

Title: Using development in zebrafish larvae to extract the rules of collective behavior

Authors: *R. C. HINZ, G. DE POLAVIEJA;
Collective Behavior Lab., Champalimaud Fndn., Lisbon, Portugal

Abstract: Advances in neurobiology and genetics have opened up the possibility to study the cognitive mechanisms and genetic basis of social behavior. However, while there exists a variety of state-of-the-art techniques for brain imaging and manipulation for zebrafish, *Danio rerio*, tools for the quantification and analysis of social behavior in free-swimming animals are scarce. Moreover, strong shoaling behavior can be found in adult zebrafish, while imaging and

manipulation techniques are mostly applied to zebrafish at early stages of development when animals are transparent but show little social interactions.To overcome these difficulties, we have developed idSocial, a toolbox for the analysis of social behavior in freely moving animals. Performing experiments and tracking the interactions between animals in groups of free swimming zebrafish larvae, we have generated a dataset of trajectory data for the first 24 days post fertilization. The analysis with idSocial finds a continuous decrease of inter-individual distances and a continuous increase in attraction from 7-8 dpf on, while the tendency to align the direction of movement stays almost constant during the observed development. At early stages, individuals show strong repulsive interactions with other animals around them and attractive interactions at larger distances are less frequent. During development, the repulsion region shrinks and animals spend an increasing amount of time in attractive interactions.
We found that the properties of attraction are explained, without the need to fit parameters, by a model in which each animal follows another animal chosen effectively at random. The experimental data eliminates models that use more sophisticated rules, and explains collective behavior simply by animals statistically choosing a larger group by randomly selecting an individual. We propose this rule as a basic reference in collective animal behavior. The emergence of collective behavior as an accumulation of different properties during development is expected to help dissecting how different properties of brain processing underlie animal interaction rules.

Title: Optimal group size in collective decision making

Authors: ***J. VICENTE-PAGE**[1], C. IOANNOU[2], A. PEREZ-ESCUDERO[3], G. DE POLAVIEJA[1];
[1]Champalimaud Res., Fundaçao Champalimaud, Lisboa, Portugal; [2]Sch. of Biol. Sciences, Univ. of Bristol, Bristol, United Kingdom; [3]MIT, Boston, MA

Abstract: Collective decision making has been observed in different animal species, from ants to humans, and the usual modeling theory has always predicted that the accuracy of the decision

increases with group size. This prediction has usually been obtained by the implementation of the models themselves, where individuals are only allowed to vote once and sequentially. This reduces extremely the information of the first deciding individuals, as they never have access to the actions of the rest of the group. Here we present a completely general collective decision making model in which individuals are allowed to reevaluate their decisions in several voting rounds, favoring the information exchange betwen the members of the group. Our model predicts that the optimal accuracy is achieved at intermediate group sizes, as the advantage of having more information in large groups can be penalyzed by the possibility of amplifying initial mistakes. We further confirmed the existence of an optimal group size in collective decisions by conducting a set of experiments in groups of guppies.

Title: Early life social isolation in larval zebrafish alters behavior in social and non-social contexts

Authors: *A. H. GRONEBERG[1], J. C. MARQUES[2], M. B. ORGER[2], G. G. DE POLAVIEJA[1];
[1]Collective Behavior Lab., [2]Vision to Action Lab., Champalimaud Res., Lisbon, Portugal

Abstract: Early social experience can have long lasting effects on social behavior and development. Zebrafish are a shoaling species with oviparous development and transparent bodies in the larval stage, allowing for non-invasive imaging of neural activity as well as very controlled manipulation of the environment during very early development. Here we set up to test how the social environment during early development affects the development of social and non-social behavior. We reared wild-type zebrafish in isolation or in groups until 6 days post fertilization and subsequently measured spontaneous locomotion at high temporal resolution, allowing for the analysis of single tail beats. Our results show that when swimming in groups or pairs, isolatedly raised larvae avoid each other at a larger distance than group raised larvae. This difference was absent when the same test was performed in darkness, suggesting that this increased avoidance is visually mediated. However, raising larvae in isolation while allowing visual access to age-matched conspecifics did not rescue the enhanced avoidance reaction.

Further, we noticed several differences in morphology, as well as general locomotion kinetic parameters irrespective of the social context during testing when comparing isolated and group raised larvae. Such differences could not be fully explained by a mere shift or retardation in development. We hypothesized that the absence of non-self sensory stimuli could lead to reduced swimming activity during development and thus affect development of the muscular system. Yet, repeated artificial mechanosensory stimulation failed to rescue the morphological and locomotion phenotypes. In summary, we here characterized a model of social isolation during early development in larval zebrafish. Further molecular, behavioral and neural circuit experiments will allow us to study how the developing brain is altered when exposed to social deprivation early in life.

Title: The role of the serotonin 2A receptor system in self and other initiated social interaction in LSD-induced states

Authors: *K. H. PRELLER[1], L. SCHILBACH[2], T. POKORNY[1], J. FLEMMING[1], R. KRAEHENMANN[1], P. STÄMPFLI[3], M. LIECHTI[4], E. SEIFRITZ[1], F. X. VOLLENWEIDER[1]; [1]Dept. of Psychiatry, Psychotherapy and Psychosomatics, Psychiatric Univ. Hosp. Zürich, Zurich, Switzerland; [2]Independent Max Planck Res. Group for Social Neurosci., Max Planck Inst. of Psychiatry, Munich, Germany; [3]MR Ctr. of the Psychiatric Univ. Hosp. and the Dept. of Child and Adolescent Psychia, Univ. of Zurich, Zurich, Switzerland; [4]Dept. of Biomedicine and Dept. of Clin. Res., Univ. Hosp. Basel, Basel, Switzerland

Abstract: Distortions of self-representation are critical symptoms of major psychiatric disorders such as schizophrenia. Furthermore, a coherent sense of self is vital for successful participation in social interactions. In light of the immense need for improved treatment of transdiagnostic

social impairment in psychiatric disorders, it is important to better understand the neurochemical substrates of social interaction abilities. In the current study we, therefore, investigated the pharmacological and neural correlates of gaze-based social interaction and joint attention which has been shown to rely upon recruitment of the brain's reward system. In a double-blind, randomized, counterbalanced, cross-over study 24 healthy participants received either 1) placebo+placebo (Pla condition) 2) placebo + lysergic acid diethylamide (LSD) (100 µg p.o., LSD condition), or 3) ketanserin (40 mg p.o.) + LSD (100 µg p.o., Ket+LSD condition) at three different occasions. Participants completed an interactive social paradigm in which their gaze was recorded by an eye-tracking device that controlled the gaze of an anthropomorphic virtual character while undergoing functional magnetic resonance imaging. They completed trials of self- and other-initiated joint and non-joint attention. Activation of dorsal medial frontal cortex and the posterior cingulate cortex observed in a self vs. other contrast was reduced after LSD administration compared to Pla and Ket+LSD.conditions (all $p<0.05$, FWE corrected). Comparing joint attention vs. non-joint attention was associated with reduced BOLD signal in the ventral striatum in the LSD condition compared to Pla. Furthermore, LSD increased ratings on the 5D-ASC scales "experience of unity" and "disembodiment". All LSD-induced effects were blocked by the serotonin 2A receptor antagonist ketanserin (all $p<0.05$). Our study demonstrates that LSD induced a feeling of loosening of self-boundaries, which is consistent with previous reports. Concordantly, LSD reduced neural activity in brain areas, which are known to be important for self-processing, but also social cognition. Reduction of brain activity in reward-related areas during social interaction after LSD administration might further explain social withdrawal symptoms in patients suffering from distortions of self-experience such as schizophrenia. These LSD-induced effects appear to be attributable to serotonin 2A receptor stimulation, since these alterations were normalized after pretreatment with ketanserin.

Title: Negative gender-related information reduces social cognition in breast cancer patients

Authors: *A. N. SOKOLOV[1], M. A. PAVLOVA[3], S. Y. BRUCKER[1], D. WALLWIENER[2], E. SIMOES[1];
[1]Dept. of Women's Health, Women's Hlth. Res. Inst., [2]Women's Hlth., Eberhard Karls Univ. Hosp. Tübingen, Tuebingen, Germany; [3]Biomed. Magnetic Resonance, Eberhard Karls Univ. of Tuebingen, Tübingen, Germany

Abstract: Implicit negative information perceived as a threat impedes visual social cognition (e.g., Pavlova et al., 2014): telling that men are usually better than women on the event arrangement, EA, task (with no initial gender differences) drastically reduces women's performance. When diagnosed with breast cancer, women face with a lot of threatening information that may hinder their cognition, decision making and eventually, coping with the disease. We examined whether gender-related information affected performance on visual social cognition task in patients with mastocarcinoma. Two separate groups of patients (aged 40-55 years) and two control groups of matched healthy women were administered the EA task with standard instruction. In addition, one patient and one control group were told that men were commonly better on the task. With negative information, patients scored lower than controls, and lower than patients with standard instruction, indicating effects of both disease and information. Remarkably, the lowest scores occurred in patients with negative information. The outcome shows for the first time the impact of disease and information on visual social cognition, presumably blocking visual cognitive processing. This offers novel insights on improving physician-patient communication for enhanced visual cognitive processing in oncologic and other diseases.

Title: Long-term treatment with methylphenidate for mental fatigue and pain after traumatic brain injury

Authors: *L. 0. RONNBACK[1], B. JOHANSSON[2];
[1]Inst. of Neurosci. and Physiol., Gothenburg, Sweden; [2]Inst. Neurosci and Physiol, Göthenburg, Sweden

Abstract: Objectives: Traumatic brain injury (TBI) may cause long-lasting post-concussive symptoms, such as mental fatigue and concentration difficulties and this may become the main hindrance for returning to work, studies and normal social life. There is currently no effective treatment for long-lasting mental fatigue. In this hypothesis generating study the long-term effects of methylphenidate on mental fatigue, cognitive function, pain and safety were assessed. Materials & methods: Thirty participants who suffered from long-term post-concussion symptoms after mild or moderate TBI and who had reported positive effects with methylphenidate during an initial phase of this follow-up study were treated with methylphenidate for a further six months. Results: After six months follow-up, effects on Mental Fatigue Scale (MFS), depression, anxiety and cognitive function (processing speed, attention, working memory) were significantly improved compared to baseline data ($p<0.001$ respectively). Pain was not improved as measured with VAS but the patients tolerated their pain much better. Heart rate was significantly increased ($p=0.01$), while blood pressure was not changed. Conclusions: Individuals suffering from prolonged symptoms after TBI reported reduced mental fatigue and improved cognitive functions with long-term methylphenidate treatment. They tolerated pain better. It is suggested that methylphenidate can be a treatment option for long-term mental fatigue and cognitive impairment after TBI, but further randomized control research is warranted.

Title: Can everyone see the target? Cross-cultural differences in bottom-up and top-down attention: A computational modelling study.

Authors: *E. MAVRITSAKI[1], P. RENTZELAS[2];
[1]Birmingham City Univ., Birmingham, United Kingdom; [2]Dept. of Psychology, Birmingham City Univ., Birmingham, UK, United Kingdom

Abstract: Can we all see salient items presented to us? Members of collectivist East Asian cultures when compared with individualist European American cultures into picture perceptions

showed that East Asians are more likely to attend to perceptual field as whole and to perceive relationships between a salient object and background than European Americans [1]. The effect was observed when target object presented amongst clearly separated background objects (distractors) and the subject did not look for a specific target on the display (bottom-up search). In our previous work we showed that when using the spiking Search over Time and Space (sSoTS) model [2] with reduced saliency, we could simulate similar effect in the traditional bottom-up visual search experiment [3]. In our previous work we also predicted that similar affects can be observed in top-down visual search [3] and this outcome was confirmed in our behavioural studies.
To further investigate the relationship between target and distractor in the two groups and the differences amongst the groups we used traditional visual search experiment in both bottom-up and top-down search, where the target was bigger in size that the distractors. In the current work we present computational modelling studies where we investigate the underlying processes of the cross-cultural differences for bottom-up and top-down visual search using different size of target and distractors.

Title: Emergence of distinct dynamical states in the brain network for self-other processing

Authors: *Y.-A. CHEN[1], T.-R. HUANG[2];
[1]Dept. of Psychology, South Hall, office S104, [2]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Self-other processing, as a domain-specific function, has implications for understanding social cognition and some psychiatric conditions. Empirical research has confirmed the relevance of some anatomical structures, such as medial prefrontal cortex and temporo-parietal junction, in the processing of self-other-related information. Some recent studies pursued a finer-grained spatial demarcation of these structures into “self-specific” and “other-specific” sub-regions. This approach, however, overemphasizes the assumption of spatial localization and neglects the potential role of dynamical states as representational states. Other studies treated these structures as components of a dynamical system by analyzing their functional connectivity. Nevertheless, the seeds in these studies were usually chosen arbitrarily, leaving some room of ambiguity. Employing a data-driven approach, we registered the term-based meta-analytic results from the Neurosynth human fMRI database to the NTU-122 diffusion spectrum image template and applied end-to-end fiber tracking algorithm and hierarchical clustering to identify the vertices and edges, thus obtaining a network that maximally preserves the activation and connectivity pattern of self-other processing brain regions. We then implemented computational simulation to explore the synchronization spectrum and compared the results with those derived from an anatomically defined, arbitrary network. It revealed that the data-driven network has a higher probability of settling into some discrete states than does the arbitrary network. The co-existence of discrete limit sets within the same dynamical system suggests an alternative hypothesis of self-other processing to the conventional spatial localization argument.

Title: Brain networks associated with neuroticism, social networks, and loneliness in Traumatic Brain Injury

Authors: *J. N. BEADLE[1], A. RIGON[2], M. VOSS[3], M. DUFF[4];
[1]Gerontology, Univ. of Nebraska at Omaha, Omaha, NE; [2]Neurosci., [3]Psychological and Brain Sci., [4]Communication Sci. and Disorders, Univ. of Iowa, Iowa City, IA

Abstract: INTRODUCTION. Traumatic brain injury (TBI) can significantly impact cognition, emotion, and social behavior, as well as contribute to personality changes that may negatively affect social relationships. However, little is known about the impact of TBI on social network size and loneliness, and interactions with personality. Furthermore, by studying the brain networks supporting these processes, researchers can develop targeted interventions to improve social well-being in TBI. Thus, we investigated relationships between social network size, loneliness, and personality in TBI and examined brain networks supporting social relationships. METHODS. Participants included 22 individuals with chronic moderate-severe TBI and 19 demographically-matched healthy comparison participants (HC). Participants completed self-report questionnaires measuring perceived loneliness (UCLA loneliness scale), neuroticism (NEO-FFI), and social network size (NSHAP). Additionally, participants underwent resting state functional magnetic resonance imaging (rs-fMRI) to obtain a measure of functional connectivity (rs-FC). RESULTS. Individuals with TBI and HCs had comparable social network sizes ($p>.05$). Despite this fact, individuals with TBI had higher perceived loneliness ($p<.05$) and neuroticism ($p<.05$) than HCs. Within the TBI group, there was a strong, positive correlation between loneliness and neuroticism [$r(21)=.86$, $p<.001$], and significant, negative correlations between social network size and loneliness [$r(21)= -.53$, $p<.05$], and neuroticism [$r(21)= -.49$, $p<.05$]. A mediation analysis revealed that within the TBI group, loneliness had a significant indirect effect on social network size which was mediated by neuroticism [b=.-1.32, 95% BCa CI [-2.54, -.43]; large effect size, $k^2=.45$]. To examine the relationship between neuroticism and brain connectivity in TBI, we conducted an exploratory whole-brain analysis selecting the amygdala as a seed region. Individuals with TBI who reported higher neuroticism had less functional connectivity between amygdala and precuneus than HC. DISCUSSION. We found that despite having similar numbers of friends to healthy adults, patients with TBI felt lonelier, and high neuroticism mediated this relationship. Furthermore, in TBI patients, brain networks related to neuroticism involved regions important for social relationships (amygdala) and self-regulation (precuneus) in healthy adults. Taken together, the present study provides evidence that in TBI the brain networks supporting neuroticism may be an important target for rehabilitation efforts aimed at improving social well being.

Title: Perceived social isolation is associated with altered functional connectivity in neural networks associated with tonic alertness and executive control

Authors: *E. LAYDEN[1], J. T. CACIOPPO[1], S. CACIOPPO[2], S. F. CAPPA[3], A. DODICH[4], A. FALINI[4], N. CANESSA[3];
[1]Psychology, [2]Psychiatry and Behavioral Neurosci., The Univ. of Chicago, Chicago, IL; [3]Inst. Universitario di Studi Superiori, Pavia, Italy; [4]San Raffaele Scientific Inst., Milan, Italy

Abstract: Perceived social isolation (PSI), colloquially known as loneliness, is associated with selectively altered attentional, cognitive, and affective processes in humans, but the neural mechanisms underlying these adjustments remain largely unexplored. Behavioral, eye tracking, and neuroimaging research has identified associations between PSI and implicit hypervigilance for social threats. Additionally, selective executive dysfunction has been evidenced by reduced prepotent response inhibition in social Stroop and dichotic listening tasks. Given that PSI is associated with pre-attentional processes, PSI may also be related to altered resting-state functional connectivity (FC) in the brain. Therefore, we conducted the first resting-state fMRI FC study of PSI. Five-minute resting-state scans were obtained from 55 participants (31 females). Analyses revealed robust associations between PSI and increased brain-wide FC in areas encompassing the right central operculum and right supramarginal gyrus, and these associations were not explained by depressive symptomatology, objective isolation, or demographics. Further analyses revealed that PSI was associated with increased FC between several nodes of the cingulo-opercular network, a network known to underlie the maintenance of tonic alertness. These regions encompassed the bilateral insula/frontoparietal opercula and ACC/pre-SMA. In contrast, FC between the cingulo-opercular network and right middle/superior frontal gyrus was reduced, a finding associated with diminished executive function in prior literature. We suggest that, in PSI, increased within-network cingulo-opercular FC may be associated with hypervigilance to social threat, whereas reduced right middle/superior frontal gyrus FC to the cingulo-opercular network may be associated with diminished impulse control.

Title: All Together Now: The neural basis of social development associated with music training

Authors: ***M. SACHS**[1], B. ILARI[2], J. KAPLAN[1], H. DAMASIO[1], A. DAMASIO[1], A. HABIBI[1];
[1]Brain and Creativity Inst., Los Angeles, CA; [2]Thorton Sch. of Music, USC, Los Angeles, CA

Abstract: Playing music, particularly in an ensemble setting, requires a certain degree of social acuity in that the performer must learn to identify and match the emotional states of others. Despite this, while active musical engagement has been shown to be associated with enhanced cognitive capabilities that are rooted in structural and functional changes in the brain, the relationship between socio-emotional abilities, music education, and the brain remains largely unexplored. Using fMRI, and a novel, non-language based measure of emotional judgment, we investigated the behavioral and neural correlates of socio-emotional processing in young musicians who had received varying degrees of formal music training. Violinists between the ages of 8-12 were scanned while performing two tasks, one musical and one nonmusical, that involved inferring the emotional states of others. In the musical task, the participant either watched (video condition) or listened to (audio condition) a musical performance of a violinist and had to identify which of four emotions the performer was conveying. In the nonmusical task, the participant was presented with a face and had to identify the emotion that was being conveyed. Behavioral results showed that years of musical training was positively correlated with accuracy on identifying the emotion of the faces as well as identifying the emotion of the performer in the audio condition only. The fMRI results showed that the task conditions differentially activated regions known to be involved in distinguishing between emotions. Furthermore, in the audio only condition, children with more music training showed a greater difference in BOLD signal between positive and negative valence emotions in the parietal cortex (superior parietal lobule and post-central gyrus) and the prefrontal cortex (superior frontal gyrus and medial prefrontal gyrus). These regions belong to the action observation network, which underlies our ability to infer the intentions of other's actions. The results therefore suggest that in the absence of visual cues, children with more musical training are engaging part of this action observation network in order to distinguish between certain emotions. Such findings provide support for the notion that music education has social and emotional benefits and have

implications for our understanding of neurodevelopmental disorders in which emotional processing is attenuated.

Title: Social Disorganisation links autism and schizophrenia spectrum disorders through excitation-inhibition neurotransmitter imbalance.

Authors: ***T. C. FORD**[1], R. NIBBS[2], D. P. CREWTHER[1];
[1]Ctr. for Human Psychopharmacology, [2]Brain and Psychological Sci. Res. Ctr., Swinburne Univ. of Technol., Melbourne, Australia

Abstract: The phenotypes of autism and schizophrenia spectrum disorders show an overlap both in the clinical and non-clinical population, which has been conceptualized as Social Disorganization (SD). In this study, the glutamate/gamma-aminobutyric acid (GABA) concentration ratio between high and low scorers on SD was investigated. A low (female: n=10, age=22.90(4.15); male: n=8, age=25.75(7.13)) and high (female: n=20, age=23.50(6.65); male: n=10, age=22.20(4.61)) SD scoring group aged 18 to 40 years underwent proton magnetic resonance spectroscopy (^{1}H-MRS) for glutamate and GABA concentrations in two superior temporal voxels of right and left hemisphere. Glutamate spectra were isolated from glutamine and GABA using a PRESS sequence with an echo time of 80ms, while MEGA-PRESS was used to isolate the GABA spectra. Separate 2 (hemisphere) by 2 (group) mixed ANOVAs were conducted for glutamate level, GABA level and glutamate/GABA ratio followed by *post hoc* analyses. Reduced GABA level ($t(20.70) = -2.93$, $p = 0.008$, Hedge's $g = 1.05$) and increased glutamate/GABA ratio ($t(29.21) = 3.88$, $p < 0.001$, Hedge's $g = 1.35$) was found in the right temporal voxel for the high SD group. In the left temporal voxel, GABA was significantly higher for the high SD group ($t(32.59) = 2.26$, $p = 0.031$, Hedge's $g = 0.73$). Results point toward an excess excitation to inhibition imbalance in the right superior temporal region as a function of

reduced inhibition in this region for those with high scores on the shared autism and schizophrenia spectrum phenotype SD.

Title: Psychotherapists show significant differences in perspective taking, emotional regulation and brain network connectivity

Authors: *V. E. OLALDE[1], S. ALCAUTER, 76230[2], F. BARRIOS, 76230[2], R. MERCADILLO[3], S. FEDERICA[2], E. PASAYE[2];
[1]UNAM, Inst. De Neurobiología, Queretaro, Mexico; [2]Univ. Autonoma de Mexico, Queretaro, Mexico; [3]Univ. Autónoma Metropolitana Unidad Iztapalapa,, Ciudad de Mexico, Mexico

Abstract: There is recent evidence of the cognitive modulation of empathy, which is of great interest to delineate strategies to improve social interactions and reduce conflicting behaviors, such as bullying. However, little is known about the neural substrate of the components of the empathic response and how they can be modulated with training. To get more understanding of these interactions we characterized a group of alliance-therapists which long-term training is based in the frequent modulation of such empathic components, including perspective taking and emotional regulation. We contrasted behavioral scores and resting state functional connectivity (FC in a group of therapists and non-therapists. The behavioral scores of the perspective taking and the emotional regulation components were measured by the interpersonal reactivity index and the emotional regulation questionnaire, in a sample of 52 therapists (mean age 49.3y, 22 males) and 62 controls (mean age 51.7y, 36 males). For the resting state fMRI study two groups of 10 therapists (mean age 55.8y, 3males) and 10 controls (mean age 55.7y, 3 males) were included, they were paired by economic status, years of formal studies, age and sex. Both groups had more than 13y of professional experience
The resting state datasets were acquired with a 3T scanner, while subjects were awake with eyes closed. After standard preprocessing (no global signal regression), five noise based time series (CompCor) and movement affected volumes were regressed out. Spherical seeds located in the right Temporal Parietal Junction (TPJ), right middle TPJ and Anterior Insula were used to

generate corresponding connectivity maps. After Fisher Z transformations, two group t-tests were applied to identify differences between groups.
The therapists showed significantly higher scores in perspective taking, and significantly lower scores in emotional suppression. In addition, therapists showed less FC between posterior areas of the brain, involved with inference process and autobiographical retrieving. They also showed higher FC with ventral areas involved in language processing and emotion regulation. In sum, these results suggest that the therapists use different strategies to infer the mental state of others, and that these strategies can be represented in the FC between different networks. Although, we don't know if such differences were present before training and predispose subjects for such profession, these results warrant further research on the effects of shorter training strategies.

Title: Shared cortical alterations in anorexia nervosa and autism spectrum disorder

Authors: *M. BJORNSDOTTER[1,3], M. DAVIDOVIC[2], L. KARJALAINEN[2,4], G. STARCK[2], H. OLAUSSON[3], E. WENTZ[2];
[1]Ctr. for ethics, law and mental health, Univ. of Gothenburg, Goeteborg, Sweden; [2]Univ. of Gothenburg, Gothenburg, Sweden; [3]Ctr. for Social and Affective Neurosci., Linköping Univ., Linköping, Sweden; [4]Anorexia-Bulimia Unit, Queen Silvia Children's Hosp., Sahlgrenska Univ. Hosp., Gothenburg, Sweden

Abstract: Converging findings point to a considerable overlap in cognitive and behavioral traits between anorexia nervosa (AN) and autism spectrum disorder (ASD): women with AN exhibit perfectionism, particularly regarding symmetry and exactness (Srinivasagam et al. Am J Psychiatry, 1995:152) and impaired social cognition (Cassin et al. Clinical Psychology Review, 2005:25; Zucker et al. Psychol Bull, 2007:133). Here, we asked whether the two conditions share cortical alterations. We acquired structural magnetic resonance imaging (MRI) scans in women

diagnosed with AN (n = 25) and matched control women (n = 25), as well as in all age and gender-matched participants with an ASD diagnosis (n = 14) and control participants (n = 22) of the Autism Brain Imaging Data Exchange. Regional gray matter volume alterations were assessed using voxel-based morphometry (VBM). Women with AN scored higher on the Autism spectrum Quotient (AQ) than the control group (p = 0.010). AN patients exhibited significantly reduced gray matter volume of bilateral superior temporal sulcus (STS), extending into the temporoparietal junction (TPJ), relative to control participants (p<0.005, k≥247)(Figure A). AQ correlated significantly with average gray matter volume of the left, but not right, STS region in women with AN (r = -0.41, *p* = 0.045)(Figure B). Women with ASD exhibited significantly reduced gray matter of the left STS region compared to control participants (p<0.005, k≥256)(Figure C). The same left STS region was affected in both AN and ASD: women with AN exhibited reduced average gray matter of the left STS region identified in the ASD group comparison (p=0.002), and women with ASD showed significantly reduced volume of the left (p=0.027) region identified in the AN group comparison. Our results show that women with AN and ASD share cortical alterations in the form of reduced gray matter of a key brain structure involved in social cognition, supporting the previously suggested link between the two conditions (Gillberg, 1983:142).

Title: Divergent facial scanning patterns in behavioural-variant frontotemporal dementia and semantic dementia

Authors: *R. HUTCHINGS[1,2,3], R. PALERMO[4,3], J. BRUGGEMANN[2,1], J. R. HODGES[1,2,3], O. PIGUET[1,2,3], F. KUMFOR[1,2,3];

Abstract: Faces offer an incredible wealth of information for social interactions. Emerging evidence suggests that some clinical groups (e.g., autism) with impaired emotion recognition do not appropriately attend to parts of the face that display emotion (e.g., eyes). Two variants of frontotemporal dementia (FTD): behavioural-variant frontotemporal dementia (bvFTD) and semantic dementia (SD), have frontal and/or temporal atrophy, which overlaps with brain networks involved in face and emotion processing. Existing evidence has shown that both bvFTD and SD patients have behavioural deficits in labelling facial expressions. Whether this impairment is due to inappropriate facial scanning, however, is unknown. This study investigated facial scanning in 20 bvFTD, 12 SD and 21 control participants. Eye tracking was recorded while participants passively viewed faces across 72 trials (3 blocks of 8 fearful, 8 happy, 8 neutral faces). Results revealed a significant group difference in the number of fixations to the eyes during the first block ($p = 0.044$). Specifically, bvFTD participants showed more fixations to the eyes than controls in both the happy ($p = 0.046$) and fearful ($p = 0.023$) condition. Furthermore, bvFTD patients showed more fixations to the eyes in the fearful condition than the SD group ($p = 0.048$). This difference diminished over repeated exposure to stimuli (i.e., across blocks), with all groups looking less at the eyes with repeated viewings of the face ($p < 0.005$). These results indicate that despite evidence of emotion labelling deficits, both bvFTD and SD are looking at emotionally relevant face regions. In particular, bvFTD participants look more at they eyes than healthy controls when viewing emotional faces, which may be suggestive of an attempt to compensate for deficits. Differences in facial scanning between these subtypes of FTD suggest distinct underlying processes influencing facial emotion decoding. Future analyses will identify the neural correlates of facial scanning patterns in these dementia syndromes. Overall, our results

provide impetus for further investigation into the mechanisms of face and emotion processing in these FTD syndromes, which will, in turn, inform our knowledge of the face-processing network.

Title: Neural and computational processes underlying dynamic changes in self-esteem

Authors: *G.-J. WILL[1], R. B. RUTLEDGE[1,2], M. MOUTOUSSIS[1], R. J. DOLAN[1,2]; [1]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom; [2]Max Planck Univ. Col. London Ctr. for Computat. Psychiatry and Ageing Res., London, United Kingdom

Abstract: Onset of psychiatric disorders is often preceded by a decline in self-esteem, and this is thought to be related to a heightened sensitivity to negative evaluation from peers. The mechanisms through which repeated negative evaluation leads to declines in self-esteem are largely unknown. To characterize the neural and computational processes underlying changes in self-esteem, we asked healthy young adults to perform a task in which they received acceptance and rejection feedback from peers who evaluated them based on an online profile. Participant expectations were manipulated by sorting peers into four groups based on the overall likelihood of giving positive social feedback to other participants. On each trial, participants were provided with a visual cue that indicated which group a peer belonged to and predicted whether the peer would like or dislike them before receiving acceptance or rejection feedback. After every 2-3 trials, participants reported their current level of self-esteem. Using computational modeling, we found that moment-to-moment fluctuations in self-esteem were best explained by the combined influence of: 1) recent expectations about social feedback and 2) social prediction errors arising from those expectations upon receipt of feedback (i.e. the difference between actual and expected feedback). Using functional magnetic resonance imaging, we show that social

prediction errors correlate with activity in the ventral striatum and momentary changes in self-esteem co-vary with activity in ventromedial prefrontal cortex. These findings provide insight into the computations performed in the brain during social feedback processing and the likely mechanisms through which social feedback cumulatively impacts on self-esteem. These results are relevant to understanding why volatility in self-esteem is a vulnerability factor for mental health problems.

Title: A neural correlate of math anxiety in the ventromedial prefrontal cortex

Authors: *K.-W. CHOE[1], A. MATTARELLA-MICKE[2], M. G. BERMAN[1], S. L. BEILOCK[1]; [1]Dept. of Psychology, Univ. of Chicago, Chicago, IL; [2]Grad. Sch. of Educ., Stanford Univ., Stanford, CA

Abstract: Many individuals report strong feelings of tension, apprehension, and fear of math (Richardson and Suinn, 1972) as exemplified by the fact that 30% of students feel helplessness when solving math problems (OECD, 2013). This emotional reaction, termed Math Anxiety (MA), has long been associated with avoidance of math and poor math performance (Hembree, 1990), which may be depriving societies of individuals with the mathematical expertise needed for economic and technological development (National Mathematics Advisory Panel, 2008). The underlying neurocognitive mechanisms of math anxiety remain unclear (Artemenko et al., 2015), hindering the development of effective preventions and interventions. Using functional magnetic resonance imaging (fMRI), we investigated how MA modulates brain activity while nineteen participants were solving easy and hard math problems. MA is more pronounced when solving hard math problems (Ashcraft and Kirk, 2001; Lyons and Beilock, 2012), therefore we focused

on the difficulty-related activation by contrasting easy and hard trials. SPM12 was used to preprocess and analyze fMRI data, including motion correction, coregistration, spatial normalization into the MNI space (voxels resampled to 2 x 2 x 2 mm), spatial smoothing (6 mm FWHM Gaussian kernel), and statistical modeling of each participant. Difficulty-related activation was related to MA using a group-level multiple regression model, in which the participants' MA scores, age, and gender were entered as covariates. To identify significant voxel clusters, a non-parametric permutation test was performed using SnPM13 (Nichols and Holmes, 2001) with a cluster-forming threshold equivalent to $p < 0.001$ at the voxel level. The analysis revealed only one cluster (x, y, z = 0, 42, -14; $k = 169$; $T(15) = 7.16$; P [FWE] = 0.019) in the ventromedial prefrontal cortex (vmPFC). Consistent with previous research (Young et al., 2012), the vmPFC deactivated in hard relative to easy math trials, and MA was positively associated with the level of vmPFC deactivation. Interestingly, this part of vmPFC has been shown to deactivate when people judged trait adjectives to be less self-descriptive or less important to oneself (D'Argembeau et al., 2012), indicating a plausible link between MA and distancing one's self-representation from math (Necka et al., 2015). When faced with difficult math tasks, the higher one's MA, the more they may distance their self-concept from math.

Title: When cultures mix: neurobehavioral responses to the visual mixing of cultural symbols

Authors: *G. CHRISTOPOULOS[1,2], W. YAP[3], B. CHEON[2], Y.-Y. HONG[4];
[1]Nanyang Business Sch., Singapore, Singapore; [3]Nanyang Business Sch., [2]Nanyang Technological Univ., Singapore, Singapore; [4]Chinese Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Recent work in cultural psychology suggests that humans represent the intrusion of foreign cultures using mechanisms similar to contamination detection and rejection. Similarly, social neuroscience studies have identified brain areas that signal violations of social norms or

order. Here, we examine how the human brain represents the visual depiction of cultural mixing. We developed images where cultural symbols from the home culture were mixed with symbols from a foreign culture. These images were employed in an N-back task, without any further instructions. Neuroimaging results suggest the involvement of amygdala in the response to mixing with foreign cultural symbols (but not when mixing with same-culture symbols). Specifically, bilateral amygdala responses (paired ttest p(fwe) = .014; region of interest analysis using bilateral amygdala) were higher when the local cultural symbol was mixed with the foreign cultural symbol, as compared when it was mixed with another local symbol. These preliminary results suggest that the human brain is sensitive to cultural symbols, especially when they are mixed with symbols representing foreign cultures. These results could help us understand how humans respond to an increasingly multicultural world.

Title: Excessive association between negative intentionality and immorality is diminished in autism spectrum disorder

Authors: *K. IIJIMA[1,2], Y. YOMOGIDA[1], K. ASADA[3], K. ABE[1], A. SUGIURA[2,4], S. KUMAGAYA[3], K. MATSUMOTO[1];

Abstract: Moral judgment is a highly complex mental process, and the features that drive it have been the center of research in psychology, neuroscience, and philosophy. Classical models assumed that intentionality of an action guides moral judgments on that action. However, recent findings suggest that moral judgment could inversely affect judgment on intentionality. Specifically, most people attribute intentionality to morally bad side-effects, but not to morally good side-effects. In the present study, we focused on this phenomenon, known as 'the Knobe effect', and examined the psychological and neural mechanisms underlying this effect using functional magnetic resonance imaging (fMRI) by comparing adults with autism spectrum disorder (ASD) and neurotypical adults (NT). We prepared various types of scenarios, including not only negative but also positive scenarios, such as intended, attempted, and accidental harms/helps. Furthermore, we prepared two distinct sets of 20 negative and 20 positive side-effects in contrast that previous studies examined the Knobe effect with only few typical scenarios, so that we could quantify the effect and eliminate scenario-specific factors. Thirteen ASD and 11 NT judged the degree of morality and intentionality of the protagonist's action for each scenario in the scanner. We found that both ASD ($P = 0.02$) and NT ($P < 0.001$) showed significant Knobe effects. Interestingly, attribution of intentionality in negative side-effects was significantly smaller in ASD than NT ($P = 0.03$), with no significant difference in positive side-effects, indicating that the Knobe effect is attenuated in ASD. In addition, moral judgments for attempted harms were less severe in ASD than NT ($P < 0.05$). We hypothesized that this decreased dependence of moral judgment on intentionality is related to the diminished Knobe effect in ASD. We quantified how much moral judgment of each individual depends on intentionality (the degree of intentionalism: DOI) by comparing moral judgments for attempted helps to attempted harms. We could derive DOI from these scenarios, since protagonists brought the same morally neutral outcomes with either good or bad intentions there. Interestingly, as with the Knobe effect, DOI was significantly lower in ASD than NT ($P < 0.05$). Moreover, DOI showed a significant positive correlation with the strength of the Knobe effect ($P < 0.001$), that is, those who depends more on intentionality in moral judgment showed stronger Knobe effects. These results suggest that the Knobe effect is subserved by a bidirectional interaction between intentionality and morality, and help to understand the social difficulties in people with autism.

Title: Neural responses to moral violations do not support a division between individualizing and binding categories

Authors: *E. HANNA[1], V. IYENGAR[1], S. CLIFFORD[2], F. DE BRIGARD[1], R. CABEZA[1], W. SINNOTT-ARMSTRONG[1];
[1]Psychology & Neurosci., Duke Univ., Durham, NC; [2]Univ. of Houston, Houston, TX

Abstract: Moral Foundations Theory (MFT) is the predominant social psychological explanatory framework for the recurrence of moral themes across cultures, decomposing morality into the canonical foundations of authority, loyalty, purity, fairness, and harm. Recent additions to this framework have proposed a liberty foundation. These themes have been theoretically united under superordinate headings of "individualizing" foundations (harm and fairness), which center on wrongs perpetrated against an individual; and "binding" foundations (authority, loyalty, and purity), which center on wrongs perpetrated against the community. To date, no neuroimaging study of morality has examined the entire set of moral violations proposed by the MFT. The present study used functional magnetic resonance imaging (fMRI) to investigate the neural correlates underlying each of the proposed moral foundations, and to probe whether the superordinate categories of individualizing and binding are appropriate ways to dissociate morality at the neural level. While in the scanner, participants provided judgments of the moral wrongness of actions which violated the canonical foundations (including liberty) as well as violations of nonmoral social norms. Analysis of the imaging data revealed that almost all violations deemed morally wrong elicited activity from a set of regions comprising the default mode network. Regions included the dorsomedial prefrontal cortex, and medial posterior cortical regions, extending across retrosplenial and posterior cingulate cortex as well as precuneus. Exceptions to this activation pattern were found in violations of the authority foundation and violations of the harm foundation when the harm was physical as opposed to emotional. Additionally, violations of fairness and loyalty both elicited bilateral activity in ventrolateral parietal cortical areas and medial prefrontal cortices, potentially reflecting foundation-level differences in attentional allocation and/or mentalizing respectively. Collectively, these findings support the idea that it may not be appropriate to unite foundations under the headings of individualizing and binding when discussing the neural substrates of morality.

Title: A neuroimaging account of accountability in allocentric decision making

Authors: *S. FITZGERALD[1,3,4], G. CHRISTOPOULOS[2,3,4];
[1]DEcision and Organizational Neurosci. Lab. at The Culture Sci. Inst., [2]Nanyang Technological Univ., Nanyang Business Sch., Singapore, Singapore; [3]Nanyang Business Sch., Culture Sci. Inst., Singapore, Singapore; [4]Nanyang Business Sch., Decision and Organizational Neruoscience Lab., Singapore, Singapore

Abstract: Neural mechanisms of subjective reward valuation are well established in the literature; however little research has explored neurological mechanisms of vicarious reward valuations. This occurs when decision makers choose outcomes for recipients other than themselves and have no vested interest in the outcomes. We refer to these scenarios as allocentric decisions. One important control mechanism on allocentric decision making is accountability from external regulators. Here, we examine the role of accountability as participants made choices for another about a typing task with decision trade-offs between a task's effort and monetary reward (Masser et al. 2015). Using fMRI, we examined the neural processes of participants making both socially accountable and private decisions within-subjects. Behavioral analyses show socially accountable decisions discounted effort more than non-social accountability choices and resulted in more low-effort low-reward outcomes. Fitting the behavioral data with a sigmoidal model of effort discounting shows an increase in both the discounting rate (t_k = -2.95, p_k = 0.006) and the threshold level at which discounting begins (t_p = -2.90, p_p = 0.007) under social accountability. Preliminary neuroimaging analysis identified bilateral activation of inferior parietal lobule (IPL) when contrasting decision making under social accountability compared with non-social accountability (48, -61, 47; $p_{(unc)}$ = .002; -45, -58, 38; $p_{(unc)}$ = .007). This brain area has been repeatedly associated with self-other discrimination and social cognition more generally (Uddin et al. 2006). These results could further

understanding of how social controls - intrinsic to organizational environments - could affect decision mechanisms.

Title: Over-entrainment to the partner’s eye-blinks during eye contact in autistic spectrum disorders

Authors: *T. KOIKE[1], H. K. TAKAHASHI[1], E. NAKAGAWA[1], S. OKAZAKI[1], H. C. TANABE[2], H. KOSAKA[3], H. OKAZAWA[3], N. SADATO[1];

Abstract: It has been proposed that the difficulty in shifting mental set, which is critical in social interaction, may be the root of cognitive impairment of persons with autism spectrum disorders (ASD). ASD have difficulty in joint attention: sharing attention with social partners towards third object. As an initial eye contact prior to looking at an object is a critical cue for establishing joint attention, eye contact and joint attention are tightly coupled. We hypothesized that the impairment in shifting mental set is reflected in the train of eye contact alternated with joint attention task. Because joint attention task forces to synchronize the temporal attentional window demarked by eye-blink (Koike et al. 2016), the mental set is to be casted to the task. As interleaved eye contact does not require specific task, mental set should be shifted.
To test the hypothesis, we analyzed the video-recorded eye-movement including blink previously obtained during block-design hyperscanning fMRI with joint attention task by 20 pairs, i.e. ASD paired with typically-developed (TD) subjects, and 26 TD-TD pairs (Tanabe et al. 2012). In joint attention blocks (JA), one subject shifts own gaze toward the object on the screen. At the same time, other subject follow partner' gaze shift to share their attention on the same object. In eye contact blocks (EC) both subjects keep eye contact. The noise contribution ratio (NCR), the measure of influence, was evaluated with a multivariate autoregressive model. As a baseline of NCR, we calculated the non-pair-NCR across all possible combination of subjects and blocks. The ΔNCR, enhancement of NCR from the baseline, was used as a degree of influence of eye blink from the partner.
During EC, ΔNCR was negatively correlated with verbal IQ (VIQ) both in ASD and TD. After modeling out the variance due to the VIQ, two-way ANOVA of condition [EC, JA] × group [ASD, TD] showed the significant main effect of condition ($F(1,25)=10.03$, $p=0.004$) and interaction ($F(1,38) = 4.929$, $p=0.036$). The interaction was not significant in TD-TD group. That is, partner's eye blink influenced own eye blink during EC, more prominent in ASD than TD. As JA tasks were strictly identical across the block and subjects, partner-specific influence was minimized. During EC, no specific task was requested, thus partner's influence became evident which may represent the carry-over of the JA task-specific influence from the partner. Furthermore, the degree of influence was negatively correlated to the VIQ reflecting executive function. Thus the over-entrainment of the ASD conceivably reflects their impaired executive function of shifting mental sets.

Title: Connectivity between auditory and visual cortices mediates the impact of argument strength on the efficacy of anti-smoking videos among low-sensation-seeking smokers

Authors: *Z. SHI[1], V. FAIRCHILD[1], A.-L. WANG[1], C. ARONOWITZ[2], J. N. CAPPELLA[3], D. ROMER[2], D. D. LANGLEBEN[1];
[1]Dept. of Psychiatry, [2]Annenberg Publ. Policy Ctr., [3]Annenberg Sch. for Communication, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Smoking-cessation videos with high argument strength (AS) are more effective at reducing smoking behavior than low-AS ones. Prior research suggested that the interaction between AS and sensory aspects of the video messages are associated with their overall effectiveness. In addition, studies agree on the importance of the sensation-seeking trait in smokers' sensitivity to smoking-cessation interventions. We hypothesized that integration of visual and auditory (i.e. multisensory) processing would mediate the effectiveness of high-AS smoking-cessation videos on subsequent smoking behavior, and that such mediation would be moderated by smokers' sensation seeking. Using functional magnetic resonance imaging (fMRI), we recorded the brain response of 66 smokers (32 females) randomly assigned to view either 16 high-AS or 16 low-AS smoking-cessation videos. A validated I² content analytic measure (Lang et al. 2006) quantified the amount of visual and auditory information in each video, which was matched between high-AS and low-AS videos. Multisensory processing of the videos was indexed by the functional connectivity between sensory cortices. Specifically, such connectivity was assessed by identifying cortical regions whose activity was parametrically modulated by the visual and auditory I² scores, and computing the correlation between fMRI signals extracted from these regions. Sensation seeking was measured using the Brief Sensation Seeking Scale (Hoyle et al. 2002). Smoking behavior was assessed with urine levels of nicotine metabolite cotinine immediately before (baseline) and approximately 30 days after (follow-up) the fMRI session. We tested a moderated mediation model using AS as the input variable, follow-up cotinine level (adjusted for baseline) as the outcome variable, multisensory neural connectivity as the mediator, and sensation seeking as the moderator. We found a significant (p=.01) moderated mediation effect: the high-AS videos produced greater connectivity, which in turn negatively predicted follow-up cotinine levels among the low-sensation-seeking smokers. This

effect was absent in the high-sensation-seeking group. Our results suggest that 1) audiovisual neural integration underlies the greater efficacy of high-AS smoking-cessation videos, and that 2) high sensation seeking confers resistance to anti-smoking arguments. These findings highlight the importance of accounting for brain connectivity and individual differences in the evaluation of anti-smoking messaging in particular and public health communication in general.

Title: Affective bias is sensitive to acute electrical stimulation of two limbic regions: subcallosal cingulate white matter and amygdala

Authors: *K. C. ROWE[1], H. S. MAYBERG[2], C. K. KOVACH[5], C. S. INMAN[3], A. L. CROWELL[2], R. E. GROSS[3], D. L. DRANE[4], J. T. WILLIE[3];

Abstract: Background: Electrical brain stimulation is a currently being evaluated as an experimental therapy for depression, as well as being investigated as a method for mapping emotional brain functions. As deep brain stimulation (DBS) expands in the realm of psychiatric disorders, sensitive measures are needed to quantify effects of stimulation on emotional processing. We examined the effects of acute stimulation to two limbic regions, the subcallosal cingulate (SCC) and the amygdala, on affective bias in the perception and evaluation of

emotional facial expressions. We hypothesized that transient electrical stimulation to the limbic system would produce acute reductions in negative bias. **Methods:** A novel affective bias task was developed to quickly and implicitly measure emotional state. Over 4-6 minutes, patients rate the intensity and valence of images of emotional facial expressions. We examined stimulation effects in two groups: patients with treatment-refractory depression undergoing SCC DBS therapy, and epilepsy patients undergoing amygdala stimulation via stereo-EEG electrodes during inpatient intracranial monitoring. Patients completed the task during high-frequency stimulation of the SCC or amygdala, and during sham stimulation conditions. **Results:** Three SCC DBS patients showed significant positive shifts in affective bias with chronic DBS therapy. Furthermore, two DBS patients showed a rapid negative shift in bias following acute (18 minutes) discontinuation of chronic stimulation. Likewise, seven epilepsy patients show significantly positive shifts in affective bias with acute amygdala stimulation. **Discussion:** Affective bias shows rapid, significant changes with stimulation at one white matter limbic target and one gray matter limbic target, suggesting utility as an emotional outcome measure in brain stimulation studies. This task may facilitate tracking and predicting treatment response in DBS therapy. Future studies will determine whether affective bias can predict possible neuropsychiatric complications in patients undergoing mapping of brain circuitry ahead of resection surgery for epilepsy.

Ctr., Dallas, TX

Abstract: Background: The adaptability of the human brain to the constantly changing environment is often reduced in patients with psychotic disorders, leading to impaired cognitive functions. Brain signal complexity, which may reflect adaptability, can be readily quantified via resting-state functional magnetic resonance imaging (fMRI) signals. We hypothesized that resting-state brain signal complexity is altered in psychotic disorders, and is correlated with cognitive impairment.
Methods: We assessed 156 healthy controls (HC) and 330 probands, including 125 patients with psychotic bipolar disorder (BP), 107 patients with schizophrenia (SZ), 98 patients with schizoaffective disorder (SAD) and 230 of their unaffected first-degree relatives (76 BPR, 79 SADR, and 75 SZR) from four sites of the Bipolar-Schizophrenia Network on Intermediate Phenotypes (B-SNIP) consortium. Using multi-scale entropy analysis, we determined whether patients and/or relatives had pathologic differences in complexity of resting-state fMRI signals toward regularity (reduced entropy in all time scales), or toward uncorrelated randomness (increased entropy in fine time scales that decays as the time scale increases) and how these complexity differences might be associated with cognitive impairment.
Results: Compared to HC subjects, all proband groups showed significantly increased brain signal randomness in dorsal and ventral prefrontal cortex (PFC), and unaffected relatives showed no complexity differences in PFC regions. SZ had the largest area of involvement in both dorsal and ventral PFC. BP and SAD probands shared increased brain signal randomness in ventral medial PFC, BP and SZ probands shared increased brain signal randomness in ventral lateral PFC, whereas SAD and SZ probands shared increased brain signal randomness in dorsal medial PFC. Only SZ showed increased brain signal randomness in dorsal lateral PFC. The increased brain signal randomness in dorsal or ventral PFC was weakly associated with reduced cognitive performance in psychotic probands.
Conclusion: These observations support the loss of brain complexity hypothesis in psychotic probands. Furthermore, we found an overlap of pathologic brain signal complexity between psychotic probands by DSM diagnoses, thus providing a biological basis for categorizing psychosis based on functional neuroimaging data.

Title: Perineuronal net-associated extracellular matrix clusters in the normal human amygdala: relevance to SZ

Authors: *K. T. PILOBELLO[1], H. PANTAZOPOULOS[2], S. BERRETTA[2], R. MCCULLUMSMITH[3], S. ODONOVAN[3], R. KOENE[3], P. W. TILLBERG[4], E. S. BOYDEN[4]; [2]Mailman Res. Ctr., [1]McLean Hosp., Belmont, MA; [3]Col. of Med., Univ. of Cincinnati, Cincinnatti, OH; [4]Media Lab., MIT, Cambridge, MA

Abstract: Recent findings from our group show marked abnormalities affecting distinct components of the extracellular matrix in subjects with schizophrenia (SZ) and bipolar disorder (BD). In particular, perineuronal nets (PNNs) and glial cells labeled with markers for chondroitin sulfate proteoglycans (CSPGs) were altered in several brain regions in these disorders. The interactions between perineuronal nets and glia are multifold, as glial cells significantly contribute to making perineuronal nets and intimately regulate synaptic functions and plasticity. In the human amygdala, CSPGs bearing the CS-6 sulfation pattern form larger CSPG aggregates, named here 'CS-6 clusters', encompass several glial cells and are in close spatial relationship with PNNs labeled with the same markers. Subjects with SZ and BD showed profound decreases of both CS-6 clusters and CS-6 perineuronal nets. In the context of their relevance to these disorders, we tested the hypothesis that CS-6 clusters may represent conglomerates of perisynaptic CSPG aggregates within specialized multicellular domains.
In healthy human amygdalas (n= 3), CS-6 clusters were laser dissected and co-immunoprecipitated with CS-6 antibody, followed by mass spectrometry (MS) to identify proteins specific to CS-6 clusters. Confocal microscopy using CS-6 antibodies in combination with glial markers (glial fibrillary acidic protein (GFAP)) and a combination of expansion microscopy (ExM) and confocal microscopy were used to examine the relationship between CS-6 clusters, glial cells, PNNs and synapses.
The MS results show the CSPG versican as a major component of CS-6 clusters. Versican, involved in PNN formation, has splice-forms with developmentally regulated subunits of different CS-6 levels. Confocal microscopy shows that CS-6 clusters range in size (60-100 microns) and present with a pattern punctate labeling reminiscent of synaptic cartridges, radiating from their center. They are surrounded by glial fibrillary acidic protein (GFAP)-positive glia, while these cells are more sparsely distributed inside the clusters. CS-6-labeled

PNNs directly connect with the clusters. Images of CS-6 clusters using ExM, confirm this finding and are currently being used to test spatial relationship between punctate CS-6 condensations with the cluster and synapses.
Our results are consistent with the hypothesis that CS-6 clusters represent functional structures related to synaptic function and interact with PNNs, as well as subpopulations of glial cells. In SZ and BD, reductions of CS-6 clusters may represent specialized forms of extracellular matrix contributing to the synaptopathology of these disorders.

Title: Proteomic signatures associated with cognitive deficits in schizophrenia

Authors: *J. LAVOIE, C.-H. NA, L. SHAFFER, R. WARD, D. SCHRETLEN, K. ISHIZUKA, A. PANDEY, A. SAWA;
Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The discovery of novel molecular signatures that may represent biomarker candidates is essential to understand the pathophysiology of schizophrenia (SZ). Cognitive deficit is a key feature of SZ and a predictor of functional outcome in patients. However, the molecular signatures associated with cognitive impairment are not yet well understood. Recent major advances in human cell technologies have provided us opportunities to use neuronal cells from patients, such as olfactory epithelium (OE)-derived neuronal cells, that show immature neuronal traits and have been enriched to near homogeneity from biopsied OE. In the present investigation, we aimed to describe proteomic signatures in OE-derived neuronal cells from SZ patients and study their association with cognitive deficits. To do so, we have performed a pilot study with mass spectrometry using TMT labeling with OE-derived neuronal cells taken from age-, gender-, race- and smoking status-matched 10 controls and 10 SZ patients. Neuropsychological assessments were conducted for all subjects. The investigated domains include: full scale IQ, processing speed, verbal memory, visual memory, ideational fluency and

executive functioning. Among 7,179 quantified proteins, we reported 71 proteins differentially expressed between SZ patients and controls (q-value<0.05). Several KEGG pathways were found to be enriched, including the DNA replication pathway. Additionally, we found significant ($p<0.05$) differences in performance across neurocognitive tests with patients' performance being worse than controls for processing speed and ideational fluency, as well as trends ($p<0.1$) for lower IQ and verbal memory in SZ patients. The composite score was also significantly lower in SZ patients ($p=0.019$). The association between the differentially expressed proteins and the cognitive deficits in SZ was further investigated and several positive correlations were reported. These observations suggest that some proteomic signatures measured in OE-derived neuronal cells are associated with cognitive deficits in SZ. We believe that our unique approach of combining two observations from the same subject - protein expression and neuropsychological assessment - will help identifying new drug targets by connecting molecular phenotypes and clinical outcomes.

Title: Abnormal trajectory of intracortical myelination in schizophrenia implicates white matter in disease pathophysiology and the therapeutic mechanism of action of antipsychotics.

Authors: *T. A. TISHLER[1], G. BARTZOKIS[1], P. H. LU[1], E. P. RAVEN[2], M. KHANOYAN[1], C. KIRKPATRICK[1], M. PYLE[1], P. VILLABLANCA[1], L. L. ALTSHULER[1], J. MINTZ[3], J. VENTURA[1], L. CASAUS[1], K. L. SUBOTNIK[1], K. H. NUECHTERLEIN[1], B. M. ELLINGSON[1];
[1]UCLA, Los Angeles, CA; [2]Georgetown Univ., Washington, DC; [3]Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Background:
Post-mortem and imaging studies provide converging evidence that frontal lobe myelination trajectory is dysregulated in schizophrenia and suggest that, early in treatment, antipsychotic medications increase myelination and specifically intracortical myelin (ICM). We used magnetic resonance imaging (MRI) to examine whether in schizophrenia, the ICM trajectory is dysregulated compared to healthy control subjects, altered by treatment with oral antipsychotics, and associated with cognitive performance.
Methods:
Frontal lobe ICM volume was estimated using a novel method that combines distinct tissue contrasts provided by inversion recovery (IR) and proton density (PD) MRI images. One hundred and one subjects with schizophrenia (71 males and 30 females) were examined in conjunction with 85 healthy control subjects (57 males and 28 females). At the time of MRI acquisition the subjects with schizophrenia had lifetime oral antipsychotic medication exposures ranging from 0-333 months.
Results:
When plotted against medication exposure, the ICM trajectory of subjects with schizophrenia reached a maximum value at one year of antipsychotic treatment, significantly increasing during the first year of treatment and significantly decreasing thereafter. In subjects with schizophrenia, better cognitive processing speed and working memory were associated with greater ICM volume. ICM of subjects with schizophrenia declined with age, while ICM of healthy control subjects did not.
Conclusions:
In vivo MRI can dissect subtle brain tissue differences and could help clarify mechanisms of action of treatment interventions. In adults with schizophrenia, oral antipsychotic treatment is associated with an increase in ICM during the first year of treatment followed by a decline despite continued treatment. This ICM trajectory resembles clinically observed antipsychotic response trajectory with high rates of remission in the first year followed by progressively lower response rates. The inverted U of the ICM trajectory also resembles the typical pattern of initial antipsychotic medication adherence followed by nonadherence. Antipsychotic treatment may modify the tendency for ICM to decline in schizophrenia, possibly through inhibition of the constitutively active enzyme glycogen synthase kinase 3 (GSK3). Dopamine and serotonin receptor blockade provided by antipsychotics inhibit GSK3 and promote myelination. The results support post-mortem evidence that schizophrenia pathophysiology involves ICM deficits and suggest that correcting these deficits may be one mechanism of action of antipsychotics.

Title: Causal relationship between the antioxidant glutathione, kynurenic acid and glutamate in rat prefrontal cortex

Authors: *H.-Q. WU, R. SCHWARCZ;
Maryland Psychiatric Res. Ctr., Baltimore, MD

Abstract: Oxidative mechanisms play key roles in brain physiology and pathology. The neuromodulatory tryptophan metabolite kynurenic acid (KYNA), which can control normal and abnormal cognitive processes in rodents (Schwarcz et al., 2012), is biosynthesized from its precursor L-kynurenine (L-KYN), both by irreversible enzymatic transamination [via kynurenine aminotransferases (KATs)] and by oxidation (Blanco-Ayala et al., 2015). Here, we tested the respective contributions of these two mechanisms by performing microdialysis in the prefrontal cortex of unanesthetized rats, focusing mainly on a possible role of the endogenous antioxidant glutathione (GSH). Extracellular levels of KYNA and glutamate - which is bi-directionally influenced by KYNA fluctuations in the brain (Pocivavsek et al., 2011) - were used as outcome measures. Applied locally by reverse microdialysis for 2 h, GSH (1 - 5 mM) caused a dose-dependent, reversible decrease in extracellular KYNA levels (to a nadir of -26% of baseline values). Reverse dialysis of the reducing agent dithiothreitol (5 mM) produced a qualitatively similar reduction in extracellular KYNA. Perfusion with 5 mM GSH also resulted in a ~2-fold, reversible increase in extracellular glutamate levels. Co-application of KYNA (100 nM) with

GSH (5 mM) effectively prevented the increase in glutamate induced by GSH alone. In separate rats, local perfusion with L-KYN (5 μM) increased extracellular KYNA levels ~4-fold and caused a modest reduction in glutamate (-30%). This L-KYN-induced KYNA elevation was partially blocked by co-perfusion of GSH (5 mM) alone and completed abolished by the combination of GSH (5 mM) and ESBA (3 mM), a selective inhibitor of the major KAT isozyme KAT II. Finally, reverse dialysis of the GSH synthesis inhibitor L-buthionine sulfoximine (5 mM; 4 h) produced a relatively slow, reversible increase in extracellular KYNA (peak: 160% of baseline levels). Taken together, these results suggest that the astrocyte-derived α7 nicotinic and NMDA receptor antagonist KYNA may constitute a mechanistic link between endogenous GSH and glutamate in the rat prefrontal cortex. As all three of these compounds have been proposed to participate in the pathophysiology of schizophrenia and other major brain diseases, careful scrutiny of this link may lead to novel insights regarding the etiology and treatment of these diseases.

Title: Characterization of cellular localization of OTX2 in human prefrontal cortex and its alterations in schizophrenia

Authors: *K. M. ATHANAS[1], M. I. ARDELT[1], S. BERRETTA[2,3], W. T.-U. WOO[1,4,3,5]; [1]Lab. for Cell. and Mol. Neuropathology, [2]Lab. of Translational Neurosci., McLean Hosp., Belmont, MA; [3]Dept. of Psychiatry, Harvard Med. Sch., Boston, MA; [4]Dept. of Psychiatry, Beth Israel Deaconess Med. Ctr., Boston, MA; [5]Program of Neurosci., Harvard Univ., Boston, MA

Abstract: OTX2 is a homeobox transcription factor that has long been known to play a key role in many aspects of early embryonic brain development. Increasing evidence from rodent studies suggests that OTX2 may also play a key role in orchestrating the postnatal development of the cerebral cortex by regulating the postnatal maturation of the inhibitory interneurons that contain parvalbumin (PVB) and extracellular matrix structures called perineuronal nets (PNNs). More

recent research suggests that OTX2 is synthesized and secreted from the choroid plexus and is transported via the cerebral spinal fluid (CSF) to reach cortical destinations. Deficits of OTX2 may therefore contribute to disturbances of PVB neurons and PNNs and hence cortical circuitry dysfunction in schizophrenia. Our preliminary findings suggest that OTX2 is not only associated with PVB neurons and neurons that are encapsulated with PNNs but is also found in non-PVB cells, including possibly glia, and non-PNN-encapsulated cells. In this study, we will use double immuno-colocalization to characterize the specific cellular stoichiometry of OTX2 localization in the human prefrontal cortex (PFC) and its alterations in schizophrenia. We will also investigate whether OTX2 concentration in the CSF may be altered in subjects with this illness.Altogether, findings of this study will deepen our insight into the possible pathophysiological mechanisms that underlie PFC dysfunction in schizophrenia and may shed light on novel, targeted therapeutic strategies.

Title: Glutamatergic signaling is disrupted in the PSD of the amygdala and the nucleus accumbens in schizophrenia

Authors: J. CESARE[1], A. BANERJEE[1], S. WILLARD[1], N. BOWMAN[1], C.-G. HAHN[1], *K. BORGMANN-WINTER[2,3];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Dept Psychiatry, Univ. Pennsylvania, Philadelphia, PA; [3]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Previously, we reported the first direct evidence for altered glutamatergic signaling, i.e., decreased GluN2 phosphorylation, which was traced to hypoactivity of Src kinases in the postmortem DLPFC of patients with schizophrenia. Here, we examine these dysregulations in the amygdala and nucleus accumbens (NA), which are implicated in negative symptoms of schizophrenia.Postmortem amygdala and NA from 10 matched pairs of schizophrenia patients and controls were fractionated for PSD enrichments. Liquid chromatography-selected reaction

monitoring mass spectrometry (LC-SRM/MS) was used to quantify 250+ proteins. The resulting protein expression was correlated with findings from a previously conducted Src kinase activity assay. Decreased Src activity and altered association of GluNs with signaling partners were observed in the NA and amygdala in schizophrenia. In proteomics analyses, the two brain regions show parallel increases in GluN2B ($p<0.05$), but differential alterations by region in mGluR2/3. Presynaptic vesicular proteins and adhesion molecules were strikingly decreased in the amygdala, but less so in the NA in schizophrenia. Src kinase activity was highly correlated with GluN1 ($r=.46, p<0.05$) and CAMKII ($r=.44, P<0.05$) in the PSD enrichments. Our results show molecular signatures for altered NMDA receptor signaling in the amygdala and NA of patients with schizophrenia. As shown in the DLPFC, both brain regions exhibit Src hypoactivity, with differing molecular underpinnings between regions. The amygdala and NA of schizophrenia cases show overall parallel changes in glutamatergic receptors, PSD signaling proteins and presynaptic vesicular molecules, pointing to glutamate release and post-synaptic receptor signaling as loci of dysregulation.

Title: Emerging roles of Disrupted-In-Schizophrenia 1 in microglia

Authors: *F. OGAWA, A. NOMURA, K. MATSUZAKI, S. MIYAKE;
Juntendo Univ. Sch. of Med., Tokyo, Japan

Abstract: Microglia are the resident immune cells in the CNS that play crucial roles in maintaining brain homeostasis. Dysregulated microglial function has been increasingly implicated in the pathophysiology of psychiatric disorders such as schizophrenia. Among schizophrenia risk genes identified to date, *Disrupted-In-Schizophrenia 1* (*Disc1*) is considered to be one of the most convincing risk factors. Although its biological significance has been studied intensively in neurons, functional roles of Disc1 in microglia remain completely

unknown. Here, we performed a large scale co-immunoprecipitation assay using a mouse microglial cell line coupled to LC-MS/MS analysis to dissect the contribution of Disc1 to microglial function. We identified a number of novel Disc1-binding partners, some of which are likely to be expressed predominantly in microglia, suggesting microglia-specific roles of Disc1. Of particular interest are those that regulate cytoskeletal rearrangement and intracellular cytokine trafficking since microglia are highly motile and also known as a major source of inflammatory cytokines in the brain. Furthermore, live imaging of microglial cells expressing either mutant forms of Disc1 or a Disc1-siRNA was conducted and reveals that Disc1 profoundly influences motility of microglial cells. We therefore propose that Disc1 may participate directly in regulation of intracellular cytokine transport and cell motility in microglia. Impaired Disc1 function may cause dysregulation of these biological processes in microglia, which could potentially lead to increased risk for psychiatric disorders.

Title: Changed cortical BQCA modulation of [^{3}H]NMS binding in schizophrenia

Authors: ***B. DEAN**[1], S. HOPPER[1], J. CONN[2], E. SCARR[1];
[1]Mol. Psychiatry Lab., Parkville, Australia; [2]Vanderbilt Ctr. for Neurosci. Drug Discovery, Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: The hypothesis that activation of cortical muscarinic M1 receptor (CHRM1) will improve the symptoms of schizophrenia can now be challenged using CHRM1 allosteric modulators. However, whilst allosteric modulators have been shown to change the activity of CHRMs using cloned human CHRMs and CHRM knockout mice, data on CHRM1 in human CNS is lacking. Here we show, *in vitro*, that BQCA, a positive allosteric CHRM1 modulator, brings about the expected change in affinity of the CHRM1 orthosteric site for acetylcholine in human cortex. That there was no change in [^{3}H]NMS binding to the cortex from subjects

schizophrenia, whether or not they had changed levels of CHRM1. By contrast there was a 57% reduction in responsiveness, as measured as the area within the acetylcholine shift cause by 3uM BQCA, to BQCA in the cortex of a subset of subjects with schizophrenia who have a profound loss (-75%) of CHRM1 as measured using [^{3}H]pirenzepine binding. These data suggest BQCA responsiveness is not simply governed by CHRM1 levels in the human cortex. To better understand the control of [^{3}H]pirenzepine and [^{3}H]NMS binding to human cortex we studied the impact of Zn^{2+} and Mg^{2+} which have both been shown to affect the binding sites on G-protein coupled receptors. We showed total [^{3}H]pirenzepine and [^{3}H]NMS binding was reduced by Zn^{2+}, acetylcholine displacement of [^{3}H]NMS binding was enhanced by Mg^{2+} and Zn^{2+}, acetylcholine displacement of [^{3}H]pirenzepine was reduced by Mg^{2+} and enhanced by Zn^{2+} whilst BQCA effects on [^{3}H]NMS, but not [^{3}H]pirenzepine, binding was enhanced by Mg^{2+} and Zn^{2+}. These data suggest the orthosteric and allosteric sites on CHRMs respond differently to divalent cations and changes in cortical micro-environments may contribute to drug binding to CHRM1 in the human cortex.

Title: Neurons expressing parvalbumin in the thalamic reticular nucleus and their potential role in the pathophysiology of schizophrenia

Authors: *S. A. BUKHARI[1], H. PANTAZOPOULOS[1,2], S. BERRETTA[1,2,3];
[1]Translational Neurosci. Laboratory, Basic Neurosci. Div., McLean Hosp., Belmont, MA; [2]Dept. of Psychiatry, [3]Program of Neurosci., Harvard Med. Sch., Boston, MA

Abstract: Background: Growing evidence from imaging studies points to a disruption of thalamo-cortical connectivity as a critical element of the pathophysiology of schizophrenia (SZ) and, potentially, bipolar disorder (BD). This study focuses on the Thalamic Reticular Nucleus (TRN), a nucleus critically involved in modulating cortico-thalamic-cortical circuits. The TRN has been postulated to enhance cognitive and emotionally relevant stimuli while suppressing irrelevant stimuli - functions that resonate with symptoms of these disorders, such as disruption of sensory gating and emotion processing. We hypothesize that the TRN may be impacted in the pathophysiology of SZ and BD. As a fist step toward testing this hypothesis we measured numbers of neurons expressing parvalbumin (PVB), a predominant TRN neuronal population, in subjects with these disorders. **Methods:** Serial sections containing the TRN from 15 SZ patients, 15 BD patients, and 20 control subjects were immunostained using antibodies raised against PVB. Computer-assisted quantitative light microscopy was used to estimate total numbers and numerical densities of PVB-immunoreactive (IR) neurons as well as TRN volume. Linear regression models were used to test the effect of diagnosis as well as the effects of potentially confounding variables, such as age, gender, exposure to pharmacological agents and substance abuse. **Results:** In subjects with SZ, we detected significant reductions of PVB-IR numerical density ($p=0.0001$) and total numbers ($p=0.0001$) as compared to healthy controls. Numbers of PVB-IR neurons significantly and positively correlated to antipsychotic exposure within the last 6 months of life. Similarly, significant decreases of total numbers ($p=0.001$) and numerical density ($p=0.001$) were found in subjects with BD. **Conclusions:** Decreased numbers of PVB-IR neurons were observed in the TRN in both SZ and BD. Results from these studies are interpreted in the context of parallel decreases of perineuronal nets in the TRN of both these disorders, detected in a parallel study. Together these findings point to an overall reduction of PVB neurons. Deficits of PVB-IR neurons within the TRN may contribute to a dysregulation of thalamo-cortical circuitry and, in turn, to disruption of emotional and cognitive processing in SZ and BD.

Title: Modeling heterochromatin: Method for determining epigenetic effects of antipsychotics at immune promoters

Authors: *B. M. FEINER[1], J. K. MELBOURNE[1], K. A. CHASE[2], R. P. SHARMA[1];
[1]Psychiatry, UIC Psychiatry, Chicago, IL; [2]Psychiatry, Univ. of California, La Jolla, CA

Abstract: Background: Schizophrenia is a debilitating mental illness affecting about 2.4 million American adults. Dysregulation of immune function, notably elevated levels of certain cytokines, is a perennial finding in the schizophrenia literature. That said, the majority of individuals diagnosed with schizophrenia are prescribed one or more antipsychotics. These drugs classically function through dopamine D2 receptor antagonism, increasing intracellular levels of cAMP and thus PKA activity, which affects numerous kinase cascades, some of which elicit epigenetically permissive changes in the nucleus. In this study, we looked to determine what effect antipsychotic treatment might have on immune response gene promoters that can be reliably heterochromatinized through chronic treatment with the bacterial endotoxin lipopolysaccharide (LPS).
Methods: Human SW872 cells which express both D2 and the LPS receptor TLR4 were cultured in the presence of LPS, Risperidone, or both for 24 hours. Cells were harvested and underwent chromatin immunoprecipitation for a transcriptionally permissive euchromatin mark (phospho-H3S10) and transcriptionally repressive heterochromatin marks (HP1γ, H3K9me2). Expression levels of epigenetic modifications at the promoters of IL6, TNFα, PPARγ, and IL1β of were determined via qPCR, with GAPDH and ZNF333 promoters as controls. Values are expressed as pulldown relative to input control. To determine functional significance, mRNA levels were also evaluated using qPCR, with values normalized to GAPDH and β-actin.
Results: LPS alone significantly increased heterochromatin marks after 24 hours, which resulted in significantly decreased mRNA levels. Risperidone alone significantly increased phospho-H3S10 levels from vehicle, while also significantly increasing phospho-H3S10 levels from LPS treatment levels when cells were treated with LPS and Risperidone concurrently. HP1γ and H3K9me2 levels significantly increased with LPS treatment, but were reduced to at or near vehicle levels with concurrent Risperidone treatment. Functionally, Risperidone was found to have a significant normalizing effect on mRNA levels of IL6, TNFα, PPARγ, and IL1β when cells were treated with both LPS and Risperidone, resulting in mRNA expression at or near vehicle levels.
Discussion: This platform provides a streamlined method to examine the downstream epigenetic effects of different antipsychotic medications. The fact that heterochromatin can reliably be assembled on specific gene promoters makes for an intriguing methodological jumping off point in not only the epigenetic effects of antipsychotics, but other compounds as well.

Title: Inhibition of the schizophrenia associated microRNA miR-137 disrupts neuregulin-induced protein synthesis

Authors: *K. THOMAS[1], B. ANDERSON[1], N. SHAH[1], Q. GU[1], G. J. BASSELL[1,2];
[1]Cell Biol., [2]Neurol., Emory Univ., Atlanta, GA

Abstract: Schizophrenia is a debilitating neurodevelopmental disorder with no cure and complex underlying genetics. Recent genome wide association studies have repeatedly found that genetic variants near and within *MIR137*, which encodes the microRNA (miRNA) miR-137, are enriched within schizophrenia patient populations. miRNAs are small noncoding RNAs that regulate mRNA translation through direct complementary base pairing to their mRNA targets. Many predicted miR-137 targets have previously been associated with schizophrenia through independent genetic studies, yet relatively few have been experimentally validated. Among these predicted targets are components of the glutamate and neuregulin (Nrg) signaling pathways, both of which may be dysregulated in schizophrenia patients. While both pathways have previously been shown to regulate neuronal development and protein synthesis, their relationships to miR-137 remain largely unexplored. In the present study, we examine the molecular relationship between miR-137, the glutamate receptor subunit GluA1, and signaling ligand neuregulin-1α (Nrg1). We find that acute stimulation with a soluble form of Nrg1 increases GluA1 levels and phosphorylation of the ribosomal protein S6 in dendrites of primary hippocampal neurons when measured by quantitative immunofluorescence. When endogenous miR-137 is inhibited, however, both responses are ablated. Puromycin labeling and proximity ligation assay experiments show that Nrg1 stimulates the synthesis of proteins including GluA1 and that this stimulation is also miR-137 dependent. Western blot analysis indicates that manipulation of miR-137 may disrupt the levels of several key proteins that lie downstream of Nrg1, providing a mechanism by which altered miR-137 activity may disrupt Nrg1 signal transduction. Together these data elucidate a novel role for miR-137 in the regulation of Nrg1-dependent mRNA translation in the dendrites of hippocampal neurons, and link miR-137, GluA1, and Nrg1 together in a novel schizophrenia associated translational control pathway.

Title: Activated pSTAT1 levels as a biologically relevant immune signal in schizophrenia

Authors: ***J. K. MELBOURNE**[1], B. FEINER[1], C. ROSEN[1], K. A. CHASE[1,2], R. P. SHARMA[1,3];
[1]Psychiatry, Univ. of Illinois At Chicago, Chicago, IL; [2]Psychiatry, Univ. of California, San Diego, CA; [3]Jesse Brown Veterans Affairs Med. Ctr., Chicago, IL

Abstract: Background: A subclinical immunoreactive state, broadly characterized by elevated levels of serum/plasma cytokines as well as several parameters of immune cellular functioning, has been widely reported in subjects with schizophrenia. Activation of STAT1 is directly downstream of cytokine receptors that relay the signal from specific pro-inflammatory cytokines (IFNγ, IL-6, IL-2, and IL-10) shown to be dysregulated in schizophrenia, as well as a number of additional circulating molecules. If the increased cytokine levels repeatedly observed in schizophrenia have biological consequences, then the measurement of pSTAT1 is a logical step forwards. **Methods**: Peripheral blood mononuclear cells (PBMCs) from controls (n=13) and participants with schizophrenia (n=22) were extracted using a Ficoll density gradient. Participants with schizophrenia were diagnosed using the SCID, clinical symptomology was measured using the Positive and Negative Syndrome Scale (PANSS), and cognitive functioning was measured using the MATRICS Consensus Cognitive Battery. Levels of activated STAT1 (Y701; phosphorylated STAT1; pSTAT1) were measured by ELISA in nuclear extracts from PBMCs. **Results:** There was a significant bimodal distribution in the sample, with a subgroup of participants with schizophrenia expressing significantly greater levels of activated pSTAT1 than the remainder of participants. In this schizophrenia subgroup, levels of pSTAT1 were 68% higher than the control group, and 62% higher than the remainder of the participants with schizophrenia. Furthermore, this subsample of participants manifested significantly poorer cognitive performance on several measures of the MATRICS. **Discussion:** pSTAT1 levels may provide a measure of the biological relevance of widely reported elevations in levels of cytokines in individuals with schizophrenia over the past several decades. Activation of kinase cascades

can be used to partition or disassemble the composite immune signal in living patients with schizophrenia. As PBMCs are a heterogeneous cell population, using flow cytometry to measure pSTAT1 levels will enable us to determine which cell types exhibit high levels of activated STAT1 and give deeper insight into the potential consequences of altered cell signaling in schizophrenia.

Title: Effects of selective attention on gamma activity in auditory steady-state response (ASSR): an EEG study.

Authors: *A. TOYOMAKI[1], A. MIYAZAKI[2], N. HASHIMOTO[2], I. KUSUMI[2];
[1]Hokkaido univ, Sapporo, Japan; [2]Hokkaido Univ., Sapporo, Japan

Abstract: In recent years, gamma synchronization during auditory steady-state response (ASSR) paradigm has been used in the field of schizophrenia research. Most studies reported significant reduction of gamma activity in patients with schizophrenia. Some studies proposed that abnormality of gamma synchronization is derived from the dysfunction of cortical pyramidal neuron and GABAergic inter-neuron. However little attention has been given to effect of attentional modulation on gamma activity. Most patients with schizophrenia have deficits of sustained attention and thus this might affect reduction of gamma synchronization. Previous studies using ASSR paradigm have been inconclusive for attentional modulation on magnitude of gamma rhythm. Our goal was to investigate effect of selective attention on gamma synchronization in ASSR paradigm. We used auditory stimulus which was intermissive at 40 Hz and had a 500 ms duration. This tone was presented with an average 1.5 s ISI. This stimulus was regarded as standard stimulus. On the other hand, infrequently same tone was presented with 200 ms ISI. This stimulus was regarded as standard stimulus and then participants should press a button. This oddball like task allowed that participants allocate different attentional resource to physically same stimulus. We thought that target stimulus demand much selective attention than standard stimulus. Thirty-four normal controls participated in this EEG study. We conducted on

time frequency analysis to standard stimulus and target one respectively and compared for EEG synchronization. The results demonstrated that there were no differences between these stimuli. On the other hand, delta, theta and alpha band synchronization were augmented in target stimulus. Attentional modulation in present study does not affect gamma band activity. We concluded that evoked gamma activity is derived from exogenous sensory process.

Title: The acute and chronic effects of ketamine on cross-frequency couplings and alterations in locomotive speed in the rat hippocampus: Implications for translational models of schizophrenia.

Authors: *T. I. MICHAELS, L. L. LONG, I. H. STEVENSON, J. J. CHROBAK, C.-M. A. CHEN;
Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Disrupted neuronal oscillations have been identified as a potentially important biomarker for the perceptual and cognitive symptoms of schizophrenia. Emerging evidences suggest that interactions between different frequency bands, cross-frequency coupling (CFC), serve an important role in integrating sensory and cognitive information and may contribute to the pathophysiology of schizophrenia. Animal studies have utilized ketamine as a pharmacological model of disrupted neuronal oscillations, but few studies have examined its effects on CFC. While ketamine is known to increase locomotive speed in animals, the relation between speed and CFC is not well understood. In the present study, we investigated the acute and chronic effects (14-day period) of ketamine (30 mg/kg i.p. each day) versus saline on alterations in the coupling of theta (6-12 Hz) phase and gamma (50-100 Hz) amplitude in the CA1 region of the rat hippocampus. We hypothesize that there would be both acute and chronic ketamine effects on cross-frequency coupling which would vary as a function of locomotive speed. Electrode recordings were conducted while the rats were running in a four-arm maze. Physiology data were matched by locomotive speed across animal, condition and time point in order to control for variations in speed when analyzing the CFC data. Visual inspection

confirmed an ellipse between 60-90Hz amplitude and 5-14Hz phase. The ellipse was analyzed by fitting two Gaussian distribution and analyzing changes in the position of the center frequency. Results indicate a chronic shift in the post-injection CFC for the ketamine group but not the saline group for both phase ($F(2,22)= 5.61$, $p=0.01$) and amplitude ($F(2, 22)=3.36$, $p= 0.04$). CFC strength also varied as a function of locomotive speed. Our results demonstrate that chronic ketamine administration alters the interaction of low-frequency phase and high-frequency oscillations in the rat hippocampus. These findings provide evidence that CFC may serve as an important neuronal mechanism for cognitive and perceptual processes known to be impaired in schizophrenia.

Title: Over-expression of CNRIP in the ventral hippocampus of rodents produces a schizophrenia-like phenotype

Authors: *A. M. BOLEY[1], S. M. PEREZ[1], J. J. DONEGAN[2], D. D. AGUILAR[2], A. GIUFFRIDA[2], D. J. LODGE[2];
[1]Dept. of Pharmacol., [2]Pharmacol., UTHSCSA, San Antonio, TX

Abstract: Schizophrenia is a debilitating disease that affects up to 1% of the population with an onset of symptoms starting in late adolescence to early adulthood. This is also a period of development when many adolescents experiment with drugs and abuse cannabis. Cannabis use has been shown to increase the risk of schizophrenia in genetically susceptible individuals and can trigger psychotic symptoms. Taking the growing legalization of marijuana into consideration, it is important to understand the role of the endocannabinoid system in the pathology of schizophrenia. We have previously shown that aberrant dopamine system function is secondary to a hyperactive hippocampus driving the multisynaptic circuit. In addition, it has been postulated that there are alterations in the endocannabinoid system that contribute to the

pathogenesis of schizophrenia, known as the cannabinoid hypothesis of schizophrenia. In this experiment, we examined the role of cannabinoid receptor interacting protein (CNRIP) in the pathology of schizophrenia. Sprague Dawley rats were bilaterally injected with lentivirus expressing CNRIP1 in the ventral hippocampus to increase expression. We then examined behavioral correlates of symptoms associated with schizophrenia followed by electrophysiology to determine the effects on the dopamine system. We found that overexpression of CNRIP led to impairments in social interaction and a deficit in latent inhibition similar to what is observed in patients and rodent models of schizophrenia. Furthermore, there was a significant increase in VTA dopamine neuron population activity in rats overexpressing CNRIP. These data provide evidence that CNRIP may be involved in the pathophysiology of schizophrenia, as it was sufficient to produce various physiological and behavioral correlates of the disease.

Title: Links between auditory hallucination and regional functional dysconnectivity in schizophrenia

Authors: *D. K. SHUKLA, J. CHIAPPELLI, P. KOCHUNOV, L. M. ROWLAND, L. HONG; Psychiatry, Univ. of Maryland, Baltimore, MD

Abstract: Schizophrenia (SCZ) is a severe mental illness characterized by positive and negative symptoms as well as behavioral, motor and mood disturbances. Auditory hallucinations are one of the most debilitating symptoms of SCZ. Resting-state functional magnetic resonance imaging (rsfMRI) studies have suggested various brain network abnormalities associated with auditory hallucinations in SCZ patients. In this study, we used a data driven regional homogeneity (ReHo) approach to measure the temporal homogeneity of blood oxygen level dependent (BOLD) signal for exploring regional brain concordance in patients with SCZ. Resting-state fMRI data of 96 patients with SCZ and 90 healthy control (HC) participants were acquired. Motion-corrected time series for each participant were detrended. Kendall's coefficient of concordance (KCC) was used to measure correlation between the time series of each voxel and those of its 27 nearest neighbors. Furthermore, KCC was correlated with perception auditory state and trait scores. Multiple comparisons correction was performed to a significant level of $p < 0.005$ with a

minimum cluster size of 79 voxels. ReHo results showed reduced KCC in the SCZ group compared to the HC group in the default mode regions such as bilateral medial prefrontal cortex, posterior cingulate cortex, precuneus, and middle temporal lobe. Reduced KCC was also found in other regions associated with auditory-verbal hallucinations in the anterior cingulate, inferior frontal gyrus (including Broca's area) and superior and middle temporal gyri (including Wernicke's area) bilaterally. Regression analysis showed that KCC was negatively correlated with perception auditory state score in the left inferior frontal gyrus (including Broca's area), left middle frontal gyrus, right precentral gyrus, right lingual gyrus, bilateral posterior cingulate and cuneus. Perception auditory trait score was also negatively correlated with KCC in the right posterior cingulate and bilateral cuneus. Our results point toward a reduced connectivity between frontal and temporal language areas in SCZ patients, which may be driven by auditory hallucinations. Reduced connectivity in the default mode regions may imply sociocommunicative impairments in SCZ. Our results add to limited rsfMRI findings of abnormal local functional connectivity in SCZ patients, which could reflect impaired local functional differentiation. Our study served to explore the ReHo approach in SCZ, which is complementary to the conventional model-driven activation approach. The ReHo approach may also help subsequent inferential methods to reduce type 1 error due to heterogeneity of fMRI timecourses.

Abstract: Accumulating evidence suggests that morphological changes of subcellular-scale structures such as dendritic spine and mitochondria may be involved in the pathogenesis/pathophysiology of schizophrenia. Previously, we have proposed mice lacking Schnurri-2 (Shn2), an MHC enhancer binding protein, as a schizophrenia model with mild chronic inflammation. In the mutants, there are decreases in the expression level of PSD95, synaptic marker, and increases in C1q family genes (C1qa, C1qc and C1ql2), which are considered to mediate synapse elimination during the postnatal development. In the present study, we analyzed three-dimensional morphological changes in dendritic spines and mitochondria in dentate gyrus granule cells in Shn2 knockout (KO) mice by serial block-face scanning electron microscopy. The mutants showed about 13% increase in spine length, and about 25% increase in spine neck length. There were no significant differences between Shn2 KO and wild-type mice in their spine density, volume of spine, spine head length, or spine head diameter. The mutants exhibited decreased number of constricted mitochondria, suggesting that a balance between mitochondrial fusion and fission is compromised in Shn2 KO mice. Additionally, there were significant decreases in nuclear volume in the mutants. These morphological changes may be associated with functional impairments of those subcellular-scale structures, and represent potential endophenotype of schizophrenia.

Title: Dysbindin regulates mitochondrial fission in hippocampal excitatory neurons through the Dynamin-Like-Protein DLP1

Authors: *J. ZHAO, Z. LI;
NIMH/NIH, Bethesda, MD

Abstract: Background: Mitochondria have several functions, such as the production of energy and reactive oxygen species (ROS) and calcium buffering, which are essential for neuronal activity and connectivity. Mitochondria form networks in the cell. The mitochondrial network is dynamically regulated by mitochondrial fission and fusion, which are required for the biogenesis

and quality control of mitochondria. Mitochondria dynamics is controlled by mitochondrial fission and fusion proteins, such as MFN-1, DLP1, FIS-1 and so on. Earlier reports have implicated a possible linkage between mitochondrial dysfunction and schizophrenia. However, how schizophrenia risk genes regulate mitochondrial functions and mitochondrial network have not been investigated. Result: In our study, we investigated the role of the human schizophrenia susceptibility gene *DTNBP1*, encoding dysbindin protein, in mitochondria dynamics. We found that a lack of dysbindin in excitatory neurons results in shorter mitochondria with lower mitochondrial membrane potentials, and overexpression of dysbindin significantly changed the subcellular localization of DLP1 and acvitity-induced mitochondrial fission. With STED imaging, we found that dysbindin protein is co-localized with DLP1 on mitochondria. Furthermore, we found that mitochondria fission increases during gamma oscillation in hippocampal neurons, and blockers of mitochondrial fission reduces gamma oscillation. In dysbindin null mutant mice, hippocampal gamma oscillation significantly decreased and it can be partially rescued by dysbindin overexpression. Conclusion: Our results indicate that dysbindin regulates mitochondrial dynamics and function through DLP1, mitochondrial fission is required for gamma oscillation, and therefore dysbindin deficiency may contribute to impaired neural network activity in schizophrenia by causing mitochondrial defects.

Title: GSK3β modulates NR2A subunit expression by regulating β-catenin abundance in the prefrontal cortex

Authors: *S. MONACO[1], W. GAO, 19107[2];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Drexel Univ., Philadelphia, PA

Abstract: Cognition, more specifically working memory, is a fundamental process mandatory in order to successfully navigate through a persistently dynamic environment. The ability to perceive, filter, prioritize, update and ultimately act appropriately to incoming stimuli requires efficient prefrontal cortex-dependent processing, with both NMDA receptors (NMDARs) and GABAergic interneurons playing a major role. NMDA receptors are considered the cellular

entity associated with learning, memory, as well as higher-order cognitive processes including executive functioning. Additionally, GABAergic interneurons in the prefrontal cortex (PFC) regulate working memory, attention, and cognitive flexibility. Correspondingly, disruption of both NMDARs and GABAergic signaling is strongly implicated in several disorders that are characterized by cognitive impairments, particularly schizophrenia. However, what remains to be known is how NMDARs on GABAergic interneurons are regulated and how this affects physiological function. We predict GSK3β is an upstream linking factor among NMDARs, GABAergic signaling, and prefrontal-dependent cognition. Therefore disruption of this enzyme may serve as an underlying factor for common pathological phenotypes observed in schizophrenia such as NMDA hypofunctioning and reduced GABAergic signaling. Our findings demonstrate that lithium treatment in mature primary prefrontal neuronal cultures, significantly increased levels of phosphorylated GSK3βser9 and decreased β-catenin33/37/41 phosphorylation, demonstrating GSK3β inhibition and reduced β-catenin degradation. Total β-catenin and NR2A subunit levels concurrently increased following lithium treatment, suggesting that GSK3β inhibition enhanced β-catenin availability and thereby upregulated NR2A expression. We found similar changes in vivo. Our data suggests that GSK3β regulates NR2A-specific expression via β-catenin availability, which can have important implications for NMDAR expression on GABAergic interneurons.

Title: Dysregulation of schizophrenia-associated genes by elevation of microRNA biogenesis machinery

Authors: *M. GEAGHAN[1,2], M. CAIRNS[1,2,3], A. BRICHTA[1,2];
[1]Univ. of Newcastle, Australia, Callaghan, Australia; [2]Priority Res. Ctr. for Translational Neurosci. and Mental Hlth., Hunter Med. Res. Inst., New Lambton, Australia; [3]Schizophrenia Res. Institue, Sydney, Australia

Abstract: MicroRNAs (miRNA) are short, ~22 nucleotide-long strands of RNA that are vital post-transcriptional regulators of gene expression. They are generated through several processing

steps by various proteins, including the nuclear microprocessor components DGCR8 and DROSHA, and the cytoplasmic RNase III DICER. MiRNAs are a significant regulatory mechanism within the cell, with a single miRNA able to target and silence hundreds of genes, making them particularly interesting in the context of polygenic disorders such as schizophrenia (SZ). Previous studies have shown an upregulation of the miRNA biogenesis genes *DGCR8*, *DROSHA*, and *DICER* in both the dorsolateral prefrontal cortex and superior temporal gyrus of people with SZ, suggesting a role for elevated miRNA production in the pathophysiology of this disorder. The aim of the current study was to identify the molecular consequences of elevated miRNA biogenesis by overexpressing either *DGCR8* or *DICER* in differentiated, neuron-like SH-SY5Y cells *in vitro*. RNA was extracted from these cells and analysed by mRNA and miRNA sequencing, as well as qPCR. Sequencing results were passed through pathway analyses to identify common themes amongst dysregulated genes. This predicted significant alterations to neuronal pathways such as axonal guidance signalling, glutamate signalling, and wnt/β-catenin signalling, which all have relevance to SZ. Furthermore, specific SZ-associated genes, such as ionotropic glutamate receptor subunits *GRIA2* and *GRIA3*, reelin (*RELN*), and the miR-137 host gene (*MIR137HG*) were found to be significantly differentially expressed. Additionally, following overexpression of *DICER*, several genes involved in inflammatory and immune pathways, including MX dynamin-like GTPase 1 (*MX1)* and interferon-induced protein 44 (*IFI44)*, were amongst the most highly upregulated genes. This result is particularly significant as the immune system is thought to play a significant role in the pathophysiology of SZ. Overall, the results of this study suggest that the overexpression of either *DGCR8* or *DICER* is able to influence neuronal function, including synapse formation and synaptic signalling, and adds support to the hypothesis that elevation of miRNA biogenesis machinery components may be part of the pathophysiology of SZ.

Title: dopamine D_3 receptor blockade rescues hyperdopamine activity-induced deficit in novel object recognition memory

Authors: *P.-K. CHANG, J.-C. CHEN;
Chang-Gung University/ Grad. Insititute of Biomed. Sci., Kwei-Shan Tao-Yuan, Taiwan

Abstract: Overeactivity of dopamine signaling is thought to underlie the pathophysiology of a number of psychiatric disorders, such as psychosis, mania and attention-deficit/hyperactivity disorder (ADHD). These mood disorders are frequently associated with cognitive deficits such as disturbances in attention processes or learning and memory, suggesting that persistent changes in dopamine signaling may alter neural plasticity and lead to disease progress. Mice with reduced DAT expression (knockdown, KD) display hyperdopaminergic phenotypes, hence serve as models for mania and ADHD. In comparison with WT mice, DAT KD mice exhibited a deficit in novel object recognition when test (NORT) was performed 24 h later. This deficit could be rescued by acute exposure to D_3 selective antagonist, FAUC365, before recognition training. In consistent with this result, D_3/DAT double mutants reverse the functional loss of NORT due to DAT knockdown. Further, we found acute methamphetamine treatment (1 mg/kg) impaired NORT in WT mice (no change in D_3KO mice), which could also be compensated by the FAUC365 pretreatment, indicating that synaptic dopamine strength may compromise object recognition capability through D_3R. Overall, the present data implicate dopamine D_3 receptors participate a functional role in object recognition. The underlying biomedical mediators are currently under investigation.

Title: Parkinsonism predicts personality traits related to genetic risk and treatment outcomes in schizophrenia

Authors: *J. MOLINA[1], M. CALVO[2], M. BALDA[3], G. GUERRERO[2], E. PADILLA[2], C. CLONINGER[4], G. DE ERAUSQUIN[5];
[1]Psychiatry, UCSD, Miami, FL; [2]Fundación de Lucha contra los Trastornos Neurológicos y Psiquiátricos en Minorías, Buenos Aires, Argentina; [3]Morsani Col. of Medicine, Univ. of South Florida, Tampa, FL; [4]Departments of Psychiatry and Genetics, Washington Univ. Sch. of Med.,

St. Louis, MO; [5]Div. of Neurosciences and Dept. of Psychiatry and Neurology, UTRGV Sch. of Med., Harlingen, TX

Abstract: Schizophrenia is a devastating neuropsychiatric condition with manifest social and interpersonal impairments. Identifying endophenotypes of schizophrenia is of critical importance and has profound implications on clinical practice. Here we propose an innovative approach to clarify the mechanism through which temperament and character deviance relates to risk for schizophrenia and predict long-term treatment outcomes. We recruited 61 antipsychotic-naïve subjects with chronic schizophrenia, 99 unaffected relatives, and 68 healthy controls from rural communities in the Central Andes. Diagnosis was ascertained with the Schedules of Clinical Assessment in Neuropsychiatry; parkinsonian motor impairment was measured with the Unified Parkinson's Disease Rating Scale; mesencephalic parenchyma was evaluated with transcranial ultrasound; and personality traits were assessed using the Temperament and Character Inventory. Ten-year outcome data was available for 24 (~40%) of the index cases. Patients with schizophrenia had higher Harm Avoidance and Self-Transcendence (ST), and lower Reward Dependence (RD), Cooperativeness (CO), and Self-Directedness (SD). Unaffected relatives had higher ST and lower CO and SD. Parkinsonism reliably predicted RD, CO, and SD after correcting for age and sex. The average duration of untreated psychosis (DUP) was greater than 5 years. Further, SD was anticorrelated with DUP and antipsychotic dosing at follow-up. Baseline DUP was related to antipsychotic dose years. Further, multidimensional personality profiles (i.e., '*explosive/borderline'*, '*methodical/obsessive'*, and '*disorganized/schizotypal'*) were associated with increased risk of schizophrenia. In summary, parkinsonism predicts core personality features and treatment outcomes in schizophrenia. Our study suggests that RD, CO, and SD are endophenotypes of the disease that may, in part, be mediated by dopaminergic function. Further, baseline SD may serve as an important determinant of treatment course and outcome.

Title: Delusions of influence correlate with reduced temporal binding in patients with schizophrenia

Authors: M. J. ROTH[1,2], M. J. BUEHNER[3], K. HESSE[4], D. WILDGRUBER[4], H. WONG[5], *A. LINDNER[1];
[1]Hertie Inst., Tuebingen, Germany; [2]Intl. Max Planck Res. Sch. for Cognitive and Systems Neurosci., Tuebingen, Germany; [3]Sch. of Psychology, Cardiff Univ., Cardiff, United Kingdom; [4]Dept Psychiatry and Psychotherapy, Univ. of Tuebingen, Tuebingen, Germany; [5]Werner Reichardt Ctr. for Integrative Neurosci., Tuebingen, Germany

Abstract: Delusions of influence (DoI) are a first-rank symptom and hallmark of schizophrenia. Patients suffering from DoI lack the feeling of control over their thoughts and actions. Here we tested whether such disturbed sense of agency could be captured with a temporal binding paradigm. Temporal binding describes the fact that intentional causal actions (e.g. a key press) and the sensory events triggered by them (e.g. a delayed LED flash) are bound together in subjective time: The sensory outcome of an intentional action is perceived as happening earlier in time than an identical sensory event preceded by a non-intentional signal. Such temporal binding is also referred to as "intentional binding" and is considered an implicit marker of the sense of agency. Temporal binding thus should be altered in patients suffering from DoI.
We investigated temporal binding in a group of 20 patients with schizophrenia and 13 healthy controls. Participants had to predict the time of a *target LED* flash via a timed button press. The flash of the *target LED* occurred at a fixed target interval of 500ms following either (i) a participant's button press or (ii) a *signal LED* flash. Therefore, in (i) participants' actively caused the *target LED* to flash while in (ii) there was no intentional (or causal) link between the behavior of the participant and the *signal* and *target LED* flashes, which were just following one another with the same 500ms interval.
While our control group showed clear temporal binding, i.e. significantly ($p < 0.05$) earlier button presses in condition (i) as compared to (ii), this effect was absent in the group of patients with schizophrenia. Furthermore, we found a significant negative correlation between the strength of patients' DoI and the amount of binding ($r = -0.6$, $p = 0.005$): lower scores for DoI were associated with greater temporal binding. Accordingly, when we performed a median split of our patient group based on the DoI scores, we recovered a significant binding effect in the subgroup of patients exhibiting less DoI ($p < 0.05$).
Our results show that patients with schizophrenia suffering from DoI exhibit altered temporal binding. Furthermore, we could demonstrate that reductions in temporal binding correlate with the strength of DoI. These results are paralleled by our earlier findings in which we show that patients with DoI are impaired in predicting the sensory consequences of their actions due to imprecise forward models. Such imprecise sensory predictions might likewise underlie altered temporal binding.

Title: Decreased lactate dehydrogenase activity and abnormal expression of lactate shuttle transporters in schizophrenia

Authors: *C. R. SULLIVAN[1], K. CLICK[2], R. KOENE[2], A. RAMSEY[3], C. MIELNIK[3], R. MCCULLUMSMITH[2];
[1]Psychiatry, [2]Univ. of Cincinnati, Cincinnati, OH; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Schizophrenia is a devastating illness that affects over 2 million people in the U.S. and costs society billions of dollars annually. Patients with schizophrenia experience a wide range of psychotic symptoms, as well as cognitive deficits and profound negative symptoms that are often treatment resistant. Synaptic transmission relies heavily on a net flow of energetic molecules from astrocytes to neurons, such as the astrocyte-neuron lactate shuttle. Glycogen rich glial cells rapidly synthesize pyruvate from glucose, convert pyruvate to lactate via lactate dehydrogenase (LDH), and transport lactate via monocarboxylate transporters (MCTs) to neurons for energetic use. Working memory performance and long term memory formation in rodents are impaired following disruption of this lactate shuttle pathway. Schizophrenia displays a number of abnormalities associated with glucose metabolism and the lactate shuttle, suggesting energy storage and usage deficits in the brain.This suggests lactate metabolism and neurotransmission are tightly coupled to cognitive function, and these pathways could be important pathophysiological substrates in schizophrenia. We hypothesize that the lactate shuttle pathway is differentially regulated in schizophrenia.
In schizophrenia, LDH activity was significantly decreased in the dorsolateral prefrontal cortex (n=16) when compared to control subjects (n=16). We assessed lactate concentrations in the DLPFC of schizophrenia (n=18) and control subjects (n=19) and found no change in lactate levels. Additionally, in an animal model of schizophrenia, the NR1 knockdown mouse model, we see substantial decreases in MCT4 (63%) and glucose 3 transporter (60%) transcripts in the frontal cortex.
Decreases in expression and activity of key lactate shuttle targets could diminish the capacity of astrocytes to supply neurons with energetic substrates. In conclusion, the lactate shuttle is altered in schizophrenia possibly contributing to abnormal neuronal transmission.

Title: Systematizing the construction of connectomes using an interactive Excel-based platform to facilitate data entry and collation.

Authors: *J. D. HAHN, L. W. SWANSON;
Biol. Sci., USC, Los Angeles, CA

Abstract: Recent investigations of deep-brain neural connectivity have underscored the magnitude of the complexity of the brain's neural circuits [1]. Approaches that seek to make this complexity more tractable therefore offer a route to increasing our understanding of brain structural organization, which is foundational to gaining new insights into diseases that affect the brain and nervous system. Three hierarchical (nested) levels of scale for brain connectivity may be defined [2]: 1) a top macroscale level, which includes connections between histologically defined gray-matter regions; 2) a middle mesoscale level, which includes connections between defined neuron types (defined according to specified criteria such as connections, shape, location, and gene-expression patterns); 3) a bottom microscale level, which includes the specific connections of individual neurons. Several recent high-throughput efforts seek to construct brain-wide connectomes at all three levels. While these efforts generate vast amounts of data, a potential weakness lies in the accuracy with which the data generated is analyzed and represented. This is a particular concern with automated or semi-automated methods that do not yet offer the level of critical and careful analysis that expert collators can provide. With this in mind, a different approach is to mine the existing substantial body of literature on brain connections with an expert-led collation effort. The value of this approach was demonstrated recently by construction of the first comprehensive macroscale association connectome for the cerebral cortex of the rat [3]. To streamline and fast-track the process of data entry and analysis with this approach, we have developed an interactive, highly structured Excel workbook template. The current version is designed for macroscale data entry; it may also form the basis of future versions suited to entry of mesoscale, or microscale data. The interactive template is supported by a guide and rigorous workflow, to facilitate training and participation of additional expert collators (especially student researchers) to support these efforts.

Title: 'What does this gene do': Data presentation in Mouse Genome Informatics for the scientific community including neuroscientists

Authors: *L. NI, &. ON BEHALF OF MOUSE GENOME INFORMATICS GROUP; Mouse Genome Informatics, The Jackson Lab., Bar Harbor, ME

Abstract: The Model Organism Databases (MODs) have a strong history of i) gathering relevant data from the biomedical literature, and from data loads from other sources, ii) strenuously integrating that data for heterogeneous data types, and iii) providing that data to the scientific community in a variety of forms including web interfaces, APIs, dataMines, ftp files, and more. The Mouse Genome Informatics (MGI) project (www.informatics.jax.org), one such MOD, is the community resource for the laboratory mouse, a premier model for the study of genetic and genomic systems relevant to human biology and disease. MGI data includes data from over 220,000 publications for almost 23,000 protein-coding genes. These data include information about 46,000 mutant alleles with over 11,000 genes with mutant alleles in mice. There are over 14,000 genes with expression results, and over 24,000 genes with GO annotations. In addition, MGI captures homology data especially data about human orthologs (>17,000) and mouse models for human diseases (>4,800).
Recently, MGI completed a comprehensive revision of data summation and presentation to provide comprehensive yet interpretable overviews of information available for mouse genes. MGI Gene Detail pages have always provided links to all the information we have on the mouse gene. With this release, the Gene Detail pages display more information and provide more ways to view subsets of data and access details. New graphical displays provide a synopsis of a gene's

functions, where it is expressed and the phenotypes of mutant alleles. Particular emphasis is on the homology between human genes and diseases, with details about mouse models for these diseases. Links to curated Wikipedia pages for the human genes provide textual summation of available data
Matrix grids that highlight the highest level categories of gene function, phenotype, and expression data (sometimes referred to as 'slims') represent carefully considered high-level terms that may be transferable to other MODs and like resources. Each square in the grid drills down to the details of underlying experimental data.
As the volume of heterogeneous data continues to rapidly increase, the ability to provide high level summation of information about entities such as genes along with access to the deepest data available is essential for navigation of these data resources by the diverse scientific community including neuroscientists. MGI provides some models that may see general adoption by bioinformatics resources.

(LN), Natl. Inst. of Mental Health, Natl. Inst. of Neurolog. Disorders and Stroke, and Natl. Eye Institute, Natl. Inst. of Health; Natl. Inst. of Mental Hlth. (NIMH/NIH), Bethesda, MD

Abstract: Macaque researchers need to determine the areal location from both anatomical and functional MRI scans. Using a 2D atlas for this purpose typically requires comparing an MRI dataset with labeled histological sections from one plane. The Saleem and Logothetis (2012) atlas offers three planes, with its areal boundaries initially identified in horizontal and coronal sections, and then interpolated into sagittal sections. However, what is really needed is a high quality 3D volumetric atlas that can be automatically computer-registered to the 3D anatomical or functional scan from any animal, and thus used to specify the areal designation relative to experimental locations of interest. One desirable feature of the Saleem and Logothetis atlas is, its initial registration to a high-resolution anatomical MRI scan of the same macaque subject, thus preserving the native, in vivo geometry of the brain. Here we present and validate a new 3D template atlas derived from and registered to original Saleem and Logothetis atlas. In addition to the template atlas itself, we outline a number of steps involved in the conversion and digitization of the 2D atlas into 3D template form, and its application to projects that involve anatomical, functional, or connectional imaging.

Steps:

1) The architectonic subregions of different cortical and subcortical areas from each 2D drawing of the sections (Saleem and Logothetis atlas) were digitized into a 3D volume of labels.
2) A surrogate anatomical MRI volume of better gray/white matter tissue contrast and higher spatial resolution was created by registering a high quality ex vivo MRI scan of a perfused brain to the original atlas space defined by the native geometry of the original MRI scan from the atlas.
3) The 3D volume of labels was then processed with anatomically constrained interpolation to match the surrogate MRI volume, followed by manual editing to remove any residual mismatch and artifacts.
4) Finally, the accuracy and usability of the 3D template atlas was demonstrated by applying the atlas data to a range of macaque brains of different sizes, and functional imaging data.

Key Points:

1) The atlas provides a readily usable standard for region definition while the template provides a standard reference and space.
2) This standard space allows for macaque research to be reported on a common basis across research sites and across macaques.
3) Additionally, the atlas allows for automated analysis against a set of standard region locations. Atlases and templates are available as both volumes and surfaces in standard NIFTI and GIFTI formats. It is worth noting that this 3D digital atlas can be used in different image registration and analysis softwares.

Title: Neuroimaging phenome-wide association study of mathematical disability

Authors: *S. YARED[1,2], C. GONZALEZ-ZACARIAS[1,2], F. SEPEHRBAND[1,2], L. ZHAO[1,2], K. LYNCH[1,2], I. MACPHEE[1,2], S. SALUJA[1,2], A. W. TOGA[1,2], K. A. CLARK[1,2];
[1]Lab. of Neuroimaging, USC Stevens Neuroimaging and Informatics Inst., [2]Keck Sch. of Med., USC, Los Angeles, CA

Abstract: Mathematical disability has long been thought to have a hereditary component. Yet, due to its high comorbidity with other learning difficulties such as dyslexia, it is difficult to study in isolation. A number of genome-wide association studies (GWAS) have suggested potential SNPs that may give insight as to the genetic nature of this mental handicap. Among them rs789859 and rs133885 have shown to be the most significantly correlated with math disability, although neither result has been widely replicated. rs789859 is located on the 3q29 chromosome, for which deletions have been associated with other learning difficulties including autism. It showed significance correlation (4.57×10^{-6}, n=542) to math disability in a 16-18 year-old cohort of students while controlling for reading ability. On the other hand, rs133885 was most significantly correlated to math disability in a dyslexic population (7.71×10^{-10}, n=699), with a smaller effect size found for a general population. Little has been established, however, as to the neuroanatomical correlates of this impairment. In the aforementioned study, rs133885 was associated with a decreased intra-parietal sulcus depth and right IPS volume. A number of other studies have pointed to IPS deficits associated with math disability, making that structure a plausible candidate. We conducted a neuroimaging phenome-wide association study (PheWAS) in an attempt to further examine a possible relationship between these structural abnormalities and the particular genotypes associated with mathematical disability. With this method, we are able to extract the particular neuroanatomical phenotypes that are most significantly modulated by these genetic SNPs across a database. We checked 628 subjects (294 males, 334 females) from the Philadelphia Neurodevelopmental Consortium, 8-22 years old (mean=14.77), for genotype data on our SNPs of interest, and ran their T1-weighted structural MR images through surface-based processing using FreeSurfer and volumetric processing with various co-registration tools. Extensive quality control was performed at every step, to preserve the integrity of the data. Anatomical parcellation was performed using an exhaustive set of atlases, ultimately

generating several thousand metrics per subject. After correcting for multiple comparisons, the gray matter volume of the hIP3 sub-region of the right anterior IPS was significantly modulated by the presence of rs133885 (1.55×10^{-11}), successfully replicating the previous finding.

Title: Optimal trajectories for brain state transitions

Authors: ***S. GU**[1], R. F. BETZEL[2], M. CIESLAK[3], S. T. GRAFTON[3], F. PASQUALETTI[4], D. S. BASSETT[2];
[1]Applied Mathematics, Univ. of Pennsylvania, PHILADELPHIA, PA; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]The Univ. of California, Santa Barbara, Santa Barbara, CA; [4]The Univ. of California, Riverside, Riverside, CA

Abstract: The complexity of neural dynamics stems in part from the architectural complexity of the underlying anatomy. Yet how the organization of the white matter architecture constrains the possible (or observed) brain states and how the brain alters its activity to transition among states along certain trajectories remain elusive. Here we use the term state to refer to a pattern of activity across neurons or brain regions and the term trajectory to refer to the path of the

transition among states. The question of modeling the underlying mechanism of the brain's state transition can be addressed by drawing on recent insights from the application of network control theory to neuroimaging data [1]. Prior work using these techniques has assessed the average or global role of white matter emanating from single brain regions in explaining state transitions [2]. In contrast, here we examine transitions that are elicited via the collective control of region sets [3]. This choice is motivated by our growing understanding of large-scale brain dynamics, as measured by functional magnetic resonance imaging. Specifically, we examine how the brain moves from a specified initial state to a specified target state in finite time, and we focus on examining transitions from the so-called default mode into target states of high activity in primary sensorimotor cortex. Across all state transitions, we observe that the supramarginal gyrus and the inferior parietal lobule consistently acted as efficient control hubs with less energy cost. These areas are structurally interconnected with ventral premotor complex, the key input to primary sensorimotor cortex. We further quantify the robustness of the control tasks and compare the associated energetic impact of nodes by removing them from the network. We observe that compared to healthy individuals, patients with mild traumatic brain injury (mTBI) display a higher level of robustness to removal, potentially due to greater homogeneity in network structure. Together these results suggest that network control theory may offer new insights into the mechanisms driving brain state transitions in support of behavior.

Title: A bioinformatic pipeline for the discovery of translational targets relevant to cocaine abuse

Authors: *R. J. ELLIS, J. L. GOMEZ, L. A. RODRIGUEZ, M. MICHAELIDES; Biobehavioral Imaging and Mol. Neuropsychopharm. Unit, Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Science is generating data at an exponential pace, and advances in web-based computational technologies facilitate data sharing initiatives aimed at guiding scientific discovery via public sharing of such data. While such practices have been increasing in prevalence, the amount of publicly available experimental data is vast and ever-increasing, and tools that allow efficient retrieval and/or processing of accessed data is limited. Furthermore, the majority of such tools do not permit easy data accessibility and compatibility across different platforms. Here we describe the first-stage development of an automated software pipeline which integrates both human and animal phenotypic, genomic, gene expression, and disease information derived using a variety of independent web-based empirical databases. We further describe a first-stage assessment of the performance capability of our approach by examining mechanistic involvement of the predicted targets in cocaine-related behaviors. Ultimately, our goal is to develop and apply this automated pipeline to guide efforts aimed at discovering novel translational therapeutic targets relevant to substance abuse and addiction.

Title: Finding neuronal cre-expressing mutant mice using www.creportal.org

Authors: *H. ONDA[1], S. A. MURRAY[2], M. KNOWLTON[1], C. L. SMITH[1], J. T. EPPIG[1]; [1]Mouse Genome Informatics, [2]Genet. Resource Sci., The Jackson Lab., Bar Harbor, ME

Abstract: Conditional mutagenesis is a powerful method for studying cell type- and stage-specific gene interactions during brain development and in neurological disease processes. Mice carrying a target gene with inserted loxP sites are mated with mice bearing cre-recombinase

transgenes or knock-in alleles. Depending upon its driver/promoter, cre recombinase is activated in a temporal and spatial-specific manner, causing excision of the genomic region flanked by the loxP sites of the target gene. This technique is particularly useful to examine gene function temporally where a conventional knock-out might result in embryonic lethality or to examine age-specific tissue expression. The CrePortal (www.creportal.org) facilitates identification of the most suitable cre mouse lines for such conditional mutagenesis experiments. It describes over 2,550 recombinase containing transgenes and knock-in alleles with detailed molecular information and tissue- and age-specific cre activity. Over 700 cre transgenes and knock-in alleles exhibit activity in the nervous system. Data on cre-expressing mice with neuronal drivers have been integrated from individual laboratories and large-scale programs including the NIH Neuroscience Blueprint Cre Driver Network, the Allen Institute for Brain Science, the Pleiades Promoter project, the JAX Cre Resources project, and EUCOMMTOOLS. Cre activity data are annotated using the Abstract Mouse (EMAPA) ontology with images of intended and off-target activity. The CrePortal can be searched by the anatomical structure in which recombinase activity was assayed and/or by the driver used to activate the cre recombinase. The search summary provides a list of drivers, the recombinase-containing allele symbols, associated gene and allele name, allele synonym, a list of tissues in which recombinase activity was detected or not detected, the inducible agent if required, links to references, and links to the International Mouse Strain Resource (IMSR, www.findmice.org) for locating those strains available through public repositories. Filters allow users to refine search results. Allele symbols are linked to the Mouse Genome Informatics Database (MGI, www.informatics.jax.org) phenotypic data pages for the cre transgene and alleles that provides a more detailed cre activity summary and phenotypic information for genotypes involving the cre transgene and allele. We encourage you to explore the CrePortal and submit your laboratory's cre line observations for inclusion at www.informatics.jax.org/submit.shtml.

Title: An inter-region model of the mouse brain mesoscale connectome.

Authors: *N. S. GRADDIS[1], K. D. HARRIS[2], N. CAIN[1], J. D. WHITESELL[1], K. E. HIROKAWA[1], E. T. SHEA-BROWN[2], J. A. HARRIS[1], S. MIHALAS[1];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Applied Mathematics, Univ. of Washington, Seattle, WA

Abstract: Knowledge of an organism's connectome - the existence and strength of connections between individual neurons (microscale), populations of neurons (mesoscale) or larger areas (macroscale) - can guide experimentation, provide a scaffold for models of neural computation, and may help explain disease progression. The Allen Mouse Brain Connectivity Atlas is a large effort to systematically map axonal projections across the whole brain using viral tracers, high-throughput serial two-photon tomography, combined with informatics processing and registration of images to a 3-D common coordinate reference space. This pipeline results in quantitative measures of connection strengths between injection sources and target brain regions, and is currently the most comprehensive dataset for analyses on the mouse mesoscale connectome. However to characterize the connections originating from regions not injection sites, which can include neurons in multiple areas, a model is required. We previously build such a model explaining connectivity strength in each target region as a linear weighted sum of the injection volumes across injected regions, and was based on two assumptions, 1) projections can be described by the relationship between the total signal in source and target regions and 2) the contributions of multiple source regions can be linearly combined. These assumptions allow us to address the problems of incomplete injection coverage, variable injection locations, and overlap of region boundaries by injections, but was not able to provide full coverage. Here, we present an extension and update to the original linear model. Our specific goals were to expand the coverage and improve the reliability of the model. We deal with the ill-conditioning of our design matrix by employing ridge regression and account for the presence of outliers by replacing our least-squares loss term with Huber loss. When tested against presence/no presence expert classification of a subset of connections, our model achieves true positive rates of around 80% (versus 75% in the unmodified linear model) and false-positive rates around 13% (16%). These improvements to model performance allow us to more accurately, completely, and quantitatively parameterize mesoscale connectivity in an automated and high-throughput fashion. This enables, among other things, more rigorous graph theoretical analyses of large-scale network topology and more accurate simulations of population-level activity.

Abstract: Making sense of complex neuroscience data requires integration of information from multiple sources. Recorded data need to be joined with metadata describing experimental conditions and analyses. Data identification and retrieval is considerably enhanced by tightly linking data with their corresponding metadata. We previously developed a format for metadata, the odML[1], and here present a data format and tools to link data and metadata meaningfully for easy data exploration, selection, retrieval, and sharing. The NIX[2] format can store various kinds of scientific data, like electrophysiological, imaging, or other recorded or derived data, together with the metadata and including relationships between data items. Data are stored with units and dimension information, for direct interpretation. The format allows specifying regions of interest, such as areas in an image or events in a recorded signal, and references between data items. Integration into the recording or analysis software is made possible through libraries for different languages, including C++, Python, Matlab, and Java. Installable packages exist for the major platforms, together with documentation, examples, and tutorials. The NixView program[3] can be used to explore, plot and export the stored data in a user friendly and convenient way. An I/O backend for the Neo Python objects for electrophysiology [4,5] enables conversion of data from various proprietary formats to the open NIX format. Moreover, results of data analysis done with Neo, for example using the Elephant[6] toolkit, can be saved in the very same format. The NIX project thus facilitates data integrity and reproducibility through comprehensive annotation and efficient organization of neuroscience data during everyday lab work.

Title: Inferring "driver" transcription factors from RNA-Seq data

Authors: ***M. DANZI**[1], J. L. BIXBY[2], V. P. LEMMON[2], S. WUCHTY[3];
[2]Miami Project to Cure Paralysis, [3]Dept. of Computer Sci., [1]Univ. of Miami, Miami, FL

Abstract: Data science approaches to analyzing gene expression datasets often involve derivation of a "signature", comprising a set of genes consistently regulated in the experimental or diseased condition. These analyses generally find patterns that fit the data at hand, but do not generalize to new datasets. This non-generalizability may arise because gene expression profiling is measuring the "passengers" rather than the "drivers" of the biological event being studied. We hypothesize that identification of "driver" genes will lead to greater consistency and thus generalizability in the patterns discovered in biological datasets. One major, well-studied class of "drivers" affecting gene expression comprises transcription factors. Therefore, investigators have proposed methods to use information about the activities of transcription factors in conjunction with RNA-Seq data to derive the "driver" transcription factors responsible for observed changes in gene expression. Here, we propose a new algorithm for this purpose. The algorithm uses a decision tree structure to group genes into similarly regulated cohorts based on the degree to which their expression changes across experimental conditions and the combinations of transcription factors proposed to regulate them. This approach can also be combined with epigenetic data describing the location of regions of accessible chromatin in the cell type of interest. We find that filtering the underlying transcriptional regulatory network to include only

interactions in which the target DNA is accessible further enhances the performance of this algorithm.

Title: Structural analysis of membrane myelin zero and mannose binding proteins from neurons, that modulate immune response against Mycobacterium leprae infection

Authors: ***M. CORREDOR**[1], V. CARDONA[3], A. MUÑOZ-GOMEZ[2];
[2]GEBIOMIC group, [1]Univ. of Antioquia, Medellín, Colombia; [3]Univ. of Antioquia, Biol. Inst., Medellín, Colombia

Abstract: Introduction: Leprosy is a chronic infectious disease that invade neurons caused by Mycobacterium leprae infection to severe neuronal damage. M. leprae has the capacity to invade the peripheral nervous system and cause neuropathy. The molecular mechanisms responsible have begun to be clarified: Myelin protein Zero (MPZ) is a major structural component of the myelin sheath, and its deficiency due to various mutations in the MPZ gene; Mannan-binding lectin (MBL) activates the complement system via the lectin pathway and was associate with Alzheimer and Schizophrenia diseases . Genetic and environmental factors favor infection and disease development. Mutations in allele's MPZ and MBL proteins and lead to nonsynonymous changes that alter some points binding proteins and their structures; as myelin protein zero and C mannose binding protein, respectively. Structural analysis allows to study the putative amino acids regarding their possible effect on structure and function, as well as sequences which are part of these gene variants and their value within the protein. **Methods:** nucleotide sweep was initially performed in patients from three Colombian populations with the disease SNPs obtained in exons of two genes, MPZ and MBL. Additionally a measure of synonymous mutations was performed and nonsynonymous using the KaKs tool that evaluates significant differences in nonsynonymous and synonymous mutations. Subsequently, an analysis of the domains with the Muscle, Hammer, tools Hmmerview compared with SMART databases. Then the protein structures built using the server I-TASSER and structural alignments with the tool are effected Chimera. **Results:** At nonsynonymous mutations observed in both proteins apparently not affect

the structure but such amino acid changes affect the net charge of some regions conferring differential to the putative functions. By making a structural analysis of these two proteins it is determined that such mutations fall on seemingly minor structural zones (loops). These loops or loop regions play an important role. In the case of MPZ mutation in amino acid on the KNPPD loop (T / I) VGK threonine (T) by isoleucine (I) does not change the loop charge but makes this region exposed to the outside of the membrane more hydrophobic by isoleucine. For the case of MBL amino acids change in a rich giant loop glycine reveals much more drastic changes especially in charge on the GTK (G / E) EKGE sequence, carrying the loop from neutral to acidic (- 1), that happens because glycine (G) to glutamic acid (E) mutation.

Abstract: Neuron reconstruction from microscopic images is recognized as one of the major technical challenges in the digital era of neuroscience. The BigNeuron project (Peng, Hawrylycz et al. Neuron, 2015, DOI: 10.1016/j.neuron.2015.06.036; Peng, Meijering et al. NeuroInformatics, 2015, DOI: 10.1007/s12021-015-9270-9) is a global effort to standardize the interfaces of algorithms and neuron image data, and to provide a common platform to facilitate fair, high-throughput bench testing of various neuron reconstruction methods. We have chosen to use Vaa3D (Peng, Ruan et al. Nature Biotechnology, 2010, DOI:10.1038/nbt.1612, 2010; Peng, Bria et al. 2014, Nature Protocols, DOI: 10.1038/nprot.2014.011) as the software platform for researchers and developers to port their methods, followed by comparing and analyzing such reconstruction algorithms. Specifically, we have leveraged Vaa3D's unique open source plugin interface to help developers quickly port their algorithms in the course of a number of hackathons in China, UK, and USA during 2015~2016.
With the community contribution from about 200 researchers, more than 30 reconstruction algorithms have been ported onto Vaa3D as standalone plugins with a standardized software and data interface. These algorithms cover several major known categories of methods, including structure pruning, fitting geometrical elements, ray casting, spanning trees and shortest paths, integer programming, linear programming, deformable curves, machine learning, 2D to 3D mapping, tips finding, and others.
With about 10 million CPU hours provided by the supercomputing facilities at the Oak Ridge National Lab, the Lawrence Berkeley National Lab, and the Allen Institute for Brain Science, we bench tested all ported algorithms versus all contributed neuron image data. So far, for almost 40,000 single neuron image stacks including human, mouse, rat, fly, chicken, frog, zebrafish, etc., we have generated over 2.6 million neuron reconstructions including about 1.5 million reconstructions for explorative testing and another 1.1 million reconstructions with refined

implementation of the ported algorithms. All these reconstructions will be further analyzed and the results will be shared with the entire neuroscience community as a useful new resource.

Title: Bigneuron data analysis for massive-scale, automated neuron reconstructions

Authors: ***X. LIU**[1], Z. ZHOU[1], T. GILLETTE[2], G. ASCOLI[2], M. HAWRYLYCZ[1], S. HILL[3], C. KOCH[1], E. MEIJERING[4], H. PENG[1];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]George Mason Univ., Fairfax, VA; [3]Ecole

polytechnique fédérale de Lausanne (EPFL), Lausanne, Switzerland; [4]Erasmus Univ. Med. Ctr., Rottertham, Netherlands

Abstract: BigNeuron [1] is a worldwide community project to advance the research and applications of single neuron reconstruction, which remains to be an important challenge in brain science. So far, the BigNeuron project has bench-tested 38,769 contributed neuronal microscopy image stacks from worldwide institutes, and in the current second version of batch testing the project has generated 1,110,590 reconstructions from more than 30 contributed neuron tracing algorithms.

To evaluate the automatic tracing results quantitatively, we have calculated morphological properties/features (such as BlastNeuron [2] metrics) and spatial distances to measure the accuracy of the reconstructions with respect to manually curated reconstructions (the gold standard) and to compare the differences between the reconstructions from the same image datasets. Due to the diversity of the BigNeuron image datasets and the different engineering designs of BigNeuron algorithms, the performance ranking of the algorithms is quite different across different image datasets. For images that are relatively challenging due to lower signal-to-noise ratio or intense imaging artifacts, the reconstructions from different algorithms tend to capture different characteristics of the underlying neuron morphology.

In order to leverage all the automatic tracing results and produce faithful representative reconstructions for all BigNeuron images, we have developed an algorithm to fuse multiple reconstructions into a single consensus reconstruction for each image based on the neuronal skeleton locations and connections agreed upon by the majority of the input reconstructions. When comparing the consensus results to individual auto reconstructions on a dataset of 166 images with gold standard reconstructions, we found that the consensus is closer to the gold standards than each and any of the individual algorithms. For another dataset of more than 25,000 images, of which no gold standards are provided, we found that the consensus is closer to the population center (has a smaller total distance to individual reconstructions) than the median case reconstruction for each dataset.

Title: Bioinformatic analysis of phenotypic data of ASD rodent models.

Authors: *W. PEREANU[1], M. A. ESTEVEZ[1], I. DAS[1], S. B. BASU[2];
[1]Mindspec, Mc Lean, VA; [2]Mindspec, McLean, VA

Abstract: Background: The Autism Database (AutDB) is a publicly available, manually annotated, modular database that serves as an ongoing collection of genes linked to Autism Spectrum Disorders (ASD). The animal model module of AutDB catalogues over 600 ASD-related rodent models, extracted from primary literature.
Objectives: Although there have been other comparative analyses of ASD rodent models, they have been limited in scope, both in terms of the number of animal models and the extent of phenotypic assessments used. By looking at the total data sets of rodent models that is available in AutDB, we are expanding our analysis to more than 600 ASD rodent models, and about 375 phenotypic parameters, divided in 16 larger categories. A bioinformatics analysis of this scope can be used to elucidate ASD research trends and etiology
Methods: All data is extracted from published, peerreviewed primary reports. The metadata is standardized in a phenotypic database, which is a routinely updated comprehensive list of phenotypic terms (phenoterms) and experimental paradigms. These phenoterms reflect the actual research and are divided into categories that align with human ASD phenotypic features. For each individual model, annotated phenoterms contain a given value (e.g. increased, decreased, no change, abnormal). Using the aggregate of these phenoterm values, models are clustered into functional groups.
Results: ASD rodent models cluster based on phenotypic data that reflect neurophysiological, behavioral and developmental complexity. By looking at a broad genetic and environmental model set we are able to ascertain common underlying biological mechanisms in ASD etiology.
Conclusions: The AutDB animal model module serves as a detailed repository of rodent model phenotypes reported in the ASD field. The scientific standardization of phenotypic parameters allows for data mining and bioinformatics analysis. Our present analysis provides a glimpse of the complexity of ASD etiology, and allows us to visualize the contribution of both genetic and environmental factors by using animal models.

Title: Comparison of single cell and pooled cell expression data from mouse and human brain

Authors: ***O. MANCARCI**, L. TOKER, P. PAVLIDIS;
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Transcriptomics-based approaches are becoming increasingly popular for characterizing different cell types. Due to limited sensitivity of classical gene expression studies, transcriptomics-based classification was originally applied to pooled cell samples, using canonical markers for their isolation and purification. Recent developments in single cell RNA sequencing (scRNAseq) techniques allow classification of cell types based on post-hoc clustering of individual cells based on similarity in their gene expression patterns. However, despite the existence of multiple transcriptomics-based studies targeted towards classification of cell types in similar tissues (e.g. cerebral cortex), the concordance of these studies is still unclear. We sought to evaluate 1) the similarity between the clusters identified in individual scRNAseq datasets 2) correspondence between pooled-cell-based and single-cell-based cell type classification and 3) correspondence between expression profiles based on mouse vs. human cell-type specific expression data.
To address these questions we compared multiple datasets of publically available mouse and human scRNAseq data alongside data from Neuroexpresso - a rigorously curated cell-type specific expression database of pooled cell types in mouse brain compiled within our lab. Our results show that while major cellular clusters (such as oligodendrocytes, pyramidal cells) are highly similar across datasets, this similarity is decreasing with increased classification resolution. Namely, specific cellular clusters found in individual scRNAseq dataset was often absent from other scRNAseq datasets. Comparison of mouse and human data emphasizes the similarities and the difference between the two species. For example, despite the general similarity among genes highly enriched in major brain cell types, we found that about 1/3 of genes highly expressed in mouse astrocytes are not detected human astrocytes.
Evaluating the robustness of cell-specific expression data and their applicability for analyses in different species is crucial for future studies of the brain.

Title: SciCrunch: A cooperative and collaborative data, information and resource discovery portal for scientific communities

Authors: *J. S. GRETHE[1], A. E. BANDROWSKI[1], M. CHIU[1], T. H. GILLESPIE[1], J. GO[1], Y. LI[1], I. B. OZYURT[1], L. MARENCO[2], P. L. MILLER[2], R. WANG[2], G. M. SHEPHERD[2], M. E. MARTONE[1];
[1]Ctr. for Res. in Biol. Systems, Univ. of California San Diego, LA Jolla, CA; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: SciCrunch was designed to allow communities of researchers to create focused portals that provide access to resources, databases, information and tools of relevance to their research areas. The SciCrunch data and information discovery index is one of the largest aggregations of scientific data, information, and tools available on the Web. Just as you can search across all the biomedical literature through PubMed, regardless of journal, SciCrunch lets you search across hundreds of databases and millions of records from a single interface. SciCrunch was designed to break down the traditional types of portal silos created by different communities, so that communities can take advantage of work done by others and share their expertise as well. When a community brings in a data source, it becomes available to other communities, thus ensuring that valuable resources are shared by other communities who might need them. At the same time, individual communities can customize the way that these resources are presented to their constituents, to ensure that their user base is served. SciCrunch currently supports a diverse collection of communities, each with their own data needs: The Neuroscience Information Framework (NIF) - is a biological search engine that allows students, educators, and researchers to navigate data resources relevant to neuroscience. NIF is the core community from which SciCrunch was developed; NIDDK Information Network (dkNET) - serves the needs of basic and clinical investigators by providing seamless access to large pools of data relevant to the mission of The National Institute of Diabetes, Digestive and Kidney Disease (NIDDK); Research Identification Initiative (RII) - aims to promote research resource identification, discovery, and reuse to improve and enhance reproducibility in scientific research; Drug Design Data Resource (D3R) - aims to advance computer-aided drug discovery through the interchange of protein-ligand datasets and workflows, and by holding community-wide challenges.

Title: Mouse Phenome Database: A curated and integrated resource for studying sex differences and sex x genotype interactions.

Authors: *M. BOGUE, S. C. GRUBB, V. PHILIP, E. J. CHESLER;
The Jackson Lab., Bar Harbor, ME

Abstract: The Mouse Phenome Database (MPD; phenome.jax.org) is a widely used online resource providing access to primary experimental data, protocols and analysis tools for mouse phenotyping studies. Data are contributed by investigators around the world and represent a broad scope of behavioral endpoints and disease-related characteristics in naïve mice and those exposed to drugs, environmental agents or other treatments. Most data in MPD are from inbred strains and other reproducible strains such that the data are cumulative over time and across laboratories. MPD provides an important venue for compliance with data sharing policies and facilitates data reuse and data integration to provide a means of assessing replicability and reproducibility across experimental conditions and protocols. MPD has consistently provided rigorous curation of experimental data and supporting documentation. The breadth of data in MPD is amenable to the exploration of sex differences and sex x genotype interactions across many diverse phenotypes. For example it has been suggested that female laboratory animals must be monitored for estrous cycle in order to control for variation. Using a large quantity of MPD trait data from many strains of mice, we found that differences in variation are not statistically significant in randomly cycling females compared to males, suggesting that it is not necessary to monitor estrous cycle and that sample sizes of females do not need to be quadrupled in order to control for variation. Furthermore, our analysis shows there is significantly more variation in both males and females for behavioral phenotypes compared to either morphological or physiological phenotypes.

Title: Sparse, strong and large area targeting of genetically encoded voltage indicators

Authors: S. ANTIC[1], C. SONG[2], *T. KNOPFEL[2];
[1]UConn Hlth., Farmington, CT; [2]Imperial Col. London, London, United Kingdom

Abstract: Understanding the dynamic activity of neural circuits depends on large scale recording of electrical signals produced by neurons. Large scale voltage imaging should be compatible with experiments in behaving animals and minimally invasive. Genetically encoded voltage indicators (GEVI) are arguably the most promising technique for in vivo optical monitoring of electrical activity in many neurons simultaneously. During recent years a variety of GEVIs have been developed and some of them are now expressed in transgenic mice under regulatory sequences that facilitate cell class-specific voltage imaging ex vivo and in vivo. However, current transgenic expression approaches result in a dense expression pattern. Since GEVIs fluorescence intensity depends on the area of indicator-expressing plasma membranes within the tissue voxel from which photons are sampled (and not cytosolic volume as in the case of calcium indicator), the dominant fraction of the optical signal arises from dendrites and axons. As the optical signals from many neighbouring neurons blend together in each voxel, efficient allocation of signals to individual cells is challenging. To address this issue we developed a strategy for genetic targeting sparsely but at high expression levels (so that only a single or very few cells contribute to each voxel signal), making it possible to allocate the optical signals to individual cells under conditions suitable for high frame rate wide field imaging and low optical resolution one photon and two photon laser scanning-based imaging. Importantly, our approach does not require the use of viruses but instead is based on controlling the activation of destabilized Cre (dCre) by titrated application of the antibiotic Trimethoprim (TMP). Cre-mediated recombination in a TMP dose dependent fraction of cells - within a subpopulation determined by the regulatory sequences for dCre expression - then activates GEVI expression under a strong promoter.

Title: Engineering and characterization of genetically encoded red and far-red voltage indicators for imaging neuronal activity

Authors: *M. KANNAN[1,2], G. VASAN[1,2], A. YANG[1], V. A. PIERIBONE[1,2];
[1]The John B Pierce Lab., New Haven, CT; [2]Cell. and Mol. Physiol., Yale Univ., New Haven, CT

Abstract: Genetically encoded calcium indicators (GECIs) are revolutionizing the way we study the brain by offering a non-invasive means to monitor neuronal activity. However, the slow kinetics of neuronal calcium responses and the inability of GECIs to report inhibitory potentials, limit their overall usefulness. Genetically encoded voltage indicators (GEVIs), on the other hand, directly capture changes in membrane potential and hence, offer a faster readout of action potentials as well as of sub-threshold excitatory and inhibitory membrane potentials. Here, we report the identification of a palette of GEVIs consisting of red and far-red fluorophores fused to different voltage-sensing domains (VSDs), including the *Ciona intestinalis* VSD and microbial opsins. These scaffolds were evolved using multiple rounds of site-directed mutagenesis combined with high-throughput screening to select for the largest size of the voltage-dependent fluorescent response (ΔF). The constructs that exhibited the largest ΔF were subsequently electroporated *in utero* into the mouse neocortex, and acute brain slices from adolescent mice were subjected to whole-cell patch clamp experiments with concomitant wide-field or two-photon imaging. The red GEVIs were compared with each other, as well as with other voltage indicators such as Arclight and Ace2N-mNeon, for brightness and membrane localization, signal size, signal-to-noise ratio, kinetics and the ability to resolve fast trains of action potentials in pyramidal neurons. Given the high tissue penetrability, with lower susceptibility to absorption or scattering as compared to GFP-based probes, red-shifted GEVIs may represent a whole new generation of voltage indicators for imaging deep brain activity.

Title: Genetically encodable hybrid optical voltage sensing with high temporal resolution in neurons using a novel quencher.

Authors: *M. PABST[1], T. ALICH[1], B. SZALONTAI[1], P. TRAN[1], G. C. FAAS[2], I. MODY[1,2];
[1]Univ. of Bonn Med. Ctr., Bonn, Germany; [2]Neurol., The David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: Optical voltage sensing using genetically expressed probes is highly desirable for large scale recordings of neuronal activity. The presently available genetically encodable Ca^{2+} indicators (GECI) are not well-suited for accurate detection of single action potentials (APs) and are unable to record membrane hyperpolarizations or depolarizations below AP threshold. The genetically encodable voltage indicators (GEVI) currently in use also have several drawbacks including slow response, low fluorescence, or excessive bleaching. The hybrid voltage sensing approach uses a genetically encoded fluorophore targeted to the membrane and a small quencher molecule that moves in the membrane in a voltage-dependent manner to quench or unquench the fluorophore. The most widely used quencher is dipycrilamine (DPA). However, this molecule presents several drawbacks including its explosive properties, large capacitive load on the membrane, and a narrow absorption spectrum. We have set out to search for molecules to replace DPA in the hybrid voltage sensing approach. After testing several compounds, we identified an inorganic dye (D3) with an absorption spectrum comparable to that of DPA. In hybrid voltage sensing experiments, D3 outperformed DPA in every aspect studied. Whereas DPA significantly increased membrane capacitance at a concentration of 3-5 μM, as previously reported, D3 at 20 μM did not produce significant changes in resting membrane potential, input resistance, membrane capacitance, AP threshold or width of AP at half amplitude. When optically measuring the voltage signal with 10 μM D3 in cultured mouse or rat cortical neurons expressing membrane-targeted GFP, both hyperpolarizations and depolarizations below AP threshold could be recorded with a significantly more linear voltage response than that given by DPA. Optical recordings sampled at >1,300 s^{-1} accurately reflected the shapes and amplitudes of APs elicited in the cultured neurons by depolarizing steps in whole-cell current-clamp recordings. One of the possible advantages of D3 was observed in an optical recording lasting over 60 min after the dye has been washed out from the media surrounding the cells. This indicates that D3 remains in the membrane in the vicinity of the fluorophore for a significant amount of time even after washout. This property will most likely enable its future use *in vivo*. Our findings indicate that the hybrid voltage sensor method with compounds other than DPA may hold great promise for the GEVI approach, possibly even for fluorophores spanning over a wide range of emission wavelengths.

Title: Characterization of the neural activity integrator CaMPARI for all-optical functional connectivity mapping in acute brain slices

Authors: *T. A. ZOLNIK[1], E. SCHREITER[2], F. JOHENNING[1], L. LOOGER[2], M. LARKUM[3], R. SACHDEV[3];
[1]Charité Universitätsmedizin, Berlin, Germany; [2]Janelia Res. Campus, Ashburn, VA; [3]Humboldt Univ., Berlin, Germany

Abstract: The calcium-modulated photoactivatable ratiometric integrator CaMPARI (Fosque et al., 2015) facilitates the study of neural circuits by permanently marking cells active during user-specified temporal windows. Permanent marker fluorescence enables tissue preservation, recording signal from large swathes of the sample, and easily correlating functional readout with other labels such as proteins and nucleic acids. One potential application of CaMPARI is labeling neurons downstream of specific populations targeted for optogenetic stimulation, giving rise to all-optical functional connectivity mapping. Here, we characterize the response of CaMPARI to several common types of neuronal calcium signals (action potentials and synaptic inputs) in mouse acute cortical brain slices. Our experiments show that CaMPARI is not only effectively converted by spikes but also by synaptic inputs. There is little photoconversion in the absence of extracellular calcium or neuronal activity. In addition, at low photoconversion light levels CaMPARI offers a wide dynamic range due to slower conversion rate; at high light levels conversion is more rapid and sensitive to activity. With these characteristics of CaMPARI defined, we stimulated posteromedial (POm) thalamic axons with channelrhodopsin-2 activation to map their functional connectivity with CaMPARI-expressing cortical neurons in acute brain slices. We found that stimulation of POm axons triggers robust photoconversion of layer 5 cortical neurons and weaker conversion of layer 2/3 neurons. Thus, CaMPARI enables network-wide, all-optical functional circuit mapping. We are using this technique to map the functional connectivity of primary motor cortex, POm, ventroposteriormedial thalamus, and layer 6B (layer 7).

Natl. de la Recherche Scientifique 3157, Paris, France

Abstract: A long-term goal of the BRAIN Initiative is to capture the information processing done in brain circuitry by tracking neuronal activity in large numbers of individual cells in a behaving animal. The messenger ion Ca^{2+} acts as a universal signal of activity in neurons, allowing its use as a proxy for neural activity. At present, the efficiency of genetically encodable calcium indicators (GECI) to extract spike activity is limited by the slow binding kinetics and nonlinearity of the indicators. We are working to improve the kinetics of Fast-GCaMPs, a family of fast-responding GECIs, through mutagenesis of the calmodulin domain and its intramolecular binding partners. Screening of novel GECI variants was performed using stopped-flow fluorimetry on purified protein, followed by *ex vivo* and *in vivo* measurements using AAV-driven expression, including a Cre-dependent conditional expression strategy. Our mutagenesis strategies have already yielded kinetic gains. Our best-performing variants exhibit sub-micromolar affinity for calcium and show up to four-fold acceleration over GCaMP6f of rise kinetics and six-fold acceleration of decay kinetics (to a half-decay time of 8 ms at 37 °C). To detect individual action potentials as discrete events, we are monitoring Fast-GCaMPs in small

neuronal processes, where action potential-evoked calcium transients have rapid kinetics. In imaging of action potential-triggered calcium transients in parallel fiber boutons in brain slices, one of our variants, GCaMP6f-RS09, had spike-evoked signals with a half-decay time of 63 ms, opening the possibility of monitoring activity at ~20 Hz. Extrapolation from data obtained using a low-affinity small-molecule indicator suggests that detection of single APs for trains ~100 Hz should be possible with a Fast-GCaMP with sufficiently accelerated kinetics.

Abstract: Optical imaging of voltage-sensitive dyes (VSD) offers unique opportunities for obtaining minimally invasive measurements of neuronal activity in the living brain and, in principle, is ideally suited for multiplexed measurements from large volumes of brain tissue. The available VSDs, however, do not work well under 2-photon excitation limiting their utility for *in vivo* imaging in the light scattering/absorbing brain tissue. Here, we demonstrate 2-photon excitation of VF2.1(OMe).H - a novel member of the VoltageFluor family of voltage-dependent photo-induced electron transfer (PeT) sensors [1,2].

First, we combined 2-photon voltage imaging with whole-cell patch clamp recordings in cortical brain slices. The VF probe was pressure microinjected into the slice tissue through a glass micropipette. We stimulated patched neurons with 500-ms long depolarizing current pulses while imaging a ~ 50x50 μm field of view (FOV) in a frame scan mode at ~20 Hz. As expected, the spatial profile of VF signal change followed the cell boundary.

Next, we performed 2-photon voltage imaging in layer 2/3 of the mouse SI *in vivo* in response to a sensory stimulus. VF was microinjected in cortical tissue using the same procedure as in brain slices. ~ 20x100 μm FOVs were acquired in a frame scan mode at ~20 Hz. Local Field Potential (LFP) recordings were obtained simultaneously in the vicinity of the imaged FOV. Our results show that negativity in the LFP was accompanied by a simultaneous depolarization of the membranes (Figure). This is compatible with excitatory synaptic inputs and a local current sink in layer 2/3.

Thus, VF2.1(OMe).H faithfully reports neuronal membrane potential under 2-photon excitation and is well suited to obtain local voltage measurements of the neuropil *in vivo*. In the future, this type of measurements combined with depth-resolved LFP recordings would allow underpinning of the circuit behavior during evoked and spontaneous neuronal activity.

Title: Stabilizing proteins with a novel chemical technique to preserve function in unphysiological conditions

Authors: ***M. G. MCCUE**[1], Y.-G. PARK[2], H. CHOI[2], R. CHEN[2], J. YOON[2], W. TRIEU[2], K. CHUNG[2,3];

Abstract: The preservation of fluorescent protein (FP) signal is crucial in many biological studies. Chemical methods for abating loss of FP fluorescence exist but they are far from perfect. Fluorescent protein signals are highly unstable and they fade over time. FPs degrade more rapidly when they are exposed to high temperatures or harsh chemicals, conditions that are often required for many protocols in biology. Therefore, there is an urgent need for a method to increase stability of fluorescent proteins. We have developed a novel chemical treatment that incorporates our lab's recently published SWITCH concept in order to increase stability of fluorescent proteins and make them highly heat and chemical resistant. We have proven that our treatment enhances the stability of fluorescent proteins under temperatures as high as 70°C. We have also shown enhanced fluorescent protein stability under a range of harsh chemical conditions including acidic pH, detergents, and organic solvents. Finally, we have demonstrated the application of this chemical treatment as a method of preserving fluorescent protein signal during both stochastic electrotransport and passive high temperature clearing. Our method does not increase the level of autofluorescence, which has been a major issue in tissue preservation methods using glutaraldehyde. Low background autofluorescence allows for imaging of weaker signals across a wider range of fluorophore emission spectra. Ultimately, our novel chemical treatment allows for rapid tissue clearing with complete fluorescent protein preservation and significantly enhanced signal to noise ratio during imaging. This enables imaging of endogenous weak signal (such as from a viral vector injection or weakly expressing transgenic mouse line) as well as multicolor imaging to a degree which was previously not possible.

Sch., Charlestown, MA; [9]Princeton Univ., Princeton, NJ

Abstract: Measuring diverse molecular and structural traits over multiple length scales remains a major challenge in biology. For decades, two-dimensional molecular phenotyping techniques have been utilized for investigating tissue samples. These techniques ensure similar reaction conditions by sectioning and limiting the length scale through which reactive molecules—such as fixatives, molecular probes, and antibodies—need to diffuse. Clearing techniques such as CLARITY are able to preserve the three-dimensional spatial arrangement of endogenous molecules and enable fluorescence imaging of intact biological systems. However, slow diffusion of reactive molecules and molecular probes over system-wide length scales can cause uneven fixation and staining, respectively. Here, we introduce a simple method for the scalable, high-dimensional phenotyping of animal tissues and human clinical samples. This method, termed SWITCH, synchronizes tissue fixation across the entire system to uniformly secure the tissue architecture and native biomolecules. The preserved samples are robust to heat and chemical treatment and can be subjected to multiple rounds (>20) of relabeling. We have performed 22 rounds of labeling of a single tissue in combination with precise image co-registration. By attenuating reaction kinetics, SWITCH can also be applied to labeling reactions to improve probe penetration depth and overall staining uniformity. With SWITCH, we performed combinatorial protein expression profiling in the human cortex as well as examined the geometric structure of fiber pathways within mouse brains. SWITCH enables the extraction of high-dimensional protein expression information and may expedite our understanding of biological systems over multiple levels.

Title: Rapid and scalable molecular phenotyping of intact biological systems using eTANGO

Authors: *J. H. CHO[1], K. CHUNG[1,2,3,4,5];
[1]Dept. of Chem. Engin., [2]Dept. of Brain and Cognitive Sci., [3]Inst. of Med. Engin. and Sci., [4]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [5]Broad Inst. of Harvard Univ. and Massachusetts Inst. of Technol., Cambridge, MA

Abstract: Three-dimensional imaging of intact tissues has long been limited by the lack of a reliable tissue staining method. We developed a rapid and reliable labeling technique, eTANGO, that allows complete and uniform labeling of large-scale intact tissues within two days compared to weeks to months by conventional methods. eTANGO combines the SWITCH framework and stochastic electrotransport to modulate the reaction kinetics and increase the transport speed. SWITCH inhibits antibody reaction during transport into the tissue. Stochastic electrotransport rapidly transports antibodies into the tissue without damaging the tissue structure. The combined process allows all antibodies to penetrate the tissue at their maximum rates without binding to target molecules and enables complete and uniform labeling throughout the tissue. This process also works for carbohydrate binding proteins and nucleus dyes. We have successfully performed multiple rounds of labeling of the same sample using eTANGO, and have visualized 10 different cell-type markers in large-scale brain tissues. In addition, we developed an all-in-one, fully automated system to carry out the process. We envision eTANGO to accelerate discoveries in a

broad range of biological research by enabling rapid structural and molecular phenotyping of large-scale biological systems.

Abstract: Biological processes require the coordination of multiscale interactions: from the nanoscale architecture of molecular complexes to the tissue-wide interconnectivity of cell populations. Here, we introduce a simple method for characterizing the multiscale organization of intact tissues. This method, termed MAP (Magnified Analysis of Proteome), magnifies organ architecture four-fold linearly while preserving its three-dimensional proteome organization. We discovered that preventing crosslinking within endogenous proteins during hydrogel-tissue hybridization allows for natural expansion upon protein denaturation. The magnified proteome library preserves both fine subcellular details and organ-scale intercellular connectivity. Off-the-shelf antibodies achieve multiplexed labeling and imaging of a tissue's magnified proteome with

an 82% success rate (100/122). With MAP, sample size can be reversibly modulated to accommodate proteomic imaging of inter-regional connections as well as fine synaptic architectures in the brain. The integrated multiscale mapping of the proteome within an intact tissue may enable new approaches for studying the organization and function of complex biological systems.

Title: Cell-MAP for super-resolution proteomic imaging of cultured cells

Authors: ***A. ALBANESE**[1], J. SWANEY[2], T. KU[1,3], J.-Y. PARK[1,4], K. CHUNG[1,2,3,4,5]; [1]IMES, [2]Chem. Engin., [3]Dept. of Brain and Cognitive Sci., [4]Picower Inst. for Learning and Memory, [5]Broad Inst., MIT, Cambridge, MA

Abstract: Cell-cell interactions, such as synapses, involve the coordination of organelles, proteins, and biomolecules at the nanoscale. Confocal fluorescence microscopy enables multiplexed detection of biomolecules but cannot resolve structures below the Abbe diffraction limit (~200 nm for a 63X/1.3 objective). Here, we introduce a simple method, called Magnified Analysis of Proteome (MAP), for the detailed characterization of the subcellular proteomic landscape of cultured cells. MAP processing utilizes controlled sample fixation and gel

embedding to favor protein-hydrogel over inter-protein crosslinking. Cell monolayers are captured in a polymer matrix, denatured to dissociate multi-protein complexes, and isotropically swollen in aqueous buffer. Cell-MAP preserves the three dimensional configuration of the proteome while achieving a 4-fold magnification of cell architecture. Comparison of cells before and after MAP processing with off-the-shelf antibodies reveals a remarkable improvement in the visualization of microtubules, vesicles, and organelles. Cell-MAP achieves the resolution of microtubules < 100 nm in diameter and allows us to visualize proteome architecture beneath the Abbe diffraction limit. Polymer swelling produced relatively little distortion in our embedded samples. The estimated distortion error (root-mean-square error, RMSE) was less than 3% of measured lengths at both the subcellular scale and the multicellular scale. Analysis of diversely populated cell regions confirms uniform gel expansion independent of cell density. Since our technique does not require protease digestion and preserves the spatial arrangement of proteins, we performed multi-round antibody labelling and produced super-resolution images offering unprecedented visualization of the intracellular proteome. Cell-MAP enables nanoscale characterization of organelles, vesicles, and protein complexes using conventional microscopes, common polymers, and off-the-shelf antibodies. Imaging the proteomic landscape beyond optical diffraction limits will facilitate future studies in cell and molecular biology.

Title: A photoconvertible genetically encoded glutamate indicator for neuronal imaging

Authors: S. PAPADOPOULOS[1], J. DONG[1], J. LAMBERT[2], K. ZITO[2], *L. TIAN[1]; [1]Biochem. and Mol. Med., Univ. of California, Davis, Sacramento, CA; [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Synaptic transmission is a critical event of information processing in the brain. In particular, the specific patterns of neural activity at individual synapses can drive the growth, stabilization and elimination of synaptic connections. However, how complex patterns of neural activity at multiple synapses interact to drive changes in circuit connectivity remains poorly defined. Recently, improved genetically-encoded indicators of neuronal activity have allowed for functional measurements through optical recordings of calcium, glutamate and voltage. These applications have significantly advanced the field of systems neuroscience by permitting optical recordings in specific subpopulations of neurons; however, they don't provide information to link the activity to the structural changes. Here we developed a new class of photo-convertible genetically encoded glutamate indicator that would enable one to specifically record glutamate activity in subcellular compartments, such as single spines and axonal termini within the densely labeled neurons. We demonstrate the utility of this new glutamate indicator in cells and rat hippocampal neurons. We expect that our design strategy can be applied to other types of neurotransmitter indicators in the pipeline to allow multiplex imaging of synapses.

Title: A novel optical probe, FFN270, enables *In vivo* multiphoton imaging of presynaptic noradrenergic synapses in mouse sensory cortex.

Authors: *S. CLARK[1], M. DUNN[2], A. HENKE[2], Y. KOVALYOVA[2], R. KARPOWICZ[2], K. KEMPADOO[3], D. SULZER[3], D. SAMES[3];

Abstract: Norepinephrine (NE) is a monamine neurotransmitter expressed in both the central nervous system (CNS) and periphery that is important for mediating mood and maintaining homeostatic balance. Dysregulation of noradrenergic signaling has been implicated in numerous cognitive and neuropsychiatric disorders. Additionally, NE regulation is believed to control both

the depolarization and hyperpolarization of neurons in the neocortex and hippocampus, which is critical for memory and forms of synaptic plasticity. Despite these observations and the importance of NE in CNS function, there are limitations in methodology to directly explore the role of NE in normal brain function and CNS disease. Here we report the first *in vivo* optical observation of noradrenergic synapses and amphetamine's action with single synapse resolution. We utilized in-vivo multiphoton imaging of a novel norepinephrine specific fluorescent false neurotransmitter (FFN), FFN270, in mice surgically implanted with a cranial window to visualize noradrenergic release from individual synapses. We designed this FFN from a library of rationally designed, structurally related analogs and characterized it in cell culture and acute brain slice. FFN270 exhibits dual substrate activity at NET and VMAT2,. This represents the first expansion of the FFN concept beyond dopaminergic systems. For use *in vivo*, we either infused or microinjected FFN270 into barrel cortex of wild-type B6 mice, an area critical for processing sensory perception. We hypothesized that amphetamine would release NE and that the magnitude of its effect may differ between synapses. We found that in anesthetized controls, in the absence of sensory stimuli, only a small subset of noradrenergic synapses actively released FFN.. However, at 1mg/kg *d*-amphetamine (i.p.), a dosage thought to be equivalent to treatment for ADHD, the FFN was emptied from all synapses within 10 minutes. This is a first optical *in vivo* confirmation of amphetamine's role in vesicular release of NE at therapeutically relevant doses and at the level of resolution of individual synapses. Release was more rapid with 10 mg/kg a dosages consistent with amphetamine abuse. This technique far exceeds the spatial and temporal resolution of either SPECT or PET imaging, and by providing a means to study of individual synapses in vivo, elucidates the synaptic mechanisms of noradrenergic drugs.

Title: Anatomical and functional characterization of wake-promoting dopamine neurons in the dorsal raphe nucleus

Authors: *J. CHO[1], J. TREWEEK[2], M. ALTERMATT[2], A. GREENBAUM[2], V. GRADINARU[2];
[1]Computation and Neural Systems, [2]Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Unlike other monoamines, the role of dopamine (DA) in sleep-wake control is still ambiguous. Previous studies with pharmacological (e.g. psychomotor stimulants amphetamine and modafinil) or genetic (e.g. DA transporter knockout mice) means confer the role of DA in behavioral arousal and hyperactivity. Chemical lesion of sparse DA cells in the dorsal raphe nucleus (DRN) was observed to cause a sustained increase in sleep, while wakefulness elicited c-fos expression selectively in DA cells (Lu et al., 2006). These data, however, do not clarify whether the relationship between DRN DA activity and wakefulness is correlative, or if DA activity plays a crucial role in the entry into and maintenance of wakefulness. Here we used optical and genetic methods to investigate the role of DRN DA neurons in sleep-wake control in tyrosine hydroxylase::IRES-Cre mice. From synchronized fiber photometry (a method for monitoring bulk GCaMP6 fluorescence in deep brain regions, Lerner et al., 2015) and EEG/EMG recordings, we found that DRN DA activity increased at sleep-to-wake transitions (NREM-to-wake: 0.11 ± 0.10 versus 3.04 ± 0.39, REM-to-wake: 0.51 ± 0.2 versus 3.54 ± 0.42, in z-scored fluorescence, n=6) and at NREM-to-REM transitions (0.22 ± 0.11 versus 1.30 ± 0.16), but decreased at wake-to-NREM transitions (-0.05 ± 0.12 versus -0.73 ± 0.16). Likewise, spontaneous activity of DRN DA neurons was also highest during wakefulness. Phasic activation of ChR2-expressing DRN DA neurons induced immediate sleep-to-wake transitions (ChR2 group: +58 ± 12% versus eGFP group: -1 ± 7%, in change of wake probability, both n=6). Chemogenetic inhibition with hM4Di at the time of highest wake drive reduced the time spent in wakefulness (CNO: 47 ± 11% versus Saline: 86 ± 9%, n=4). To explore the potential ramifications of DRN DA participation in sleep-wake patterning, we performed projection mapping and found rich DRN DA innervation in the forebrain limbic structures such as medial prefrontal cortex and extended amygdala. These results open new avenues for investigation of DRN DA neurons in the allostatic or emotional regulation of sleep-wake states.

Title: Progression of Parkinson's-like pathology following inoculation of alpha-synuclein preformed fibrils in the gut

Authors: *C. CHALLIS[1], T. R. SAMPSON[1], B. YOO[1], S. K. MAZMANIAN[1], L. A. VOLPICELLI-DALEY[2], V. GRADINARU[1];
[1]Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Neurol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The primary hallmarks of Parkinson's disease (PD) include the formation of inclusions composed of insoluble alpha-synuclein (aSyn) fibrils known as Lewy bodies and neurites, the loss of catecholaminergic neurons, and motor impairments. However, emerging findings suggest that a prodromal phase characterized by non-motor symptoms such as gastrointestinal (GI) and olfactory deficits may precede clinical diagnosis of PD (Hawkes et al., 2010). Postmortem biopsies from asymptomatic and PD-diagnosed individuals revealed the presence of pathologic aSyn assemblies in GI and olfactory tissue, suggesting propagation of aSyn fibrils from peripheral organs to the central nervous system where they precipitate PD. This is supported by findings that aSyn fibrils are interneuronally transported and can seed the formation of additional fibrils from endogenous aSyn monomers (Volpicelli-Daley et al., 2011). Here, we inoculated stomach and duodenum lining of adult C57Bl/6 mice with aSyn preformed fibrils (PFF) and assessed GI health, motor function, and histology at 7, 21, 60, and 90 days post-PFF injection (dPPI) compared to saline-injected controls. At 7 and 21 dPPI, fecal composition and output was significantly altered, with measures returning to baseline levels by 60 dPPI. Using a battery of tests of motor strength and coordination we found significant deficits in the inverted wire hang and adhesive removal tasks at 60 and 90 dPPI. We performed PACT (PAssive CLARITY Technique) on whole, intact stomach and duodenum as well as 500µm thick brain sections and stained for phosphorylated (P)-aSyn, a pathological modification of aSyn fibrils not present on PFF. In the gut, fibril formation increased at 7 dPPI and peaked at 21 dPPI

in enteric neurons of the villi, crypts, and submucosal and myenteric plexuses, with signal diminishing to baseline levels at 60 dPPI. At 21 dPPI we observed an increase in P-aSyn signal in vagal nuclei of the brainstem and at 60 dPPI, P-aSyn was observed in the midbrain. Our results indicate time-dependent aSyn fibril propagation from the gut to the central nervous system via the vagus nerve following gut PFF inoculation that triggers early GI dysfunction and subsequent motor deficits.

Title: Engineering novel adeno-associated viruses for enhanced transduction and target specificity across the CNS by adopting high-throughput *In vivo* and in silico methods.

Authors: *T. DOBREVA, D. BROWN, S. KUMAR, Y. LUO, R. HURT, B. E. DEVERMAN, V. GRADINARU;
Caltech, Pasadena, CA

Abstract: In recent years, adeno-associated viruses (AAVs) have found increasing success as gene delivery vehicles for basic neuroscience applications and are being evaluated in gene therapy clinical trials owing to their non-pathogenicity and transduction capabilities. To broaden their scientific and therapeutic applications, AAVs can be engineered for improved transduction

efficiency and cell-type/tissue specificity. We recently developed a Cre recombination-based AAV targeted evolution (CREATE) method to identify AAV capsid variants from capsid libraries that exhibit improved central nervous system (CNS) transduction characteristics following intravascular administration in adult mice (Deverman et al, 2015). When delivered systemically, one of the recovered variants, AAV-PHP.B, was 40-92 fold more efficient at gene transfer to the CNS compared to AAV9. One limitation of this method is that it is not feasible to recover all the enriched variants from the mouse brain using the traditional clonal sequencing. Here we report an improved methodology where we combined our selection platform with next-generation sequencing (NGS) of recovered variants as well as the starting library. This high-fidelity quantification of recovered sequences gives a quantitative understanding of the relative differences in transduction between variants. By using NGS to recover sequences from multiple Cre-expressing target cells, we are able to apply both positive selection across multiple cell types as well as negative selection to identify variants with more selective tropisms. In addition, we are using machine learning methods such as softmax logistic regression to extract the specific amino acid and nucleotide sequences from the capsid library that contributed, with highest probability, to enrichment in a specific cell type. This serves as a feedback loop, allowing us to systematically identify new variant candidates. Using a library of amino acid characteristics such as hydrophobicity, charge, and flexibility, we are testing the predictive value of our *in silico* selection pipeline by experimentally verifying the transduction of variants that do not explicitly show up in the deep sequencing results. In our pilot experiment, we achieved 80-90% accuracy in predicting whether or not a variant was highly enriched for a specific Cre-line. As a proof of principle, we are presenting some novel AAV variants that were identified using the methods described. These insights from our *in silico* methods can help elucidate what features of the viral capsid contribute to tropism, and thus help develop the next generation of gene delivery vehicles for biomedical applications.

Title: Long-term tracking and automated image analysis reveals that the upside-down jellyfish has a sleep-like state.

Authors: C. N. BEDBROOK[1], R. D. NATH[1], M. J. ABRAMS[1], J. S. BOIS[1], L. A. GOENTORO[1], P. W. STERNBERG[1], *V. GRADINARU[2,1];
[1]Biol. & Biol. Engin., [2]Neurosci., CALTECH, Pasadena, CA

Abstract: Long-term behavioral tracking is an invaluable tool for investigating the full diversity of behaviors an animal can perform, especially when applied to understudied, non-traditional model organisms. We looked within the phylum Cnidaria, which diverged from Metazoa prior to the Cambrian explosion. Any shared characteristics between Cnidarians and humans represent deep evolutionary homology as their last common ancestor lived over 600 million yeas ago. Cnidaria are one of the earliest animal phyla to have evolved neurons, which organize into diffuse nerve nets. Cnidarian jellyfish *Cassiopea,* commonly known as the upside-down jellyfish, live in shallow waters and pulse for critical functions, e.g., gathering food, eliminating waste, and dispersing gametes. We built a long-term recording and tracking system to quantify the pulsation rate of *Cassiopea*. In this system we record jellyfish pulsing behavior at 15 fps followed by automated pulse counting based on changes in pixel intensity of the jellyfish in the relaxed vs contracted state. We tracked behavior over several days, with a 12/12 hr light-dark cycle. Remarkably, we found that *Cassiopea* display three hallmark behaviors of sleep: a reversible quiescent state, rebound after sleep deprivation, and reduced responsiveness to stimuli during the quiescent state. Beyond behavior, we found evidence for molecular conservation in sleep regulation. Melatonin is a known regulator of sleep across animals. We found that jellyfish pulsed less in the presence of melatonin, and resumed normal pulsation when melatonin is removed from the seawater**.** Sleep is common among vertebrates, and has been found in insects and worms. ***The discovery of sleep in a Cnidarian shifts the hypothesized root of sleep earlier in the phylogenetic tree, and raises the possibility that sleep is ancestral in the animal lineage.*** Development and application of tools for interrogating *Cassiopea's* primitive nervous system (i.e. whole animal imaging and staining) could shed light on the evolution of sleep.

Title: Optical and viral vector strategies for mapping the structure and function of the cardiac autonomic nervous system

Authors: *P. S. RAJENDRAN[1], R. C. CHALLIS[2], K. Y. CHAN[2], B. E. DEVERMAN[2], A. GREENBAUM[2], K. SHIVKUMAR[1], V. GRADINARU[2];
[1]UCLA Cardiac Arrhythmia Ctr., Univ. of California - Los Angeles, Los Angeles, CA; [2]Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: The autonomic nervous system regulates all aspects of cardiac function and undergoes adverse remodeling in cardiac diseases. Neurons involved in mediating cardiac control are located from the insular cortex to the heart. At the organ level, the intrinsic cardiac nervous system (ICNS), a distributed network of ganglia on the surface of the heart, serves as the final common pathway for integration of neural inputs. However, the anatomical structure and function of the ICNS is not well understood, primarily due to a lack of tools that target the peripheral nervous system. Therefore, we have developed an adeno-associated virus (AAV)-based toolbox to express fluorescent proteins for multicolor labelling and anatomical characterization of peripheral neurons. This toolbox contains a novel AAV variant, PHP.S, engineered though a Cre recombination-based AAV targeted evolution (CREATE) method (Deverman et al., 2015). We utilized PHP.S and Cre-based transgenics to map the structure of the ICNS circuitry in defined cell types, including choline acetyltransferase- (Fig.), tyrosine hydroxylase- and transient receptor potential vanilloid 1-positive neurons and fibers, in the heart. To facilitate mapping of intact circuits, we employed tissue clearing techniques including PACT (PAssive CLARITY Technique) and Sca*l*eSQ together with confocal and light-sheet microscopy

to visualize transduced neurons in mouse hearts. Through this approach, we have characterized the morphology and innervation of various neuronal cell types that comprise the ICNS (e.g., sensory afferents and sympathetic and parasympathetic motor efferents). To complement our structural studies, ongoing experiments are using PHP.S to deliver opsins to intrinsic cardiac neurons to probe their function *in vivo*. This work can provide critical insights into the structure and function of the ICNS as well as the development and progression of cardiac diseases. Moreover, our novel AAV-based approach can be readily used to interrogate the morphology and function of any peripheral neural circuit that regulates organ function.

Title: Tissue clearing of bones for enhanced optical and molecular access to osseous neuro-immune environments using PACT-deCAL

Authors: *A. GREENBAUM[1], K. CHAN[1], T. DOBREVA[1], D. BROWN[1], D. H. BALANI[3], C. CHALLIS[1], A. LIGNELL[2], L. CAI[2], H. M. KRONENBERG[3], V. GRADINARU[1];
[1]Biol. and Biol. Engin., [2]Chem. and Chem. Engin., Caltech, Pasadena, CA; [3]Endocrine Unit, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA

Abstract: Many neuro-relevant circuits and pathways are embedded within difficult to access osseous tissue, which poses a fundamental limitation when conducting structural investigation using light-microscopy. The practice of bone removal (e.g. vertebrae and skull) when studying the central nervous system often leads to structural artifacts or to damage of functional structures that reside at the interface between osseous and nerve tissue. For instance, functional lymphatic vessels have been recently discovered lining the dural sinuses of the skull (Louveau et al., 2015, Aspelund et al., 2015). The unique location of these lymphatic vessels (interfaced against the typically removed skull) masked their existence, and by such hindered their discovery. This important discovery might shed light on neurodegenerative diseases linked to dysfunctions within the immune system, and highlights the significance of non-invasive structural investigation (Louveau et al., 2015, Aspelund et al., 2015).
Toward this end, we expanded upon the PAssive CLARITY Technique (PACT) (Treweek et al., 2015) to clear intact bones e.g. skull, vertebral column, femur and tibia. A key step in our proposed method is decalcification while securing tissue integrity with hydrogel embedding. The PACT-deCal technique (PACT with decalcification) retains the structure of the marrow, preserves endogenous fluorescence, and shows compatibility with small molecule dyes. Using PACT-deCal we cleared, in ~ 3 weeks, an intact mouse skull and underlying brain tissue - which allowed us to image through the skull and to observe motor and sensory neurons within the cortex (~ 500 μm deep, Thy1-YFP). Furthermore, using a custom built light-sheet microscope (LSM) we obtained multicolor images of an intact tibia and femur with micrometer resolution, and quantified the distribution of fluorescently labeled multipotent progenitor cells (endogenous fluorescence) along the bone using a high-throughput computational pipeline. The pipeline is designed for visualization, stitching and auto-detection of cell candidates in large datasets (50-500 GB). Therefore, PACT-deCal with LSM imaging provides a unique platform to study the interplay between a complex osseous tissue and neuronal circuits, as well as bone-specific phenomena such as remodeling and haematopoiesis.

Title: Retinal characterization of the Thy1-GCaMP3 mouse after optic nerve transection

Authors: ***S. N. BLANDFORD**[1,2], S. R. FARRELL[1,2,4], M. L. HOOPER[1,4], B. C. CHAUHAN[1,3,4], W. H. BALDRIDGE[1,2,3];
[1]Retina and Optic Nerve Res. Lab., [2]Med. Neurosci., [3]Ophthalmology and Visual Sci., Dalhousie Univ., Halifax, NS, Canada; [4]Nova Scotia Hlth. Authority, Halifax, NS, Canada

Abstract: The Thy1-GCaMP3 transgenic mouse has been used extensively to monitor intracellular calcium levels ($[Ca^{2+}]_i$) in the central and peripheral nervous systems, but few studies have examined the retinas of these animals. We therefore assessed which neurons in the ganglion cell layer express GCaMP3 and determined if GCaMP3 expression and response (elevated $[Ca^{2+}]_I$ produced by kainic acid) are maintained in a model of retinal ganglion cell (RGC) damage, optic nerve transection (ONT). Retinas from Thy1-GCaMP3 mice (B6; CBA-Tg(Thy1-GCaMP3)6Gfng/J; Jackson Laboratories) were examined with conventional calcium imaging. In a subset of animals, ONT was performed in one eye 3, 5 or 7 days prior to sacrifice and calcium imaging. Retinas were mounted and transient increases of $[Ca^{2+}]_i$ evoked by superfusion of kainic acid (KA; 10 μM, 50 μM, 100 μM). After live imaging, retinas were fixed and processed for immunohistochemistry with antibodies against RBPMS (an RGC specific marker) and ChAT (a selective cholinergic amacrine cell marker). Data (mean ± 95% confidence interval) were analyzed by one-way ANOVA. Baseline GCaMP3 fluorescence did not change in RGCs of ONT retinas compared to controls; however, the density of GCaMP3+ cells examined by calcium imaging was reduced 5 and 7 days post-ONT compared to control experiments (Control: 2224±1022 vs. 5 days: 1383±598; 7 days: 913±283 cells/mm^2; $p<0.05$). After axonal

injury, fewer GCaMP3+ cells responded to modest concentrations of KA compared to controls (10 μM: Control: 38%; Day 3: 7%; Day 5: 3%; Day 7: 1%; 50 μM: Control: 97%; Day 3: 54%; Day 5: 47%; Day 7: 48%). However, all cells examined responded to 100 μM KA. Ca^{2+} transient amplitudes were smaller after ONT compared to controls (10 μM KA: Control: 0.15±0.02; Day 3: 0.05±0.01; Day 5: 0.03±0.01; Day 7: 0.01±0.01; $p<0.05$; 50 μM: Control: 0.10±0.02; Day 3: 0.31±0.02; Day 5: 0.23±0.02; Day 7: 0.29±0.04; $p<0.05$; 100 μM: Control: 1.29±0.04; Day 3: 0.53±0.02; Day 5: 0.50±0.05; Day 7: 0.47±0.04; $p<0.05$). Immunohistochemical analysis demonstrated that GCaMP3 was expressed in many, but not all RBPMS+ RGCs, but not in ChAT+ amacrine cells in both control and ONT retinas. These results show that GCaMP3 is expressed in some, but not all, RGCs and shows increased fluorescence in response to KA. After ONT, the number of GCaMP3-expressing cells was decreased; however, functional responses declined in advance of RGC loss. We conclude that the Thy1-GCaMP3 transgenic mouse will be useful for future retina research, in particular because it allows for functional assessment of RGCs over time in an animal model of RGC death.

Title: Recording neuronal networks with BeRST 1, a photostable far red/near-infrared voltage sensitive dye

Authors: ***A. WALKER**[1], Y.-L. HUANG[1], E. W. MILLER[2];
[1]Chem., [2]Chemistry, Mol. and Cell Biol. & Helen Wills Neurosci. Institiute, UC Berkeley, Berkeley, CA

Abstract: Voltage sensors are an important component of the cellular neuroscience toolbox for measuring neuronal activity. They combine the direct measurement of membrane potential and high temporal resolution characteristics of electrophysiology with the highly advantageous addition of spatial information and multi-cell recording showcased by calcium imaging. We have developed BeRST 1, a novel voltage sensitive dye (VSD), which shows excellent properties for measuring neuronal activity. BeRST 1 localizes to the plasma membrane where fluctuations in

membrane potential are reported via unquenching of fluorophore emission due to photoinduced electron transfer. This mechanism acts on the nanosecond scale ensuring excellent temporal read-out of membrane potential and exerting negligible effects on membrane capacitance. BeRST 1 emits in far red/near-infrared allowing combinatorial use with widely used tools such as GFP and its derivatives (GCaMPs, ASAP 1), as well as Channelrhodopsin. The high sensitivity (24% ΔF/F per 100mV), signal-to-noise and photostability of BeRST 1 combine to allow the recording of spontaneous neuronal activity over extended imaging periods. We are employing BeRST 1 and its derivatives to simultaneously record spontaneous activity from groups of neurons and with this methodology can demonstrate the characteristic firing patterns of different neuronal subtypes, and furthermore resolve the functional connectivity of these subtypes in dissociated hippocampal culture. Current efforts are focused on applying these optical voltage sensing methods to better understand the dynamics of neural connectivity, with a special interest in understanding changes in network output and integration that occur during the pathogenesis Alzheimer's disease.

Title: High-speed recording of neural activity in awake mice and flies using a fluorescent voltage indicator

Authors: ***Y. GONG**[1,2], C. HUANG, 94305[2], J. MARSHALL[2], J. LI[2], B. GREWE[2], Y. ZHANG[2], S. EISMANN[2], M. SCHNITZER[2];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Stanford Univ., Stanford, CA

Abstract: Genetically encoded fluorescent voltage indicators (GEVIs) are a promising emerging technology for optical readout of fast neuronal spike trains and dendritic voltage dynamics. Prior GEVIs had insufficient signaling speed and dynamic range to report single action potentials in live animals. We coupled fast voltage-sensing domains (<1 ms response) from a rhodopsin

protein (Ace) to bright fluorescent proteins via fluorescence resonance energy transfer (FRET). The resulting GEVIs are sufficiently bright and fast to report action potentials and membrane voltage dynamics in the brains of awake mice and fruit flies resolving fast spike trains at rates >75 s^{-1} with 0.25 ms timing precision and spike detection error rates orders of magnitude below those of prior GEVIs. In vivo imaging in drosophila revealed sensory-evoked responses, including somatic spiking, dendritic dynamics, intracellular voltage propagation, and inter-hemispheric differences in neuronal activity. Optical monitoring of the voltage dynamics of neuronal populations in behaving mice revealed synchronized electrical activity in genetically identified cell types. These results empower in vivo optical studies of neuronal electrophysiology and motivate novel experimental designs that will allow researchers to relate high-speed neuronal dynamics and information processing to animal behavior.

Title: Subcellular localization of algal light-sensitive anion channelrhodopsin ACR2 and cation channelrhodopsin ChR2 in mammalian neurons

Authors: E. M. RODARTE[1], F. RIVERA-MILIAN[1], *R. JANZ[2];
[1]Neurobio. and Anat., Univ. of Texas Hlth. Sci. Ctr. Houston, Houston, TX; [2]UT-Houston Med. Schl, Houston, TX

Abstract: There has been a longstanding interest in optogenetics to develop tools that inhibit neuronal activity to complement the existing optically-sensitive cation channels (e.g. ChR2). Recently, the first anion-specific light-sensitive channelrhodopsins (ACR 1 and 2) from the algae *Guillardia theta* were isolated and proven capable of suppressing electrical activity in mammalian neurons (Govorunova et al. 2015). However, the efficiency of neuronal inhibition by anion channels is strongly dependent on the subcellular distribution of these channels. Here we analyze the subcellular localization of ACR2 expressed in mammalian neurons in comparison with ChR2. EGFP-tagged ACR2 and ChR2 were expressed under the control of the glutamatergic-neuron-specific alpha-CamKII promoter in cultured mouse hippocampal neurons

by using a lentiviral system. One week post-infection, the cells were fixed and stained with specific antibodies to determine the distribution of ACR2 and ChR2 in relation to calreticulin (ER marker), giantin (golgi marker), Na^+/K^+ ATPase (plasma membrane marker), Tau (axonal marker), MAP2 (dendritic marker), SV2, synapsin (presynaptic markers), CaMKII, VGAT (GABAergic synapse marker) and VGLUT1 (glutamatergic synapse marker). The labeled neurons were counterstained with fluorescently-labeled secondary antibodies and analyzed by confocal microscopy. We observed strong presynaptic staining of ChR2 in CAMKII+ glutamatergic neurons, which colocalizes with SV2, synapsin and VGLUT1, sharing their granular pattern along Tau-stained axons. ChR2 does not colocalize with VGAT. The soma and cytoplasm display faint diffuse staining of ChR2. These findings strongly indicate that ChR2 gets preferentially trafficked to the presynaptic plasma membrane. In contrast, ACR2 is arranged in distinct linear structures following the Na^+/K^+ ATPase lining of the plasma membrane of the soma and the dendrites, but not along the axons. It is found in close apposition to presynaptic components (SV2, Synapsin, VGLUT1, and VGAT), but does not colocalize with them. This pattern indicates that ACR2 gets preferentially trafficked to the dendritic and postsynaptic plasma membrane. No aggregates in the ER (calreticulin+) or Golgi (giantin+) were visualized on either case. Our findings suggest that endogenous targeting signals in algal ACR2 and ChR2 mediate preferential trafficking to different compartments in mammalian neurons. Further optimization will involve restricting targeting of ACR2 to axo-somatic synapses, to confer light-stimulus cell-body specificity for accurate neural network dissection.

Title: Cell-type specific optical recording of membrane voltage dynamics in freely moving mice

Authors: *J. D. MARSHALL[1], J. LI[1], Y. GONG[1], F. ST PIERRE[1], M. Z. LIN[1], M. J. SCHNITZER[2];

Abstract: Electrophysiological field potential dynamics are of fundamental interest in basic and clinical neuroscience, but how specific cell types shape these dynamics in the live brain is poorly understood. To empower mechanistic studies, we created an optical technique, TEMPO, that records the aggregate trans-membrane voltage dynamics of genetically-specified neurons in freely behaving mice. TEMPO provides >10-fold better detection fidelity than prior fiber-optic techniques and attains the sensitivity limits set by quantum mechanics. After validating TEMPO's capacity to track well-established cortical and hippocampal oscillations in the delta, theta, and gamma frequency bands, we compared the dynamics of D1- and D2-dopamine-receptor-expressing subtypes of striatal medium spiny neurons (MSNs), which are interspersed and electrically indistinguishable. Unexpectedly, MSN population dynamics exhibited two distinct coherent states that were commonly indiscernible in electrical recordings and involved synchronized hyperpolarizations across both MSN subtypes. Overall, TEMPO provides general means to deconstruct the neurophysiological features of normal and pathologic brain states into trans-membrane voltage activity patterns of specific cell types.

Title: Automated functional, mesoscopic, cortical imaging, self-initiated by gcamp6 transgenic mice in their home-cage.

Authors: *J. LEDUE, F. BOLANOS, M. VANNI, G. SILASI, J. BOYD, D. HAUPT, T. H. MURPHY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Many neuroscience experiments rely on head fixed mice to obtain optical recordings of brain activity during various behaviors or sensory stimuli of interest. Animals are often stressed upon removal from the vivarium and handling by experimenters which could introduce potential confounds. Additionally, the animals must be trained to tolerate long periods of head restraint and are usually repeatedly, individually imaged over many sessions, all of which is time intensive for the experimenter. We have developed a mouse training protocol and a home-cage based imaging system in which water restricted mice are trained to self-initiate imaging trials in exchange for water rewards. Up to five Ai93 (GCaMP6f) or Ai94 (GCamP6s) transgenic female mice can be housed together in the automated home-cage imaging system. Mice are identified by RFID and wide-field, mesoscopic imaging of the dorsal cortex is performed to assess functional connectivity and responses to sensory stimuli. Here we show data from a cohort of mice which we monitored up to 24 hours a day over ~90 days. They initiated >7,000 imaging trials without the intervention of the experimenter. We have based the automated home-cage hardware on the Raspberry Pi single board computer. Mice tolerated 30 to 125 s sessions of head-fixation. Auto-head-fixed mice were able to produce maps of visually evoked responses (response to unilateral flash stimulus). The Pi controls the cage via a Python program which triggers LED illumination, a water reward valve and the solenoid driven head fixation mechanism while reading RFID tags and grabbing images from the camera module. Trials of head restraint are chosen at random and the user controls the percentage of head fixation via the Python software. Using the Pi minimizes cost and maximizes the potential to scale up the automated home-cage imaging to many vivarium hosted, remote controlled cages. The system is also ideal for scenarios where handling animals can perturb results such as studies of circadian rhythms, micro-biomes, or social interactions.

Title: Neuronal activity depending on zinc concentration on multi-electrode array

Authors: ***H. JEONG**[1], S. HWANG[1], S. JUN[1,2];
[1]Electronics Engin., Ewha Womans Univ., Seoul-City, Korea, Republic of; [2]Brain and Cognitive Sci., Ewha Womans Univ., Seoul-city, Korea, Republic of

Abstract: Zinc is an essential trace element for mammalian cells and used as a neurotransmitter or modulator in the central nervous system. The highest concentrations in the brain were found in the hippocampus and the cerebral cortex where Zn^{2+} is primarily localized in nerve endings of glutamatergic neurons. It is reported that the exposure of neurons to high concentrated zinc leads to selective neuronal death. Moreover, zinc contribute to the brain function and neuropathology associated with a neuronal problem, such as Alzheimer's disease, stroke, and seizures. Nevertheless, exact function of zinc is still not well known. In this study, we observed the alteration of neuronal activity in accordance with the change of zinc concentration on the hippocampal neurons cultured on microelectrode arrays (MEAs). The zinc chloride was added exogenously into the cultured hippocampal neurons and concentration of zinc used in the experiments varied from 1uM to 100uM. Depending on the zinc concentration, the different phenomenon has been found. When the measurement was held by electrical method, the frequency of action potentials increased at low concentrations of zinc and decreased at high concentration. In addition, we measured the long-term time dependent changes of action potential activity at constant zinc concentration. The result showed that the effect was different according to zinc concentration.

Title: From lab-to-marketplace: Commercialization of a stretchable microelectrode array

Authors: *O. GRAUDEJUS[1], R. PONCE WONG[2], S. AHUJA[3], S. WAGNER[4], B. MORRISON, III[3];
[1]Sch. of Mol. Sci., BMSEED Llc/Arizona State Univ., Tempe, AZ; [2]BMSEED Llc, Tempe, AZ; [3]Biomed. Engin., Columbia Univ., New York, NY; [4]Electrical Engin., Princeton Univ., Princeton, NJ

Abstract: Most cells in the human body are constantly subjected to mechanical deformation, e.g., near the heart, the lung, and blood vessels. This physiological stretching and compressing is important for the proper functioning of cells, and is also an important cue for the differentiation of stem cells in tissue engineering applications. Stretching or compressing cells too much (pathological stretching) causes a trauma, e.g., traumatic brain injury (TBI) and spinal cord injury (SCI). It is currently not possible for *in vitro* models of TBI and SCI, nor in tissue engineering, to carry out electrophysiological measurements while stretching the cells. BMSEED's **M**icro**E**lectrode **A**rray **S**tretching **S**timulating **u**nd **R**ecording **E**quipment (MEASSuRE) enables such measurements, because the microelectrodes stretch and relax elastically with the cells. MEASSuRE consists of five modules: (1) the *s*tretchable microelectrode array (sMEA) contains at its center the microelectrodes that interface with the cell culture, and at its perimeter the interface with a data acquisition system; (2) the mechanical stretcher that applies strain to the culture under study; (3) software that controls the motion of the stretcher and its interface with the data acquisition system; (4) an optional microscope with video camera captures images of the cells before, during and after stretching; (5) a data acquisition system for amplification, storage, and manipulation of the recorded data. MEASSuRE has the following demonstrated capabilities: (i) stable mechanical and electrical interface with cell cultures during mechanical stretching, (ii) accurate comparison of pre- and post-stretch responses, (iii) high reproducibility of mechanical strain, (iv) biocompatibility, and (v) repeated stretch and relaxation enabling the study of the accumulated effect of repeated blows to the head that individually do not cause injury (soldiers, American football players). In previous work, we have demonstrated the utility of sMEAs in neurotrauma research. sMEAs were critical in the investigation of the impact of TBI on bicuculline-induced, long-lasting network synchronization in the hippocampus. The mechanical stimulation from TBI significantly disrupted bicuculline-

induced, long-lasting network synchronization (a measure of learning ability) 24 hours after injury, despite the continued ability of the injured neurons to produce action potentials (Kang et al., J. Neurotrauma, 2015). BMSEED LLC is currently developing the fabrication technology with funding from an NIH SBIR award to make MEASSuRE widely available commercially by providing an easy-to-use, integrated system.

Title: Immobilization induces a sleep-like state in *C. elegans*

Authors: *D. L. GONZALES[1,2], K. N. BADHIWALA[3], J. T. ROBINSON[2,3,4];
[1]Applied Physics, [2]Electrical and Computer Engin., [3]Bioengineering, Rice Univ., Houston, TX; [4]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Sleep is necessary for most animals, yet the neural circuits involved in this process are difficult to study in anatomically complex animals such as mice and primates. In the roundworm *C. elegans*, periods of lethargus provide a powerful model behavior for probing the molecular, genetic and neural mechanisms of sleep[1-3]. These quiescent states are hallmarked by locomotive cessation and reduced calcium activity; however, we have found no studies of electrophysiological activity during quiescence due to the invasive dissections necessary for patch-clamp measurements. To overcome this challenge we used our recently developed nanoscale suspended electrode arrays (nano-SPEARs) to measure body-wall muscle electrophysiology in intact *C. elegans* for extended periods of time. We found that worms confined to a narrow microfluidic channel show a substantial decrease in body-wall muscle activity resembling a sleep-like state. This quiescence appears in the absence of external heat or other noxious stimuli, therefore we hypothesize that worms are stressed by the mechanical forces presented by narrow microfluidic channels. To the best of our knowledge, this is the first

observation of quiescence in adult worms triggered by mechanical stimuli. To better understand this state we used simultaneous electrophysiological recordings from the body-wall muscles and neuronal calcium imaging to measure the effects of mechanosensor loss of function mutations on this quiescent state. Additionally, we attempt to dissect the neural circuit involved in this stress response by optogenetic manipulation of specific neurons known to be involved in mechanoreception and lethargus. Finally, we discuss the potential to use this state to study habituation and sensitization in immobilized *C. elegans*. 1. Cho J. Y. and Sternberg, P. W. (2014). Title: A novel electrodiffusive scheme for modeling ion dynamics in neural tissue

Authors: *A. V. SOLBRÅ[1], A. MALTHE-SØRENSSEN[1], G. T. EINEVOLL[2,1], G. HALNES[2]; [1]Dept. of Physics, Univ. of Oslo, Oslo, Norway; [2]Norwegian Univ. Life Sci., Aas, Norway

Abstract: In models of brain dynamics, most focus has been put on the electrical dynamics of neurons. A common modelling assumption is that the extracellular space represents an isopotential background where ion concentrations remain constant over time. However, periods of neural hyperactivity may induce local shifts in extracellular space ion concentrations, and such shifts are associated with pathological conditions such as hypoxia, anoxia, ischemia and spreading depression.

Ion dynamics in the extracellular space depends on both diffusion and electric drift. Previous electrodiffusive models of extracellular space dynamics have typically been based on the Poisson-Nernst-Planck (PNP) formalism, which computes the ion dynamics from the Nernst-

Planck equation, and the electric field from the Poisson equation. The PNP formalism is highly accurate, and explicitly accounts for charge relaxation processes that take place on very small temporal and spatial scales (nanoseconds and nanometers). Accordingly, the PNP formalism is extremely computationally expensive, and unsuited for simulations at the tissue level.
An alternative to the PNP scheme is the electroneutral scheme, which replaces Poisson's equation with the constraint of local electroneutrality (Mori et al, PNAS, 2008). Recently, we developed the Kirchhoff-Nernst-Planck (KNP) scheme, a version of the electroneutral scheme which was particularly tailored to simulate extracellular space dynamics at the tissue level (Halnes et al, Plos Comp Biol, 2013; Arxiv, 2015). This scheme does not model the charge relaxation processes explicitly; instead it ensures that no net charge enters a subvolume of the bulk solution at any time point in the simulation, which is approximately true at time scales larger than a few nanoseconds.
Here, we compare the performance of the KNP and PNP schemes in terms of accuracy and computational efficiency in various scenarios, and identify the conditions under which the KNP scheme represents a useful approximation. For simulations at the level of neural tissue, we show that the KNP scheme allows for a dramatic computational speed-up, with very little loss in accuracy in the predicted dynamics of ion concentrations and the electrical field in the extracellular space at timescales longer than microseconds.

Title: Local versus global effects of isoflurane anesthesia on visual processing in the fly brain

Authors: ***D. COHEN**[1], O. H. ZALUCKI[2], B. VAN SWINDEREN[2], N. TSUCHIYA[1]; [1]Psychology, Monash, Melbourne, Australia; [2]Queensland Brain Inst., Brisbane, Australia

Abstract: What characteristics of neural activity distinguish the awake and anesthetized brain? Drugs such as isoflurane abolish behavioral responsiveness in all animals, implying evolutionarily conserved mechanisms. However, it is unclear whether this conservation is reflected at the level of neural activity. Studies in humans have shown that anesthesia is characterized by spatially distinct spectral and coherence signatures that have also been implicated in the global impairment of cortical communication. We questioned whether anesthesia has similar effects on global and local neural processing in one of the smallest brains, that of the fruit fly (*Drosophila melanogaster*). Using a recently developed multi-electrode technique, we recorded Local Field Potentials (LFPs) from different areas of the fly brain simultaneously, while manipulating the concentrations of isoflurane. Flickering visual stimuli ('frequency tags') allowed us to track evoked responses in the frequency domain and measure the effects of isoflurane throughout the brain. We found that isoflurane reduced power and coherence at the tagging frequency (13 or 17Hz) in central brain regions. Unexpectedly, isoflurane increased power and coherence at twice-the tag frequency (26 or 34Hz) in the fly's optic lobes, but only for specific stimulus configurations. By modeling the periodic responses, we show that the increase in power in peripheral areas can be attributed to local neuroanatomy. We further show that the effects on coherence can be explained by impacted Signal to Noise Ratios (SNR). Together, our results show that general anesthesia has distinct local and global effects on neuronal processing in the fruit fly brain.

Title: Cognitive and symptom correlates of EEG time-frequency domain decomposition during a flanker task in subjects with PTSD

Authors: *G. MAY[1,2,3], H. WAHBEH[4], S. NELSON[1,2,5];
[1]VA VISN 17 Ctr. of Excellence, Waco, TX; [2]Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX; [3]Psychiatry and Behavioral Sci., Texas A & M Univ., Temple, TX; [4]Oregon Hlth. & Sci. Univ., Portland, OR; [5]Psychology and Neurosci., Baylor Univ., Waco, TX

Abstract: PTSD remains a difficult disorder to treat, in part because it is suspected to comprise homogenous subtypes that respond differentially to treatment. EEG event-related spectral

dynamics provide a time-varying measure of oscillatory brain activity, and may serve as a set of biomarkers by which patients can be clustered. They have been used to discriminate subjects with severe PTSD from healthy controls, but to our knowledge, they have not been used to identify homogeneous clusters of patients with PTSD. 64 patients with a mean age 50.3 years completed a number of psychological measures, and underwent a 10 minute flanker task. Evoked potentials were decomposed to the time-frequency domain using wavelet convolution. Subjects were clustered using UPGMA, yielding a cophenetic correlation coefficient of 0.86. Clusters were generally laid out along a single principle component axis, which weakly correlated with several indicators of mental health as well as adherence to therapy. This dataset demonstrates feasibility of clustering patients based on the time-frequency decomposition of a task-related EEG. Future work might focus on stimuli that are designed to elicit differential responses in putative subtypes of PTSD, and use fMRI to elucidate the anatomical sources of functional differences between groups.

Title: Biophysical modeling of single-neuron contributions to EEG and ECoG signals

Authors: *S. NAESS[1], T. V. NESS[2], G. HALNES[2], E. HALGREN[3], A. M. DALE[3], G. T. EINEVOLL[2,1];
[1]Univ. of Oslo, Oslo, Norway; [2]Norwegian Univ. of Life Sci., Aas, Norway; [3]UCSD, San Diego, CA

Abstract: Electroencephalography (EEG), i.e., recordings of electrical potentials at the scalp, and electrocorticography (ECoG), i.e., potentials recorded on the cortical surface, are two prominent techniques probing brain activity at the systems level. Despite their long history and widespread use, the proper interpretation of these brain signals in terms of the biophysical activity in underlying neurons (nerve cells) and neuronal networks is still lacking. Present-day analysis is predominantly statistical and limited to identification of phenomenological signal generators without a clear biophysical interpretation. New biophysics-based analysis methods are thus needed to take full advantage of these brain-imaging techniques (Einevoll et al., Nat Rev

Neurosci, 2013).
Here we used biophysical modeling based on morphologically detailed multicompartmental neuron models to explore single-neuron contributions to ECoG and EEG signals and in particular the feasibility of using the so-called current-dipole approximation in predicting these signals (Hamalainen et al, Rev Mod Phys, 1993). Specifically, we used the open-source Python package LFPy (lfpy.github.io) which builds on Neuron (www.neuron.yale.edu) and is based on well-established volume-conductor theory for numerical calculations of extracellular potentials. The LFPy package was supplemented with new Python tools for calculating the current-dipole moment of a neuron for use of the current-dipole approximation to predict ECoG and EEG signals. Current-dipole approximations were explored in the inhomogeneous four-concentric-spheres head model (Srinivasan et al., IEEE Trans Biomed Eng, 1998), and compared with results from using the Finite Element Method (Dhatt et al., John Wiley & Sons, 1977).
When comparing computed cortical-cell contributions to the EEG and ECoG signals from using the current-dipole approximation with results from the full model explicitly including all transmembrane currents, we find that the current-dipole approximation is applicable for modeling EEG signals. This allows for a drastic simplification of future biophysics-based computation of EEG signals from cortical cell populations. However, we find that the current-dipole approximation is not generally applicable for computing ECoG signals.

Title: A library of human electrocorticographic data and analyses

Authors: *K. J. MILLER[1], J. OJEMANN[2];
[1]Neurosurg., Stanford, Stanford, CA; [2]Univ. of Washington, Seattle, WA

Abstract: Electrophysiological data from implanted electrodes in humans are rare. Most recordings that have been performed are with epilepsy patients who have electrocorticographic (ECoG) electrodes implanted in the course of diagnostic localization of seizure focus prior to surgical resection. Only a small group of scientists have had the opportunity to work with these patients, and access to ECoG data has remained somewhat exclusive. It is recorded at only a few institutions around the country, often with different amplification setups, sampling rates, and

behavioral variations (even within the same institution).
Therefore, we have compiled a set of 16 benchmark experiments, with over 200 individual datasets made with the same amplifiers, at the same settings, with the same person interacting with the subject and performing the experiment. Depending on where the electrodes were placed for clinical indication, we performed experiments known to be associated with covered brain areas. In every case, electrode positions have been registered to brain anatomy. All data, anatomic, and analysis files (MATLAB code) are in a common, intuitive file structure. Every study/task has at least 4 subjects with confirmed task- modulated signal change in at least 1 electrode. Four of the sixteen experiments have not been published in any form.
In the course of analyzing these data, a large number of novel analysis techniques were developed. We are releasing our code base with the data, in such a way that all figures from published manuscripts describing these data can be directly reproduced. These data, along with behavioral parameterizations, anatomic localizations, and brain- surface renderings are now available for download worldwide, without restriction on use (other than proper citation).
The experiments/analyses contained in the library are:
• Baseline fixation
• Simple cue-based movement of hand&tongue
• Individual finger movements
• Joystick cursor tracking
• Hand Gestures
• Baseline fixation (with high sampling rate to fit power law form)
• Movement imagery (hand&tongue, with corresponding movement data included as well)
• One Dimensional Cursor control by imagery-based feedback (with corresponding movement and imagery data)
• Real time speech mapping from Noun reading & Verb generation
• N-back working memory task with pictures of houses
• Visual search task
• Basic Face-house picture presentation tasks
• Noise-masked face-house picture presentation tasks
• Baseline fixation (phase-amplitude coupling analysis)
• Mouse cursor tracking
• Noun reading & verb generation repeat runs, with multiple word lists

Title: High-density opto-electrical neural probe based on silicon nitride photonics for single neuron recording and stimulation

Authors: *L. HOFFMAN[1,2,3], S. LIBBRECHT[3], M. WELKENHUYSEN[1,4], A. ANDREI[1], V. BAEKELANDT[3], S. HAESLER[2], D. BRAEKEN[1];
[1]IMEC, Leuven, Belgium; [2]NERF, Leuven, Belgium; [3]KULeuven, Leuven, Belgium; [4]marleen.welkenhuysen@imec.be, ;, Belgium

Abstract: We present a multichannel optoelectrical depth probe which enables low noise extracellular electrical recording and optogenetic manipulation of neural tissue with high spatio-temporal precision. Simultaneous recording and site-specific optogenetic manipulation are widely used to determine the contribution of particular neural populations to behavior. Moreover, it has become common practice to optically identify specific ChR2-tagged cell types in extracellular recordings. However, current technologies for combined optical and electrical brain interfacing are often bulky or only provide a limited number of optical/electrical channels. Improving this situation is the main goal of our optogenetic neural probe.

The probe features 24 low-impedance titanium nitride contacts alongside 12 optical outputs (‘optrodes'). These optrodes are activated with light carried through silicon nitride waveguides that originate at the base of the probe and run along the shank. At the optrode site, the light is extracted from the waveguide with an optical grating coupler which redirects the optical power almost perpendicularly away from the probe plane. Additionally, the probe has the highest number of combined electrodes and optrodes (n=36) reported so far with a small cross-sectional area (100 μm width and 30 μm thickness). The electrode and photonic platforms have been monolithically integrated with a fully CMOS compatible process in a semi-industrial pilot line.

Different options can be used to couple light into the proposed optical neuro probe, which are either based on laser diodes, optical fibers or LEDs. All of them have complementary advantages that can serve different applications, thereby increasing the versatility of the system. Finally, we present a characterization of these different options along with in vivo experiments, which demonstrate highly localized artefact free optical stimulation.

Title: Spatial correlation in a 400 micron pitch electrocorticography grid

Authors: ***N. ROGERS**[1], J. HERMIZ[2], E. KAESTNER[3], M. GANJI[2], B. S. CARTER[3], S. S. CASH[4], D. BARBA[3], S. DAYEH[2], E. HALGREN[3], V. GILJA[2];

[4]Neurol., Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA

Abstract: Higher density electrocorticography (ECoG) grids allow for recordings with greater spatial resolution. In addition to recording from more locations on a relevant patch of cortex, higher density recording may open up the potential for new techniques for analyzing ECoG data. Features that are sensitive to the activity of smaller neural populations may become accessible at this scale. Here we explore the correlation between pairs of channels on the grid as a function of distance. Changes in the structure of this relationship measured at the sub-millimeter scale could be indicative of changes in the dynamics of underlying physiological responses.
The electrodes used were nanofabricated gold embedded parylene C with 40 um diameter contacts coated in PEDOT:PSS. The low impedance of PEDOT allows the contacts to be made smaller and with higher density while maintaining a tolerable signal-to-noise ratio. The electrodes were configured in a 7x8 grid with a pitch of 400 μm. For comparison, a standard clinical ECoG grid has contact areas three orders of magnitude larger, and a pitch that is over 20 times larger.

Correlation between channels gives a measure of the similarity between the signals measured, but it will also include external noise that appears on all channels. The average correlation between pairs of channels decreases with distance, and the rate at which it decreases depends on the frequency-- with lower frequencies generally maintaining a higher correlation across the grid. For pairs spaced at the pitch of the device, 400μm, the correlation across all frequencies is very high, 0.8 or higher. Between pairs of electrodes spaced at greater distances there is a smooth decrease of correlation with distance across theta (3-8 Hz), beta (15-30 Hz), gamma (30-50 Hz), and high-gamma (70-110 Hz). In an example experiment for pairs 2mm apart the high gamma bands will become mostly uncorrelated (correlation coefficient ~0.4) while the lower bands will maintain some correlation (0.5-0.8). These values are averages over tens of minutes of recording. However, the drop in correlation with distance changes on short time scales (on the order of seconds or faster).

Title: Ear-EEG as a novel technology for wearable brain wave monitoring

Authors: *C. GRAVERSEN[1], E. B. PETERSEN[1,2], A. FAVRE-FELIX[1,3], L. FIEDLER[4], J. OBLESER[4], T. LUNNER[1,2];

Abstract: Electroencephalography (EEG) is a well established technology widely used in brain research and clinical applications. Current technologies mainly record the potentials by multiple surface electrodes distributed over the scalp in a fixed laboratory environment. This approach generates potentials with high spatial and temporal resolution, which however is limited for every-day use due to stationary recording systems and visual design. To establish a platform feasible for every-day use in brain-computer-interface and clinical applications, we here propose

a wearable device recording the brain waves from the ear canal (Ear-EEG). Hence, the recordings are limited in spatial distribution, but on the other hand provide an invisible and easily wearable device that can be used 24/7. Furthermore, the sensors can even be integrated into a hearing aid, and by this approach be used to steer future hearing aids as a new type of brain-computer-interface for hearing-impaired persons. To test the optimal configuration of this new electrode array, several electrode materials, number of electrodes, positions, and references were tested. In our present design, we conducted a pilot study on 8 normal hearing persons by combined recordings from conventional 64 EEG scalp electrodes and three Ear-EEG electrodes in each ear. We found that the Ear-EEG in each ear was highly correlated to scalp-near electrodes as shown in figure 1. Furthermore, we demonstrated the possibility to record relevant neural responses from the Ear-EEG electrodes in both auditory oddball and audiobook paradigms. Additionally, we found that the neural responses assessed by cross-correlation between EEG responses and auditory stimuli statistical differed between auditory stimuli presented to the left ear compared to the right ear at several time-points. In conclusion, we expect the development of Ear-EEG devices to be a major step towards an unobtrusive and easy-to-use alternative to conventional EEG systems, which may pave the road for new EEG applications in brain-computer-interface and clinical applications.

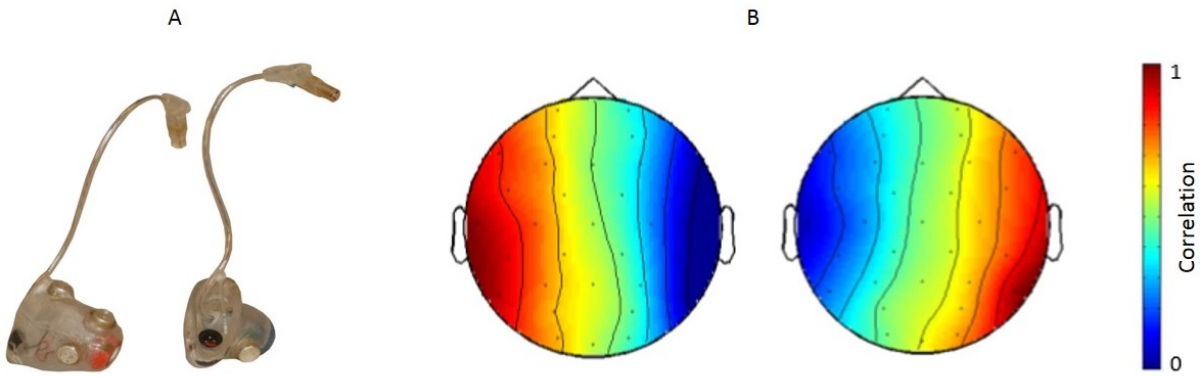

Figure 1. Ear-EEG devices with three electrodes in each earmold (A), and the correlation from the average Ear-EEG potentials in left and right ear respectively to each of the 64 scalp potentials (B).

Title: An attention model of binocular rivalry

Authors: *H.-H. LI[1], J. RANKIN[2], J. RINZEL[3], M. CARRASCO[4], D. J. HEEGER[4]; [1]Dept. of Psychology, [2]Ctr. for Neural Sci., [3]Ctr. for Neural Science; Courant Inst. of Mathematical Sci., [4]Dept. of Psychology; Ctr. for Neural Sci., New York Univ., New York City, NY

Abstract: Purpose: Previous models of binocular rivalry fail to explain the evidence that rivalry ceases when attention is diverted away from the stimuli (Zhang et al., 2011; Brascamp and Blake, 2012). We propose a computational model of rivalry to address how the dynamics of rivalry depends on attention.
Methods: In the model, the sensory representation is composed of 4 monocular neurons (both eyes, selective for two orthogonal orientations), 2 binocular-summation neurons that sum responses of the monocular neurons with the same orientation preference, and 4 binocular-opponency neurons that compute differences between the monocular neurons. In addition, two 2nd-layer neurons, selective for orthogonal orientations, are driven by the responses of the summation neurons (low-pass filtered over time), and provide orientation-selective feedback to the monocular neurons. Rivalry is driven by: (1) Slow adaptation in monocular & summation neurons. (2) Attention: Orientation-selective feedback from the 2nd-layer neurons, analogous to feature-based stimulus-driven attention, is active when observers attend to the stimuli but silent when attention is diverted. This feedback enhances the multiplicative gain of whichever orientation has stronger sensory responses at any moment, and suppresses the gain of the other orientation. (3) Mutual inhibition: The opponency neurons respond when there is conflicting information between the two eyes, and provide subtractive suppression to the monocular population with weaker responses.
Results: We simulated the neural responses for two stimuli (dichoptic gratings and monocular plaid) under focused and diverted attention. The model exhibited rivalry for attended dichoptic gratings, but not for the plaid or unattended stimuli, consistent with experimental results. In addition, the model exhibited two hallmarks of binocular rivalry: (1) When the two images were swapped between eyes repetitively and rapidly, the dominant percept either stayed with one eye or followed one orientation for a period of time, depending on the temporal characteristics of the

stimuli relative to the low-pass filtering in the 2nd-layer neurons. (2) The dominance duration changed with stimulus strength following Levelt's propositions. A bifurcation analysis allowed us to completely characterize the model, and to identify the parameter values for which the model's behavior was consistent with experimental results.
Conclusion: Attention affects rivalry by biasing the competition toward the dominant feature, thereby stabilizing the percept. The dynamics of binocular rivalry are determined by a combination of attention and mutual inhibition.

Title: A new 3D in-vitro model for studying human sensory neurons

Authors: *E. GRAS LAVIGNE[1], N. PY[2], D. BUTTIGIEG[1], L. L'HOMME[1], F. MAGDINIER[2], R. STEINSCHNEIDER[1];
[1]Neuronexperts, Marseille, France; [2]Equipe "Epigénétique, Chromatine & Maladies" Lab. INSERM UMR S_910, Marseille, France

Abstract: Numbers of peripheral neuropathy are due to an abnormal innervation of skin or to a dysfunction of sensory receptors. For example in the peripheral neuropathic pain occurring in diabetes, patients have abnormal sensory perception like hypersensitivity to hot, burning sensation··· Thus it is important to develop pharmacological topical formulations able to treat symptoms and improve the life's quality of patient. In this way, some TRPV1 topical agonists, such as capsaicin, have already been used to desensitize dysfunctional sensory receptors. To test other agonists or antagonists of nociceptors or receptors implied in the skin inflammation process, we developed a new model of reconstructed skin innervated with human sensory neurons derived from induced pluripotent stem cells (iPS cells). To complete our 3D model we propose to use multi electrode arrays (MEA) system to evaluate the functionality of sensory receptors. Once the model will be characterized and calibrated with normal reconstructed skin, it will be possible to mimic pathological diabetic skin cells for example, and to assess topical formulation designed to treat symptoms. First we established the proof of concept by demonstrating that it is possible to produce functional human sensory neurons derived from iPS cells. We demonstrated by immunocytochemistry that these cells express several sensory

receptors (TRPV1, TRPA1, PAR2, opioid receptors…) and that these receptors are functional (calcium mobilization assays on TRPV1 and TRPA1, neurite outgrowth assays with NGF). Secondly we demonstrated that it is possible to assess sensory neurons activity using MEA systems. To do that, we proceeded in two steps. In the first step we used well characterized rat neurons and in the second step we made the comparison with our human sensory neurons. Another part of this project was to innervate reconstructed skin with human sensory neurons and to characterize the type and number of the different sensory receptors in our 3D innervated model by immunohistochemistry. Our final goal is to place the 3D innervated model on MEA system, to register the electrophysiological activity of sensory neurons upon different stimuli applied on the skin, to discriminate the different receptor activated and to decrease the activity of nociceptors by using topically applied formulations.

Title: Tunnel culture systems on microelectrode arrays to measure electrical conduction in a controlled-network system

Authors: *S. GEISSLER, A. HIERLEMANN;
Dept. of Biosystems Sci. and Engin., ETH Zurich, Basel, Switzerland

Abstract: In an effort to advance the common neurobiological tool set, our lab has developed a high-density microelectrode array based on CMOS technology, featuring 26,400 recording sites. Such high resolution allows efficient investigation of electrical conduction with multiple measurement sites along a single axon. In this project, we will introduce microtunnels to this microelectrode array system to direct axonal growth along specific paths while minimizing noise from neuronal background activity during recording. Using standard SU-8 photolithograpy techniques, we developed 5 μm × 5 μm polydimethylsiloxane (PDMS) tunnels connecting two culture chambers. E18 primary rat cortical neurons were isolated and cultured on coverslips and

on microelectrode arrays to examine cell function and growth under the tunnels. Neurons were successfully cultured in these devices and axons grew across the 500 μm long tunnels. *The goal of this project is to develop a culture system to introduce multiple cell types onto the microelectrode array in a controlled network to examine the effects of cell-cell interaction on signal conduction.* To achieve this goal, we have met two milestones; (1) we cultured neurons on microelectrode arrays to examine signal to noise ratio and learn the techniques required for multi-neuron recording, and (2) we developed microfluidic tunnel systems and cultured neurons in this device on coverslips. Next, we will culture neurons with the tunnel systems on the microelectrode array and add oligodendrocytes to the second culture chamber to examine the changes in electrical conduction through the axons after myelination. This in vitro platform will allow researchers to examine demyelinating diseases, test pharmaceutical effects on neurons, and measure real-time changes in neuronal activity.

Title: Laser and oxygen plasma treated carbon fiber electrode array for the detection of electrophysiological and dopaminergic activity

Authors: *P. R. PATEL[1], P. POPOV[2], A. MOHEBI[2], D. G. D. EGERT[3], A. A. HAMID[2], K. NAJAFI[3], J. D. BERKE[2], B. J. ARAGONA[2], C. A. CHESTEK[1];

Abstract: Monitoring the electrical and chemical activity from neighboring but distinct populations of neurons while maintaining a stable interface is crucial to better understanding neural dynamics and information processing. This holds particularly true for the nucleus accumbens, a substructure of the striatum, which is of importance for decision making. Moreover, there are subregions of the nucleus accumbens (core and shell) that have functionally distinct dopamine release characteristics. To date, sampling from these subregions with multiple

electrodes has been difficult due to the size of existing glass insulated carbon fiber electrodes. To overcome this issue we have developed a high density carbon fiber electrode array that can alternatingly monitor electrophysiological and dopaminergic activity between the two subregions.
An array was fabricated using a thin (t=50μm) flexible printed circuit board as the underlying substrate. The board has a long extension (l=9mm) that permits measures within both the core and shell. At the end of this extension five carbon fibers, at a pitch of ~200μm, were secured using silver epoxy. The fibers extended past the edge by 500μm and were insulated with parylene-c. The tips of the fibers were then laser etched to re-expose a carbon surface and treated with oxygen plasma to remove any remaining debris. The laser and oxygen plasma steps result in a low electrode impedance and eliminate the need to electrodeposit poly(3,4-ethylenedioxythiophene). To implant the array, first a small glass cannula was inserted just above the nucleus accumbens, then the array was inserted into the cannula, and cemented in place.
For one rat, electrophysiology measurements were taken, during which time unit activity was detected on 9 of 15 days. Average unit peak-to-peak amplitude across all channels and days was 90μV. In addition, on the first and last day, phasic surges in dopamine concentration (i.e. dopamine 'transients'; indicative of dopamine release from burst firing of dopamine neurons) were detected on one fiber using fast scan cyclic voltammetry after the administration of a cocaine and raclopride mixture through a venous port.
Taken together, these results point to the viability of this technology to sense both electrophysiological activity within the striatum and dopamine fluctuations within the striatum's extracellular volume using the same electrode. Thus, the array configuration of these electrodes allows for sampling of electrical and chemical activity from neighboring, but still distinct, neuronal populations. Increasing the electrode density and count will only continue to provide more information about population dynamics.

Abstract: Recently much attention has been focused on the electrocorticogram (ECoG) as a source signal especially for clinical BMIs because of its good balance of features: Less invasive than penetrating electrodes, and higher spatial resolution than that of the scalp EEG. Until recently clinical ECoG electrodes were generally designed and utilized for identifying epileptogenic focus, and a typical size of those electrodes was diameter of ~4 mm and an inter-electrode distance of ~10 mm. However, to achieve more precise and naturalistic control of external devices such as multi-joint prosthetic arms, it may be beneficial to increase the number and density of recording channels to obtain richer motor/sensory information. There have been several reports attempting to increase the number and density of electrodes. However, little is reported about the validity of the high density ECoG arrays.Here, we report our analysis of somatosensory evoked potentials (SEP) of two monkeys in order to evaluate our high density ECoG array. We fabricated a high-density flexible array with MEMS technology. A gold layer was sandwiched between two Parylene-C layers (10 μm each). A unit array consisted of 32 channels. The inter-electrode distance was 700 μm, and the recording site of each channel was 350 μm square. Next, we executed an acute experiments using two macaques. The central sulcus was opened carefully and fabricated arrays (96-128 ch) were placed over the posterior wall of the central sulcus and the post-central gyrus, which corresponded to the digit representations of areas 1 and 3b. Spatiotemporally high-resolution SEPs were recorded by giving electrical stimuli and mechanical vibratory stimuli to each digit. Stimulation of different digits evoked different patterns of response and spatial patterns were approximately accordant with somatosensory mapping reported in previous researches using a penetrating method. In offline decoding analysis, we predicted stimulated fingers and stimulation intensity from SEP waveforms using a support vector machine. Especially in electrical stimulation condition, high (~98%) prediction accuracy was achieved. Further analysis showed that increasing channel counts improved prediction accuracy. On the other hand, depending on composition of feature vectors, combinations of just a few good channels could achieve high prediction accuracy. These results showed an effectivity of our higher density electrode on high-precision sensory decoding or spatiotemporal visualization of ECoG signal pattern. It is expected that utilization of high-density ECoG electrodes makes brain-machine interface more reliable.

Abstract: A brain-machine interface (BMI) is a device, which interfaces directly with brain to control an external efforter (e.g. a robotic arm or computer). Here we present an electrocorticogram (ECoG) -based BMI , utilizing a flexible ECoG electrode and optogenetic neuromodulation for sensory feedback. Position or touch sense is important for clinical applications of the BMI because ideal prosthetic limbs should be perceived as natural extensions of the users' bodies. We have started to design a cortical modulator using optogenetics- a new method for the manipulation of neurons to dial in potential sensory input in a bi-directional manner. Optogenetics is based on genetically modified ion channels that respond directly to light. These light-gated ion channels, such as Channelrhodopsin-2 (ChR2), allow precise, millisecond control of specific neurons. This technique reduces most of the key problems associated with electrical brain stimulation: there is no associated electrical artifact to interfere with the electrophysiological recordings, nor any tissue damage from the current injection. It also allows for precise control of the spatial pattern of stimulation. A prototype optogenetic implant is presented, that will simultaneously record the activity of cortical neuronal ensembles and bring complex modulation patterns through optogenetic stimulation of cortical sensory areas. Our newly-invented optogenetic devices consist of both flexible ECoG and LED for optical stimulation. Here we report data from initial bench testing and implantation for the flexible

ECoG with LED in both the rat and non-human primate. We have shown that the flexible ECoG is effective as a chronic implant in rats, providing high fidelity neural recordings for up to 7 weeks. The initial results suggest that the new ECoG array can be successfully translated from rodents to accommodate the technological challenges associated with successfully interfacing with the non-human primate brain.

Title: Measurement and characterization of low frequency extracellular potential from cultured neuronal networks

Authors: S. JOO, *Y. NAM;
KAIST, Daejeon, Korea, Republic of

Abstract: To study the signal processing such as learning and memory between neurons in network scale, in vitro neural network have been used as a powerful and controllable model system. Measuring spike from neural network means that spatial and temporal activity of each neuron in network. In the brain, the recording of local field potential (LFP) by extracellular recording methods enable us to infer the physiological activity of a population of neurons. Even if the analysis of LFP was important to understand the information transfer principles of the brain, no previous studies have examined the LFP in cultured neural networks. Here, we report the recordings of LFPs and spikes from in vitro neuronal circuits cultured on the microelectrode array (MEA). We tracked the feature of LFP signals during the development of the networks and confirm that the measured spontaneous LFP were originated from synaptic activity of the neural network.We cultured clustered neural network on 60-channel ITO MEA by fabricating agarose hydrogel microwells through the MIMIC (Micromolding in capillaries) technique. On the MEA, neurons formed the clusters which were around 100 micrometer in diameter on the electrode array due to the patterned agarose hydrogel. From the networks, electrical signals which were measured by amplifier with wideband filter (Gain: 50, bandwidth: 0.02 Hz ~ 8 kHz) contained both spiking activity with high frequency component and LFP with low frequency component.

From immature stage of the network, there were no spiking activities from the clustered neural network. On the other hand, LFP traces were recorded from the networks spontaneously. We measured features (power spectrum, amplitude, and half-maximum full width) of LFP signal. Using drug response test, we confirmed that the LFP type signals is derived from synaptic activity. In this study, we showed that LFP and spike from clustered neural network was successfully measured by MEA system. Our method can provide diversity about LFP parameter for studying of neural network dynamics with in vitro cultured neural network.

Title: Assessing very high density intraoperative ECoG grids using a 7x8 grid with 400 um pitch

Authors: ***J. HERMIZ**[1], N. ROGERS[1], E. KAESTNER[1], M. GANJI[1], B. CARTER[1], S. CASH[2], D. BARBA[1], S. DAYEH[1], E. HALGREN[1], V. GILJA[1];
[1]UCSD, La Jolla, CA; [2]MGH, Harvard Med. Sch., Boston, MA

Abstract: There is growing interest in higher densities grids (>2 channels/cm^2) for human electrocorticography (ECoG). A key question raised by this trend is, “What is the optimal density?” Tradeoffs between design parameters need to be measured to address this question. In this work, we begin addressing this question by describing the design space and comparing decoding performance of “virtual” square grids constructed by sub-sampling a 7x8 grid with 400 um pitch and 40 um diameter electrodes. This allows assessment of grids with densities as high as 670 channels/cm^2.There are 3 design parameters for square grids (excluding electrode

geometry): channel count (c), pitch (p), and area (A). We search this design space (S) for all possible square grids, varying c and p, as there are only 2 degrees of freedom. To assess grid performance, we trained a linear model to decode trials (n=180) where the subject was presented with 3 classes of audio-visual stimuli intraoperatively. Spectrotemporal features, integrating band power relative to stimulus onset, were used: {(4-15),(15-30),(30-55),(70-115)} Hz × {(0-0.25),..,(1.25-1.50)} sec. We used an algorithm called Shrunken Centroids Regularized Discriminant Analysis to learn the model because it has been shown to have competitive performance for high-dimensional datasets with limited training data (Guo et al., Biostatistics 2007). The performance metric used is percentage of trials decoded accurately. As expected, optimal performance was achieved when all 7x8 channels were used: 73% +/-7% (95% CI s.e.m; baseline chance is 33%; 8-fold cross validation). Consistent with this result, we found that when fixing p = 400 um or p = 800 um, there was a significant correlation (ρ) between accuracy and channel count, ρ = 0.54 and 0.49, respectively ($P < 0.01$, t-test). It's important to observe that A also increases with c when p is fixed. To examine if higher density grids can be more useful than lower density grids, we restricted A and increased c to see if accuracy increased. A reasonable comparison would be for all virtual grids $s_h \in S$ s.t. c=25,p=400 um and $s_l \in S$ s.t. c=9,p=800 um. The distribution of performance change between high and low density grids is positively skewed with an 80% confidence interval ranging from -8.7% to +17%, the difference between the medians of these distributions is statistically significant at 4.5% ($P < 0.01$, Wilcoxon signed-rank test), indicating that s_h can be more informative than s_l.

Title: A 512-channels, whole array readout, CMOS implantable probe for acute recordings in the brain

Authors: ***M. MALERBA**[1], G. ANGOTZI[1], G. MANDELBAUM[2], B. SABATINI[2], L. BERDONDINI[1];
[1]Italian Inst. of Technol., Genova, Italy; [2]Harvard Med. Sch., Boston, MA

Abstract: Despite huge progress, the understanding of the mechanisms underlying brain complexity is still hindered by a lack of experimental methodologies, able to disentangle, at a single-neuron level, the largely distributed functional brain circuits. From a neuro-technological point of view and with the aim of providing new experimental capabilities, the aim of our work is to realize a novel generation of microelectronic micro-machined neural probes that can provide large-scale single-neuron recording capabilities in different brain circuits [1]. As already demonstrated in-vitro on brain slices, cell cultures and retina whole mounts [2], a highly integrated design based on CMOS technology enables whole array recordings at sub-millisecond resolution from densely packed microelectrodes, allowing to literally image spiking activity and field potentials in multiple brain circuits at the same time. Here, we report on a complete probe system designed for in-vivo recordings with scalable circuit architecture. In detail, we present a modular approach in which 16 matrices yield 512 electrode-pixels along a single shaft, realizing a first generation of implantable CMOS neural probes. The device is capable of recording from the whole electrode array at sub-millisecond resolution, over a sensing area of 6 mm in length and 110 μm in width. Each electrode is an active pixel that comprises the recording site and an underneath first-stage amplifier; each module counts 32 pixels (25μm pitch), a column buffer for time division multiplexed readout (30kSample/s per pixel) and a programmable gain amplifier for further signal amplification (42dB to 72dB). An active feedback loop, shared among multiple electrodes, finally allows the cancellation of DC offsets without the need of integrating large input capacitors. To minimize tissue damage upon insertion, silicon micromachining techniques were used to shape the probe and reduce overall dimensions to LxWxH = 6 mm x 110 μm x 50 μm. We will report on recording capabilities, validated both in-vitro from mouse brain slices and in-vivo from head-fixed behaving mice, also discussing perspectives and future development. The final goal is coupling such devices with state-of-the-art optogenetic stimulation tools.

Abstract: Cross-validating new methods for recording neural activity is necessary to accurately interpret and compare the signals they measure. Here we describe a procedure for precisely aligning two probes for *in vivo* "paired-recordings" such that the spiking activity of a single neuron is monitored with both a dense extracellular silicon polytrode and a juxtacellular micro-pipette. Our new method allows for efficient, reliable, and automated guidance of both probes to the same neural structure with micron resolution. We also describe a new dataset of paired-recordings, which is available online. We propose that our novel targeting system, and ever expanding cross-validation dataset, will be vital to the development of new algorithms for automatically detecting/sorting single-units, characterizing new electrode materials/designs, and resolving nagging questions regarding the origin and nature of extracellular neural signals.

Title: Cognitive responses recorded during neurosurgery using microarray pedot:pss electrodes

Authors: *E. KAESTNER[1], J. HERMIZ[2], N. ROGERS[2], M. GANJI[2], R. CARTER[2], S. CASH[3], D. BARBA[2], S. DAYEH[2], V. GILJA[2], E. HALGREN[2];
[1]Univ. of California San Diego, San Diego, CA; [2]UCSD, San Diego, CA; [3]Massachutsetts Gen. Hosp., Boston, MA

Abstract: Human intracranial recordings combine spatial and temporal precision unmatched in modern human neuroimaging. But these recordings are rare and spatial coverage is often coarse and dictated by clinical considerations. Our team developed an approach to address both these concerns. First, to increase the number of recordings we developed a system to record cognitive activity during awake neurosurgeries. Second, we have developed a poly(3,4-ethylenedioxythiophene): polystyrene sulfonate (PEDOT:PSS) micro-array of 56 electrodes with high spatial precision (400 um pitch) able to be placed on the pial surface during surgery. Recordings: During awake neurosurgery for clinical language mapping, patients volunteered for a 10 minute task and microarray placement. The PEDOT:PSS microarray was placed on the anterior superior temporal gyrus (STG) for Patient 1 (P1) and posterior STG for Patient 2 (P2). P1 was asked to read visual words, repeat auditory words, and name visual pictures. P2 was asked to make a match/mismatch decision about paired letters and auditory phonemes. Interspersed were visual (false fonts) and auditory (noise-vocoded) control stimuli. Results: Analysis focused on high-gamma amplitude (HGA; 70-170Hz) and linear discriminant modeling (LDM). For HGA, ANOVAs were run between stimulus classes and corrected with false-discovery rate. For the LDM, we used Shrunken Centroids Regularized Discriminant Analysis. Task performance during surgery was high (P1 verbally responded on >95% of trials; P2 was correct on 98% of trials). P1 had 42 good electrodes (impedance < 60k ohms @ 1kHz) with 15 electrodes (36%) showing a HGA increase to auditory words relative to visual words and pictures. LDM discriminated the 3 language modalities at 70% accuracy (chance: 33%). P2 had 33 good electrodes with all showing a HGA increase to auditory noise trials relative to the other three trial types. With no response to visual stimuli at this electrode placement, LDM only discriminated the 4 trial types at 32% accuracy (chance: 25%) but was able to discriminate human voice from noise-vocoded stimuli at 76% (chance: 50%). Discussion: During surgery, cognitive responses can be recorded and discriminated from PEDOT:PSS micro-arrays. This approach promises to increase the number of recordings by expanding the volunteer pool to anyone undergoing awake neurosurgery. Second, the high-density PEDOT microarray can reliably discriminate stimuli, both between language modalities (P1) and within a language modality (P2). Combining these advantages will allow us to test theories of language function rapidly and with a high degree of anatomical precision.

Title: A long-term feasibility study for neural recording with carbon-fiber based microelectrode array

Authors: *Y. LEE[1], Y. LIM[2], S. HWANG[1], S. JUN[1,3];
[1]Ewha Womans Univ., Seodaemun-Gu, Seoul, Korea, Republic of; [2]Convergence Res. Ctr. for Diagnosis, Treatment, and Care Syst. for Dementia, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [3]Dept. of Brain and Cognitive Sci., Ewha Womans University, Seodaemun-Gu, Seoul, Korea, Republic of

Abstract: Microelectrode arrays are commonly used to record the neural activities in the brain or to make a neuronal interface between brain and machine. However, the traditional system often induces tissue reaction around the implanted microelectrode array, thereby limiting the possibility of long-term experiments. It is believed that the extent of tissue damage is associated with the geometrical size of the electrode. In this study, in order to reduce the reactive tissue response, carbon fiber-based microelectrode arrays are developed. Since the diameter of the carbon fiber (7 μm in diameter) is much smaller than the conventional micro-wires, it is possible that the carbon fiber neural probe may be appropriate for the long-term neural recording. Here, we introduce a multi-channel microelectrode array where each channel is composed of carbon fiber bundles. To verify the feasibility of long-term recording, we implanted the carbon-fiber based electrode in the motor cortex of freely behaving rats and monitored movement related neural responses and impedances of electrode for several weeks. These were also compared with the electrophysiology data obtained from conventional tungsten electrode implanted either in the same or different animal. Finally, we conducted immunohistochemistry of brain tissues for two

different electrode systems to confirm the possibility of chronic implant for the new carbon-based electrode.

Title: Persistence of dysfunctional auditory information processing following pharmacotherapy in Internet gaming disorder: an event-related potential study

Authors: ***M. PARK**[1], Y. KIM[1], J. LEE[1], D. KIM[2], J.-S. CHOI[1,3];
[1]SMG-SNU Boramae Med. Ctr., Seoul, Korea, Republic of; [2]Seoul St. Mary's Hosp., Seoul, Korea, Republic of; [3]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Internet gaming disorder (IGD), defined as inability to control internet-based games, leads to serious impairment in psychological and social functioning, but few studies exist that identify neurophysiological characteristics in IGD. The aim of this study was to determine neurophysiological markers associated with symptom changes in IGD patients following pharmacotherapy with outpatient management. Eighteen patients diagnosed with IGD (22.61 ± 5.10 years), and 29 healthy controls (HCs; 24.66 ± 3.80 years) participated in this study. IGD patients completed a 6-month of serotonin reuptake inhibitors (SRIs)-based pharmacotherapy. Event-related potential (ERP) were acquired during an auditory oddball task in participants who were young adult males. For the IGD patients, ERP recorded prior to and after treatment. Between-group differences and the pre-post treatment differences in P300 components were investigated using repeated measures analysis of variance, respectively. The primary treatment outcome was a change in score on the Young's Internet Addiction Test from before and after treatment. The IGD group showed significantly reduced P300 amplitudes at midline centro-parietal and parietal site compared with those in HC. Reduced P300 amplitudes in the IGD were not correlated with scores on Internet Addiction severity. After 6 months of treatment, there were no significant changes in P300 amplitudes between pre- and post-treatment of IGD, even though, the IGD patients exhibited significant improvements of their IGD symptoms measured by

Young's Internet Addiction Test. Furthermore, there were no significant ERP differences between responder and non-responder to a 6-month pharmacotherapy in patients with IGD. These results indicate that IGD has abnormalities of P300 index and reduced P300 amplitudes could be considered as a candidate trait marker of IGD. This study enhances our understanding of neurophysiological characteristics of IGD.

Title: Trial for drug-induced epileptogenic phenotype classification in primary rodent neurons and human induced pluripotent stem cell- derived neurons

Authors: ***N. MIYAMOTO**[1], T. KADOWAKI[2], K. SAWADA[1];
[1]EISAI Co., Ltd., TSUKUBA, Japan; [2]Eisai Co., Ltd., Tsukuba, Japan

Abstract: Many drugs have been reported to have the risk of seizures. Spontaneous neuron activity recordings by multi-electrode array (MEA) system from networks of cultured neurons could be a good risk evaluation method for drug-induced seizure events. Spontaneous electrical activity in neural networks consists of action potential spikes and organized patterns of action potential bursts. Those activities are able to be observed after a couple of week's cultures in primary rat cortex and hippocampal neurons. Epileptogenic response was induced in those cells by $GABA_A$ antagonism with gabazine or picrotoxin as generation of periodic synchronized burst spike patterns among multiple electrodes in a probe. The response was enhanced in a dose-dependent manner of $GABA_A$ antagonism. We previously reported that the spontaneous neuron activity was hardly obtained from human induced pluripotent stem cell (hiPSC)-derived neurons alone; but we succeeded in accelerating the activity generation by co-culture with iCell neurons and mouse primary astrocyte conditioned medium (mACM). And the potentiated hiPSC-neurons by humoral factor(s) from mACM showed epileptogenic response pattern after gabazine or picrotoxin treatment as well as rodent primary cells. In this study, we developed new MEA data analysis application for classification of the epileptogenic phenotype by amplitude pattern in a synchronized burst event. The application digitalizes repetition number of strength change in the single burst event on selected threshold value of spike amplitude and period of time duration.

$GABA_A$ antagonism by gabazine and picrotoxin increased the number of repetition in a dose-dependent manner in both primary rodent neurons and hiPSC-neurons. Analysis of epileptogenic responses using reagents other than $GABA_A$ antagonists is underway. This application might be a useful tool for MEA data analysis for drug-induced epileptogenic phenotype classification. Title: Low intensity low frequency ultrasound neuromodulation in cultured rat hippocampal neuron

Authors: *S. HWANG[1], H. JEONG[1], S. KIM[1], Y. LEE[1], T.-S. KIM[3], S. JUN[1,2];
[2]Dept. of Brain and Cognitive Sci., [1]Ewha Womans Univ., Seoul, Korea, Republic of; [3]Kyung Hee Univ., Yongin, Korea, Republic of

Abstract: Ultrasound is non-invasive neuromodulation method with high spatial selectivity and high penetrating power. The advantage of noninvasiveness, ultrasound has gained increasing attention of promising treatment approach of neurologic disease. In the past few years, a number of studies have been performed to observe the affect to ultrasonic neurostimulation in a rodent model. However, the underlying mechanism of ultrasound induced neuro-modulation are sYTnot clearly elucidated yet. Therefore, we have been aiming to investigate the principles and verified the effective sonication time with low-intensity, low-frequency (LILFU) ultrasound. In this study, we used 0.5MHz center frequency ultrasound with 17.4 mW/cm^2 spatial-peak, time-

averaged intensity based on 0.12 MPa peak acoustic pressure, 600 Hz pulse repetition frequency and 320 cycle pulse duration. Primary hippocampal neurons were cultured from embryonic 17-day gestation Sprague Dawley rat and seeded in microelectrode array (MEA). At DIV 14, the medium was changed to artificial cerebral spinal fluid (aCSF) for 10 minutes and LILFU was applied to the neural networks. Individual spontaneous action potentials (APs) were analyzed before, during and after ultrasound application. The frequency of APs increased during and after ultrasound stimulation. In order to figure out the synaptic change induced by sonication, immunocytochemistry was performed.

Title: *In vivo* testing of the neural sewing machine: a method for inserting fine, flexible neural probes

Authors: ***T. L. HANSON**[1], C. DIAZ-BOTIA[2], S. JUNG[3], M. M. MAHARBIZ[3], P. N. SABES[1];
[1]Physiol., UCSF, San Francisco, CA; [2]Biomed. Engin., [3]EECS, Univ. of California, Berkeley, Berkeley, CA

Abstract: In an effort to improve the quality, bandwidth, and reach of neural interfaces, we have been working on a system of fine and flexible electrodes that are robotically implanted via a fine and maximally stiff needle - a neural 'sewing machine'. This integrated system is design to increase the range and targetability of large-scale neural interfaces and to improve recording longevity. Specifically, the system aims to alleviate problems due to mechanical impedance mismatch between the electrode and brain tissue by implanting flexible and very thin probes. The small probe size (4 um x 16um) was design to minimize the foreign body response. By inserting probes individually, they can be targeted to nearly any location and depth, while also avoiding vaculature, thereby reducing blood-brain barrier disruption.
The system has five tightly integrated components: 1) Platinum-polyimide electrodes, with a silicon carbide adhesion layer and parylene-SiO2 release layer; 2) Vacuum / hydrogen micro-

brazing chamber for fabricating stepped 12 x 25um tungsten-copper inserter needles; 3) 16-DOF inserter robot, including closed-loop critically-damped ballistic needle retraction, ultrasonic cleaning station, microdurotomy drill, and four high-resolution targeting microscopes; 4) Custom 65nm, 2.25mm x 2.25mm neuromodulatory integrated circuit, with 64 recording channels and 16 stimulation channels that is directly wirebonded to the electrodes; 5) suite of programs for closed-loop anatomical targeting of individual recording and stimulation sites.
We present extracellular recordings and histological responses from the full electrode-inserter system when 64-channel arrays were implanted both acutely and chronically in rats, as well as acutely in monkeys. Elements of scaling the system to a full 2048 chronically implanted channels in a monkey will also be discussed, particularly speed, targeting accuracy, and importantly overall system yield.

Title: Opto-EEG constructs mesoscopic and stimulant-dependent functional connectome in mice

Authors: ***S. LEE**[1], E. HWANG[2], D. LEE[3], W.-S. JUNG[4], J. CHOI[2];
[1]KIST, Seoul-City, Korea, Republic of; [2]KIST, Seoul, Korea, Republic of; [3]Inst. of Basic science, Daejeon, Korea, Republic of; [4]POSTECH, Pohang, Korea, Republic of

Abstract: Connectome, the comprehensive architecture of brain elements and connections among them (Sporns et al., PLoS Comput. Biol. 2005), is fundamental to the understanding of brain functions. Recently, technical advances in optical imaging allow us to construct structural connectome. However, major issues of functional connectome needed to be addressed with cell-specific, state dependent approach in diverse situation. However, it mainly has been discussed separately that macroscopic functional connectome and brain states because of lack of methods that satisfying both in freely behaving animal. Opto-EEG combines optogenetics and high density electroencephalogram (EEG) which is designed to obtain whole cortical activity with high spatial resolution (Lee et al., JoVE, 2011). Optrodes readily approach into the brain through the space between micro-electrodes of high density EEG. Opto-EEG makes it possible to

stimulate a cell-specific or region-specific target circuit and record the consequent cortical activation simultaneously. To visualize the dynamical changes of functional connectome, dynamical analysis and source localization (Lee et al., PLoS One. 2013) tools also have been developed. By applying the Opto-EEG to well-defined somatosensory circuit, we could demonstrate the difference between anatomical and functional connectome. Repetitive optogenetic stimulation of ventral posteromedial nucleus of thalamus induced cortical activation propagating from the primary somatosensory to other cortices. Different propagation patterns were observed with respect to the stimulation frequencies, such that the stimulation at beta frequency induced resonance of synchrony between somatosensory and motor cortex. On the other hands, stimulation at gamma induced rapid synchronization between both hemispheres whereas the stimulation at lower frequencies showed gradually propagating pattern. This demonstration shows that different functional outcomes arise from a single entity of somatosensory circuit, depending on the diverse stimulation conditions. This result suggests that differently anatomical connectome, functional connectome is altered by stimulus conditions and opto-EEG becomes important piece to macroscopic functional connectome.

Title: Cortical spreading depression simulator

Authors: ***S. C. JONES**[1], Z. A. BARNES[2], A. M. BECK[2], W. S. HARLAM[2], B. J. RHINDRESS[2];
[1]Cerebroscope, Pittsburgh, PA; [2]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: To aid in the development of a system to non-invasively detect cortical spreading depression (CSD), a CSD simulator consisting of a mechanical-electrical device that simulates the scalp surface voltage of a brain surface CSD, CerebroSim, has been designed and produced. This CSD simulator will enable pre-clinical bench testing of a non-invasive CSD detector to detect real-time scalp potentials in human patients.
CerebroSim generates a simulated CSD that propagates through electrically modeled layers of head tissue. The system consists of a touch screen user interface enabling: 1) the choice of CSD speed and various CSD propagation patterns, 2) the display of user details of the simulation, 3) a real-time display of the CSD motion, and 4) pausing or stopping the propagation at any time. The

electrical subunit of the device consists of custom demultiplexing printed circuit boards (PCBs) with integrated shift registers and transmission gates that control each pin of an 800 pin array. A Raspberry Pi microcontroller determines which pins output the -20 mV signal that is characteristic of a CSD. Pins not propagating the CSD signal act as disconnected and short circuit with a surrounding, aluminum ground plate, which is connected to a 20 mV, high output impedance signal. The plate prevents current draw into the array. With the ground plate maintained at 20 mV, the CSD signal propagated is held at 0 V to create the -20 mV differential. The pins are in contact with layered resistive fabrics that simulate the electrical properties of the cerebral spinal fluid, dura mater, skull, and scalp. The materials fit between two acrylic plates that "sandwich" layers to maximize contact and prevent expansion. The prototype CSD detection system will be validated by placing it on the topmost material layer (representing the skin) to locate and detect the simulated CSD propagation on the scalp surface.
With respect to circuit design, the simulator can generate complex CSD patterns of known forms. The system's ability to accurately control -20 mV transmissions to each pin of the electrode array was proven by direct measurement. Measured surface resistivity, multi-level isotropy, and unhindered voltage propagation of the layered resistive fabrics were found to be as expected. This physical CSD simulator will provide bench-testing and preliminary validation for a to-be-developed non-invasive CSD detection system before human clinical trials by providing a non-human model that simulates the scalp surface voltage of a brain surface CSD.

Title: Mapping and modeling EEG signals before and after a craniotomy procedure

Authors: *D. ISSAR[1], A. SNYDER[3], M. SMITH[2];
[1]Bioengineering, [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Electroencephalography (EEG) at the scalp is used to enhance our understanding of the brain's underlying computational mechanisms and for clinical diagnosis. It is the primary method for measuring electrical correlates of brain activity in humans because it is non-invasive; however, the signals weaken as they pass through layers of tissue, bone, and skin. With non-human subjects, experimenters use more precise but invasive methods of neural recording that penetrate the brain and require creating a small opening in the skull (craniotomy). EEG signals measured from animal subjects allow us to translate between internal brain signals observed through more invasive means and external brain signals that can be measured in human studies. However, the opening in the skull may alter the way the brain's electrical signals travel. We analyzed EEG signals from rhesus macaque monkeys during a visual attention task before and after perforating the skull to determine the effect on our method of mapping between neural activity and EEG signals. Using MRIs, we constructed pre- and post-craniotomy computer models of the electrical properties of each subject's head to infer the neural sources of the EEG signals. We analyzed the similarity between the pre- and post-models' time-courses, scalp electrical maps, and source localizations and found strong correlations regardless of whether there was a hole in the skull. These results suggest a craniotomy over visual cortex does not cause significant deviations in our ability to map visually evoked EEG signals. Our results are the first step in improving the translational ability between human and animal brain studies. This method of mapping EEG in the presence of a small hole in the skull is also important for the feedback and control capabilities of neural prosthetic devices that are often implanted via craniotomy.

Title: Computational infrastructure to enable whole-brain mesoscale circuit mapping for Marmoset

Authors: *M. LIN[1], Y. S. TAKAHASHI[1], K. WEBER[1], K. HOSSAIN[1], B. HUO[1], A. S. TOLPYGO2[2], D. D. FERRANTE[2], S. BAI[3], M. G. ROSA[3], H. OKANO[1,4], P. P. MITRA[1,2]; [1]Brain Sci. Inst., Riken, Japan, Wakoshi, Japan; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [3]Dept. of Physiol., Monash Univ., Clayton, Victoria, Australia; [4]Dept. of Physiol., Keio Univ. Sch. of Med., Shinjuku, Tokyo, Japan

Abstract: Modern whole-brain imaging techniques employing light microscopy generate large data volumes, requiring the development of specialized software tools to support the acquisition, quality control, pre-processing, analysis, and dissemination of such data sets. A software suite developed to this end in the Mouse Brain Architecture Project at CSHL, has been replicated and suitably modified to serve the needs of a high-throughput neurohistological pipeline at the RIKEN Brain Sciences Institute to process marmoset brains. The goal of the RIKEN BSI pipeline is to carry out brain-wide mesoscale circuit mapping of the common marmoset (*Callithrix Jacchus*) using the injections of anterograde and retrograde tracers, as part of the Japan Brain/MINDs project. The software suite developed includes a storage/communications setup, an integrated Laboratory Information Management System (LIMS), imaging quality control (QC), section registration and a web portal component, and is tailored to the scanning of whole marmoset brains at the light microscopy resolution together with auxiliary MRI scans of the same brains. The hardware infrastructure on which the suite is deployed uses a 10g network to connect image acquisition, storage and analysis engines. The image database consists of a distributed file system containing raw and compressed images in JPEG2000 format together with MySQL databases of metadata. A customized LIMS is used to track brains and associated metadata and also to facilitate laboratory process management. A responsive web data service is used locally for QC, and an IIPImage based viewer is used for remote web-based viewing of the high-resolution images for purposes of analysis and quality control. The neurohistological pipeline uses tape-transfer assisted cryosectioning that produces sections that preserve their rigid 2D geometries, but these need to be registered together to obtain 3D brain volumes. The corresponding section-registration code from the mouse pipeline was customized for the Marmoset, and is able to post-process the acquired images within a time frame consistent with the data acquisition rates, enabling a steady production of 3D brain volumes (~10TB/brain for LM data). Lessons learned from scaling up the mouse pipeline software to enable the steady processing of much larger marmoset brains (8x by volume) will be presented, together with the details of the associated software/hardware suite, and its integration with the associated web-portal for data dissemination. The successful replication and scaling up of the MBAP software pipeline demonstrates the generalizability of the approach to other species with brains of comparable sizes.

Title: Computational topology algorithms for skeletonizing whole mouse brain tracer-injection data using discrete Morse theory.

Authors: *D. D. FERRANTE[1], S. WANG[2], Y. WANG[2], P. P. MITRA[1];
[1]Cold Spring Harbor Labs., Cold Spring Harbor, NY; [2]Computer Sci. and Engin., Ohio State Univ., Columbus, OH

Abstract: We digitized anterograde fluorescent tracer injected mouse brain sections and examined their skeletonization structure. Most existing neuron tracing algorithms require good neuron segmentation as preprocessing before the skeletonization step, and decisions in the segmentation step are typically based on local information, making it hard to capture the global structures behind data, and make the results noise-sensitive. Furthermore, the tracing methods often use greedy procedures to extract a neuron tree (e.g. approaches based on shortest path or maximum spanning tree), and the topology of the final tree relies heavily on the specific greedy strategies used. Non-homogeneous distribution of signal in input raw data remains challenging to handle, an issue that is especially important for tracer injection data, in which signal strength can differ greatly between the injection site to terminal regions. Finally, existing algorithms focus on single-neuron reconstruction, and do not address the more challenging problem of summarizing tracer injection data, which involves multiple neurons. We use recently developed techniques drawn from discrete Morse theory [cf. S. Wang et al., SIGSPATIAL/GIS 2015, DOI: 10.1145/2820783.2820833] to summarize tracer-injected whole-brain data sets. The output of our approach is a skeletonization of the tracer injection-label into a consensus tree structure. Our

Morse theory-based approach is effective at recovering the global one-dimensional non-linear (i.e., geometric graph) structure behind the input data and is robust without any special processing. No explicit segmentation or thresholding is needed. As our method relies on global information, it is robust to noise, small gaps in signal, and non-homogeneous signal distribution, such as the signal becoming weaker as it travels away from the injection site. There is also a natural persistence-simplification procedure to help prune less important and reliable branches. We show that our method produce robust data summaries of AAV-tracer injected whole mouse brain data sets from the Mouse Brain Architecture Project. Details of the algorithmic approach together with the resulting skeletonization patterns will be presented.

Title: Automated segmentation of Nissl-stained somata from whole-brain histological image data

Authors: *A. SINGH[1], T. PARAG[2], D. FERRANTE[3], P. MITRA[3];
[1]Electrical engineering, IIT Madras, Chennai, India; [2]HHMI Janelia Res. Campus, Ashburn, VA; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Modern neuroanatomical research relies on whole brain imaging usinglight microscopic techniques. Applications of current interest include mesoscale mapping of connectivity at a whole-brain scale and other structural/functional whole-brain studies (in mouse, marmoset, and other species). An important step of a neuroanatomical study is ”mapping”, ie identifying the brain compartment in which a labelled cell or process is located. Classically, this mapping was done by visual examination of one or more histochemical stains, of which the Nissl stain is the most widely utilized variety, dating from the times of Brodmann. In the modern era of neuroanatomical research, it is desirable to perform this step using techniquesfrom machine vision, given the large data volumes (~ 10^{12} pixels/brain for mouse). As a first step, we have developed algorithms to segment Nissl-stained sections into the component objects (somata of neurons, glial cells and other microscopic objects in the image), which can be further grouped to obtain information about the brain region involved. Several past studies (e.g., Inglis et.al. 2008,

J. Microscopy 230(3):339-52; He et.al. 2015, Scientific Reports 5, no. 12089) addressed similar problems by fitting preconceived shape models to a set of image pixels. Given the large variation in the shapes and pixel intensities of the objects of interest, conceptually it is more reasonable to learn their appearances and boundaries instead. Weadopt such an approach proposed in Parag et.al. (2015, PLoS One, 10:e0125825) for electron microscopy data segmentation. Each pixel of a Nissl image is classified into 3 classes: cell interior, cell boundary and background. On the real valued outputs of a pixel detector, we apply a region growing algorithm (watershed) that typically oversegments the cells into fragments or superpixels. A superpixel agglomeration algorithm, equipped with a superpixel boundary classifier, is then utilized to refine the oversegmentation to produce the final result. We have used interactive inter-faces for training the pixel classifier (ilastik.org) as well as the superpixel boundary classifier (implementation of technique described in Parag et.al., 2014, MICCAI, LNCS 8673:389-397) with limited groundtruth data to generate our baseline segmentation results. On a small set of test images with sparsely located cells, we achieved an F-score of 88% of precision-recall values (at 94% recall) in determining the cell centers computed from the segmentation output. A natural future direction to improve this performance is to train a deep convolutional network on densely annotated images for pixel classification.

Title: Automated detection of GFP labelled nuclei in whole-brain light-microscopic data sets for mouse with high precision and recall.

Authors: *S. DAS[1], V. V. GOPAL[1], G. PAHARIYA[1], D. D. FERRANTE[2], P. P. MITRA[2]; [1]Computer Sci. and Engg, Indian Inst. of Technol. Madras, Chennai, India; [2]Cold Spring Harbor Lab., New York, NY

Abstract: Whole-brain data sets with light microscope resolution are now available using a variety of light microscopic methods, with applications to structural and functional neuroanatomy. The size of these data sets (~1TB) make it necessary to develop automated methods for detection and counting of objects of interest in the image. We studied the automated detection of GFP labelled nuclei in wide-field fluorescent microscopy, and applied the resulting algorithms to the analysis of the spatial distribution of a set of CRE-defined GABAergic neuronal types in wild type (+/+) and ASD model (16pdf/+) mice.
We found that classical image processing techniques produced effective algorithms with high precision and recall (~96% on average). The algorithms we have developed for these data proceed via detection of salient regions, boundary detection, distance transform of the edge map leading to detection of peaks and ridges, and consequent detection of cell centers. This process efficiently detects the cell centers including the complex case of overlapping cells. The most significant stage is the ridge detection method involving a sequence of six sub-stages.
Manual annotation of two whole mouse brains (~1 Teravoxel each) was done by human operators (a 10 member team cross-verified by two master annotators) to produce the ground truth of cell centers for use in performance evaluation. The average Precision-Recall values for the two brains (totaling ~600 Gigapixel images), was ~96%, indicating the efficiency of the algorithm used. The accuracy of this algorithm was found to be better than recent competitive baseline methods for supervised object detection (ADABOOST, Latent SVM trained using Deformable Part Models). Supervised methods were observed to fail in the case of detecting overlapping cells, as in these cases the foreground blobs form a large variety of non-unique (2D) shape patterns with different sizes. The computational time required to analyze each Gigapixel image, for cell center detection, was around 5 minutes on an i7, 3GHz CPU, 64GB RAM. Output of the automatic cell detection algorithm were used as inputs to subsequent analysis stages (estimation of the spatial density and statistical properties of the centers of the detected nuclei) as well as for visualization purposes. The details of the algorithmic framework and comparison of the results with the comprehensively manually annotated data sets will be presented.

Title: Methods from computational topology for comparing neuronal shapes

Authors: *Y. WANG[1], Y. LI[1], G. A. ASCOLI[2], P. P. MITRA[3];
[1]Computer Sci. and Engin., The Ohio State Univ., Columbus, OH; [2]Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Classifying neuronal shapes is a classical problem in neuroscience with current relevance: high throughput EM and LM based reconstructions are giving rise to large numbers of reconstructed neurons (cf: NeuroMorpho.org, FlyCircuit.org) that call for advanced and automated analysis techniques. Existing approaches mostly convert neuronal shapes into feature vectors, largely manually determined. Once neurons are described as vectors, standard vector-space concepts (eg the Euclidean distance between vectors to classify neuronal shapes) can be used. However, neuronal shapes are fundamentally non-linear objects, which cannot easily be "added" or "subtracted". Therefore it is of interest to look at topological or geometrical analysis methods that respect the non-linear structure of neurons. Such methods have recently gained ground in other areas of data analysis, but are not yet represented in neuronal shape analysis.
In the present work we employ methods from computational topology to define metrics in the space of neuronal shapes, based on ideas of persistent homology. The tree-metrics thus derived do not rely on hand-tuned features, and can be extended to handle developmental dynamics or neuronal biophysics via the incorporation of electronic distances. These considerations lead to a natural feature vectorization based on so-called persistence-diagram summaries of tree shape. Direct metric-space approaches without resorting to intermediate feature-vector descriptions are simultaneously available using Euclidean distance (or other Lp metrics) in the persistence-based feature space.
We successfully apply these methods to classify LM and EM reconstructed neuronal shapes, drawn both from vertebrate and invertebrate preparations, and are able to recover known neuronal classes "out of the box" (ie without hand-tuned features). The methods are scalable

(have controlled computational complexity) and should enable automated analysis of large data sets.

Title: A comprehensive data set for whole-brain mesoscale connectivity mapping in mouse using injections of a viral anterograde tracer (AAV) on a brain-wide grid

Authors: *A. S. TOLPYGO, D. D. FERRANTE, F. MECHLER, S. SAVOIA, N. FRANCIOTTI, P. P. MITRA;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The architecture of brain connectivity supports and constrains nervous system function and animal behavior and reflects the work of evolution. The Mouse Brain Architecture (MBA) project aims at the comprehensive mapping of brain connectivity at the mesoscopic scale using systematic injections of anterograde and retrograde tracers on a grid of locations covering the mouse brain. We report the completion and release of a dataset of 605 whole mouse brains with 915 injections of anterograde viral tracers comprehensively covering the left hemisphere. A majority of animals were iontophoretically injected [405 animals, 715 sites] with AAV vectors in two colors (AAV2/1.CAG.tdTomato.WPRE.SV40, AAV2/1.CB7.CI.eGFP.WPRE.rBG) at pairs of sites in each brain, sampling the volume of the left hemisphere on an unbiased 3D grid. Pressure injection accounts for 22% of the material, largely for superficial and deep cortex, sampling 200 of 915 sites. Whole brains were coronally sectioned at 20µm thickness producing an alternating series of fluorescent label and Nissl stain using a customized tape-transfer method. Series were imaged at 0.46µm in-plane resolution using the NanoZoomer 2.0-HT system and each ~600 section brain was 3D-reconstructed by rigid registration of sections in each image modality. Successful injections were quantified by computational image analysis for anatomical localization, bolus volume, and the number of infected neuronal somata. The mean distance between injected sites is approximately 335µm, with 75% of all injection centers within 457µm of each other. The estimated interquartile bolus diameters are between 250-550µm with corresponding injection volumes from 0.079 to 1.01 mm^3 dependent on target region and delivery method. In comparison with two projects (AIBS Phase-I, Oh, S.W. et al., doi:10.1038/nature13186; MCP, Zingg, B. et al., doi:10.1016/j.cell.2014.02.023), the MBA dataset has finer section spacing (2.5x and 5x more sections), while providing direct measurements of cytoarchitecture via the alternate Nissl series. The dataset features a higher frequency of injections in the sample volume, with smaller mean distances and similar injection volumes. The MBA dataset and associated metadata are made freely viewable with the aid of a 3D injection browser and a high-resolution image viewer interface at the project website (http://mouse.brainarchitecture.org/). Details regarding the injection grid planning and refinement, data acquisition and quality control, and analysis of the completed AAV data set will be presented.

Title: A novel method for extracting brain connectivity information from neuroscience text articles

Authors: A. NAIDU[1], *J. JAYAKUMAR[1], S. CHAKRABORTI[1], A. SHARMA[1], P. SREENIVASA KUMAR[1], D. DEODHARE[2], P. P. MITRA[3];

Abstract: Mapping brain connectivity is of current interest to neuroscientists. There exists a century of knowledge about neuroanatomical connectivity in the literature. This information is valuable and attempts have been made to manually curate brain connectivity databases (cf. BAMS, Bota et al., 2012 *Front Neuroinform*, 6:2;CoCoMac, Bakker et al., 2012 *Front Neuroinform*, 6:30). However, manual curation is labour intensive, raising the need for automated extraction of connectivity information using Natural Language Processing techniques to convert them into a structured database of connections (cf. Richardet et al., 2015 *Bioinformatics*, 31:1640).
In this study, we provide a solution that views the problem of identifying connected brain regions from natural language sentences as that of extracting the relation *"isConnectedTo"* between a given pair of brain region mentions. Traditionally, relation extraction is done either using supervised learning methods that require considerable amount of labelled data or rule based approaches, where rules for extracting connectivity patterns are manually handcrafted. Our approach uses semi supervised learning that significantly lowers human intervention.
For the first part, we have used a surface learning approach and explored feature representations using the Bag of All Words features and the Connectivity word features (only words that indicate connectivity). We then compared their performance on a benchmark WhiteText dataset (cf. French et al., 2015 *Front Neuroinform*, 9:13).
Experiments on the dataset show that our approach using the Bag of All Words features scores well in recall (84%) but with low precision (31%), which can be attributed to the feature representations that include words that are quite noisy to determine connectivity relations.
Our connectivity word feature approach, derived with the help of domain experts, has a reasonably high precision (64%) but poor recall (52%), which can be explained by connectivity

descriptions that our feature words could not capture.
In the second part of our study, we have used syntactic learning using linkages between words by parsing the sentences and representing the shortest path between two brain regions within the link parse as a series of edges and the corresponding words that these edges connect. This approach gives the same recall (84%) but better precision (39%) than the Bag of All Words. We believe to have developed a text mining algorithm for extracting brain connectivity information that is promising but needs further refinement to improve its precision.

Title: Precision mapping of structural connectomes in individual brains

Authors: *B. MCPHERSON[1], C. CAIAFA[1], A. AVENA-KOENIGSBERGER[1], J. CONTRERAS[2], L. SHEN[2], Y.-C. WU[2], J. GONI[3], A. SAYKIN[2], O. SPORNS[1], F. PESTILLI[1]; [1]Psychological and Brain Sci., Indiana Univ. Bloomington, Bloomington, IN; [2]Radiology and Imaging Sci., [3]Engin., Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Diffusion weighted Magnetic Resonance Imaging (dMRI) and subsequent tractography-based modeling allows characterizing and quantifying connectivity and tissue properties of white-matter in living brains. By integrating this fiber-tracking information with a gray matter parcellation, it is possible to model a human connectome as a structural connectivity matrix. Such network-based representation allows for testing a wide number of integration, segregation, and overall communicability features, such as clustering coefficient and small worldness, which have been compared to differences in behavior, cognition, development and aging processes across groups. To date, connectome research has been concerned primarily with identifying principles of brain function and structure by averaging connectomes from multiple subjects. Recently, renewed interest has emerged in developing precision methods to reliably map individual connectomes. Mapping connectomes reliably in single brains would allow

measuring individuality and variability across humans as well as tracking longitudinally connectome variations within individuals in an accurate way. In this work, we introduce methods to map statistically-validated structural connectomes. We report results on the reliability of connectome estimates and network measures. We used two datasets dMRI (Van Essen et al. 2013; Pestilli et al. 2014) and multiple fiber tracking methods (Tournier et al. 2012; Descoteaux et al. 2009; Basser et al. 2000). We built ten connectomes in each individual brain and applied the Linear Fascicle Evaluation (LiFE; (Pestilli et al. 2014) method to validate each connectome. Whole brain connectomes were generated avoiding fiber-counts measures but using virtual lesions (Pestilli et al. 2014) combined with FreeSurfer (Fischl 2012). To estimate the precision of the LiFE-validated connectomes, we measured the reliability of standard brain network-properties such as clustering coefficient and small worldness across repeated instances of connectomes build in the same individual using each tracking method. We show the degree to which LiFE-based connectomes achieve reliable levels of replicability within repeats of individual subjects while maintaining good levels of between-subject discriminability as observed by within- and between-group variability. Our results show that structural connectomes processed with LiFE offer more reliable estimates of connections between brain regions. The method contributes to precision connectome mapping methods with the potential to impact detection during prodromal stages of disease or for individuals at genetic risk of disease.

Title: New methods for obtaining sparse brain connectivity networks

Authors: *G. RANGARAJAN[1], S. MODY[2];
[2]Dept. of Mathematics, [1]Indian Inst. of Sci., Bangalore, India

Abstract: It is well known that large functional networks such as the whole brain networks are often sparse. However, standard functional/effective connectivity analysis techniques often result in dense networks where it is difficult to gauge which interactions are truly significant. We present two methods based on vector autoregressive models that yield highly sparse connectivity maps even when thousands of voxels/channels are analyzed. One of the methods is a bottom up greedy algorithm and the other method follows a top down approach. Applying these methods to publicly available fMRI resting state data, we are able to determine distinct brain network communities that are consistent with known functional regions of the human brain.

Title: Path ensembles and a tradeoff between communication efficiency and resilience in the human connectome

Authors: *A. I. AVENA KOENIGSBERGER[1], B. MISIC[2], R. X. D. HAWKINS[3], A. GRIFFA[4], P. HAGMANN[4], J. GOÑI[5], O. SPORNS[2];

Abstract: Computational analysis of communication efficiency of brain networks often relies on graph-theoretic measures based on the shortest paths between network nodes. Here, we explore a communication scheme that relaxes the assumption that information travels exclusively through optimally short paths. The scheme assumes that communication between a pair of brain regions may take place through a path ensemble comprising the k-shortest paths between those regions. To explore this approach, we map path ensembles in a set of anatomical brain networks derived from diffusion imaging and tractography. We show that while considering optimally short paths excludes a significant fraction of network connections from participating in communication, considering k-shortest path ensembles allows all connections in the network to contribute. Path ensembles enable us to assess the resilience of communication pathways between brain regions, by measuring the number of alternative, disjoint paths within the ensemble, and to compare generalized measures of path length and betweenness centrality to those that result when considering only the single shortest path between node pairs. Furthermore, we find a significant correlation, indicative of a trade-off, between communication efficiency and resilience of communication pathways in structural brain networks. Finally, we use k-shortest path ensembles to demonstrate hemispherical lateralization of efficiency and resilience.

Title: Modeling of large-scale functional brain networks based on structural connectivity from DTI: comparison with EEG derived phase coupling networks and evaluation of alternative methods along the modeling path.

Authors: ***M. BÖNSTRUP**[1], H. FINGER[3], B. CHENG[1], A. MESSÉ[2], C. HILGETAG[2], G. THOMALLA[1], C. GERLOFF[1], P. KÖNIG[3];

[1]Dept. of Neurol., [2]Dept. of Computat. Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [3]Inst. of Cognitive Sci., Univ. of Osnabrück, Osnabrück, Germany

Abstract: Aim: The overall aim of the present study is to find out if networks emerging from phase coupling of band-limited oscillatory signals relate to underlying structural connectivity and if computational models can be used to increase the relation. Then, we use our modelling framework to systematically compare several alternative methods along the modeling path in order to assess their impact on the overall fit between simulations and empirical data.
Method: We use DTI data to estimate structural connectivity and subsequently model phase couplings from alpha band-limited oscillatory signals derived from multichannel EEG data. In a second step, we explore several technical alternatives along the modeling path as structural connectivity preprocessing, complexity of the model, source reconstruction and functional connectivity metrics.
Results: Our results show that about 23.4 % of the variance in empirical networks of resting-state fast oscillations is explained by the underlying white matter architecture. By simulating functional connectivity using a simple reference model, the match between simulated and empirical functional connectivity further increases to 45.4 %. Exploration of technical alternatives along the modeling path revealed the following:
First, we find that an augmentation of homotopic connections in the structural connectivity matrix improves the link to functional connectivity while a correction for fiber distance slightly decreases the performance of the model. Second, a more complex computational model based on Kuramoto oscillators leads to a slight improvement of the model fit. Third, we show that the comparison of modeled and empirical functional connectivity at source level is much more specific for the underlying structural connectivity. However, different source reconstruction algorithms gave comparable results. Of note, as the fourth finding, the model fit was much better if zero-phase lag components were preserved in the empirical functional connectome, indicating a considerable amount of functionally relevant synchrony taking place with near zero or zero-phase lag.
The combination of the best performing alternatives at each stage in the pipeline results in a model that explains 54.4 % of the variance in the empirical EEG functional connectivity.
Conclusion: Our study shows that large-scale brain circuits of fast neural network synchrony strongly rely upon the structural connectome and simple computational models of neural activity can explain missing links in the structure-function relationship. Our results serve as a technical orienting frame for the emerging field of brain network modeling.

Title: Synthetic connectomics: analyzing evolved neural networks for simple reaching with a tool

Authors: *Y. CHOE, Q. LI, J. YOO;
Texas A&M Univ., College Station, TX

Abstract: Connectomics is proving to be a powerful technique in neuroscience, however, the data is incomplete, and we lack tools for the analysis even if full data becomes available in the near future. Here, we propose a synthetic connectomics approach, where neural circuits evolved in a computer simulation (NEAT algorithm that evolves network topology) is presented as a temporary alternative to the full biological connectome, to facilitate the development of analysis techniques. The main advantage of this approach is that experimenters can have full access (including lesioning and stimulation) to structural, functional, and also behavioral data. In this abstract, we present our work on applying NEAT to control a jointed, articulated limb that can pick up and use a tool to reach targets (Fig 1A-B). It turns out that it is non-trivial to analyze a tiny network of 15 simulated neurons that evolved to solve the task (Fig 1D, hexagons), even with full information from the simulation (Fig 1F: behavior; Fig 1G: neural activity). We tested (1) graph analysis (Fig 1C) where we showed that evolved circuits with more cycles (loops) in their network topology show higher performance, (2) neural activity time series clustering (Fig 1E) where we discovered four main clusters (also marked in Fig 1G, right margin), and (3) aligning behavioral events (Fig 1F, marked as circled numbers) to neural activity (Fig 1G, see bottom row). Our work shows the complexity of connectomic analysis even with tiny (synthetic) neural networks where the full structural and functional data are known, and at the same time the potential utility of a synthetic approach to connectomics.

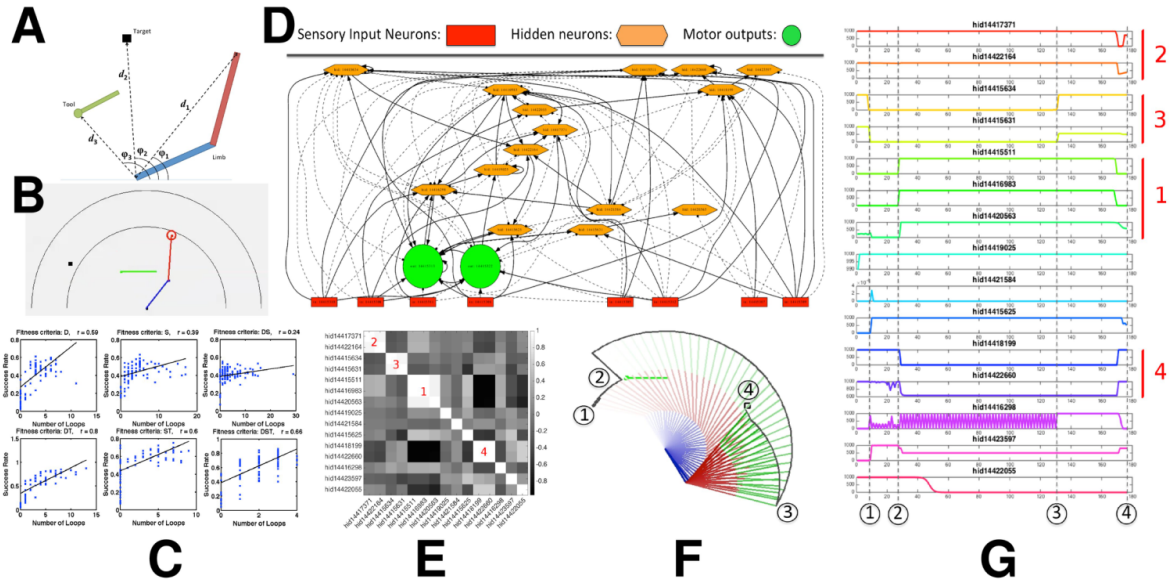

Figure 1. Evolved neural circuit for the control of an articulated arm in a tool-use task for reaching. The controller network receives as input the angle and distance to the target and the tool handle, and outputs the angle of the two joints. See [1] for details.

Title: N2A: a language and software tool for large-scale modeling

Authors: *F. ROTHGANGER;
Sandia Natl. Labs., Albuquerque, NM

Abstract: Sharing models and data is doubtless a prerequisite for progress toward a full understanding of brain function. The Neuroscience Information Framework (NIF) does this for many forms of descriptive data. Ongoing work on interchange languages such as NeuroML/LEMS promises to do this for models. Repositories such as ModelDB hold models in various formats. Excellent graphical tools such as NeuroConstruct support intuitive model building.
However, simply sharing models and data is not sufficient. It is also necessary to assemble those shared models into larger functional units, ultimately reaching the level of an entire nervous system. Beyond that, it is necessary to abstract out algorithmic structures hiding within the details, and to validate models against data.
At higher levels of integration/abstraction, it is necessary to work with declarative models, that is, models which make statements about the attributes of a neural component rather than giving step-by-step instructions for simulating it. Such models are amenable to object-oriented recombination, translation to a wide range of simulators, and algorithmic analysis.
We devised the N2A language [Rothganger et al., Frontiers in Neuroscience 2014] to explore these large-scale modeling concepts. It is a work in progress. We will demonstrate an open-source implementation which combines models and translates them to run on several target simulators, including generated C++ code.

Abstract: Two key challenges in neuroscience are quantifying the strength of non-linear interactions between network nodes (e.g., neurons) and decoding complex network activity. In our companion abstract (Friedman et al. 2016), we introduce our non-linear multi-dimensional hidden state (NMHS) approach, which combines decoding of activity in parallel data streams and computation of the strength of the non-linear interactions among them. Here, we test this approach on computer simulations of non-linear neural circuits, voices of musical groups, and socioeconomic data, comparing the performance of NMHS with that of Granger causality (GC) and cross-correlation (CC). We show that NMHS matches or outperforms GC and CC in many cases. We simulated five distinct two- and three-neuron microcircuits using non-linear Hodgkin-Huxley model neurons coupled via conductance-based models of excitatory and inhibitory synaptic connections. The strength of interactions between model neurons determined by NMHS was correlated strongly with the simulated synaptic strength. By contrast, GC and CC performed relatively poorly in evaluating these non-linear interactions. We investigated the effect of unobserved network nodes on the ability of NMHS to estimate the strength of interaction between observed nodes. In one set of simulations, we varied the number of unobserved model presynaptic neurons making synaptic connections onto the observed postsynaptic neuron. In a second set of simulations, we varied the strength of the synaptic connection from a single unobserved model presynaptic neuron onto the observed postsynaptic neuron. As expected, the calculated strength of interaction between observed neurons decreased as the number or synaptic strength of unobserved inputs increased. As a further validation of the method, we used NMHS to analyze interactions among three to six guitarists improvising classic rock music. One musician was a leader and the others were followers in determining the rhythm of the music. NMHS successfully found a greater total interactivity among co-improvising musicians as contrasted with separately improvising musicians or randomly shuffled recordings, and also found interactions between musicians that GC was unable to detect. In a final test, we applied NMHS to three sociodemographic datasets and found that it successfully identified interactions between income and education level. Our work suggests that the NMHS approach is a powerful tool in analyzing neural circuits and other multi-dimensional, non-linear networks.

Abstract: There is a critical need in neuroscience and other fields to find connections between nodes with non-linear interactions and to decode the activity of complex networks. Currently, no mathematical or computational approaches can reliably find non-linear interactions in multi-nodal networks and simultaneously decode network activity. Granger causality (GC) and cross-correlation (CC) are leading methods for computing the strength of interactions among nodes, but they are not well suited for the analysis of non-linear interactions. Hidden Markov model (HMM) approaches decode the activity of single nodes but do not incorporate information about other nodes in the network. Here, we introduce a non-linear multi-dimensional hidden state (NMHS) approach, which is a generalization of the HMM permitting simultaneous decoding of activity from multiple parallel data streams and calculation of the strength of the interactions among them. In this approach, the distribution of possible outputs given that the model is in a specific state is summarized by an emission matrix, and the probability of transitioning to each possible state is summarized by a transition matrix. An optimization algorithm finds a model that best accounts for the data. The interaction strength between two nodes is defined as the mean change in the transition matrix of one when the other changes its state. We applied this method to putative microcircuits of two or three neurons in the prefrontal cortex, dorsomedial striatum and substantia nigra pars compacta of rats recorded using tetrodes. Putative bidirectional or unidirectional connections in such microcircuits were determined using antidromic and orthodromic microstimulation, and the neurons were recorded while rats performed a decision-making task in a T-maze. Connections in two-neuron microcircuits were identified correctly by NMHS, GC, and CC. However, strikingly, NMHS was more successful than GC and CC in

analyzing three-neuron microcircuits, in which GC and CC often erroneously found interactions between neurons recorded in different sessions. NMHS also excelled in decoding when compared with HMM: the hidden states that it identified in a three-neuron microcircuit better reflected the rats' behavioral states in the decision-making task. Thus, our novel approach for network analysis compares favorably to GC and CC in detection of interactions, and it also has a substantial advantage in network decoding. Our successful tests of this approach on computer simulations of non-linear neural circuits, voices of musical groups, and socioeconomic data are presented in a companion abstract (Gibb et al. 2016).

Title: What do neurons do? A similarity matching perspective

Authors: *C. PEHLEVAN, D. B. CHKLOVSKII;
Simons Ctr. for Data Analysis, Simons Fndn., New York, NY

Abstract: Our brains analyze high-dimensional stimuli streamed by our sensory organs in multiple stages. Sensory cortices, for example, perform tasks like dimensionality reduction, sparse feature discovery and clustering. To model these unsupervised learning tasks, we pursue a principled approach and propose a new family of objective functions based on the principle of similarity matching. The principle of similarity matching proposes that similar inputs to a neural circuit should evoke similar outputs. We show that many unsupervised learning tasks can be formulated as solutions to similarity matching cost functions under different constraints. From these objective functions we derive online distributed algorithms that can be implemented by biological neural networks resembling cortical circuits. Our networks can adapt to changes in the number of latent dimensions or the number of clusters in stimuli. Furthermore, we extend our similarity matching framework to minimax optimization problems from which we derive online algorithms with two classes of neurons identified with principal neurons and interneurons. Our analysis suggest that the role of interneurons may be to clamp the power dimensions of principal neuron activity. We test our theory using recordings from various brain areas.

Title: Development of FunctionalConnectomeDB within SenseLab to incorporate and mine functional connectomics data

Authors: ***L. MARENCO**[1,2,4], R. WANG[1], R. A. MCDOUGAL[2], T. M. MORSE[2], N. T. CARNEVALE[2], P. L. MILLER[1,4,3], G. M. SHEPHERD[2];

Abstract: In order to foster discovery, in recent years the SenseLab group has enhanced neuronal content by incorporating functional connectivity information. This information, often referred to as connectomics, is fueled by research on fiber tracts and interconnectivity within brain regions. To overcome the difficulties posed by mining the highly interdisciplinary content within connectomics data, SenseLab has created several techniques to share, navigate, query and represent this information. For data sharing, we use domain-specific data models that are exposed using common internet formats such as JSON. For querying and display we have created innovative realistic microconnectome-enhanced diagrams, as well as continued to develop metadata-driven canonical diagrams. All our components (data, messaging, and client tools) are built using separation of concern principles, as independent tools that can be used separately one from each other, and with similar components from other projects.SenseLab, as an interoperable suite of databases, also supports research on dendritic properties and synaptic organization. Building on the SenseLab extensible data model, we have successfully extended our domain to incorporate the new connectivity details at the neuronal compartment level. Previously we described this information in NeuronDB, but challenges by the complexity of the information, and how to query and navigate it, required the creation of a new database, FunctionalConnectomeDB. This new resource for connectomics data in SenseLab, besides providing connectivity information, also integrates its information with that in our other neuronal databases.Current categories of information in FunctionalConnectomeDB include: a) Microcircuit; b) Brain Regions, c) Neuron: type (principal and interneurons), canonical form and compartments, and relative size; and d) Synapses: transmitter type released from a cell

compartment (e.g. glutamate from an axon terminal) and receptor type activated from a cell compartment (e.g. NMDA receptor in a proximal dendrite).

Title: Neural decoding of motor responses with Bayesian graphical models

Authors: ***B. BARIBAULT**, J. VANDEKERCKHOVE;
Cognitive Sci., Univ. of California, Irvine, Irvine, CA

Abstract: Neural decoding models are most often used to reconstruct a stimulus from neural data from sensory encoding areas. If the neural data come from a motor planning area, decoding principles allow one to instead predict a motor response from the neural data. A wide variety of neural decoding methods exist (e.g., population vector decoding, machine learning methods), however, the focus of these methods is typically restricted to predictive accuracy. This is because these methods are general. We introduce a custom decoder implemented as a Bayesian graphical model that not only allows for accurate behavioral predictions, but also allows for many parameters with meaningful interpretations (e.g., response bias) to be simultaneously estimated. These parameters may subsequently be used as the basis for further inference.
We showcase the power of this approach through application of the model to a dataset collected by Li, Gerfen, and Svoboda (2014). In their behavioral task, mice reported the position in which a bar had previously appeared with a lick to the left or a lick to the right. During the task, extracellular recordings were taken from the anterior lateral region of motor cortex (ALM). Previous research suggests that the pyramidal neurons in this area encode the upcoming motor response (i.e., the licking movement). We first used the custom Bayesian decoder to validate this assertion. If ALM neurons encode the upcoming motor response, then the model should be able

to predict lick direction from the neural data alone. Because lick responses were predicted with ~80% accuracy (chance = 50%; 50/50 split of trials between train and test), we conclude that the population of pyramidal ALM neurons indeed does encode upcoming motor responses.
We then used the Bayesian decoder to validate Li and colleagues' finding that the great majority of individual ALM neurons exhibit significantly different firing rates in advance of different motor responses. To test this, we examined the posterior distributions of all response preference parameters, which quantify the selectivity of each neuron for an upcoming left or right response. This analysis, which would not be possible with most traditional decoding methods, showed that a smaller proportion of ALM neurons are individually selective for the upcoming motor response than was previously thought.
We discuss how this novel decoder may be easily altered to accommodate different experimental contexts, and thus may be viewed as a generalizable approach to neural decoding in a Bayesian framework.

Title: Towards optimal information storage in hierarchical neural circuits

Authors: *A. ALEMI;
LNC, Ecole Normale Supérieure, Paris, France

Abstract: A main challenge in neuroscience is finding a general computational principle that explains why cortical circuits are organized in particular structures. Some pioneering works have applied the principle of optimal information storage to successfully make prediction about neural circuit architectures (Brunel 2004, 2016). However the application of this principle to hierarchical neural circuits is poorly understood. Here, I propose a hierarchical attractor network that can achieve an ultra high information capacity. The network has two layers: a visible layer with Nv neurons, and a hidden layer with Nh neurons. The visible-to-hidden connections are set at random and kept fixed during the training phase, in which the memory patterns are stored as fixed-points of the network dynamics. The hidden-to-visible connections, initially normally distributed, are learned via a local, online learning rule called the Three-Threshold Learning Rule, which does not rely on explicit error signal for learning. There are no within-layer connections. Random, uncorrelated patterns were stored at the dense regime in a network of

binary units. The simulation of the full-network suggests that capacity at zero robustness against noise grows exponentially with the expansion ratio Nh/Nv. Preliminary analytical calculation of capacity for a mean-field approximation of the model provides a lower-bound for such increase. Increasing robustness reduces drastically the high storage capacity, suggesting that single-layer of random projection amplifies the noise in the visible layer. Increasing the number of hidden layers and making the representation sparse may help to keep the high-capacity with a finite robustness (providing generalization). Additionally, it was observed that, at maximal capacity, the degree of symmetry of the connectivity between the hidden and the visible neurons increases with the expansion ratio. In summary, this work suggests that expansive hierarchy in neural circuits provides a computational advantage in terms of information storage.

Title: Replicating neurophysiological data with spiking neural networks utilizing an evolutionary framework

Authors: *E. ROUNDS[1], A. ALEXANDER[2], E. SCOTT[3], K. DE JONG[3], D. NITZ[2], J. KRICHMAR[1];
[1]Univ. of California, Irvine, Irvine, CA; [2]UCSD, La Jolla, CA; [3]George Mason Univ., Fairfax, VA

Abstract: We introduce a framework to efficiently match simulated neural networks to neurophysiological datasets recorded from awake, behaving animals. In this work, we use spiking neural networks (SNNs), which are increasingly relevant tools for the computational modeling of cognitive function as high-performance computing resources become available. They allow researchers to formulate models that are capable of capturing important realistic features of neurobiological activity, including spiking dynamics, synaptic conductances, and plasticity while retaining sufficient computational efficiency to enable the construction of large-scale networks. Thus, researchers are able to study the circuitry and mechanisms underlying specific cognitive phenomena using biologically plausible SNNs of neuronal activity and behavior. However, in order for such simulated networks to offer significant explanatory power,

they must link to, and corroborate, experimental data at multiple levels. An important step in this process involves verifying SNNs by using them to reproduce electrophysiologically recorded neuronal firing rates, but as models of brain function increase in size and complexity, it also becomes intractable to manually tune the increasingly large number of open parameters. To address these challenges, we use a GPU-accelerated automated tuning framework employing an evolutionary algorithm to optimize the synaptic plasticity parameters of a SNN in order to match synthetic neuronal firing rates with experimentally observed firing rates. The framework was applied to a neurophysiological dataset recorded from the rodent retrosplenial cortex (RSC) in which four relevant recorded behavioral variables were provided as inputs to each SNN (head direction, linear and angular velocity, and allocentric position) and then correlating the synthetic firing rates with the experimentally observed firing rates. We found that our evolved SNNs captured the behavior of the dataset at the level of the neuronal recordings (e.g., firing rates and patterns), the functional aspects of the neuronal population (e.g., turn, route, and place specific responses), and behavioral features of the data at the population level (e.g., route reconstruction). Thus, our framework produced networks whose behavior transcended multiple levels of the recorded data. This framework may be extendable to other neurophysiological datasets recorded under similar conditions in conjunction with the appropriate behavioral inputs.

Title: Multiscale interactions predict stress in adult zebrafish (Danio rerio).

Authors: *K. M. KHAN, E. M. CARAMILLO, A. D. COLLIER, J. K. DOYON, J. D. CLARK, T. SURBER, A. HAJNAL, D. J. ECHEVARRIA;
Dept. of Psychology, Univ. of Southern Mississippi, Hattiesburg, MS

Abstract: Zebrafish are a well-established translational model in neurobehavioral sciences. Several behavioral paradigms have been translated from rodent tasks to the zebrafish, as this aquatic model is amenable to high-throughput screening. In an effort to automate and streamline phenotypic screening in zebrafish, several research groups have implemented the use of video-aided computer tracking software in their research. In the present study, we compare the use of traditional behavior tracking procedures against non-traditional techniques. Adult zebrafish

exposed to a stress procedure (15 min isolation and confinement) were transferred to an open field task to assess stress-like behavior. Swim behavior was analyzed with computer tracking software (idTracker, Madrid, Spain) and video differencing in ImageJ (NIH, Bethesda, MD). Video differencing compares average pixel intensity in neighboring frames and is used as a measure of temporal change in human coordination tasks. Both resulting time series were analyzed using multifractal detrended fluctuation analysis (MFDFA). The results indicate that the traditional and non-traditional methods are equivalent, and equally capable of predicting stress conditions and behavioral outcomes. Further, multi-fractality contributes to the prediction of stress response above and beyond traditional measures of variance, specifically standard deviation. This work highlights the novel concept of predicting internal states based on structure of variability in swim patterns in adult zebrafish. Implications for developing novel procedures for diagnosing stress based on monitoring multiscale interactions in motor behavior are considered.

Abstract: Recent advances in biological imaging technologies allow us to investigate neuronal morphologies at a level unthinkable a decade ago. With light microscopy and modern day virus-based labelling techniques, different markers can be visualized simultaneously and growth can be traced. Electron microscopy meticulously outlines neuronal structures at the cellular and subcellular level. When imaging larger regions, all neurons and their interconnections can be tracked. With time, more data with higher spatial and temporal resolution over ever expanding regions will become available. How will we process all this data into meaningful insights? The answer involves collaboration, sharing and automation of work-flows, and big-data on high-performance computing platforms [1].
However, prior to addressing this question, the available data need to be stored unambiguously to unleash the full potential of big data for most effective sharing and greatest scientific impact. The current de facto standard to digitally store neuronal morphologies is the SWC format [2]. This format is two decades old and represents individual neurons as a set of linked cylinders. Its simplicity is its virtue: detailed morphologies can be represented in a parsimonious way. However, current day neuronal imaging techniques provides far more detail than can be stored. As secondary use of morphological data becomes wider practice [3], we aim to store as much detail as the experimentalist is willing to store; a limitation imposed by the format itself is unacceptable.
We propose an extension of the SWC format to include time-resolved morphological data, contextual data (such as generic environmental descriptors), and subcellular markers. The extended format is implemented as an HDF5 file [4], a binary file format that hierarchically stores data in a way similar to how folders are stored on a hard drive. As such, our proposed format serves as a container storing data related to all aspects of a neuronal morphology. The modular nature of HDF5 files also makes the format future-proof as distinct types of data associated to neuronal morphologies and their biological context can be appended to existing files without losing data. Reasonable backward compatibility with the original SWC format is achieved by also storing SWC data in the new format. Various databases and experimental and analysis tools provide support for this extended format.

Title: Generating and predicting long-range neural connectivity using the reverse geometric principle

Authors: ***P. H. TIESINGA**[1], M. BAKKER[2], R. BAKKER[3];
[2]Neuroinformatics, [3]Neuroinformatics/Donders Inst., [1]Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Cognitive processes are mediated by spatiotemporally correlated neural activity patterns, whose properties are in part determined by the underlying structural connectivity of the brain. Realistic models therefore need to get connectivity at the cell-to-cell level right. It is currently impossible to measure the connectivity with sufficient resolution across a large enough volume. State-of-the-art approaches therefore predict connectivity based on geometric or statistical principles and validate these using the limited data available. Most of the former approaches are based on Peters' principle, starting from populations of reconstructed morphologies, with close apposition between axons and dendrites predicting the presence of synapses.
Recent work has applied two strategies. First, oversampling synapses followed by pruning based on the number of expected synapses and their multiplicity distribution (the number of synapses between same pair of neurons). Second, by assigning densities to larger volumes, and matching pre and postsynaptic elements. Recent analysis of saturated reconstructions based on electronmicroscopy data has cast doubt on the validity of a direct application of Peters' principle, although it is likely to be valid at the aggregate level.

We introduce a different approach which makes it possible to get the appropriate number of synapses without pruning and incorporate statistical factors in addition to purely geometrical ones. We first place neuron somas according to the reported densities and model their axons and dendrites by smooth parametrized densities that match reconstructed morphologies, and whose parameters are sampled from a distribution representing observed morphological variability. Subsequently, pre and postsynaptic elements are sampled in voxels according to these spatial densities; a colocalization of a pre and postsynaptic element in the same voxel then yields a synapse. From the sampled elements we reconstruct neuronal morphologies and validate these using the experimentally reconstructed morphologies. The key challenge of the algorithm is overlap: where more than one pre (or post) synaptic element is in the same voxel. Removing these leads to bias in the density. We have developed three strategies dealing with overlap and report that so called selection method leads to the lowest bias and is computationally efficient. The tool will be made publicly available as part of the Human Brain Project
